ABSTRACT: The design of timber connections is of great importance since their performance is decisive for timber structures. The widely adopted technique utilizing the slotted-in steel plates could possibly be replaced by using timber-based gusset plates due to the significant advantages in terms of the environmental impact, economy, ease of prefabrication, and fire resistance of the latter one. Among the timber-based panels, plywood made of birch was chosen in the study due to the combined benefits of the cross laminated configuration of plywood and the superior mechanical properties of birch compared to most softwoods. In this paper, a preliminary experimental investigation was carried out to study the structural performance of the glulam trusses connected by means of bonded birch plywood gusset plates. Tests were performed on ad-hoc designed frame-like specimens. The plywood gusset plates were under-designed to be the weakest link in the structure, so as to study their load-bearing capacity. The knowledge obtained in this study is the first step towards the establishment of a model for the design of truss nodes with bonded plywood gusset plates. In the study, the face grain orientation of birch plywood was varied (0°, 5°, and 15° to the horizontal axis) in three test series. Test results show that the influence of the face grain angle from 0 to 15 degrees on the global stiffness of the frame structure is insignificant and it can be well predicted by a simplified planar 2D numerical models. Two analytical models, namely, the classic so-called 'Whitmore model' along with a more accurate analytical model, were utilized to illustrate the failure mechanism of birch plywood gusset plates with the concept of the effective width and the spreading angle.

KEYWORDS: Glue connection, Birch plywood, Glulam frame, Face grain angle, Effective width, Spreading angle

1 INTRODUCTION

Timber, as a building material, is paid more attention in the field of civil engineering, due to its low carbon footprint and lightweight. The design of timber connections is of great significance since their performance is decisive for timber structures. In high-rise timber buildings as well as long-span timber applications, slotted-in steel plates are widely used in joints [1].

Nevertheless, plywood plates could be an alternative to slotted-in steel plates. Timber-based gusset plates are more environmental-friendly and cost-effective, with less prefabrication demand and better fire resistance.

Essentially, two types of connections, namely connections with mechanical fasteners and bonded connections, can be adopted between plywood and other timber elements. Bonded connections are generally stronger, stiffer, and cheaper than mechanical connections. However, bonded connections have more severe requirements during assembly, e.g., the surrounding environment, applied pressure, curing time, etc., [2].

Bonded connections between plywood and other timber elements have been studied for a long time. Crutis [3] performed a number of tests on rigid lumber frames in 1960. Douglas fir plywood plates were nailed and glued to the Douglas fir lumber framing members. Three types of failures were summarized: (1) stud or rafter failed due to combined bending and axial load, (2) gusset plates failed due to combined bending and axial load, and (3) gusset plates failed in rolling shear. The effect of the face grain angle of plywood gusset plates was also investigated. It was indicated that the orientation of the face grain has a significant effect on the joint capacities. Wilkinson [4] and Josefsson and Larsson [5] compared different connection systems of the structural applications using (1) nailed plywood plate, (2) nailed steel plate, and (3) nailed and glued plywood plate. Their studies found that the third one with nailed and glued plywood plates delivered the highest stiffness and capacities for the structure.

Although connections using plywood gusset plates seem competitive, slotted-in steel plates are still dominant in the marketplace [6]. One reason of that, is the fact that there are still uncertainties - mainly due to lack of experimental data - concerning the load-bearing capacity of plywood under off-axis loading. The load-bearing capacity of the

steel plates used in timber connections is, on the other hand, easy to calculate by means of well-proven models.
Studies on the structural behavior of birch plywood gusset plates in connections with mechanical fasteners have been initiated recently [7]. This paper aims to gain more knowledge regarding the failure mechanism of bonded birch plywood plates in truss structures. For this purpose, frame-like specimens consisting of glulam elements and laterally bonded birch plywood gusset plates were laboratory tested. Plywood made of birch (*Betula pendula*) was chosen as the material for the gusset plates. The choice of birch is both because it is a wood specie widely available in Scandinavia [8,9] and because it has outstanding mechanical properties. The failure mechanism of the birch plywood plates with varying face grain angles was studied both experimentally and numerically.

2 MATERIALS AND METHODS

2.1 DESCRIPTIONS OF STRUCTURES AND MATERIALS

The structure presented in Figure 1 is composed of inclined members, horizontal members, and birch plywood plates. Inclined and horizontal members made of spruce (Picea abies) glulam GL 28cs were adhesively connected by means of birch plywood gusset plates. Inclined members have an angle of 30° to the horizontal members. The width (direction 1 in Figure 1) and the height (direction 2 in Figure 1) of the frame structure are approximately 1536 mm and 760 mm, respectively. There are three plywood plates at the top and bottom, connected with inclined members, creating four glue lines, annotated as 'Birch plywood A'. Only one gusset plate was glued to the glulam elements on the left and right sides of the frame, connecting the inclined and horizontal glulam elements. This gusset plate, annotated as 'Birch plywood B', was designed to be the weakest link in this structure. Thus, failure in birch plywood B was expected after the destructive test, which is in line with the aim of this paper. The detailed configuration of both birch plywood A and B is shown in Figure 1. The face grain of birch plywood A is parallel to direction 1, while the face grain angle of birch plywood B is varied to investigate its effect on the global behavior of the frame.
All the glulam elements have the same cross-section of 56 mm × 110 mm. These elements were produced from a number of 4 m-long glulam beams GL28cs with a cross-section of 56 mm × 225 mm by using a miter saw and format saw. The weight was measured on each element before the test in order to deduce the density. The mean density was 463 kg/m^3 with a standard deviation (STDV) of 17 kg/m^3. Moisture content (MC) was measured on each glulam element prior to the test by a resistance-based moisture meter (HT 85, GANN, Germany). The mean MC was determined to be 12.6% with a STDV of 1.1%. Five samples were measured by using both HT 85 moisture meter and oven-drying methods [10]. No significant difference between these two methods was observed on glulam elements at a 95% confidence interval. Hence, MC measured from this resistance-based measuring device is considered valid.

Birch plywood plates have a nominal thickness of 9 mm consisting of 7 veneers. The mean density was 714 kg/m^3 (STDV=29 kg/m^3). MC was measured on ten samples cut from the frame specimens after the tests using the oven-drying method. The mean MC was 8.4% (STDV=0.4%). Melamine-urea-formaldehyde (MUF) adhesive (Prefere 4546/5022) was chosen for the tests. The liquid melamine urea adhesive (Prefere 4546) and the liquid hardener (Prefere 5022) were mixed with 100:10 parts-by-weight (pbw). This adhesive system fulfills the requirements according to EN 301 [11] and is classified as a general purpose, gap-filling, and finger-jointing adhesive. However, the applicability of this type of adhesive in this case, i.e., surface bonding between spruce glulam and birch plywood for connection purposes is still uncertain. Therefore, choosing the proper adhesive and the related parameters during assembly is also one of the crucial parts of the investigation for this type of bonded connection.

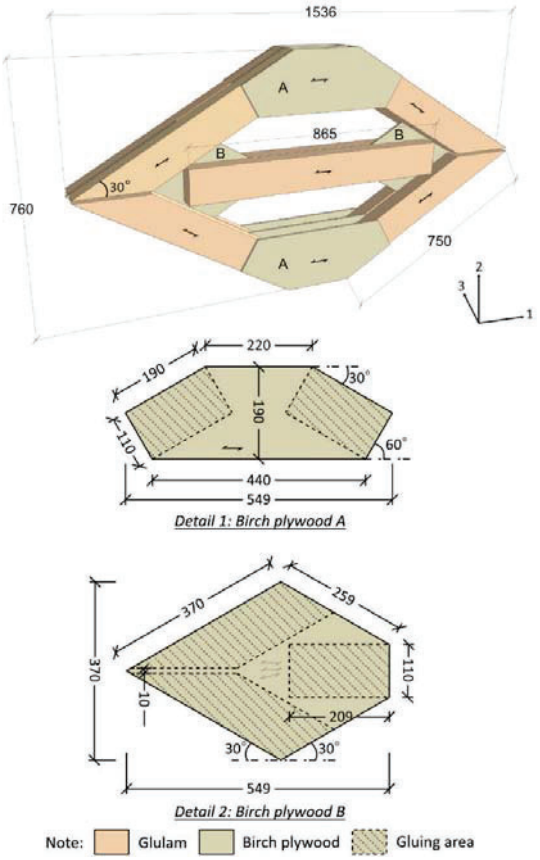

Figure 1: *Configuration of the studied frame (Length unit: mm).*

2.2 ASSEMBLY PROCESS

The assembly process is illustrated in Figure 2. Firstly, the glued areas were sanded by a sanding machine. The adhesive was spread on both surfaces of birch plywood plates and glulam elements. As shown in Figure 2(b), glulam elements were predrilled with 4 mm holes about 2 cm deep. Clamps were utilized to tighten plywood plates

and glulam together for inserting screws. Two screws with an outer diameter of 3.5 mm and a length of 50 mm were inserted into each glulam element. Then, clamps were removed so that new adhesive layers could be applied (Figure 2(c)). Similar to the previous processes, both glulam element and plywood plates were sanded, spread with adhesive, and pressed by screws (Figure 2(d)). By repeating the aforementioned procedures, all the timber elements were assembled as a whole. Lastly, screws with an outer diameter of 5.6 mm and a length of 140 mm were inserted. The positions of these screws are displayed in Figure 2(e), which are along the center axis of the inclined and horizontal members. It is noted that screws utilized in the frame are only considered for assembly purposes. The influence of the screw on the load-bearing capacity of the joints can be neglected because of their significantly lower shear stiffness, as compared to the shear stiffness of the adhesive.

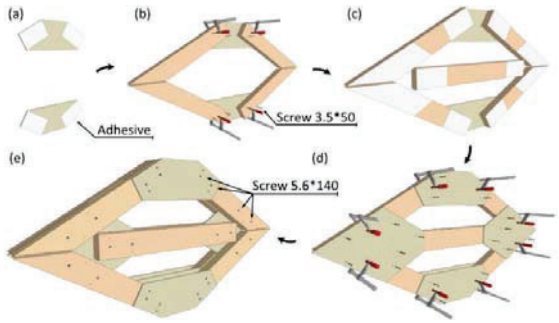

Figure 2: *Assembly process of the studied frame.*

The adhesive spreading mass per square meter was roughly 400 g/m^2. The assembled frames were cured for around 1-2 weeks before testing. The indoor temperature during bonding of the specimens was in the range10-15 °C.

2.3 TEST PROCEDURE

Three test series were performed in the presented study. As displayed in Figure 3(a), the face grain of birch plywood plate B was varied. In test series 1, three frame specimens were tested with the face grain direction of birch plywood B parallel to the horizontal axis. In test series 2 and 3, the face grain angle of birch plywood B was 5° and 15° to the horizontal axis, respectively, with four repetitions.

The test setup is shown in Figure 3(b). Tests were conducted on the MTS810 universal testing machine. All specimens were loaded in compression. During the tests, the loading head motion was constant, with a rate of 1 mm/min. The load signal and the piston movement were recorded simultaneously. In order to avoid applying load directly on birch plywood plates, wedges made of glulam were inserted between the inclined members and birch plywood plates A. The load-bearing capacity was defined as the maximum load attained during the tests. Machine compliance was measured by pressing the loading head to the support, and then it was excluded from the piston movement to derive the vertical displacement of the frame. The stiffness of the tested structure was defined as the slope of the load-vertical displacement curve in the linear portion.

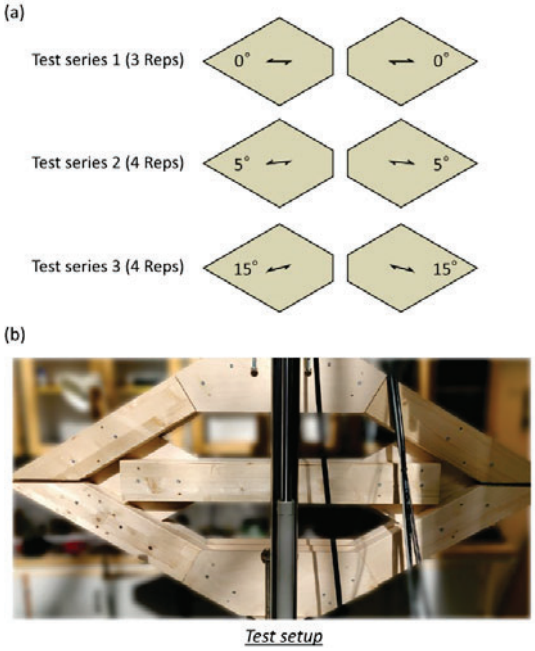

Figure 3: *Test series and setup.*

2.4 NUMERICAL ANALYSIS

Numerical analyses were performed with commercial finite element software Abaqus (Simulia, USA). A planar 2D numerical model was developed to investigate the structural behavior of the studied frame in the linear elastic stage. Both the stiffness on the global level and the section forces on the component level were checked when the face grain orientation of birch plywood plate B changed from 0° to 5° and 15°.

Ideally, structures of this type can be analyzed as 2D trusses with hinges at each joint [12]. Yet in this study, as can be seen in Figure 1-3, glue connections were adopted, and the proportion of the gluing area to the size of the frame is relatively large. Hence, all the glulam components were modeled as beam-type elements.

Glue-laminated timber is usually characterized as an orthotropic material. It can be further simplified to be transversally isotropic, with identical elastic properties in the radial and tangential directions [13]. The physical and elastic mechanical properties of glulam beam GL28cs assigned in the numerical model are listed in Table 1. The properties include the density ρ, the elastic modulus E_{ij}, the Poisson's ratios ν_{ij}, and the shear modulus G_{ij} $(i, j = 1,2,3)$. Axis 1 is along the grain direction, while axes 2 and 3 are in the transversal directions.

https://doi.org/10.52202/069179-0198

Table 1: *Physical and elastic mechanical properties of glulam GL28cs assigned for numerical analyses.*

ρ (kg/m^3)	E_{11} (MPa)	E_{22} (MPa)	E_{33} (MPa)	ν_{12}
463	12500	300	300	0.219

ν_{13}	ν_{23}	G_{12} (MPa)	G_{13} (MPa)	G_{23} (MPa)
0.219	0.582	650	650	65

The input density in Table 1 is the mean value measured in this study and reported in Section 2.1. The elastic properties have been derived according to [14] for the mean values of the elastic modulus and shear modulus and [15] for the Poisson's ratios. Further, the rolling shear modulus G_{23} was assumed to be one-tenth of the shear modulus G_{12} and G_{13} according to [16].

The inclined glulam elements were tied together. For the connection between the inclined and horizontal glulam elements, a spring with the axial stiffness defined in the horizontal direction was assigned in the numerical model. This is due to the fact that there is only one birch plywood plate transferring the axial forces and the potential bending moment between the inclined and horizontal glulam elements. Moreover, the thickness of this plywood plate was under-designed so as to study its failure mechanism after the tests. Therefore, the contribution of this single gusset plate to the global stiffness should be taken into account. It is noticed in Figure 4 that the marked triangular area would take most of the tensile force from the horizontal glulam beams considering that the frame structure was loaded in compression. This marked area was converted into a rectangular shape with the equivalent area. The axial stiffness of the spring can be calculated according to Equation (1).

$$k = \frac{EA}{L} \tag{1}$$

where k is the axial stiffness of the spring; E is the elastic modulus of birch plywood; A is the cross-sectional area of the converted rectangular shape; and L is the length of the same region. It is worth mentioning that the elastic modulus of birch plywood is angle-dependent. When the face grain orientation of the plywood plate varied from 0° to 15°, the assigned elastic modulus should also be different. The elastic modulus of birch plywood at 0° has been experimentally characterized in previous studies [8], with a mean value of 9.4 GPa. It is also found that one theoretical model can predict the off-axis (between 0° and 90°) elastic modulus fairly well [8]. By employing this theoretical model, the elastic modulus at 5° and 15° could be predicted, which is 8.6 GPa and 5.2 GPa, respectively. See Equation (2) for the calculated axial stiffness for the three tested angles.

$$k = \begin{cases} 5.7 \times 10^7\ N/m & (\alpha = 0°) \\ 5.2 \times 10^7\ N/m & (\alpha = 5°) \\ 3.2 \times 10^7\ N/m & (\alpha = 15°) \end{cases} \tag{2}$$

where α is the face grain angle of birch plywood plates B to the horizontal axis.

Moreover, the failure load obtained from the test data was applied in the numerical model to check the internal force of each glulam element at failure, especially the horizontal one that would transfer the tensile force to the birch plywood plate B. The numerical stiffness of the global frame structure was derived as the ratio of the input external load to the corresponding vertical displacement at the top of the frame. It would be further compared with the experimental ones in Section 3.1. Glulam elements were meshed with the beam element type (B21 in ABAQUS/CAE 6.14) and the size of 0.02 m.

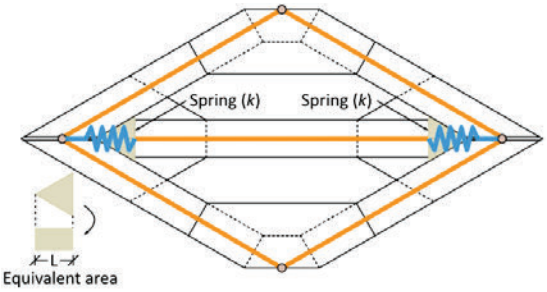

Figure 4: *Illustration of the planar 2D numerical model.*

3 RESULTS AND DISCUSSION

3.1 EXPERIMENTAL RESULTS

The failure load, the stiffness, and the failure mode of each tested frame structure are summarized in Table 2. The experimental load-vertical displacement curves are displayed in Figure 5.

Table 2: *Experimental results*

Test series	Specimen	Failure load (kN)		Stiffness (kN/mm)		Failure mode
01 (0°)	01	72.8	77.6	11.2	10.5	a
	02	81.1		9.8		a
	03	78.8		10.5		a
02 (5°)	01	86.8	80.6	10.0	10.1	a
	02	81.8		10.5		b
	03	74.5		9.7		b
	04	79.3		10.1		a
03 (15°)	01	68.2	75.2	8.0	8.9	b
	02	76.2		9.4		b
	03	79.5		9.0		b
	04	77.0		9.2		b

Note: failure mode 'a' means the bond line failure between birch plywood B and the horizontal glulam while failure mode 'b' represents the failure in birch plywood B.

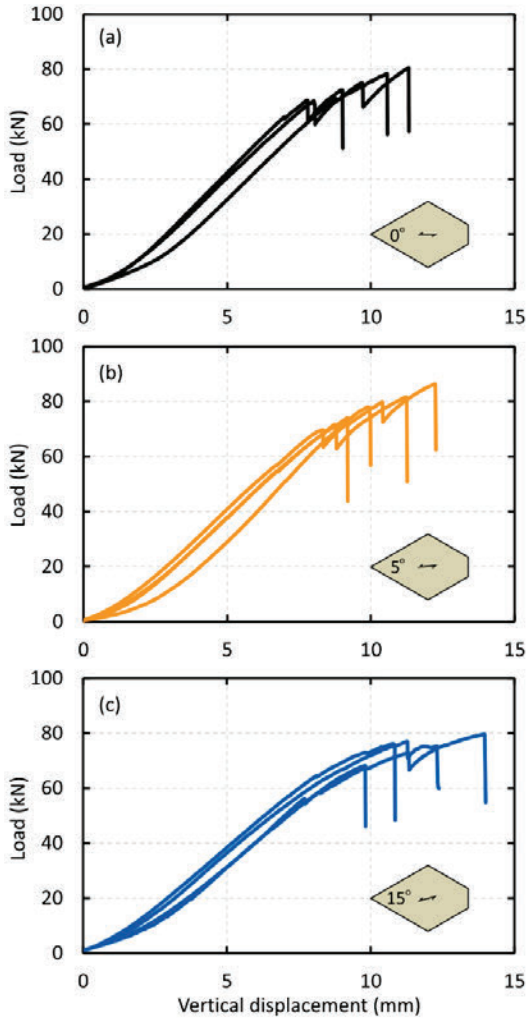

Figure 5: *Experimental load-vertical displacement curves: (a) test series 01 (0°); (b) test series 02 (5°); and (c) test series 03 (15°).*

As noticed in Table 2, test series 02 (5°) has the highest mean failure load, followed by test series 01 (0°) and 03 (15°), which could be explained by the different failure modes. As aforementioned, the birch plywood plate B was designed as the weakest part in the frame. However, for the specimens in the test series 01 (0°), the bond line failure took place prior to the birch plywood failure. The same failure mode was also observed in the first and the fourth specimens in the test series 02 (5°). For the other specimens with the failure occurred in birch plywood, the average failure load of the second and the third specimens in the test series 02 (5°) is 78.2 kN, slightly higher than the average failure load (75.2 kN) of the test series 03 (15°). The stiffness is independent on the failure load and failure mode as it indicates the structural performance in the linear elastic stage. Test series 01 (0°) possesses the highest stiffness, followed by test series 02 (5°) and 03 (15°). It was mentioned in Section 2.4 that the elastic modulus of birch plywood drops rapidly from 9.4 GPa to 5.2 GPa when the face grain angle varies from 0° to 15° to the loading axis. Nevertheless, the influence of the birch plywood face grain orientation on the global stiffness of the frame is not so dramatic, which can also be observed in Figure 5.

The difference in the load-displacement behavior of each test series is not noticeable, with a slight difference in the failure load and the stiffness as presented in Table 2. All the curves grew slowly in the initial stage, which might be because that the wedges inserted at the top and the bottom of the frame were trying to get full contact with the inclined glulam elements. After this initial consolidation stage, the load increased almost linearly with the vertical displacement in the elastic stage. It is interesting to see that, in some specimens, there was a slight reduction of the load. Then, the load increased again until the final failure of the structure. The slight reduction of the load was owing to the premature 'failure' in a certain part of the bonded area and it was more likely to be seen in the specimens with the final failure also in the bond line. To be more specific, only one specimen in test series 03 showed the load reduction before the final failure (see Figure 5(c)), while in other test series, this phenomenon took place more frequently.

Typical failure modes are presented in Figure 6. As can be seen in Figure 6(a) and Figure 6(b), for the specimens that failed in the bond line, only a small part of glulam failure was observed in the bonded area. It is evident that the strength of the timber material has not been fully exploited, and the bonding quality might have been improved. However, it does not necessarily mean that the MUF adhesives did not work for spruce-birch gluing. In fact, many factors influence the bonding quality, e.g., the surrounding environment (temperature and relative humidity), mixing ratio, assembly time, and pressing methods, etc. It is not a trivial task to determine the influence of each factor on the bonding strength between spruce glulam and birch plywood. Systematic studies should be conducted in the future to propose a proper workflow when manufacturing bonded connections made of birch plywood plates and spruce glulam beams.

Although the bonding quality was not ideal, some specimens showed failure in birch plywood gusset plates (see Figure 6(c) and Figure (d)). The plywood plates failed in tension due to the tensile force transferred from the horizontal glulam beams. The cracks are, in general, perpendicular to the horizontal direction and close to the end of the horizontal glulam beams except for a small part along the face grain direction, as shown in the upper part of Figure 6(c). The axial forces in the glulam elements were not measured during the tests. However, these forces can be estimated with reasonable accuracy by means of a numerical model calibrated with data from experimental results. The failure mechanism of the birch plywood plates can then be discussed with the knowledge of the axial forces reported in Section 3.2 by means of the analytical models proposed in Section 3.3.

https://doi.org/10.52202/069179-0198

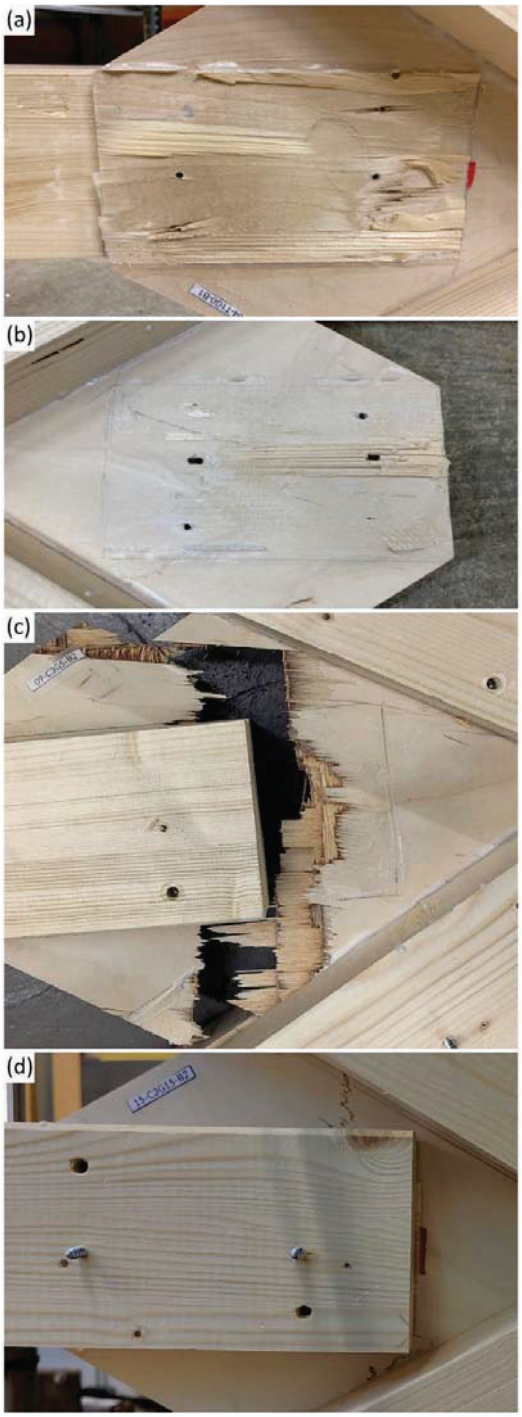

Figure 6: *Typical failure modes: (a) bond line failure in test series 01; (b) bond line failure in test series 02; (c) plywood failure in test series 02; and (d) plywood failure in test series 03.*

Similar studies regarding this frame structure but in mechanical connections have been presented in [7], where the plywood gusset plate B had the face grain orientation parallel to the horizontal axis. Thus, the structural behavior of this timber frame in mechanical connection [7] and glue connection (test series 01 in this study) can be compared (see Figure 7). Not surprisingly, the adhesively connected one possessed both higher load-bearing capacity and global stiffness.

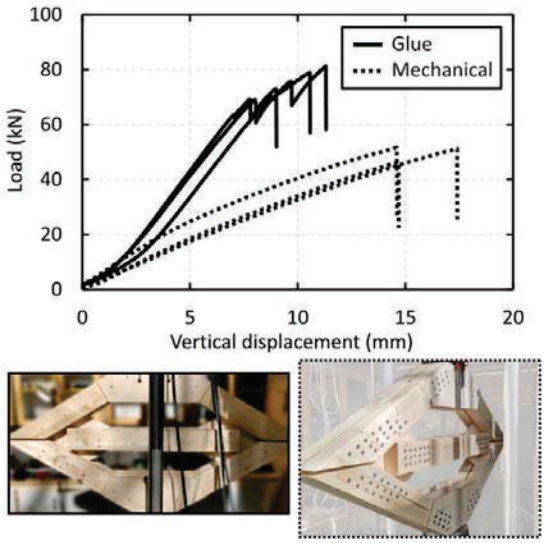

Figure 7: *Load-vertical displacement curves of the frame structures in glue connection (test series 01) and mechanical connection [7].*

3.2 NUMERICAL PREDICTION

Table 3 compares the experimental stiffness with the numerically predicted ones for each test series. The axial forces in the horizontal glulam beams are also listed in Table 3. The underlined numbers indicate that these specimens failed in the bonded area.

Table 3: *Comparison between experimental and numerical results*

Test series	Specimen	Stiffness (kN/mm)		Axial force in horizontal glulam beams at failure (kN)
		Exp. (Mean)	Num.	
01 (0°)	01	10.5	10.1	81.7
	02			91.0
	03			88.4
02 (5°)	01	10.1	9.9	95.0
	02			89.5
	03			81.5
	04			86.8
03 (15°)	01	8.9	8.0	63.4
	02			70.9
	03			73.9
	04			71.6

The stiffness of the frame structure predicted by the planar 2D numerical model showed good agreement with the experimental results. The numerically predicted stiffness was slightly lower than the experimental stiffness. This might be due to that, in this simplified 2D numerical

model, only the cross sections of glulam elements were defined and the additional thickness of the plywood plates in the glued connection regions was neglected.
Despite the slight difference, this numerical model was considered to be valid and the axial forces in the horizontal glulam beams were checked. The horizontal glulam beams were in tension during loading and the tensile forces were taken by the single birch plywood plate B, leading to the tensile failure of the plywood in some specimens. Two specimens in test series 02 (5°) showed plywood failure. The average tensile force at failure is 85.5 kN. In test series 03 (15°), the average tensile force taken by the plywood plate at failure is lower, which is 70.0 kN.

3.3 ANALYTICAL MODELS

In order to predict the failure load of the gusset plate in timber connections, one design model should be put forward. The first step is to gain knowledge with regard to the strength of the birch plywood plate. In this study, the plywood plates failed in tension with the face grain angle of 5° (in test series 02) and 15° (in test series 03) to the horizontal direction. Hence, the tensile strength of birch plywood at 5° and 15° load-to-face grain angle should be obtained. Wang et al. [8] characterized the off-axis tensile properties of 21 mm birch plywood at around 12% MC and found that the empirical Norris failure criterion predicts the closest results to the experimental data among the investigated linear and quadratic failure criteria (see Figure 8).

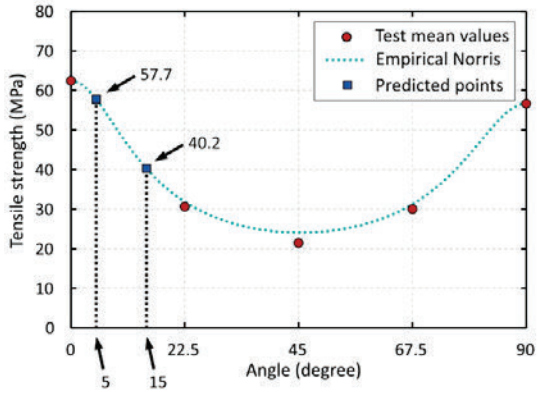

Figure 8: *Tensile strength of birch plywood at any face grain angle to the loading axis predicted by empirical Norris failure criterion.*

It is noticed in Figure 8 that the predicted tensile strength of birch plywood at 5° and 15° are 57.7 MPa and 40.2 MPa, respectively.
Having the tensile force, tensile strength, and the thickness of birch plywood plate at hand, it is possible to derive the width of plywood that was involved in resisting the load, namely, the effective width (see Equation (3)).

$$w_{eff} = \frac{F_t}{f_t \cdot t} = \begin{cases} 164.6\ mm & (\alpha = 5°) \\ 193.5\ mm & (\alpha = 15°) \end{cases} \quad (3)$$

where w_{eff} is the effective width of the birch plywood plate; F_t is the tensile force at failure; f_t is the tensile strength of birch plywood; and t is the plywood thickness. It is evident that the effective width should not be simply assumed as the width of the bonded region, i.e., 110 mm, or the entire crack length, i.e., over 200 mm in Figure 6(c). Besides, the effective width varies at varying load-to-face grain angles. It is worth noting that although the tensile strength of birch plywood decreases roughly 30% when α changes from 5° to 15°, the reduction in the load-bearing capacity of the birch plywood gusset plate in connection is less severe (less than 20%) thanks to the wider w_{eff} at 15°.
The concept of the effective width was first proposed by Whitmore [17] in the last century for the design of the steel gusset plate to mechanically connect other steel members. To define the 'Whitmore effective width' in steel gusset plate, two lines with a spread angle of 30 degrees were drawn from the outer fasteners of the first row to intersect with the line through the bottom row of fasteners. The width between the intersection points is known as the 'Whitmore effective width' [18].
The 'Whitmore effective width' could also be employed in this study for plywood gusset plates in glue connection while the spreading angle should be redefined. See Equation (4) for the derived spreading angle and Figure 9 for the illustration of the adopted 'Whitmore effective width' theory.

$$\theta = \arctan\left(\frac{w_{eff} - w}{2l}\right) = \begin{cases} 7.4° & (\alpha = 5°) \\ 11.3° & (\alpha = 15°) \end{cases} \quad (4)$$

where θ is the spreading angle for birch plywood gusset plate; w is the width of the boned area (110 mm); and l is the length of the bonded area (209 mm).

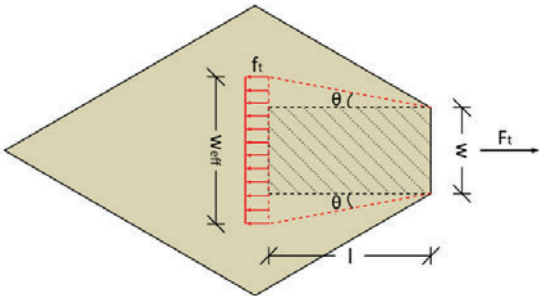

Figure 9: *Illustration of the adopted 'Whitmore effective width' theory.*

As shown in Figure 9, the spreading angle in this classic analytical model starts from the outmost line of the bonded area, resulting in a uniformly distributed tensile stress within the 'Whitmore effective width'.
A modification of the classic analytical model is proposed in the study with the assumption that the tensile force is evenly taken by each part of the bonded area. The bonded area in Figure 10(a) with a width of w and a length of dx could take the tensile force ΔF_t and the tensile stress $\Delta\sigma$ as expressed in Equation (5-7).

https://doi.org/10.52202/069179-0198

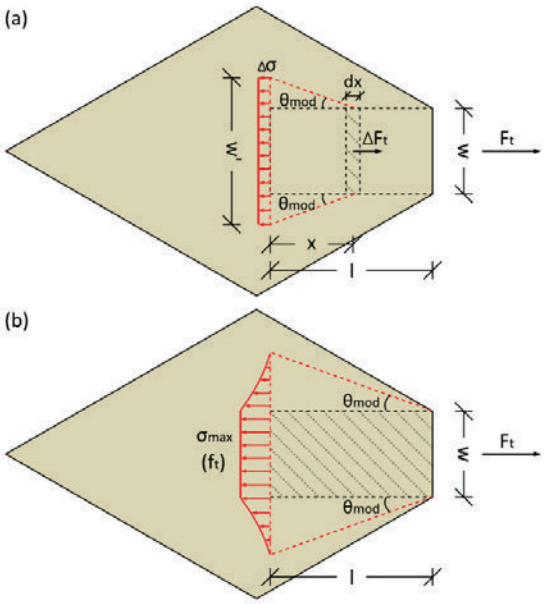

Figure 10: *Illustration of the modified analytical model: (a) the contribution from a calculated bonded region; and (b) the stress distribution.*

$$\Delta F_t = \frac{F_t}{l} dx \tag{5}$$

$$\Delta\sigma = \frac{\Delta F_t}{w' \cdot t} \tag{6}$$

$$w' = w + 2\tan(\theta_{mod}) \cdot x \tag{7}$$

where θ_{mod} is the spreading angle in the modified analytical model; x is the distance of the calculated bonded region to the end of the bonded area; and w' is the effective width of this calculated region. The effective width of the calculated bonded region decreases when it moves from the outmost to the end of the bonded area, leading to a more realistic non-uniform stress distribution. The maximum tensile stress takes place within the width of the bonded area and can be calculated by performing the integral in Equation (8).

$$\sigma_{max} = \int \Delta\sigma = \frac{F_t}{l \cdot t} \int_0^l \frac{dx}{w + 2\tan(\theta_{mod}) \cdot x} \tag{8}$$

By solving Equation (8), σ_{max} is expressed in Equation (9).

$$\sigma_{max} = \frac{F_t(\ln(w + 2\tan(\theta_{mod}) \cdot l) - \ln w)}{2l \cdot t \cdot \tan(\theta_{mod})} \tag{9}$$

Imposing that the failure occurs when the maximum tensile stress reaches the tensile strength of birch plywood:

$$\sigma_{max} = f_t \tag{10}$$

θ_{mod} can be determined (see Equation (11)).

$$\theta_{mod} = \begin{cases} 16.6° & (\alpha = 5°) \\ 25.7° & (\alpha = 15°) \end{cases} \tag{11}$$

4 CONCLUSIONS

In this paper, glulam frames were adhesively connected by means of birch plywood plates and tested monotonically in compression. The face grain of the birch plywood connecting the inclined and horizontal glulam elements was 0°, 5°, and 15° to the horizontal direction in three test series. These plywood gusset plates were designed as the weakest part so as to study their failure mechanism. Nevertheless, some specimens failed in the bonded region with little glulam fiber remaining on the bonded surface. Reasons for the failure in the bonded area have been discussed in the paper; however, more studies regarding the adhesive types and process-related parameters should be conducted in the future to enhance the bonding quality for the formation of a reliable bonded connection between spruce glulam and birch plywood. More than half of the tested specimens showed failure in birch plywood plates as expected. Moreover, a comparison between the adhesively bonded and mechanically connected glulam frames confirms the higher load-bearing capacity and global stiffness of the former one. The main findings with regard to the influence of the birch plywood face grain orientation on the global stiffness and load-bearing capacities are as follows:

Global stiffness: despite the anisotropic elastic properties of the birch plywood plate, the influence of its face grain orientation (0° to 15°) on the global stiffness of the tested frame was limited. The global stiffness was also well predicted by the simplified planar 2D numerical model developed in this paper.

Failure mechanism: for the specimens that failed in birch plywood, tensile failure was observed. With the tensile force of the glulam beams at failure load output from the numerical model and the angle-dependent tensile strength of birch plywood characterized in the previous studies, two analytical models, namely, the classic 'Whitmore' and modified analytical models, were utilized to illustrate the failure mechanism with the concept of the effective width and the spreading angle. It is found that, although the tensile strength of birch plywood at 15° is 30% lower than the one at 5°, the effective width and thus the spreading angle is larger at 15°, leading to the smaller difference in load-bearing capacities, which is beneficial for plywood gusset plates in potential structural applications where they are likely to be subjected to the forces in multiple directions.

The spreading angles derived from these two analytical models were determined from the specific frame structure tested in this study. The magnitude of the spreading angle should be further verified by performing uniaxial tests with a wider range of load-to-face grain angles involved, e.g., from 0 to 45 degrees. Moreover, research questions regarding whether the spreading angle theory is robust for birch plywood with different thicknesses and different bonded areas may also need to be considered in the future.

ACKNOWLEDGEMENT

The authors would like to gratefully acknowledge Vinnova project 2017-02712 "Bärande utomhusträ" within the BioInnovation program as well as the Kamprad

Family Foundation (reference number: 20200013) and from Produktion2030, a strategic innovation program supported by Vinnova [reference number: 2021-03681], Swedish Energy Agency and Formas. China Scholarship Council and Svenskt Trä are thanked for the financial support. Moelven is thanked for supplying the glulam materials. Koskisen is acknowledged for supplying birch plywood panels. Dynea is thanked for supplying the adhesive.

STRUCTURAL CHARACTERISTICS AND DEFORMATION BEHAVIOUR OF AN ADVANCED CARPENTRY CONNECTION IN TIMBER CONSTRUCTION

Katrin Vögele[1], Moritz Tronnier[2], Yannick Plüss[3], Mike Sieder[4]

ABSTRACT: The following paper addresses the experimental examination of the micro-offset-node, used in an innovative roof structure "ReFlexRoof" developed in the public funded project TimberPlan+ (research consortium led by HTWK Leipzig, Team FLEX). The structural form of the micro-offset-node, called MVK, leads back to a carpentry connection by Friedrich Zollinger. The characteristics of the MVK are described in more detail. In order to represent the load-bearing and deformation behaviour of the roof structure realistic input values for the nodal stiffness in the existing three-dimensional design model are needed. Therefore, laboratory tests on the micro-offset-node are executed at the Institute of Building Construction and Timber Structures (iBHolz, Technische Universität Braunschweig). The experimental methodology as well as observations during the experiments are presented. Based on load-deformation curves, resulting values for the strength and stiffness of the node are calculated. Apart from that, the methodical and manufacturing procedure is examined and discussed.

KEYWORDS: carpentry connections, glued laminated timber, connection stiffness, experimental results

1 INTRODUCTION

Carpenter connections are not part of the static and engineering calculation methods commonly used today. They usually form hyperstatic spatial trusses or frames and are mainly found in historical constructions. Due to the traditional origin of these connections and the associated lack of knowledge about realistic stiffness values of such timber connections, it is difficult for civil engineers to determine the load-bearing capacity and the deformation behaviour of these structures. [1] Today's building codes do not provide sufficient calculation methods to evaluate the connection stiffness and determine the values for numerical or analytical calculations. Therefore, such constructions are calculated on the basis of statically determined simplified models.
However, this approach no longer fits the state of the art. For numerical computational methods and simulations, the nodal stiffness values of these structures are required in order to calculate the internal force distribution. An estimation of the stiffness is not sufficient for hyperstatic structures with multiple nodes. Incorrect and unrealistic assumptions can lead to underestimation of the internal forces and, in the worst case to structural failure.
Regarding the micro-offset-node as an advanced carpentry connection and the ReFlexRoof as a hyperstatic structure, this problem became apparent in the research studies of the TimberPlan+ project.

2 STRUCTURAL DESIGN

The micro-offset-node, described in the following as MVK (German translation "**M**ikro**v**ersatz**k**noten"), is an advanced carpentry connection in the timber roof structure called ReFlexRoof. The structure of the roof can be described as a lamella roof and is shaped as an arch.

2.1 ORIGIN

The first evidence of lamella roofs can be found in the middle of the 16th century. Philibert de l'Orme had cut planks into arch shapes, joined them with wooden nails and wedged them lengthwise. [2] Friedrich Zollinger adopted this construction method in 1921 and formed the planks into a rhombic construction of lamellae instead of a layered connection [3], as shown in Figure 1.

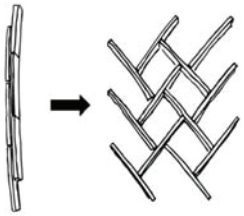

Figure 1: *Adaption of the structure from l'Orme (left) to Zollinger (right) [4]*

This formation of the lamellae generates a reciprocal framework.

https://doi.org/10.52202/069179-0199

Nodes of the Zollinger structure are characterized by a continuous lamella, to which another lamella is butted from both sides. The connection of the node and thus the lamellae is ensured by a bolt that is guided through an oblong shaped hole in the continuous lamella. On the upper side, the lamellae are curved due to the arch shape of the roof construction. On the bottom side the lamellae are straight.
For the completion of the roof boarding planks are attached which are assumed to figure as secondary structure. [3] Zollinger patented this system in 1923. [5]
Although the advantages in the standardization of components formed a fundamental prerequisite for economic efficiency, the weak points of this system became apparent over the years: The ductility of the connection due to the difference in materiality of timber and steel and the arrangement of the bolt generate forces transverse and at an angle to the fibre. This leads to local deformations at the node. In the global structure, these deformations are amplified in association with the redundancy and the creep of timber under external load. All these interactions lead to settling of the structure and thus to change of the internal load distribution. This effect amplifies as the spans become longer. For this reason, the MVK (Figure 2) was developed, which offers the following advantages: [6]

- Precise joinery methods
- Use of kiln-dried timber
- Use of form-fit principle without a bolt

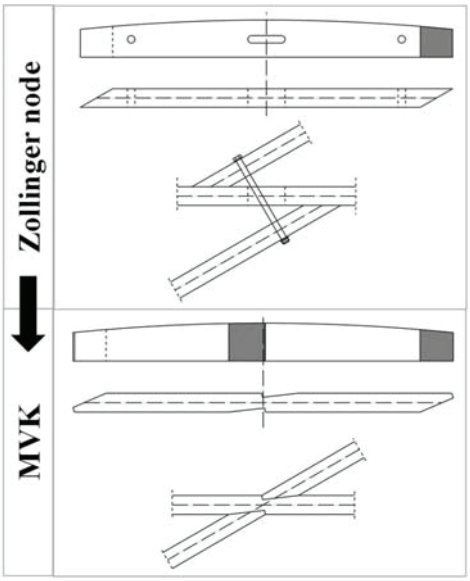

Figure 2: *Illustration of the Zollinger node in comparison to the MVK*

2.2 CURRENT LOCAL AND GLOBAL STRUCTURE

As described, the MVK is an attempt to optimise the traditional Zollinger joint and aims to reduce the creep deformations that can be observed in the construction.
The MVK consists of a step joint with two-sided incision shown in Figure 2. This ensures that the normal forces are transmitted via contact pressure. [6] In contrary to the construction of Zollinger the lamellae are not attached or connected to each other using fasteners. Similar to the original approach is that the lamellae are spanned in a rhombic shape which creates a framework of reciprocal even modules.

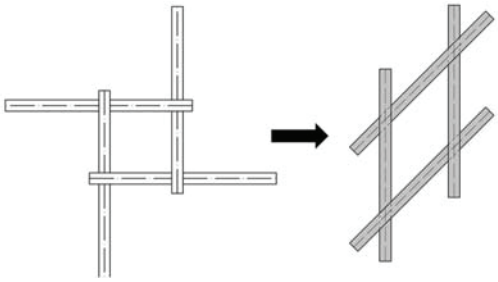

Figure 3: *An example of a reciprocal framework (left) that can be converted into a rhombic shape module (right)*

Several of these reciprocal modules then build an arch shaped roof. The construction is bordered by planks at the gable and by an edge beam the eaves as shown below.

Figure 4: *Construction of the arch shaped roof*

To form the roof structure and to ensure the global load-bearing behaviour, the construction of the lamellae is sheathed with a panel. The connection between the panel and the lamellae is made by staples.
In the global view, the structure forms a highly hyperstatic system due to the great number of reciprocal modules. The consequence is, that the stiffness values of the nodes are highly important for the structural design.
In addition, the construction of the arch shaped roof is segmented. Several MVK-connected lamellae are bonded via a standardized panel element in the factory and are transported to the construction site. At the site the elements are combined to form the final structure.
During building of the prototype construction in the research project, it is discovered that the segments could not always be joined properly. This results in gaps between the lamellae at the node points (Figure 5, right).

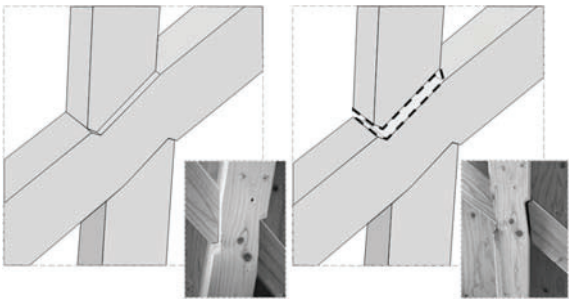

Figure 5: *Local node properties in the quasi-perfect (left) state and in the pre-deformed state (right)*

https://doi.org/10.52202/069179-0199

On one hand, these occur due to material and manufacturing inaccuracies, which are significantly more demanding to implement on the construction site because of the spatial geometry and assembly. On the other hand, the pre-curved planking causes recoil forces, which lead to pre-deformations.
In the research project these aspects have to be examined more closely.

3 MATERIAL AND METHODS

Although the basic local characteristics are approximately known from tests on preliminary models of the MVK [6], the MVK itself and its local load-bearing and deformation behaviour has not yet been extensively examined. Particularly the stiffness of the node has to be evaluated in more detail.

3.1 EXPERIMENTAL INVESTIGATION

With the aim to provide stiffness properties for the use in a computation design model, experimental investigations are carried out at iBHolz.

3.1.1 SETUP

All test specimens are made of two half-lamellae, which are butted on a continuous lamella. The loads are restricted to a compressive force acting axially on the upper lamella. This based on the assumption of an arched roof structure, which follows the line of thrust in the most optimal form. The geometric properties are selected based on the prototype. In order to contain the estimated load within the maximal capacity of the testing machine, the geometric dimensions of the prototype are scaled to the following dimensions:

$$h_S = 14\ cm \qquad t_v = 1.33\ cm$$
$$h_D = 12\ cm \qquad \gamma = 49.5°$$
$$b_D = b_S = 8\ cm$$

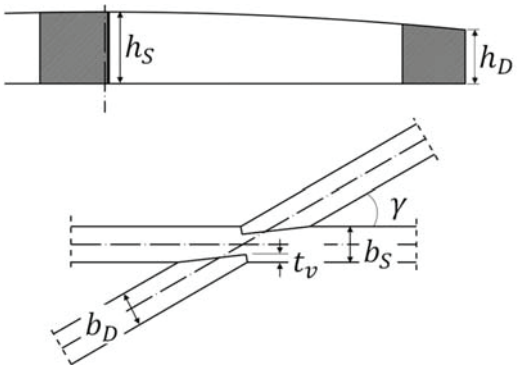

Figure 6: *Definition of the geometric variables at the lamella (top) and at the node (bottom)*

All lamellae are made of GL24h graded glulam timber. The average density of the timber used in the specimens is about 450 kg/m³.
The test concept consists of three test series with five test specimens each. The test series differs as shown in Table 1:

Table 1: *Description and over-view of the test series*

Series	Panel	Screws	Gap
A	x	-	-
B	x	-	x
C	-	x	-
***C4 / C5**	-	-	-

*the screws were removed after an applied load of 5 kN

The panel has a stapled connection (1.53x50 mm) to the lamellae. The spacing of the staples is 120 mm. 12 mm pine multiplex plywood is used as panel. The connection is ensured by three (6x120 mm) screws per half lamella. These are inserted as suggested in the patent for the MVK. In series B, a gap of 1 cm to the front-notch surface and 1 cm to the bottom-notch surface is created as shown in Figure 5 (on the right).

The tests are conducted on a walter+bai LFM 125 testing machine with a maximum capacity of 125 kN. The machine force as well as the displacement of the top pressure plate are recorded. The specimens are tested between two pressure plates which are connected to the testing machine via hinges. This assures that no bending moments are introduced by the compression plates. Before the load is applied the specimens have to be held in place by a supporting frame. The test frame is made of aluminium as shown below.

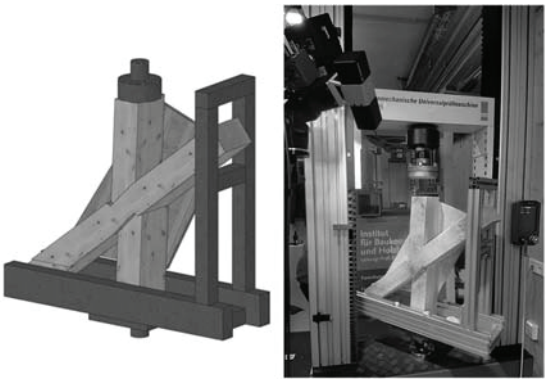

Figure 7: *Model of the test setup (left) and realization (right)*

It is ensured that no forces are transferred from the specimens to the testing frame during the experiment. The tests are accompanied by a photogrammetric measuring system, which takes 200 to 800 pictures per specimen and can be recalled at any time. In addition to the data from the testing machine this system allows further investigation of the load bearing behaviour of the node. The strain at the surface of the timber members can be measured and visualized by the software. The system replaces otherwise used strain gauges. In order to track the deformations, the specimens are painted white with a random black pattern to create better contrast for the measurements.

https://doi.org/10.52202/069179-0199

3.1.2 EXECUTION

The specimens are conditioned at 20°C and at a relative humidity of 65 % prior to the experiments. The average moisture content during the experiments is 11.5 %.
The tests are performed along the lines of DIN 26891. A preload is applied to clamp the specimen between the pressure plates before the hinges are untightened and the rotation of the pressure plates is made possible. A stress-controlled hysteresis cycle is performed between 40 % and 10 % of the expected maximum load. This eliminates any slip and ensures good contact between the lamellae. During the second cycle, the load is increased up to 60 % of the estimated load before switching to deformation control at 0.05 mm/s.
The experiments are terminated when the specimen fails and the load decreases rapidly or when the free movement of the specimen is limited by the testing frame. This happens at different piston displacement values for any specimen and is therefore monitored manually. In most cases the latter condition occurs first, due to the highly ductile behavior of the connection.

3.2 ANALYSIS

Currently, the computational model consists of a combination of beam and shell elements designed as a spatial frame model. The beam elements represent the lamellae and the panels are implemented as shell elements. For simple joints it is sufficient to consider the connection either as rigid or hinged. For more complex timber structures, the nodal stiffness needs to be characterized to provide a realistic internal force distribution.
The experimental investigation is designed to obtain stiffness values in axial direction of the lamella. Based on the load-deformation curves, an axial node stiffness C_x for the beam element (illustrated in Figure 8) can be determined.

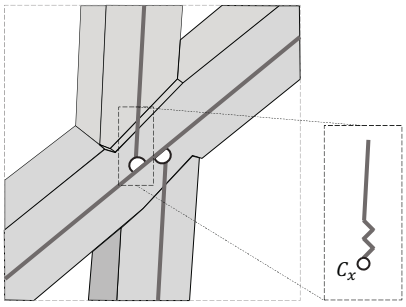

Figure 8: *Extraction of the lamella into a beam element with the node stiffness* $\boldsymbol{C_x}$ *at the joint to the continuous lamella*

Due to the pre-deformed conditions on the node, the specification of the node stiffness must include not only the stiffness in the quasi-perfect state but also the pre-deformed state (Figure 5). These two states represent the two static limit values for the stiffness of the structure.

Therefore, two methods are adopted to evaluate the characteristic mean stiffness C_x in the limit states:

- Heimeshoff and Köhler method (= HaK) [8]
- DIN EN 26891:1991 (= DIN) [9]

For the evaluation of the stiffness, the longitudinal deformation in direction of fibre of the lamella is neglected. The reason for choosing this method is that the longitudinal deformation compared to the total measured displacement does not exceed 2.5 %. The determination of the node stiffness is then simplified to half of the measured displacement regardless for both methods. In addition, for each test series only the measured values of the deformation from the second ascending branch of the hysteresis is taken into account. This excludes the initial slip. In test series B, which has significantly more slip due to the gap, the mean value of the measured slip of the setup from A and C ($u_{slip,set}$) is subtracted in order to be able to represent the effect of the gap at maximum load.

The following description summarizes the approach for the HaK and DIN method. Each load-deformation curve is analysed using both methods.

HaK method (compare to Figure 9):

1) Determination of the 95% fractile of the strengths for $f_{c,\alpha}$ and f_v according to [11] and [12]
2) Estimation of the expected loads $R_{dim,i}$ (equations based on the EC5/NA verifications for carpenter connections [13], [14])

$$R_{dim,compression} = t_v \cdot h_D \cdot \frac{f_{c,\alpha}}{\cos^2 \frac{\gamma}{2}} \quad (1)$$

$$R_{dim,shear} = 8 \cdot t_v \cdot k_{cr} \cdot h_S \cdot \frac{f_v}{\cos \gamma} \quad (2)$$

3) Formation of the mean value $R_{dim,mean}$ from the two proofs (shear force, contact pressure) of EC5/NA
4) Determination of the deformation $u_{R,dim}$ at the load $R_{dim,mean}$
5) Composition of the node stiffness C_x

$$C_x = \frac{R_{dim,mean}}{u_{R,dim}} \quad (3)$$

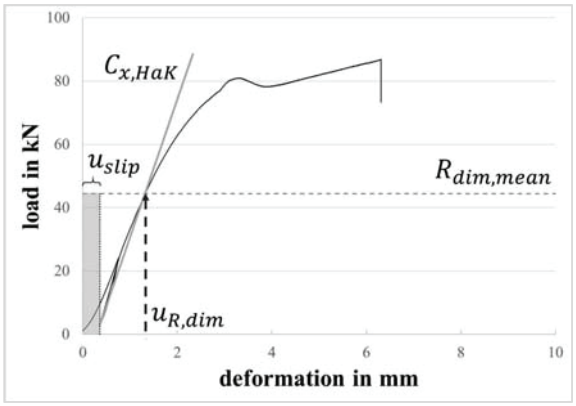

Figure 9: *Illustration of the approach based on the HaK method*

https://doi.org/10.52202/069179-0199

DIN method (compare to Figure 10):

1) Definition of the assumed elastic limit $R_{max,el}$
2) Determination of deformations u based on 0.4 $R_{max,el}$ and 0.1 $R_{max,el}$
3) Composition of the node stiffness C_x

$$C_x = \frac{0.4\ R_{max,el} - 0.1\ R_{max,el}}{u_{0.4\ R_{max,el}} - u_{0.1\ R_{max,el}}} \quad (4)$$

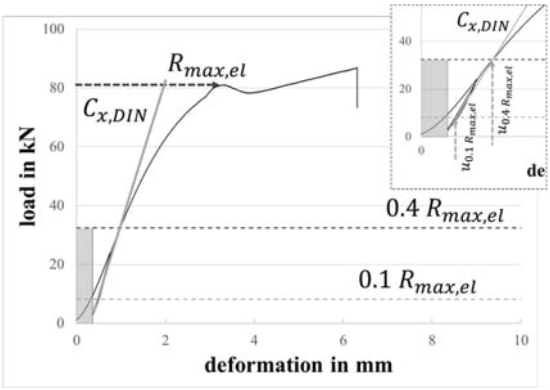

Figure 10: *Illustration of the approach based on the DIN method*

For the evaluation of test series B, a few minor adjustments are made. For the HaK method, the load-bearing capacity of the staple connection is considered to determine $R_{dim,mean}$. The determination of the initial deformation $u_{R,dim}$, the $u_{slip,set}$ is subtracted.

In the DIN method, a slightly different procedure is chosen in step 3. In equation (4), the stiffness is calculated with the consideration of u_{gap} following equation (5) and Figure 11:

$$C_x = \frac{0.4\ R_{max,el} - 0.1\ R_{max,el}}{(u_{0.4\ R_{max,el}} - u_{0.1\ R_{max,el}}) + \frac{3}{4} \cdot u_{gap}} \quad (5)$$

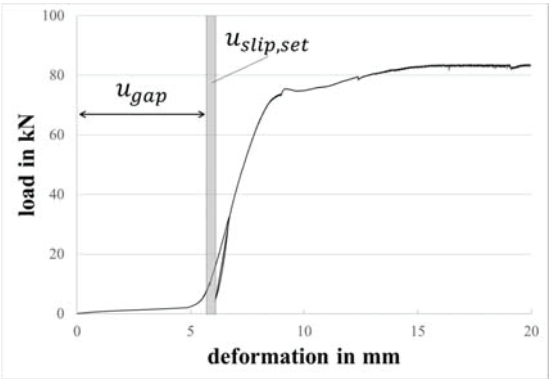

Figure 11: *Representation for the different deformations from the gap and the slip of the setup on one of the test specimen B*

The calculation of the characteristic values of the load-bearing capacity and stiffness is performed according to DIN EN 14358 Section 3 [14]. For the load-bearing capacity, a normal distribution is assumed according to $R_{c,90}$ in [11]. For the stiffness, the characterized mean value is calculated using the given equation 14 in [14].

4 RESULTS

The obtained node stiffness can be used in the numerical model to perform a sensitivity analysis for the evaluation of the internal force distribution. The following results are averages based on an evaluation of all test specimen.

4.1 ELASTIC LOAD-BEARING CAPACITY

For the value of the load-bearing capacity, the first maximum point of the load-deformation is used to determine the elastic limit $R_{max,el}$. To characterize this value to a 5%-quantile, [14] states a factor for a sample size of 5 specimens with

$$k_s(5) = 2.46$$

for the standard deviation.

The calculated standard deviation is applied to the mean values leading to the following characteristic load-bearing capacities $F_{k,el}$:

Table 2: *Average and characteristic values for the load-bearing capacity in the elastic limit state with sample size 5*

Test Series	$R_{max,el,mean}$ [kN]	s_y [-]	$F_{k,el}$ [kN]
A	73.3	7.045	56.0
B	68.1	6.101	53.1
C	66.1	8.384	45.5

It can be seen that the panel has an influence on the load-bearing properties of the node. Thus, A and B show up to 15% to 20% greater values than C at the characteristic value. The screws (in series C) that hold the step joint in position have only little influence on the elastic load-bearing capacity. By excluding C4 and C5 (MVK under preload without screws) from the evaluation of test series C, the values both of the mean and characteristic value differ by less than 4 %. However, it can be clearly noticed that the tests in C have a lower load-bearing capacity than A and B. It is assumed that the panel has a load-bearing effect, which is missing in test series C. In addition to that, the panel prevents the middle lamella from rotating and therefore loosing of form-fit.

The nodes in the overall structure are a combination of the cases A through C, A and B are randomly distributed whereas case C only occurs in planned matter. Therefore, the evaluation can be conducted over a larger sample size. The factor for the sample size decreases with the number of specimens. For the node states A, B the factor is

$$k_s(10) = 2.10$$

and for the node states A, B, C the factor is reduced to

$$k_s(15) = 1.99.$$

This allows to calculate the characteristic load-bearing capacity $F_{k,el}$ according to the Table 3.

Table 3: *Average and characteristic values for the load-bearing capacity in the elastic limit state with sample size 10 or 15*

Test	$R_{max,el,mean}$	s_y	$F_{k,el}$
Series	**[kN]**	**[-]**	**[kN]**
A, B, C	69.2	8.264	52.7
A, B	70.7	6.927	56.5

The difference in the load-bearing capacity of the node is about 7% larger for a composed case of A and B in comparison to the composed case A, B and C.
In order to compare the values with the state of art, the load-bearing capacity is determined according to the equations (1) and (2) which are derived from EC5 NDP [10]. The input strength properties are based on the 5%-fractile and on the 95%-fractile on EC5 [15]. The strength properties from NDP [10] are not used, because k_{cr} which reduces the width in order to limit the shear strength to an admissible value of 2.5 N/mm². $F_{dim,shear}$ would therefore be equal on the characteristic and on the 95 %-fractile level.
The evaluated values are shown in the following table.

Table 4: *5 %-fractile and 95 %-fractile for the load-bearing capacity according to [10] and [15]*

	$F_{5\%,DIN}$	$F_{95\%,DIN}$
	[kN]	**[kN]**
$F_{dim,compression}$	26.4	42.4
$F_{dim,shear}$	53.8	120.9

The characteristic result values of the experiments are close to the 5 %-fractile of $F_{dim,shear}$ as well as in the range of the 95 %-fractile of $F_{dim,compression}$. This shows that higher compressive forces can be transmitted via the step joint of the MVK than assumed by the design model in [10].

4.2 NODE STIFFNESS

Based on the presented methods in section 3.2 the following results for the axial stiffness C_x can be made as shown in the table below. For the analysis another evaluation is performed in test series B. It is listed as B' and shows the stiffness that results after the closure of the gap. The pre-deformation up to the point of contact in the step-joint is on average 5.27 mm based on measurements within the load deformation curve.

Table 5: *Average values for the node stiffness in the elastic limit state with sample size 5*

Test	$C_{x,DIN}$	$C_{x,HaK}$	u_{slip}
Series	**[N/mm]**	**[N/mm]**	**[mm]**
A	53453	49027	0.39
B	4682	5718	0.40*
B'	45608	53580	0.40*
C	48977	45972	0.41

*$u_{slip} = u_{slip,set}$; mean value out of u_{slip} from A and C

Comparing the two methods in each test series, differences in percentages can be observed: For A and C the differences are rather small and less than 10 %. For test series B, the percentage value increases up to 18 %. In case of the additional study B' the deviations are up to 15 %. A comparison of all lines (with exception of B) show, that the stiffnesses for a quasi-perfect node range from 45 kN/mm up to 53 kN/mm.
Considering Table 6, showing the composed test series, it is noticeable that the methods are converging and deviating by a maximum of 3,5 %.

Table 6: *Average values for the node stiffness in the elastic limit state with sample size 10 or 15*

Test	$C_{x,DIN}$	$C_{x,HaK}$
Series	**[N/mm]**	**[N/mm]**
A, B', C	49346	49526
A, B'	49531	51304

4.3 GENERAL OBSERVATIONS

Most of the deformation can be observed at the front-notch and bottom-notch surface (Figure 12) of the MVK.

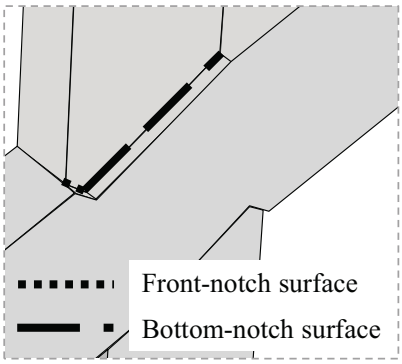

Figure 12: *Illustration of the position of the two surfaces*

At the beginning of the load application, the deformation shifts from the top lamella towards the front-notch surface. With further displacement, the bottom-notch surface is also compressed. As a result, a gap opens at the bottom-notch surface and remains as plastic deformation (Figure 13). Furthermore, it can be identified that the fibres of the abutting lamella protrude beyond the front surface. In addition, the abutting lamella rotates clockwise. Due to the compression on the front, the lamella tends to lose its optimal position. Thus, it is pushed out of the front-notch surface. This leads to an eccentricity of the resulting force and the lamella rotates. This rotation occurs especially in the test series B. Presumably, this is due to the lack of rotational support of the staple connection beyond its elastic limit. The displacement between the panel and the lamellae remains a plastic deformation after unloading.

https://doi.org/10.52202/069179-0199

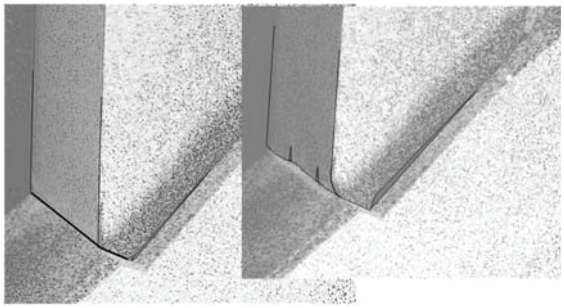

Figure 13:*Illustration of the deformations during the test phase (left) and after the test phase (right), which shows the permanent plastic deformation*

Furthermore, in test series B it is observed that the gap does not always close optimally. This means that a force- and form-fit connection cannot be guaranteed. These effects that occur at the quasi-perfect MVK are intensified in test series B. The tests in series C do not show a significantly different behaviour. In test C4 and C5 the screws are removed after applying a preload. This results in a complete failure by the abutting lamella popping out of the connection at the front-notch.
In general, the failure state of the MVK is determined by the deformations at the front-notch. The stresses in the bottom-notch surface are not decisive for the MVK.

4.4 APPROACH FOR DESIGN

For the determination of internal forces with FE-models, a limit value consideration for the stiffness for specific node states should be attempted. Therefore, three methods can be generated:

1) Design in the ultimate limit state
Historical research [16] shows that it can be assumed that the gaps are closing over time.
As long as it is ensured that the staples and quasi-perfect MVK provide enough plastic deformations capacity to close gaps, the stiffness for determining forces in the lamellae can be considered as the stiffness determined in series A and B':

$$C_x = 49000\ N/mm$$

2) Robustness estimation
In case of insufficient plastic deformation capacity of the quasi-perfect MVKs in an area next to a concentration of pre-deformed MVKs the risk of brittle failure must be addressed. An estimation for the robustness allows to find areas in the structure with a higher risk of failure due to load redistribution from softer node points. Therefore, two stiffness values have to be defined for the numerical model. The lower limit should be applied to nodes within the structure with open gaps.

- **Upper limit for quasi-perfect nodes** (test series A):
$$C_x = 53000\ N/mm$$
- **Lower limit for pre-deformed nodes** (test series B):
$$C_x = 4600\ N/mm$$

If it is considered to use screws to ensure the form-fit of the MVK, variant C can be adapted to the methods shown above.

5 DISCUSSION

Since there is no agreement in the literature ([8], [16], [17], [18], [19]) on how to evaluate the stiffness on carpenter-type connections in modern constructions, the following provides some views on the methodology, results and optimisation.

5.1 ANALYSIS METHOD

For the analysis up to the elastic limit state the linear elastic material law is observed and applied for further calculations.

Hysteresis effect is left out of the evaluation, since the MVK with gap is used to examine the effects of slip in the connection. In addition, the quasi-perfect MVK is manufactured with an accurate fit. For the investigation of the effects of repeated loads applied after closing of the gaps, cyclic tests shall be carried out.

In test series B (pre-deformed node), the nodal stiffness is very low if the closure of the gap is included in the determination of the linear elastic section. The method as proposed by HaK assumes this. The method proposed by DIN excludes this effect by default, as the stiffness value for the linear-elastic section is determined between 10 % and 40 % of the maximum load. The HaK method is therefore modified in B', and the DIN method in B in order to compare the stiffness values obtained in both methods.

If the stiffness is set as a gradient in comparison to the load-deformation curve, two areas between load-deformation curve and gradient are created (Figure 14): In the first one, the load-deformation curve is lower than the gradient. This leads to an overestimation of the internal load in the connected members and the node. In the second area there is an underestimation, because the gap of the MVK is closed. For the ultimate limit state, the overestimation of the stiffness is on the safe side, whereas an underestimation of the stiffness is on the unsafe side. In the serviceability limit state, this issue is inversed. However, a realistic description of the deformation cannot be depicted. A bilinear curve considering the slip and the closed MVK would be more suitable. It is assumed that this increases the computational effort for complex models beyond a reasonable level.

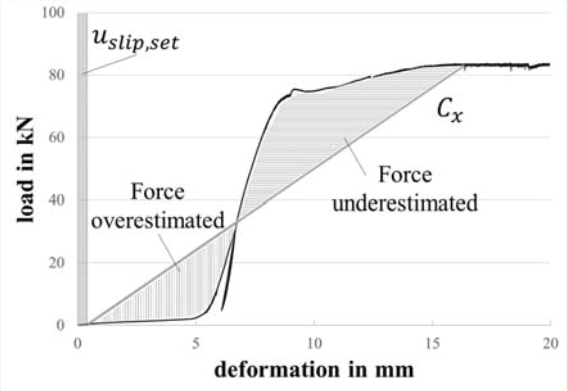

Figure 14: *Gradient of C_x from test series B and one load-deformation curve of a specimen of test series B*

The stiffness values are compared on the mean level, since no other regulations are specified for this purpose. [11]
Properties that could be applied from [11] are the distribution functions for the load-bearing capacity $R_{c,0}$ and $R_{c,90}$. However, these distribution functions differ in their nature. Thus, $R_{c,0}$ is defined as lognormally and $R_{c,90}$ as normally distributed. In order to be able to give a statement about this, an increase in the number of samples is necessary. Current evaluations show an inclination to the lognormal distributed function. This assumption has not yet been statistically tested.

5.2 VERIFICATION OF THE LOAD-BEARING BEHAVIOUR

The elastic results $R_{max,el,mean}$ are in the range of the results published in [8]. Due to the fact that the failure of the MVK is generated by the deformation of the front-notch, the values for the ultimate limit state must be defined at a set deformation limit. This may not represent the maximum elastic limit $R_{max,el,mean}$, which is given in section 4.1. It can be expected that the characteristic values will then approach the state of art for compression $F_{dim,compression}$.

Due to the experimental setup, only few results could be archived at loads above the elastic limit. Most of the tests had to be aborted because the specimen touched the testing frame or the loadcell was tilted. Therefore, only little reliable information about the plastic behavior was gained and no results can be presented.

5.3 VERIFICATION OF THE NODE STIFFNESS

The assumptions in the literature [16] for the stiffness of step joints, mainly rely on historical studies.

Different types of models of the displacement springs are used. In [17] the stiffness is given in two directions: parallel and perpendicular to the fibre – shown below for the MVK at the continuous lamella:

$$C_{\parallel} \approx C_{\perp} \approx 1 \cdot 10^5\ N/mm$$

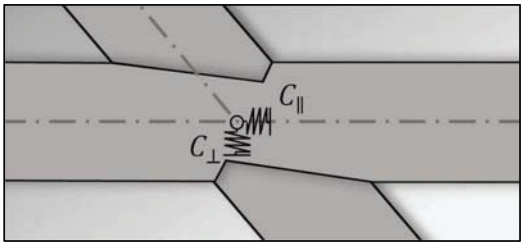

Figure 15: *Arrangement of the deformation springs in adaptation to the MVK*

This value significantly exceeds the resulting values for the MVK obtained in the current study. Another source [18] describes that the step joint can primarily transmit normal forces. This means that an elastic spring should be applied in the direction of the abutting lamella [19]. As a result, the node is designed to be hinged.

Forces perpendicular to the lamella only have a minor influence on the global load transfer. This allows for a rigid modelling regarding the shear forces.
In the mentioned literature[18], a value of the following stiffness has been assumed:

$$C_x \approx 45\ kN/mm$$

This stiffness results from a deformation of 15 mm at the elastic maximum compressive force in the direction of the abutting lamella.
This assumption fits to the result values of the tests.
In [8], another formulation for the stiffness of a step joint, is given by the following equation:

$$C_x[kN/mm] = (45.2 - 42.1 \cdot sin^2\gamma) \cdot \frac{b}{12} \cdot 1 + \frac{t_v - 2.34}{2.34} \cdot 0.1 \quad (6)$$

where b and t_v have the dimension cm

For the dimensions of the tested MVK, the resulting value is:

$$C_x \approx 20\ kN/mm$$

This value is below the load-bearing capacity of the node stiffness of the MVK, which is approximately 50 kN/mm. One possible explanation for the different results is the fact that the wood anisotropy causes very significant scattering. Especially the values from the historical investigation can be affected, because the regulation for sorting, wood moisture and assembly were not strictly specified at that time. Furthermore, different methods of measuring can lead to varying values. Regardless of these aspects, it is also assumed that the connection is strongly influenced by the stiffness perpendicular to the grain which varies considerably. [20] Therefore, there are no provisions for the distribution functions.

6 CONCLUSIONS

During experiments at the TU Braunschweig the load bearing behaviour and capacity as well as the stiffness of the MVK was evaluated. If a load is applied, deformations are primarily observed at the front-notch and bottom-notch surfaces of the MVK. Therefore, the load

https://doi.org/10.52202/069179-0199

deformation curve shows an almost linear elastic area followed by a large plastic area. Multiple test series allowed for the evaluation of the MVK in a pre-deformed and a quasi-perfect state. It was observed that a gap between the lamellae decreases the stiffness significantly while also reducing the load carrying capacity. The difference between the stiffnesses of these pre-deformed nodes and quasi-perfect nodes has to be considered in design.

The determined stiffness values can serve as the basis for a design concept that takes the stiffness distribution into account when determining the internal forces. In the lack of precise knowledge or predominant scattering effects, conservative approaches are usually adopted. In the case of internal force distributions, this does not mean to "lower" the stiffness values, as these lead to an underestimation of the internal forces. Therefore, a method shall be developed, which allows for a safe estimation of internal forces in ULS. Regarding the SLS on the other hand, the slip occurring in some connections can have a major influence on the deformation behaviour and needs to be considered. Further investigations are planned to be conducted on a prototype building located in a testing facility in Leipzig.

One goal in the development of the MVK was to improve the long-term behaviour compared to the Zollinger system. This aspect needs further investigation. Especially considering the load redistribution after closing of the gaps observed in the MVK in proximity to segment joints.

Due to the limitations of the testing equipment, notably the maximum movement during which the specimen could freely deform, no systematic valuation of the plastic deformation capacity could be made. However, qualitatively big plastic deformations can be observed. In order to exploit the full potential of the MVK, the plastic deformation capacity should be taken into consideration and included in the determination of C_u.

The curvature of the structure and therefore the needed bending of the board results in recoil forces that must be absorbed by the staples. However, it can be assumed that these forces decrease over time, so does the resistance of the stapled connection. This needs further investigation.

ACKNOWLEDGEMENT

These investigations were only possible due to project funding from Fachagentur Nachwachsende Rohstoffe e. V. (FNR, project no. 2220HV003C, funding period 2020-2023). A great thank you is given to the FLEX Team of the HTWK Leipzig as well as to the company STRAB GmbH and J. Bengel for the support in the organization, the setting and the delivery of the test specimens.

REPAIR CONNECTION WITH WOODEN WEDGED DOWELS: AXIAL TENSILE AND SHEAR VERIFICATIONS.

Elena Perria[1], Mike Sieder[2], Svenja Siegert[3], Cordula Reulecke[4]

ABSTRACT:. The present paper describes the final results of the research project by the title "Repair connection with wooden wedged dowels. New and alternative repair method that meets the demands of Monument Protection of built substance's gentle care and material fairness". The project aims to develop guidelines for static-constructive use of wood-wood (carpentry) repair connections with wooden wedged dowels as mechanical fasteners. In this paper the boundary conditions and the axial tensile and shear verifications are presented.

KEYWORDS: carpentry connections, mechanical fasteners, wooden wedged dowels, axial tensile verification, shear verification

1 INTRODUCTION

In case of repair or replacement of damaged cross sections in historical timber buildings, metal fasteners like screws and bolts are very often used, especially if the fasteners have to be designed for planned shear or tensile stress, or a clamping effect in the wood-wood connection is required. Another common solution is bonding of steel or plastic rods that realize the connection with the existing structural members by means of synthetic resin grouting, glue, etc. e.g. the so-called Beta-system [1], among others. However, these repair methods and techniques are not to be favored from the point of view of monument preservation [2, 3]. Material conformity and appropriate, durable, repair methods according to the ICOMOS principles [2, 3] play a crescent role as a requirement in the future. In the Charter of Mexico [4] is stated that (a) *traditional wood-wood connections as repair connections are prioritized, while globally recognized as effective, and part of global competences in heritage conservation*. (b) *Non-material conforming techniques have not proven themselves in practice, and their long-term effects on historic wood structures are not sufficiently known; therefore, they are not to be favorized*. This latter statement (b) was mitigated in the 1999´s *Principles for the conservation of wooden built heritage* [5], presented as revision of the Charter of Mexico [4]. Nevertheless, long-term damages can occur when non-conform repair techniques are used [1, 6–8]. The most common damages are chemical effects (e.g. corrosion) on metal fasteners that transfer the oxidation on wood [6], and water condensation in the contact area between plastic or steel fasteners with the cross section, that promotes rot in wood [8]. Comprehensive challenges in the preservation of monuments are increasingly appearing because of improperly carried out renovations in the past decades. This represents a considerable economic factor that greatly increases the expenses for the care and preservation of our architectural heritage [6].

For all these reasons, since two decades, the monument preservation office in southern Lower Saxony, Germany have been made many attempts to reduce the use of metal fasteners/ bonding rods in the repair of wooden structures, and to foster wood-wood connections as repair connections. On the other side, structural engineers are oft unable - due to the lack of calculation basis - to provide a verification for many traditional wood-wood connections; therefore, they are oft not realized.

The aim the research presented in this paper is the development of some necessary engineering tools to perform the verification of carpentry repair connections with wooden wedged dowels as mechanical fasteners (Figure 4) under axial tensile and shear load.

2 METHODOLOGY

In the performed research project [9], the hypothesis about the use of the wooden wedged dowels in the load cases shear and axial tensile load was pursued experimentally, numerically and analytically. With reference to existing theories and verification methods on wooden fasteners [10–14], systematic first-approach tests TV1 [15] were developed. The aim was to define geometric-constructive parameters like crack formation, edge distances and penetration depth. In a second step, the investigated geometric-constructive parameters were classified according to their influence on the mechanical behaviour and on load-carrying capacity, in order to define the geometric-constructive framework for a static verification of the repair connection under axial tensile and shear loading. The firstly assumed hypotheses about the geometric-constructive parameters of the wooden wedged dowels [15] were adapted to the new findings and boundary conditions were defined (tests TV2 in [9]). The results generated so far were confirmed numerically, basing on the finite element method, and experimentally. Carpentry connections with wooden wedged dowels were tested under axial tensile (tests V1 [9]) and double shear loading (tests SV1 [9]), and the characteristic values of the load-bearing capacity were further used for the development of following verifications.

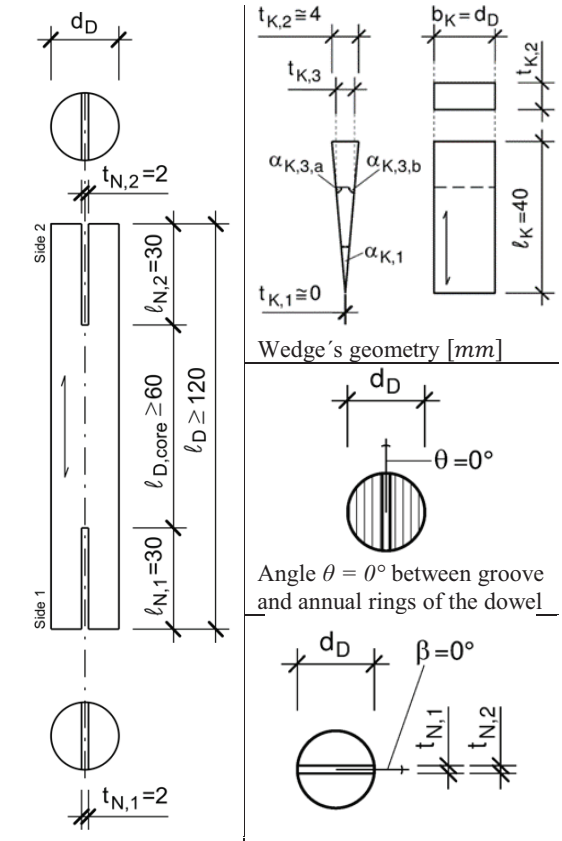
3 GEOMETRY

In order to obtain the expected results in terms of characteristic values of strength and remain in the average of the tested failure modes, general manufacturing rules and geometry features are defined. In the following Table 1, Figure 3 are explained the geometric/constructive parameters and boundary conditions in the repair connection. More information about these parameters is contained in [15].

Table 1: *Parameters of the wooden wedged dowel*

Symbol		Description of the parameter
H		Wood species combination: Dowel / Building Component (BC)
H	H1	Dowel: *Quercus*/ BC: *Picea abies*
	H2	Dowel: *Quercus*/ BC: *Quercus*
	H3	Dowel: *Fraxinus excelsior*/ BC: *Picea abies*
T1		Angle θ between groove´s orientation and direction of the annual rings on dowel´s cross section
		T1-0 → θ = 0°
T2		Angle φ between groove´s orientation on Side 1 [N,1] and fibers´ direction on building component´s surface
		T2-90 → φ = 90°
G		Angle β between groove´s orientation on Side 1 [N,1] and on Side 2 [N,2]
		Orientation of the groove on S1 parallel to orientation on S2 [G//]

As explained in Figure 2 and Table 1 the repair connection is composed by the original and repair building components and one or more mechanical fasteners, the wooden wedged dowels. The tested combinations are reported in the Table 1. More general rules are (a) the wood species for the wedge is always oak (*Quercus*) or the wedge must have a minimum strength of D30 [16] (b) the dowel must have a higher bulk density than the one of both original and repair building components $\rho_D \geq \rho_{BC}$.



Dowel geometry $[mm]$

Wedge´s geometry $[mm]$

Angle $\theta = 0°$ between groove and annual rings of the dowel

Angle $\beta = 0°$ between groove on side 1 and groove on side 2

Angle φ = 90° between groove on Side 1 and fiber direction of the building component

Margin distances:
$a_1 = a_2 = a_4 \geq 2.5 \cdot d_D$
$a_3 \geq 3 \cdot d_D$
$a_r \geq 2.5 \cdot d_D$

Figure 3: *Geometric boundary conditions for the connection with wooden wedged dowels*

https://doi.org/10.52202/069179-0200

3.1 BOUNDARY CONDITIONS AND WORKING PRINCIPLES OF THE FASTENER

The prerequisite for the transmission of load between fastener and cross section is a contact surface. A distinction is made between two types of contact surfaces for load transfer (Figure 4): A) Load-transfer effect due to wedging (spreading effect) area; B) Load-transfer effect due to skin friction area.

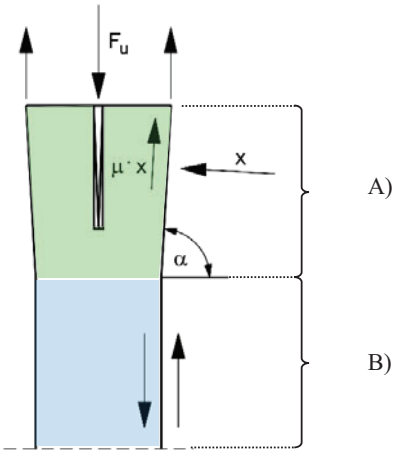


Figure 4: *Mechanical model of the wooden wedged dowel under tensile stress. A) In green, load transfer area activated due to the wedging. B) In light blue, area of action of the skin friction.*

The presented models consider a connection with wooden wedged dowel with idealized load-transfer areas. The load transfer in (A) is independent from manufacturing of connection, but dependent on the type of wood (or better, the wood combination) and the spreading angle α. The load transfer in (B) depends on the manufacturing process and can only be guaranteed if the manufacturing is carried out without deviations from the required geometry (imperfections). As this latter cannot be guaranteed in case of hand-made connections, the skin friction area (B) is neglected in the proposed verification and is considered that the load-carrying capacity of the wooden wedged dowel is determined by the two wedged extremities with the load transfer type (A) (see Figure 4).

4 Results

4.1 VERIFICATION FOR THE REPAIR CONNECTION WITH WOOD WEDGED DOWELS UNDER AXIAL TENSILE LOAD

Starting point for the development of a mechanical model for repair connections with WWD under axial tensile load was the verification model for pile foundations. The relationship between pile displacement y and the horizontal stress σ_h applies here to $\sigma_h = k_S \cdot y$ [17]. From experimental results V1 [9] is defined that the maximum displacement of the system is at the top of the wedging, on BC´s surface, and it is defined as $v(z = 0) \neq 0$. The displacement is reducing to zero along z-axis, in the direction of the center of the wedge. According to numerical simulations the displacement of the system is zero at a depth t_W, defined as $v(z \geq t_W) = 0$. This value defines the depth of load transfer area (A) as in Figure 4. The distribution of the displacement causes a stress distribution that is maximum on BC´s surface. Here, the real and idealized stress distribution is assumed as by Spörk in [18, 19] (see Figure 6, above). The maximum stress value on BC´s surface is defined as $\sigma_N(z = 0) \neq 0$ (see Figure 6, below). The stress has a linear course and is reducing along the z-axis until the maximum depth of the wedging effect t_W. At a depth $z \geq t_W$ the stress is zero $\sigma_N(z \geq t_W) = 0$ an there is no more load transfer between the fastener and the BC´s cross section (see Figure 5). Considering $(x, y, z) \leftrightarrow (u, v, w)$, the stress value $\sigma_N(z)$ in the dowel is the one defined in the eq. (1).

$$\sigma_N(z) = k_S \cdot v(z) \qquad \left[\frac{\mathrm{N}}{\mathrm{mm}^2}\right] \quad (1)$$

with:
$\sigma_N(z)$ = stress value in the system along z-axis
k_S = foundation modulus

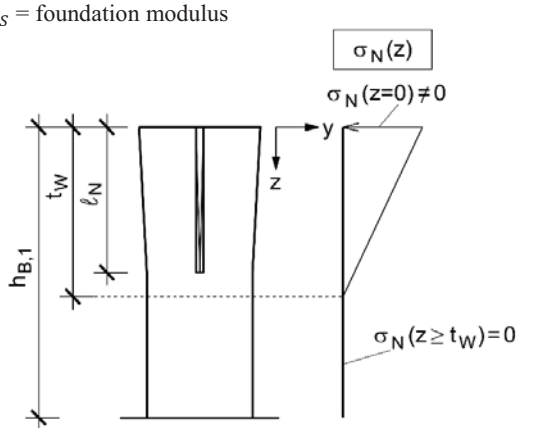

Figure 5: *Mechanical model of the wooden wedged dowel. Distribution of stress along the z-axis due to wedging.*

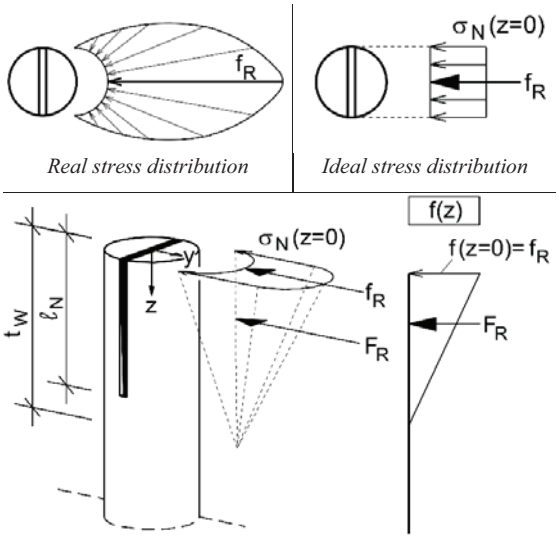

Figure 6: *Mechanical model of the WWD. Above: Two-dimensional representation of the real (left) and ideal (right) stress distribution on BC´s surface $\sigma_N(z = 0) \neq 0$ and linear load distribution f_R. Below: stress distribution along z-axis up to $\sigma_N(z \geq t_W) = 0$ in three-dimensional representation.*

https://doi.org/10.52202/069179-0200

Considering the distribution of the stress on BC´s surface $\sigma_N(z = 0) \neq 0$ constant along the diameter d_D of the dowel and the resultant linear load distribution f_R (2), (3) and taking into account along the z-axis the triangular distribution of the stress up to the maximum depth of load transfer t_W it is possible to calculate the force F_R (4) transferred from the wooden wedge´s spreading surface to the BC (see Figure 6, below). Considering the force F_R is applied on the spreading surface with an angle α, the forces acting perpendicular and parallel to the spreading surface can be calculated from it. Furthermore, the force F_R activates friction according to Coulomb's law of friction (see Figure 7). The static friction plays a decisive role for the tensile load-bearing capacity of the wooden wedged dowel. In fact, the achievement of the sliding friction is defined as the failure point of the fastener.

$$f(z = 0) = f_R \qquad \left[\frac{N}{mm}\right] \qquad (2)$$

$$f_R = \sigma_N(z = 0) \cdot d_D \qquad \left[\frac{N}{mm}\right] \qquad (3)$$

$$F_R = 0.5 \cdot t_W \cdot f_R \qquad [N] \qquad (4)$$

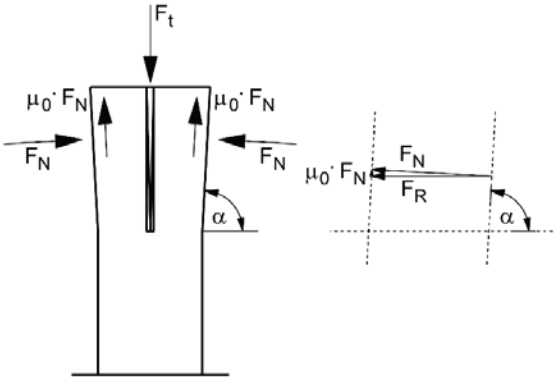

Figure 7: *Mechanical model of the wooden wedged dowel under tensile stress. Equilibrium of forces due to wedging and tensile stress.*

Since the angle α is very small and it can be considered as approximatively a right angle $\alpha \cong 90°$, it is defined that $F_R \cong F_N$ and $F_N \cdot \mu_0 \cong F_R \cdot \mu_0$. Therefore, it can be considered that the value of the tensile force F_t is the one contained in the equation (5)

$$F_t \cong 2 \cdot \mu_0 \cdot F_R \qquad [N] \qquad (5)$$

It is therefore concluded that, the verification for the repair connection with wood wedged dowels under axial tensile load is the one in following equation (6):

$$F_{t,Rk} = \mu_0 \cdot t_W \cdot k_S \cdot v(z = 0) \cdot d_D \qquad [N] \qquad (6)$$

With:
μ_0= friction coefficient between dowel and BC;
t_W = depth of the wedge action;
k_S = foundation modulus;
$v(z = 0)$ = maximum displacement of groove on BC´s surface;
d_D = dowel´s diameter.

The values to be assigned to the parameters contained in the verification (6) can be found in Table 2.

Table 2: *Value of the parameters contained in the verification for the repair connection with wooden wedged dowels under axial tensile load.*

parameter	condition	parameter description, value	unity
μ_0	H1	$\mu_{0,H1} = 0.5$	[-]
	H2	$\mu_{0,H2} = 0.6$	
	H3	$\mu_{0,H3} = 0.4$	
t_W		$t_W = 37.5$	$[mm]$
k_S	H1	$k_{s,H1} = 6.28$	$\left[\frac{N}{mm^3}\right]$
	H2	$k_{s,H2} = 46.40$	
	H3	$k_{s,H3} = 6.28$	
$v(z = 0)$	$d_D = 20$		$[mm]$
	H1	$v(z = 0) = 0.8$	$[mm]$
	H2	$v(z = 0) = 0.2$	
	H3	$v(z = 0) = 0.8$	
	$d_D = 30$		$[mm]$
	H1	$v(z = 0) = 0.59$	$[mm]$
	H2	$v(z = 0) = 0.12$	
	H3	$v(z = 0) = 0.64$	
d_D		$d_D = 20$	$[mm]$
		$d_D = 30$	

The model verification for the wooden wedged dowel under axial tensile stress is carried out taking into account the results from the test series V1 [9]. The parameters contained in the Table 2 are the result of observations in the experimental campaigns TV1 [15], and V1, literature and numerical or mathematical calculations in [9]. The parameters are following explained.
The coefficient of static friction wood-wood μ_0 is found in the literature in the range $\mu_0 = 0.4 \div 0.6$. The static friction coefficients for the verification (6) have been defined basing on the test observations for each wood combination. The definition bases on deductions from studies about the dependence of the embedment strength of fasteners from the surface roughness of drift bolts from Sjödin [20].
The depth of the wedge action t_W was determined from FE-Simulations. The depth of the wedge action defines the depth of load transfer area (A) between the building components and the WWD as in Figure 4. This value is fixed as constant for fasteners with groove´s depth $l_N = 30\ mm$, independently from the wood combination.
The displacement values on BC´s surface $v(z = 0)$ are measured in the experimental campaign V1 [9] for the dowel´s diameter $d_D = 20$ mm, and are result of observations and calculations for dowel´s diameter $d_D = 30$ mm.
The foundation modulus k_S is the resistance of the wood volume to an applied force. In the literature, only studies on embedment strength by Spörk and Hübner [18, 19, 21]

https://doi.org/10.52202/069179-0200

(for hardwoods) and Blaß [22] (for softwoods) were found. Therefore, the foundation modulus for oak (*Quercus*) and ash (*Fraxinus excelsior*) wedges was experimentally determined according to DIN EN 383:2007 [23] The dowels are loaded perpendicular to the grains, parallel to the annual rings. The results are in following (7) and (8).

$$k_{S,quercus,90,EN383} = 48{,}11 \quad \left[\frac{N}{mm^3}\right] \quad (7)$$

$$k_{S,frax.ex,90,EN383} = 35{,}31 \quad \left[\frac{N}{mm^3}\right] \quad (8)$$

The k_S-value in (7) should be valid for dowels in oak (*Quercus)* for the combination H1, H2, and the k_S-value in (8) should be valid for dowels in ash (*Fraxinus excelsior*) for the combination H3. Nevertheless, these tests only served to have first values of k_S. In fact, the k_S-value from (7) is correct to the large order for the wood combination H2 but not for the H1 so far (see Table 2), although both wood combinations have an oak dowel. Similarly, the k_S- value from (8) does not agree with the value of k_S from Table 2 for the wood combination H3. The cause of this incongruities is to be found in the EN 383:2007 [23] itself. Here, the test piece is a rectangular prism of wood loaded by a metallic fastener placed with its axis perpendicular to the surface of the test piece. On the contrary, the foundation modulus in the repair connection with wood wedged dowels is determined, not only by the k_S- value of one wooden species (the test piece), but especially by the interaction between the foundation moduli of the two encountering wood species, in the dowel and in the building component. These two components are stressing each other at a variable stress angle derived by Spörk in [18, 19] (Figure 8), and the angle and wood species with the lower foundation modulus, or reverse, the higher elasticity, determines the final k_S-value for the wood combination.

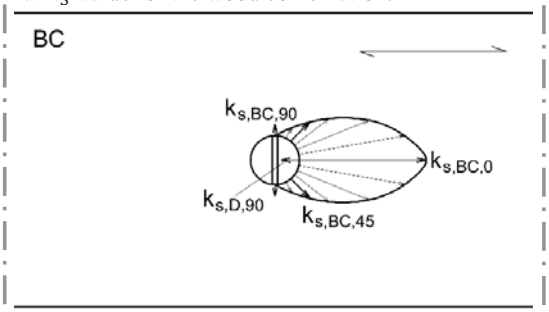

Figure 8: *Assumptions on elastic behaviour of the dowel and building component in the contact area between the building component and the dowel (wedging interaction area).*

Thus, following hypotheses about the stress behavior of the timber combinations are formulated (referring to Figure 8). Assumption for H1 and H3: The elasticity of the BC made of spruce stressed in compression parallel to the grains is greater than the one of the dowel made of oak (in H1) or ash (in H3) stressed in compression perpendicular to the grains (9):

$$k_{S,BC(spruce),0} < k_{S,BC(spruce),45} < k_{S,D(oak/ash),90} \quad (9)$$

Therefore, for the timber combinations H1 and H3, the building component made of spruce determines the properties for the foundation modulus as $k_{S,BC(spruce),0}$. Assumption for H2: The elasticity of the oak dowel, stressed in compression perpendicular to the grain, is bigger than that one of the oak building component, stressed in compression parallel to the grain (10):

$$k_{S,D(oak),90} < k_{S,BC(oak),45} < k_{S,BC(oak),0} \quad (10)$$

Therefore, for the timber combination H2, the dowel made of oak, loaded perpendicular to the grains, determines the properties for the foundation modulus as $k_{S,D(oak),90}$.

4.2 EXPECTED LOAD -BEARING CAPACITY OF WOOD WEDGED DOWELS UNDER AXIAL TENSILE LOAD

In the following Table 3 are reported the load-bearing capacities for one wooden wedged dowel under axial tensile load as fasteners for a carpentry repair connection, in dependence from the wood combination. The expected characteristic values $R_{k,WWD,mod}$ after the presented model are compared with the the 5% quantile of the characteristic values $R_{k,WWD,\exp}$ from the tests V1 [9].

Table 3: *Characteristic values of load-bearing capacity for wooden wedged dowels under axial tensile load in dependence fro the wood combination. Characteristic values of the tests V1 ($R_{k,WWD,exp}$) and the ones after the presented model ($R_{k,WWD,mod}$).*

Parameter	condition	parameter description	unity	deviation
$d_D = 20mm$				
$R_{k,WWD,\exp}$	H1	1.67	[kN]	
	H2	3.58		
	H3	1.93		
$R_{k,WWD,\mathrm{mod}}$	H1	1.88		12.6 %
	H2	4.18		16.8 %
	H3	1.51		-21.8 %
$d_D = 30mm$				
$R_{k,WWD,\exp}$	H1	2.49	[kN]	
	H2	3.14		
	H3	2.40		
$R_{k,WWD,\mathrm{mod}}$	H1	2.08		-16.5 %
	H2	3.76		19.7 %
	H3	1.81		-24.6 %

In the last column of Table 3 the deviations between the characteristic values of load-carrying capacity from the proposed model and the ones of the experimental results are shown. On one side, the load-carrying capacity for the WWD with smaller diameter $d_D = 20mm$ is a little overestimated and the one for the bigger diameter $d_D = 30mm$ is underestimated. The overestimation remains in the tolerance of +20% and the underestimation is on the safe side up to -25%. On the other side, the

experimental results [9] presents a big statistical scatter and the obtained deviation remains in the tolerance of the test results.
Concluding, from the comparison between the results of the proposed model and the experimental results, can be inferred that the proposed model predicts very good the values of load-carrying capacity for the wooden wedged dowel under axial tensile load.

4.3 VERIFICATION FOR THE REPAIR CONNECTION WITH WOOD WEDGED DOWELS UNDER SHEAR LOAD

The verification for the repair connection with wooden wedged dowels under single and double shear loading (with one or two shear planes), bases on existing mechanical models and verifications norms [11–13]. More specific, the here proposed verification model bases on the model from Blaß [12] and norm SIA 269/5:2011 [13].
In the experimental campaign SV [9] experimental tests on a mortise and tenon joint with wooden wedged dowels (WWD), and wooden dowels (WD) as mechanical fasteners under double shear have been carried out. The proposed geometric parameters for the tests are wood combination H1 (refer to Table 1) and dowel´s cross-section $d_D = 20mm$.
In the Table 4 are reported the characteristic values (5% quantile) of the tests SV carried out in [9] for the WWD and WD. The results show that the load-carrying capacity of the wooden wedged dowels is lower than the one for wooden dowels. Furthermore, in the Table 4 are reported the expected characteristic values of load carrying capacity for the WD and WWD calculated after the model from Blaß in [12]. From the comparison among these values it is clear that, on one side, the model [12] describes very well the test results for the wooden dowels, and on the other side, the results of load carrying capacity for the wooden wedged dowels calculated after [12] are too high in comparison with the test results.

Table 4: *Characteristic values of strength for repair connection mortise and tenon joint (double shear) with wooden dowels and wooden dowel under shear load: results after model in [12] and experimental test results.*

Parameter	condition	parameter value	unity
$R_{k,WWD}$	experimental	6.61	[kN]
	After [12, 13]	8.57	
$R_{k,WD}$	experimental	7.62	[kN]
	After [12, 13]	8.67	

In the verification of wooden dowels from [12, 13] the reduction coefficient δ, takes into account the effects of non-linear stress distribution along the borehole, the non-utilization of the embedding strength and rope effects due to friction in the borehole. From the observation of the tests SV [9] was revealed that these side effects are not only evident in wood dowels, but also magnified in wood wedged dowels under shear stress. The presence of the reduction coefficient δ from [12, 13] is therefore particularly interesting for the further development of the verification model for the wood wedged dowels.
In order to update the reduction coefficient δ, some explanations about the causes of reduction of the load-carrying capacity in the WWD were given: the reason may lie in the geometry of fasteners´ components. The geometry causes firstly a change in the distribution of forces along fasteners´ neutral axis and secondly causes a change in the contact area between the building component and the dowel. These phenomena may cause wooden wedged dowels experience earlier shear failure than the wooden dowels. These two hypotheses are following explained.
Hypothesis 1) (refer to Figure 9). During loading the fasteners are generally subjected between the shear joints to bending in the borehole. One half of the fastener´s cross section is loaded in compression and the other half in tension; the shear forces are maximum along the neutral axis.
On one side, the WD has a constant cross-section along the entire length and it distributes the shear forces equally along the whole neutral axis' length. On the other side, in the WWD the grooves at two far ends, exactly cut the cross-section in the ending part of the neutral axis into two half cross-sections. Therefore, the WWD presents a shorter neutral axis' length for absorbing the maximum shear force.

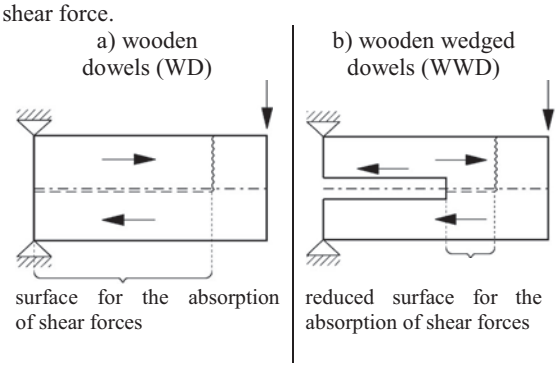

Figure 9: *Representation of hypothesis 1): assumptions on the absorption of shear forces in the two far ends of the fastener in a) WD and b) WWD.*

Hypothesis 2) (refer to Figure 10). During loading the fasteners are generally subjected between the shear joints to bending in the borehole.
On one side, the wooden dowel has no restraints in the borehole except than the skin friction as in the surface (B) described in Figure 4. Therefore, once subjected to bending it can axially shift in the borehole, depending from the contact surface and the presence of imperfections in the geometry. The WD is - mechanically speaking - a displaceable beam in axial direction (see Figure 10a). Referring to the middle wood, the cross-sections of the fasteners are subjected along the neutral axis on the lower half to tensile stress and on the upper half to compression from the bending. On the other side, the wooden wedged dowel (WWD) activates a further load transfer area due to

https://doi.org/10.52202/069179-0200

the wedging; here, the fastener is able to absorb axial tensile forces during loading, as explained in Figure 4. Therefore, once subjected to bending, the WWD cannot axially free shift in the borehole as the WD. The WWD is - mechanically speaking - a non-displaceable beam in axial direction (see Figure 10b). This causes an additional axial tensile stress in the fastener´s cross-sections. Referring to the middle wood, the cross sections are here on the lower half not only subjected to tensile stress from bending, but also to additional tensile stress from the wedging and its clamping effect. As a consequence, the neutral axis shifts from fastener´s main axis to the upper half of the cross-section. Earlier failure in this zone is expected. In experimental tests SV [9] an additional failure in this area was also observed.

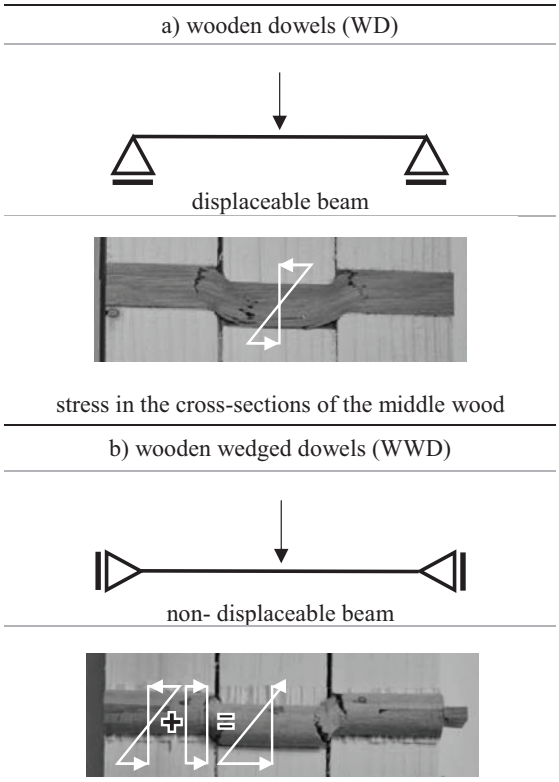

Figure 10: *Representation of hypothesis 2): mechanical interpretation, and stress in the cross-sections of the middle wood after shear loading in the a) WD and b) WWD.*

According to the hypothesis 1 and hypothesis 2, a new reduction coefficient δ', is defined. The reduction coefficient δ' considers the effects of non-linear stress distribution along the borehole, the non-utilization of the embedment strength, rope effects due to friction in the borehole, and the additional clamping effect due to the wedging in the WWD. The updating of the reduction coefficient δ' is calculated back from the characteristic values (5% quantile) of load-carrying capacity of the experimental tests SV [9] and the known variables from the equation of Blaß [11]. The new value for the reduction coefficient is determined as: $\delta' = 0.45$. The verification model for the wooden wedged dowels under shear load is defined in the following equation (11).

$$R_k = \sqrt{\frac{2 \cdot \beta}{1+\beta}} \cdot \sqrt{2 \cdot M_{u,k} \cdot \delta' \cdot f_{h,1,k} \cdot d_D} \quad [N] \quad (11)$$

With:

$$\delta' = 0{,}45 \quad [-] \quad (12)$$

$$\beta = \frac{f_{h,1,k}}{f_{h,2,k}} \quad [-] \quad (13)$$

$$M_{u,k} = \frac{f_{m,k} \cdot \pi \cdot {d_D}^3}{32} \quad [N \cdot mm] \quad (14)$$

$$f_{h,1,k} = 0{,}082 * (1 - 0{,}01 * d_D) * \rho_k \quad \left[\frac{N}{mm^2}\right] \quad (15)$$

The verification (11) describes the maximum calculated characteristic load-carrying capacity for one fastener and per shear joint. The verification is directly connected with the one from [12, 13]. In (13) β describes the ratio of the embedment strength of the side wood to the middle wood (from SIA 265:2012 [24]); here, $f_{h,1,k}$ represents the characteristic embedment strength of the side wood and $f_{h,2,k}$ of the middle wood. In (14) $M_{u,k}$ describes the characteristic value of bending moment of the cylindric wooden fasteners; here, the value $f_{m,k}$ is the value of characteristic bending strength of the wooden fasteners from DIN EN 338 [16]. Finally, the diameter of the wooden wedged dowel is described by d_D and the bulk density of the side wood by ρ_k.

As well as for the verification in [12, 13], the value of load-carrying capacity calculated by (11) is valid if the minimum wood thickness of the side wood ($t_{1,req}$) and the one of the middle wood ($t_{2,req}$) are achieved. For a single shear joint the thickness of the side wood 1 and the side wood 2 is determined in the eq. (16) and eq. (17) respectively. For a double shear joint the thickness of the middle wood is further described in the equation (18).

$$t_{1,req} = \left(2 \cdot \sqrt{\frac{\beta}{1+\beta}} + 2\right) \cdot \sqrt{\frac{M_{u,k}}{\delta \cdot f_{h,1,k} \cdot d}} \quad [mm] \quad (16)$$

$$t_{2,req} = \left(2 \cdot \sqrt{\frac{\beta}{1+\beta}} + 2\right) \cdot \sqrt{\frac{M_{u,k}}{\delta \cdot f_{h,2,k} \cdot d}} \quad [mm] \quad (17)$$

$$t_{2,req} = 4 \cdot \sqrt{\frac{\beta}{1+\beta}} \cdot \sqrt{\frac{M_{u,k}}{\delta \cdot f_{h,2,k} \cdot d}} \quad [mm] \quad (18)$$

If the middle or side woods are thinner than the required minimum timber thicknesses $t_{i,req}$, the characteristic load-bearing capacity according to eq. (11) is reduced according to eq. (19)

$$R_{k,red} = R_k \cdot min \begin{cases} \frac{t_1}{t_{1,req}} \\ \frac{t_2}{t_{2,req}} \end{cases} \qquad [mm] \quad (19)$$

4.4 EXPECTED LOAD -BEARING CAPACITY OF WOOD WEDGED DOWELS UNDER DOUBLE SHEAR LOAD

In the Table 5 the estimated maximum load carrying capacity for the wooden dowels $R_{k,WD,mod}$ is calculated after the model of Blaß [11] and the estimated load-carrying capacity for the wooden wedged dowels $R_{k,WWD,mod}$ is calculated after the proposed model [9].

Table 5: *Characteristic values of load-carrying capacity for WWD and WD under double shear load: results after model in [12], after the proposed model and experimental test results. Slip moduli after experimental results.*

	Parameter	condition	value	unity
WWD	$R_{k,WWD,exp}$	experimental	6.61	[kN]
	$R_{k,WWD,mod}$	after model [9]	6.61	
	$k_{ser,mean,WWD}$	experimental	12.57	$\left[\frac{\text{kN}}{mm}\right]$
WD	$R_{k,WD,exp}$	experimental	7.62	[kN]
	$R_{k,WD,mod}$	After model [12]	8.67	
	$k_{ser,mean,WD}$	experimental	13.21	$\left[\frac{\text{kN}}{mm}\right]$

The values of the maximum load can be used for the calculation of the slip modulus $k_{ser,mean}$ for both the repair connection with wooden wedged dowels according to the proposed verification [9], as well as for the repair connection with wooden dowels according to the model in [12]. The slip moduli $k_{ser,mean}$ presented in the Table 5 are therefore calculated for both the repair connections with WWD and WD according to the norm DIN EN 26891:1991-07 [25].

5 CONCLUSION

Concluding, this paper and the related research project [9] introduce the use of the wooden wedged dowels as mechanical fasteners for carpentry connections and clarify manufacturing rules, geometric boundary conditions, working principles, as well as develop a verification for the prediction of load-carrying capacity for the fasteners under axial tensile and shear load.

Regarding geometric boundary conditions, the definition of manufacturing rules and construction parameters, was fundamental. In fact, different load-carrying capacities are expected in dependence from wood combination and fastener´s diameter. Therefore, changing the geometric boundary conditions, divergent results than the presented ones are expected. For this reason, the presented verification models and expected characteristic load-carrying capacities are valid only under the presented boundary conditions.

Regarding peculiar properties of the fastener wooden wedged dowel, it shows, differently to a normal wooden dowel, an improved contact surface in the borehole given by the clamping effect of the wedge, that always guarantees the load transfer between the fastener and the building component. The clamping effect confers to the fastener a rope effect during the loading. This property of the wooden wedge dowels is advantageous in the case of axial load; however, in case of shear load, the wedging contributes to a reduction of the load-bearing capacity, compared to the load-bearing capacity of an equivalent connection with wooden wedges.

The developed verifications open up for engineers the possibility to apply carpentry repair connections with wooden wedged dowels as fasteners in relevant load cases, for example for hanging ceiling coffer beams (wooden wedged dowels in tensile load), or for ceiling beams and roof rafters (wooden wedged dowels in shear load).

The research project is designed as a long-term project to re-learn and understand historical techniques and carpentry connections in order to promote the "best practice" under static-constructive, economic, culturally oriented aspects in heritage conservation.

Performance Verification and Trial Design for High-rise Timber Frame Buildings with Buckling-Restrained Braces
Part.1 Connection and Frame Testing

Kazuki Tachibana[1], Hiroki Nakashima[2], Taisuke Nagashima[3], Ryota Minami[4], Toshio Maegawa[5], Nobuhiko Akiyama[6], Yoshihiro Yamazaki[7] and Takahiro Tsuchimoto[8]

ABSTRACT: A 10-story apartment building was designed with (1) multi-knife plate steel dowel connections for the joints, (2) BRBs as megastructural−columns for the seismic elements, and (3) GIR joints for the column bases. Tests were conducted to verify that these three types of high-strength connections performed as required. This paper describes the results of these tests and a discussion of the analysis method.

KEYWORDS: High-rise timber structure, Multiple Shear steel-to-timber joints, Buckling-restrained braces

1 INTRODUCTION

While demand for mid-rise and high-rise timber buildings has been increasing in recent years, non-timber structures are still dominate the market for mid-rise and high-rise buildings in Japan. One of the challenges in promoting the use of mid-rise and high-rise timber buildings is to ensure their seismic performance. In order to create a good role model, this study was designed to test a 10-story apartment building with mega-structural columns and Buckling-Restrained Braces (hereinafter referred to as "BRB"). [Fig. 1]

Part 1 describes the tests conducted for the trial design and their results. An analytical model is proposed and compared with test results to verify the validity of the analytical model.

2 CONNECTION TEST

2.1 INTRODUCTION

The Japanese standard [1] describe how to calculate the allowable shear capacity of steel dowel joints with steel inserted plate and with steel side plates, but they do not describe the case where multiple steel plates are inserted or the scope of application, for example, whether it is possible to use large-section glued laminated wood or large diameter drift pins. Here, shear tests were conducted to verify whether the shear strength could be obtained by a simple calculation. Specifically, as shown in Fig. 2, we verified whether the ratio of the number of steel dowels and the addition on the burden area (dowel length) were valid.

2.2 MATERIALS AND SPECIMEN

Fig. 3 shows an overview of the specimens: the A1 has 27 steel dowels inserted; the B1 and B3 have 5 steel dowels inserted; the A1 and B1 have 1 steel plates inserted; the

https://doi.org/10.52202/069179-0201

B3 has 3 steel plates inserted. The timber was laminated Japanese larch E95-F270 with secondary gluing in the width direction, the steel plate was SS400 with a thickness of 12mm, and the steel dowels were SNR490B with a diameter of 20mm. The hole diameter for the steel dowel s was 20mm for the timber and 21mm for the steel plate. Steel dowels were 150mm long for A1 and B1, and 350mm long for B3, with tapered end. A slit of □-16 × 1,180 was cut out in the timber for steel plate insertion. The number of specimens was one for B1 and three each for A1 and B3

2.3 METHODS

Fig. 4 shows the testing machine performance and the test setup of specimen. The test specimen and jig were fixed by frictionally joining the left and right sides of the inserted steel plate. For displacement, the relative displacement of each steel plate to the timber was measured, and the average value was used as the deformation. The load was applied monotonically from the top of the column using a hydraulic jack while measuring the load, and was applied until the load dropped to 80% of the maximum load or until the joint was deformed more than 30 mm and lost its function as a joint.

2.4 RESULTS AND DISCUSSIONS

The experimental results are shown in Fig. 5. From the obtained displacements and loads, the yield capacity P_y and ultimate capacity P_u were obtained in accordance with "How to Obtain Yield Capacity and Ultimate Capacity Using Full Elastic-Plastic Model "[2].

2.4.1 NUMBER OF STEEL DOWELS

Fig. 6 compares the history curves of the A1 specimen with those of the B1 specimen, corrected for a steel dowel count ratio of 27/5 times. Fig. 6 shows that there is a proportional relationship between the number of steel dowels and shear strength.

2.4.2 NUMBER OF INSERTED STEEL PLATES

[Sum]B1 is the prediction of the B3 result from the B1 result based on Fig. 1. The [Sum]B1 and B3 results are compared in Fig. 7, which shows that [Sum]B1 is evaluated on the safe side with respect to B3.

Fig. 8 compares [Sum]A1 obtained from the A1 test result with the results of the B3 specimen multiplied by 27/5. This result also shows that [Sum]A1 is evaluated to be on the safe side compared to 27/5 of the B3 specimen.

3 FRAME TEST

3.1 INTRODUCTION

Our trial design of a high-rise timber frame building has BRBs as the main seismic element. The design assumed that the BRBs yield first during deformation, and then the toughness of the BRBs is expected until the safety limit is reached. However, each joint of the frame is not a pin joint but a semi-rigid joint with rotational stiffness, and the frame bears a part of the seismic force after the BRB yields. The frame is designed so that the deformation of the frame is within the elastic range even at the safety limit, but it was confirmed experimentally that the load borne by the frame is as calculated and that the joints do not fail in bending under large deformation. (hereinafter referred to as "Frame test")

In order to estimate the axial force acting on the BRB joint during the frame test and to control the applied force, a cyclic test of the BRB alone (hereinafter referred to as "BRB test") was conducted in advance, and the load deformation of the BRB alone was confirmed up to the ultimate region.

3.2 BRB TEST

3.2.1 MATERIALS AND SPECIMEN

The BRB used for the test specimen was a BRB manufactured by Nippon steel engineering Co., Ltd. The specimen specifications are shown in Table. 1 and the design specifications are shown in Table. 2. Yield stress and strength are based on mill test report. The post-yield stiffness degradation rate was taken from the manufacturer's technical data [3]. The BRBs were custom-ordered with a yield capacity of 113kN and an ultimate capacity of 205kN, and end plates were added to the ends and bolted to the load jig and end plates.

3.2.2 METHODS

Fig. 9 shows the performance of the testing machine, the specimen setup, and the position of instrumentation. The polarity of the load and displacement was set to be positive on the tensile side. The loading method was cyclic loading with hydraulic jacks, which was repeated three times per a cycle. The loading schedule is shown in Table. 3, and the average value of the vertical displacement (7) and (8) of the jig column was considered to be equivalent to the displacement of the plasticized part and was used as the displacement for control.

Overall disp. $\delta_0 = (③ + ④ + ⑤ + ⑥) / 2$ ***Eq. 2***

Control disp. $\delta_1 = (⑦ + ⑧) / 2$ ***Eq. 3***

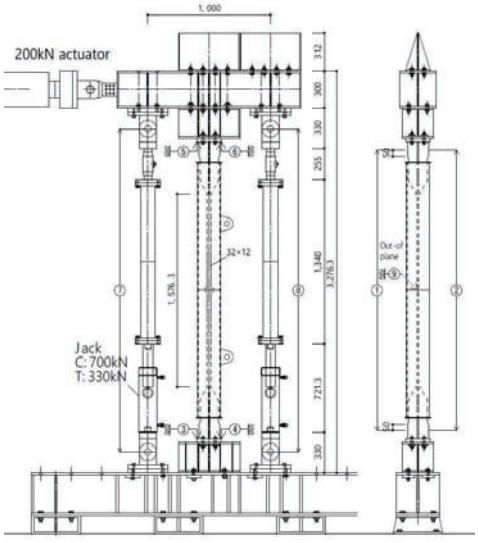

Fig. 9 Test setup of specimen

3.2.3 RESULTS AND DISCUSSIONS

Based on test result, the yield point and the 3%-L_p deformation point were read from the envelope curve and a bilinear (test) was created. The 3%-L_p deformation point was set at the maximum deformation at the first loading. The bilinear model obtained from the design values was designated as bilinear (design), and this graph was used in the analysis. These two bilinears are shown together in Fig. 10. The bilinear model based on theoretical values does not take into account the load rise, but we believe that this model is sufficient for the frame analysis, which is mainly

concerned with the first loading. The bilinear (test) model showed a difference from the bilinear (design) model in that the yield load was larger on the tensile side and the second-order slope was larger on the compressive side.

3.3 FRAME TEST

3.3.1 MATERIALS AND SPECIMEN

The BRB used in the frame tests were the same as those used in 3.2. The specifications of the members used for the frame specimen are shown in Table. 4 and the names of the parts are shown in Fig. 11. The ends of the BRBs were friction-bolted with high-strength bolts friction joints, accompanied by joint hardware and splice plates. Although frame tests were considered at full scale, the largest specimen was set up to match the testing laboratory's frame testing machine. The scale factor of the specimen scaled down from full-scale is shown in Table. 5. The specimen was also rotated 90°, so that the columns and beams were inverted as shown in Fig. 11. There are three types of connections between the beam-column hardware and the timber: C is the connection to the column, G is the connection to the beam, and B is the connection between the BRB and the beam. Joints C and G are drift pin joints with two steel plates inserted into the timber, and joint B is a bolted joint with steel plates on both sides of the timber. The reaction force fulcrums of the test specimens were made by extending the joint hardware steel plates and connecting them to a pin bearing and a roller bearing, respectively. Each joint must have sufficient bearing capacity and deformation capacity to allow the BRBs to withstand the ultimate load. The number of steel dowels was determined so that the short-term shear capacity of joints C, G, and B of the specimen would be sufficient for the axial force of the frame generated when the BRB restoring force was at its maximum, and the arrangement of the steel dowels was determined so that the rotational stiffness would be as small as possible. For joint B, a steel dowel joint with the steel-plate-insertion was planned, but since there was a possibility that the BRB would twist the beam due to the stress of the BRB during loading, bolt joint with the steel side plate was used in the hope that the torsional resistance

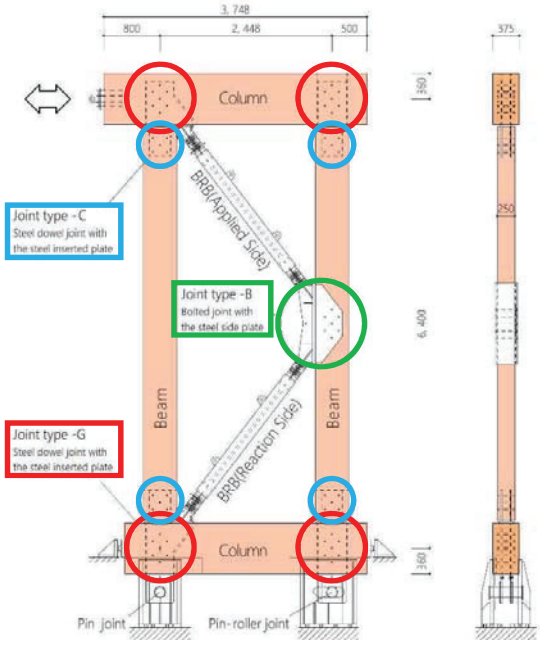

Fig. 11 Test setup of specimen

of the beam would be effectively transmitted. The short-term shear capacity of joint B is smaller than the maximum axial force of the frame and is 1.2 times the frame axial force at yield. The diameter of the holes drilled in the steel plate and timber for each joint was the same as in "2. CONNECTION TEST" for steel dowel joints with the steel-plate-insertion, and 22mm holes were drilled in both the plate and timber for the bolted joint for steel side plate, and φ20 bolts were used.

3.3.2 METHODS

The loading schedule for the tests is shown in Table. 6. Based on the results of the BRB stand-alone tests, the loading was controlled using the value of axial deformation δ_{b1} of the BRB up to the yield displacement δ_y of the BRB at the structure surface, and was repeated 3 times each at $\pm \delta_y \times 0.5$ and $\pm \delta_y$ in alternating cycles. The load was then repeated 3 times alternately at ±1/300, ±1/200, ±1/150, ±1/100, ±1/75, and ±1/50 of the deformation angle of the specimen, respectively, and after 1/50, the load was monotonically applied in the tensile direction until failure. The test was not conducted from 7C to 9C because the target interlaminar deformation angles of 7C to 9C were reached in the first cycle up to

https://doi.org/10.52202/069179-0201

6C. In the frame tests, applied loads, overall displacements, rotation angle and shear deformation of each joint element, and axial displacement of the BRB were measured. The horizontal displacement of the specimen δ was determined by the relative displacement of columns

3.3.3 RESULTS AND DISCUSSIONS

The load-deformation relationship and envelope are shown in Fig. 12. 1C to 6C, the deformations are significantly different on the positive and negative sides. This is partly because the displacement was controlled by the axial displacement of the BRB, but the main reasons for this are the clearance of the bolted joints in the Joint B hardware and the one-sided effect of the hardware, which resulted in a large slip on the tensile side. In each of the subsequent cycles, the load on the compression side was slightly higher than that on the tension side.

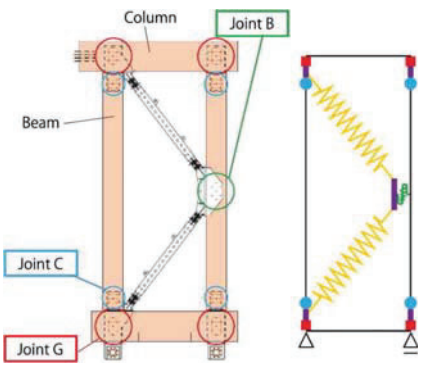

Fig. 13 Analysis model

3.4 ANALYSIS MODEL

3.4.1 JOINT

An overview of the modeling is shown in Fig. 13. The timber is modeled as a beam element, and each joint and BRB are modeled with the nonlinear springs shown in Fig. 14. The beam elements (▬) between joint C (■) and joint G (●), between BRB and joint B (●), were input as rigid bodies. Joint C (■) was modeled with rotational and shear springs, and joint G (●) with rotational and axial springs. For joint B, only the shear spring acting in the vertical direction was input, assuming no rotation. The stiffness and bearing capacity of the joints were determined by the European Yield Theory [1, 4] for performance per a steel dowel and corrected by the burden area based on the results obtained in 2. After confirming that the mode of failure did not change with the difference in burden area, these results were added together.

3.4.2 BRB

The BRB was assumed to be a nonlinear spring of an axial spring. For the modeling of BRBs evaluated as axial springs, BRBs were synthesized from the stiffness of the centrally buckling-constrained core section and the stiffness of the cross section at the ends. If the stiffness of the core section is k_{B1} and the stiffness of the end cross section is k_{B2}, the composite stiffness $k_{BRB}=1/(1/k_{B1}+1/k_{B2})$. From the cross-section of the plasticized section of 12mm x 32mm and the yield point strength of 294 MPa, the yield capacity is 113kN and the axial stiffness k_{B1} is 49.9kN/mm. The stiffness k_{B2} of the cross section was determined to be 300kN/mm for the axial stiffness except for the plasticized section. The ultimate strength of the plasticized section is 400 MPa and the stiffness reduction ratio $\alpha = 0.02$, and the stiffness is obtained by synthesizing the secondary slope in the same manner, assuming that the ends do not yield. The obtained bilinear curve of BRB is shown in Fig. 15.

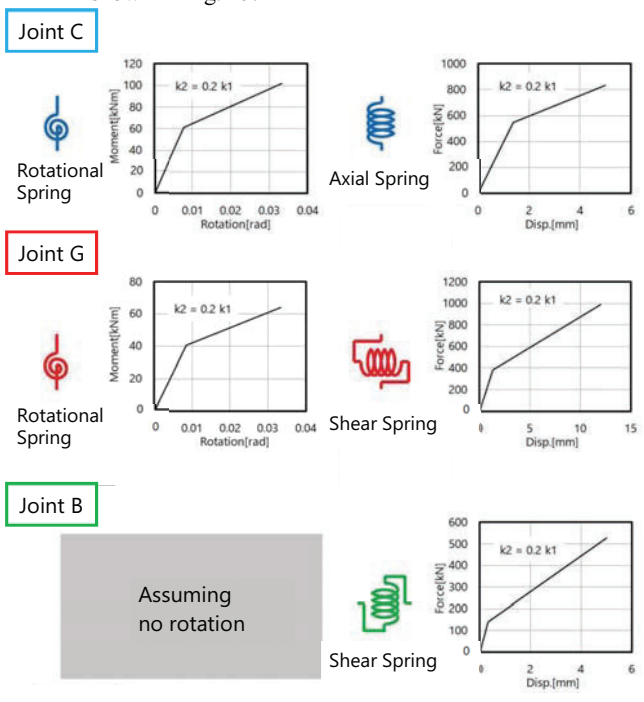

Fig. 14 Analysis model (each joint)

https://doi.org/10.52202/069179-0201

3.4.3 ANALYSIS RESULTS

For the orange graph in Fig. 16, the solid line shows the test results and the dotted line shows the analytical model applied up to 1/20 rad by pushover analysis. The solid line is a graph of the load P and displacement δ extracted at the first deformation experienced in the positive (tensile) direction from the start of the test and when the load value is greater than or equal to the load value recorded previously. The timing of the yielding of the joints during the analysis is noted in the figure. The shear and axial springs were elastic, and the rotational springs yielded at joints G and B, in that order. At these two timings, the four joints yielded almost at the same time. A comparison of the experimental and analytical jack load-deformation relationships for each joint is shown in Fig. 17.

(A) Joint C - Rotation angle

At all locations below 125kN where failure occurs, the analytical and experimental results agree well. The calculated yield rotation angle was 1/130 rad, and yield deformation was not reached.

(B) Joint G - rotation angle

Experimental and analytical values are in good agreement up to a cycle of 100kN and 1/75 rad of the specimen in terms of load value; above 100kN, the experimental value exceeds the analytical value in the large deformation region.

(C) Joint C - horizontal shear deformation

For the applied force side (U), the rotational component was subtracted from the displacement measured on the underside of the timber to obtain a value, so there is some variation in the trajectory of the graph, but the displacement is within about 1mm, which is the clearance of the joint. In North-D_C-S_H, the joint hardware is directly connected to the pin joint but there is some movement, and there is slip until the column member resists. (There are restraints at both ends of the below column to prevent horizontal movement.)

(D) Joint G Load - Vertical shear deformation

Slip of 1mm or less is observed at load 0 in general, which may be due to the effect of the gap around the steel dowel. In the analysis, the joint did not yield up to about 170kN, but in the experiment, plastic deformation occurred around 150kN on the South side at 1/50 rad or later when the joint was pulled apart; when the displacement of South- D_G-S reached 4.4mm, the joint cracked and the displacement increased to 8.8mm at once.

Glue	Epoxy	—	—	—

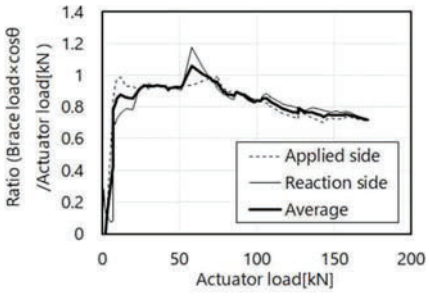

Fig. 19 Ratio of force borne by the brace

E) Joint B

In the experiment, the joint slipped about 4mm in the vertical direction. This is thought to be due to the effect of the gap of the hole on the diameter of the joint B joint. This is also evident in the initial slip of the overall deformation. The reason for the rotation of joint B is thought to be that the deformation of the frame created a hinge in the cruciform steel portion of the brace end, and because of the distance between the attachment points of the connection hardware B, the expansion and contraction of the brace created an angle in the connection hardware.

3.4.4 ESTIMATION OF HORIZONTAL LOADS TO BE BORNED BY THE BRB

In creating the orange lines in Fig. 16, the deformations δ_{b1} and δ_{b2} of the two BRBs were recorded at the same time. The axial force of the brace is estimated from these deformations and the envelope in Fig. 10, BRB test result. The load borne by the BRB during the frame test can be assumed to be the horizontal component of the estimated axial force of the BRB. (Horizontal load borne by BRB = BRB estimated axial force × cosθ [where cosθ = 2,448mm / 4,028mm]). The load-bearing ratio is the ratio of the BRB load divided by the actuator load P. The obtained load-bearing ratio of the BRB is shown in Fig. 19. Initially, the value is small due to slip, but it soon approaches 1.0 and remains at about 1.0 when a force of about 10kN is applied, and after P reaches the yield capacity, the burden ratio decreases to about 0.8. This result indicates that the forces acting on the upper and lower BRBs were almost the same. As a result, there was almost no bending moment of the beams due to the disproportionate force of the braces.

Grey line in Fig. 16 shows the average of the loads on the upper and lower BRBs and yellow line in Fig. 16 shows the load on the frame (the envelope curve of the solid orange line in Fig. 16 minus the load applied to the BRB [Grey line]). From these results, it can be confirmed that up to the yield load, the brace alone resists the load. After the yield load, the frame bears about 20% of the load, but no damage was observed up to 1/50 rad, confirming the integrity of the frame.

4 COLUMN-BASE JOINT

4.1 INTRODUCTION

As buildings rise in height, axial forces (e.g. dead weight) acting on columns increase, and it is known that axial forces affect the moment capacity of column base. Therefore, in order to model the first-floor column bases of a 10-story timber-frame apartment building and to create an *M-N* interaction curve showing this effect, bending tests were conducted using the column axial force as a parameter while applying a vertical load. The test results were used to validate the modeling and the method used to model the first-floor column bases.

4.2 MATERIALS AND SPECIMEN

Fig. 18 shows an overview of the test specimen. Table. 7 shows the specimen specs. The lumber used was E105 F300 laminated larch of symmetrical mixed-grade. The steel shoe was made of SN400B and SN400C, which were used to connect the timber to the slab. The first-floor columns were assumed to be 900mm x 900mm in cross section, but the cross section of the specimen was 300mm × 900mm with the cross section multiplied by 1/3 in the depth direction due to the capacity of the jacks to apply vertical loads and horizontal forces. A maximum axial force of 5,400kN is considered to act on the assumed first-floor columns in the design. The axial force parameters were 1,800kN (test symbol N1800), which is 1/3 of the assumed load, 900kN (test symbol N0900), which is 1/6 of the assumed load, and no axial force (test symbol N0000), and one of each was tested. The specimen setup is shown in Fig. 20 and Fig. 21. The height of the force point was set to 2,500mm, the height of point of contraflexure obtained from the analysis. The height of N0900 and N1800 timber was set to 1,925mm, subtracting

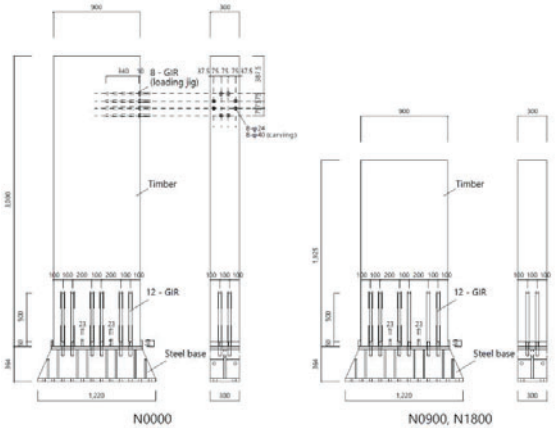

Fig. 18 Specimen detail

https://doi.org/10.52202/069179-0201

the height of the jig. The height of the N0000 timber was assumed to be 3,000mm, including the extra length. The steel shoe was also multiplied by 1/3 in the depth direction. For shear forces acting on the timber column ends, SN400B steel plates, 22mm thick and 50mm high, welded to the top of the steel shoe was designed to act as shear keys and bear the shear forces. Four shear keys were placed at the locations that divide the timber into three equal parts in the width direction and at both ends. Shear keys were inserted into grooves 23mm wide and 60mm deep on the timber side. The Glued in rods (hereinafter referred to as "GIR") for column bases were machined from SD345 D29. The gluing section was 500mm long, with a plasticized section 22mm in diameter and 50mm long, and an M27 screw machined into the end. The GIR used can be considered to have three possible failure modes: (1) failure of the plasticized section, (2) failure of the adhesive section, and (3) collective shear failure of the timber section. The upper limit of the maximum bearing capacity of the plasticized section was assumed to be lower than the lower limit of the maximum bearing capacity of the adhesive section, and it was judged that (2) would not occur. In addition, for the collective shear failure of timber, since the perimeter area surrounded by four GIRs is larger than the perimeter area of one GIR × 4 GIRs, it was judged that (3) collective shear failure of timber would not occur.

From the above, it was confirmed by manual calculations that the joints of GIR fail prior to the plasticized part during pull-out. To control the strength of the plasticized section, an upper strength limit of 550N/mm^2 (=210kN) was ordered, and the actual value (mill test report) was 554 N/mm^2 The JIS standard values and mill test report values are shown in Table. 8. Epoxy resin adhesive (Home Connector Co., Ltd.: AHC-E) was used as the adhesive. After the adhesive had cured, the threaded portion of the GIR was fixed with a double nut while measuring the strain gage value so that the initial tension of the GIR was approximately 10kN. For the specimens with axial force, the nuts were fastened after the axial force was applied.

4.3 METHOD

The specimen with axial force was loaded vertically by vertical jacks at both ends through a pin jig at the top. The pin jig was in contact with the upper timber face and the sides were clamped by brackets with a clamping mechanism. The tightening mechanism was adjusted at the maximum deformation of each cycle because a gap was created on the sides due to the pin fixture when a horizontal force was applied. The distance from the top of the steel frame trestle to the center of the pin was assumed to be 2,500mm at the height of point of contraflexure. For the specimen without axial force, a 3,000mm-high timber was used and eight GIRs were joined so that the force point was at 2,500mm. In this test, deformation was controlled by the angle of rotation between the timber and the steel shoes. The axial force of the GIRs was calculated from the average of the axial strains of the two GIRs. Two strain gauges were placed at the axisymmetric position of the plasticized GIR for the purpose of measuring the axial force of each GIR.

The loading schedule was as follows: three cycles of positive/negative alternating loading at angles of rotation θ of 1/900, 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, and 1/50 rad for the column bases between timber and steel shoes; 1/30 rad of positive/negative alternating loading; and then monotonous loading until failure. For N0000 and N1800, the deformation was controlled by the rotation angle θ. For N0900, it was determined that the rotation angle θ could not be used to control the deformation due to cracking and separation of the timber observed in the N1800 test. The corrected rotation angle θ' used for control is shown in Eq. 4. The corrected rotation angle θ' was corrected using the displacement $\delta_{1/100}$ at 1/100 rad, assuming that the horizontal displacement δ is proportional to the actual rotation angle.

$$\theta = \begin{cases} \theta & (\theta < 1/100\,rad) \\ 0.01 \cdot \delta/\delta_{1/100} & (\theta \geq 1/100\,rad) \end{cases} \qquad \textit{Eq. 4}$$

4.4 RESULT

Fig. 22 through Fig. 24 show the M-θ relationships obtained from the tests. The GIR plasticized section yielded first at the moments shown in each figure, and the bearing capacity decreased with rupture. However, in the case of N0000 and N0900, cracking occurred near the joints before the GIR plasticized section ruptured, and in the case of N0900 and N1800, cracking and separation of

the timber occurred as described above. Based on the above, the performance of this column-base joint was allowed up to the yield of the GIR plasticized section.

4.5 ANALYSIS MODELS

4.5.1 MULTI SPRING MODEL

The specimen was modeled with a multi-spring model using beam elements shown in Fig. 25. The analytical model consisted of rigid beams placed parallel to the ground plane and timber beam elements with a cross section of 300 x 900. The rigid beams were split at 50mm pitch, and GIR springs were placed at the same locations as the specimen. The ground plane was input with a surface pressure stiffness spring with stiffness acting only in compression.

4.5.2 EMBEDMENT STIFFNESS

For the embedment stiffness of the multi-spring model, k_{0c}=25N/mm^3[5] was used. For both ends of the rigid beams, 187.5kN/mm was used because the burden area is 1/2 that of other contact points. For yield capacity, a reference bearing capacity of 25.4MPa [1] was used.

4.5.3 GLUED IN RODS

The relationship between axial force and lifting (δ_{12}, δ_{34}) of GIRs obtained from all test results is shown in Fig. 26. The lifting displacement was the average of the vertical relative displacements of the front and back of the timber. From these results, the GIR stiffness k_{GIR} was read as 250 kN/mm, indicated by the thick red line in the figure, and used in this study. k_{GIR} is the composite stiffness obtained by connecting the stiffness k_f of the GIR anchorage section and the stiffness k_y of the plasticized section in series. k_f is obtained as 298kN/mm from k_y = 1,158kN/mm. Based on these results, a value of 500kN/mm was entered for the two GIR springs in the analytical model. α = 0.0088 was used for the GIR stiffness reduction rate, assuming that the elongation reaches the tensile strength at 12%.

4.6 DISCUSSIONS

4.6.1 COMPARISON OF ANARITICAL AND TEST RESULTS

To validate the analytical model proposed in 4.5, the moment-rotation angle relationship of the test results and the analytical results were compared in Fig. 27 through Fig. 29. The analytical results tended to be closer to the less stiff envelope of each positive and negative envelope of the test results. For the analysis results shown in Fig.

https://doi.org/10.52202/069179-0201

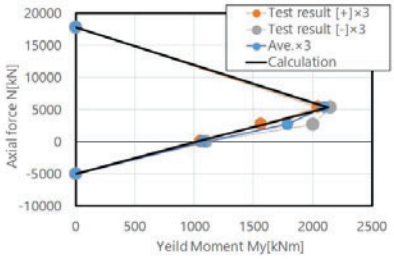

Fig. 30 M-N interaction curve (Section: 300×900)

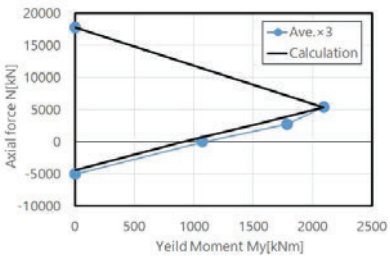

Fig. 31 M-N interaction curve (Section: 900× 900)

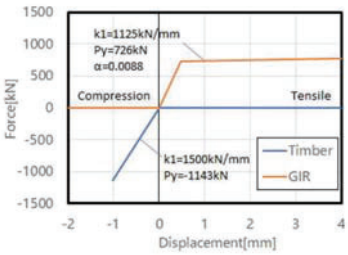

Fig. 32 Springs used for analysis

27 to Fig. 29, the yield point of GIR was taken from the mill test report value (f_y=392 MPa). The *M-N* interaction curve was prepared from the yield moment obtained and is shown in Fig. 30. It was confirmed that the analytical and experimental values were generally consistent.

4.6.2 M-N INTERACTION CURVE FOR ANALYSIS, AND VERIFICATION

The first-floor column cross section of the building under study is 900mm x 900mm. The column cross section is square. This means that in the width direction, the columns have the same configuration as the 300mm x 900mm columns used in the experiment (GIR and shear key locations), and the column cross section on the first floor is the same as three 300mm x 900mm columns in the depth direction. Here, the tripled test results are compared with the results of the analysis on the 900mm x 900mm cross section. In Fig. 31, the test results multiplied by 3 are compared with the analytical results (design specifications) using the lower limit of the reference value for yield strength of deformed bars (f_y = 345 MPa). Fig. 32 shows the parameters of each spring used as analysis conditions. It was confirmed that the values of the design specifications obtained from the reference values were inside the experimental values, i.e., on the safe side. The test ratio of the base metal at *N*=5,400kN was 0.97. The validity of the break point position was confirmed because the failure mode would change if the axial force increased beyond this point.

5 CONCLUSIONS

Multi knife-plates steel dowel connections

1. If the distance between dowels is sufficient, shear performance is proportional to the number of dowels.
2. As a simple calculation method, Multi knife-plates steel dowel connection was confirmed that the addition rule based on the burden area can evaluate.

Frame-testing

1. Using the simplified calculation method obtained in Section 2, the experimental results could be simulated with accuracy.
2. We checked the stress sharing ratio between the brace and the frame, and confirmed that almost no bending moment is applied to the beam ends until the brace yields.
3. Slip of about 4mm was observed at the connection covered by the steel plate. This was due to the clearance of the specimen. (2mm timber + 2mm steel plate) This slip deformation may have contributed to the slip in load de formation relationship.

Column-base joint

1. The performance of the column-base joints with GIR was verified through experiments to develop an *M-N* interaction curve that evaluated the effect of axial forces.
2. It was found that a multi-spring model using embedment stiffness k_{0c}=25N/mm^3 and the lower limit of the reference value for the yield strength of deformed steel bars could be used to model joint performance considering the effect of axial forces.

ACKNOWLEDGEMENT

This research was conducted as part of “Innovative technology for maintenance and management of construction and infrastructure and for disaster prevention and mitigation” in Public/Private R&D Investment Strategic Expansion PrograM (PRISM) add-on item “R&D Project for tall wood building for saving construction site of recovery housing “under the leadership of Japanese Cabinet Office.

HASLE TRE: NORWAY'S FIRST TIMBER OFFICE BUILDING DESIGNED FOR DISASSEMBLY AND REUSE

Ona Flindall[1], Jørgen Tycho[2], Moritz Groba[3]

ABSTRACT: Design for disassembly is a key strategy for ushering the building industry into the age of circular economy. Timber offers an efficient structural solution to meet growing environmental challenges. Yet the timber material lifecycle has primarily remained linear. Design for disassembly and reuse can close timbers material loop and build a circular value chain. The HasleTre project is Norway's first timber office building designed and constructed explicitly with the intention of future disassembly and reuse. In this paper, the architects at Oslotre presents the key design solutions that have been developed for the project. Timber-to-timber connections have been central to the project's design and offers interesting solutions for the circular future of timber architecture and engineering.

KEYWORDS: disassembly, demount ability, reuse, recycle, energy, carbon impact, timber-to-timber joints, carpentry joints

1 INTRODUCTION

Rising prices of timber and other building materials have put an economic incentive on material efficiency, reinforcing the moral imperative in the face of climate change to reduce overall material usage [1]. The C40 report on Building and Infrastructure consumption emissions, highlights that over 60% of the building industry's emissions are associated with the production and delivery of building materials [1].

Timber's ability to sequester carbon gives it significant environmental advantages and offers an efficient method for removing CO2 from the atmosphere and mitigate against the effects of climate change. Yet this equation is only valid for the lifetime of the relevant building components. Once decommissioned timber components are today primarily chipped and used for energy production, releasing the stored CO2 back into the carbon cycle. In 2019, it was estimated of the 815 thousand tons of wood waste produced in Norway, only 6% went to material recovery [1].

In 2021 more than half of all timber waste generated by the Norwegian building industry resulted from demolition and rehabilitation [1]. Office buildings are a typology especially prone to generation of waste materials due to the frequency of tenancy rotation and shifting interior preferences. Depending on tenancy rotation the overall emission cost of refurbishment can ultimately outstrip the emission costs of the building's material production [1].

One key strategy for reducing the environmental impact of refurbishment and end of life demolition, is to design for disassembly and reuse. Ensuring that the lifetime of individual building components are prolonged beyond the lifetime of the buildings they temporarily inhabit. It offers a way of closing material loops, reducing material consumption and waste, prolonging components service life and increasing both on- and off-site reuse.

In this paper, we present Norway's first all-timber office building designed and built to be disassembled and reused; HasleTre.

2 THE PROJECT

2.1 BUILDING, SITE AND SITUATION

HasleTre is situated at the outer edge of the central city of Oslo, Norway. The project is a 3000m2 office building split over 5 floors including basement and roof-terraces. The project is part of a larger city development, HasleLinje, which includes a range of commercial and residential properties. The site is situated as one of two gatehouse plots and frames the square in front of the 1933 Norwegian government wine monopoly distillery, Vinslottet - "the wine castle", see figure 1.

The project was initiated in December 2019 and was completed in 2022.

2.2 THE BRIEF

The initial brief given by the property developers; Höegh Eiendom and AF Eiendom, was the design and development of an environmentally friendly, flexible, and innovative commercial build.

During the early concept phase of the design process the ambitions of the project were developed in collaboration with the architects and key advisors. Resulting in a revised and ambitious brief for an all-timber building designed for disassembly and reuse. The project should also reduce overall GHG emissions with a minimum of 50% and be certified to BREEAM NOR Excellent standard.

2.3 THE CHALLENGE

Allowing for effective reuse of buildings, both during its lifetime and at the end of service life, offers several separate design challenges and requires a number of different solutions, at different levels of design and development. As a designer you are facing the challenge of designing for a second-hand market whose preferences and needs are yet unknown and in large part unpredictable.

Two key design strategies have been central to the design for disassembly solution for HasleTre. Firstly, the development of timber-to-timber joints and connections allow for reduced use of steel and ease of disassembly. Secondly, the development of technical and structural solutions that allow for flexibility in use during life, simplified separation at end of life, all the while retaining a second-hand value of components and materials.

In combination, these two key design strategies aim to retain the structure's second-hand reuse potential, flexibility and financial value.

2.4 ACKNOWLEDGEMENT

This paper will focus on the architectural and structural design solutions developed for and realised in the HasleTre project. However, the authors of this paper wish to recognise at the outset that the realisation of HasleTre has required a collaborative effort from all actors involved, including developers, contractors, and planning authorities.

HasleTre is a result of a well-established cooperation between ambitious property developers and a visionary design team, with a mutual goal of realising something extraordinary. Without the work and collaboration of Seltor as building contractors, the project would not have been realised. The collaboration and mutual goals of the entire team have been an underpinning prerequisit and requirement for realising a project of this magnitude and ambition.

3 DESIGN

3.1 DESIGN FOR LONGEVITY

3.1.1 Architectural quality and durability

Design for disassembly will mitigate against the emission costs of demolition at end of life. But the most effective climate measure is to prevent, or delay, demolition by extending the buildings service life. [1] In a social and cultural context that values the immediate and transitory extending, a buildings lifetime requires architectural design for aesthetic and material longevity.

Groba has shown how timber as a construction and surface material can increasing the lovability of buildings, and how buildings that are loved last longer and thus contribute to both ecological and social sustainability. [1]

By prioritising quality and simplicity in both structure and interiors HasleTre is designed for durability. The overall design and facades mirror the historic and 'timeless' character of the neighbouring heritage building. The high quality all timber surfaces both interior and exterior are hard wearing and will age with grace and character building on the emotional connection that encourages occupants to care for and remain in the building.

Figure 2: *Designed for longevity and lovability. Designed for enduring taste.*

3.1.2 Planed for flexibility

To extend a building's life expectancy it is important to consider and facilitate for changing needs and requirements. HasleTre embraces flexibility in use as well as reuse. The building is designed to facilitate for shifting spatial needs, technical requirements, and preferences. Organised around a central core the two wings of the plan offer a variety of available areas and a potential for division of the building and individual floors among one or multiple tenants. The floor plans are further subdivided by a 5x5m grid system which can easily subdivide the open spaces into smaller enclosed working spaces, see figure 2. The flexibilities in plan and grid allows occupants to reconfigure plans and internal elements without having to make structural and exterior changes.

Figure 3: *Typical floor plan, divided into two main segments and further subdivided by structural grid.*

Flexibility in structure and plan is facilitated further by use of a Granab subfloor system and open technical infrastructure for ventilation and sprinkling in the ceiling. The technical infrastructure needs of the future may be difficult to predict, but by giving ease of access, HasleTre ensures the building can be adapted for a variety of uses during its lifetime and handle larger societal changes and changing technical infrastructure.

Figure 4: *Subfloor system and open central ventilation system allows for swift and easy changes to interior arrangement.*

3.1.3 Design for production, effective material use and ease of assembly and disassembly

The building is a CLT slab and glulam post and beam structural system. Designed for disassembly and reuse, all components are carefully planned and designed to enable an easy assembly and disassembly process.

All of the timber components are designed to minimize cut-offs in production and designed for standard production dimensions. Designed for the Master Element production in the CLT factory each floor slab utilises the standard three by fifteen meter elements. This reduces the need for cut offs, maximise the space on the lorry and gives a fast assembly.

To retain reuse potential, all permanent fusing joints and sealants had to be avoided wherever possible. A full disassembly manual follows the building at completion.

3.2 DESIGN WITH REUSE

HasleTre was built to be dismantled and reused, but also built to include the reuse of material components where possible. The project reuses the ventilation aggregate, acoustic ceiling plates, sanitary installations like sinks and toilets, flooring in secondary rooms such as basement and technical rooms. Designing with reuse requires an attention to details to handle the overall material pallet and relies on an availability of components.

https://doi.org/10.52202/069179-0202

Figure 4: *Second-hand acoustic panels for use above ceiling battens.*

HasleTre was let to the charity Save The Children from December 2022. As tenants, the reuse approach was further adopted and incorporated in their own interior design. Ensuring that the majority of all furniture and inventory brought into the building was either reused, recycled or upcycled.

3.3 DESIGN FOR REUSE

3.3.1 Second-hand value of standard dimensions

The project aims to be the standard to beat in new circular builds. By utilising standard production formats and dimensions, the timber structure actively aims to retain value of the component for second-hand use. By limiting perforation of structural components the overall material use is reduced in the project, while the potential for second hand adaptations is secured. The CLT floor slabs are utilised as master elements in full. To facilitate for technical facilities the inherent strength of the CLT slabs is utilised to 'carry' the extension between the beam structures. Resulting from this strategy the glulam beams are not perforated to facilitate technical services and the material use and cost is reduced while the beams remain versatile and adaptable for future use.

Figure 5: *Glulam and CLT timber-structure. Note cantilevered beams give space for ventilation and fire systems.*

3.3.2 Timber-to-timber joints

The building structure is an optimised timber structure that aims to reduce the use of steel and other metals to a minimum. Replacing conventional steel joints between timber components with timber-to-timber alternatives. This is done both to reduce the overall use of steel, but also to ensure that the timber component can be reworked and remodelled using industrial tools to facilitate for future reuse without facing limitations due to the danger of steel embedded within the components.

Two key joints have been utilised in the project; Firstly the use of hardwood dowls in post-beam nodes and the use of x-fix joints between CLT slabs. In addition, all interior cladding is assembled with hardwood nails.

Through careful structural design, the tension loads on the joints have been reduced and enabled a simplified dowel joint. Using only two hardwood dowls in beech, the joint is not only materially efficient, but also labour efficient. Significantly reducing the assembly time on site. The dowels are dried to 6% before insertion. Once inserted the wood will adjust to surrounding moisture and lock the components in place. At disassembly the dowel can be drilled through and the connection released.

https://doi.org/10.52202/069179-0202

Figure 6: *Hardwood dowels during assembly of timber structure.*

CLT slabs in the building walls and floors are connected using X-Fix plywood connectors that replace the traditional use of metal screws. This is the first time the X-Fix connectors are used in Norway. This significantly reduces the overall use of steel and increases the reuse potential and value. The X-fix system has also proved to be an incredibly timesaving process in assembly on site.

Figure 7: *X-Fix dove-tail connection between CLT slabs.*

Furthering the timber-to-timber joints to its final conclusion, both interior and exterior cladding is assembled using wooden nails as fasteners. As with the structural components the use of timber joiners enables an easy remodelling or furnishment at the end of life.

Figure 8: *See the heads of the small timber nails to the left in the photo.*

4 LESSONS LEARNT

The HasleTre project has been a valuable learning experience for all parties involved and there is a desire to inspire others to think reuse, both today and for the future. The development and use of innovative and demountable structures require discipline and desire from developers, designers, and contractors. Developing a mutual understanding of collective goals and aims has been essential to the successful application and realisation from development stage to completion.

In all innovative projects the division of responsibilities will be challenging. Uncertainty and insecurity in realising untried approaches and solutions can quickly lead to conflicts and difficulties within the project teams. In the HasleTre project the architects were able to take on the responsibility for the structural engineering and mitigate against insecurities with suppliers unfamiliar with the solution.

The commercial reuse sector is growing and developing quickly, but it is still facing a number of challenges with regards to availability, lack of storage and cataloguing, just in time logistics and certification. This is reflected in the processes around HasleTre where the ambitions for reuse of materials restricted predictability and required selection and ad-hoc choices throughout the process.

Collectively, the timber-to-timber joints and solutions offer an adaptation of traditional building practices to industrial and prefabricated timber structures. Offering financial rewards in terms of reduced assembly time and a retained second-hand value of both interior and structural components.

5 DISCUSSION AND CONCLUSIONS

In 2022, the national building codes TEK17 were updated to include requirements for design and construction for disassembly. There is a political desire to increase circularity in the building sector. The attention HasleTre has drawn both nationally and internationally points to the

https://doi.org/10.52202/069179-0202

need for built projects and examples that can lead the way for implementation of these principles, and showcase the architectural potential in disassembly and reuse.

Vandervaeren, et al., have shown how current calculations methods for LCA fall short on adequately modelling material flows and stocks in demountable buildings. Failing to capture the potential benefit of designing a building for easy disassembly and reuse [1]. They go on to call for a method that captures the effects of demountable design principles in the input and output material flows during the replacement and end-of-life stages of built assemblies, and on the reusability of disassembled building parts.

As design for disassembly and reuse is developed as a design strategy, it is important to be able to show and quantify the benefits for the environment. The authors of this paper hope the HasleTre project will incentivise both the public and private sector to call for greater application and development.

The project showcases a number of key challenges faced when wanting to design, both when utilising and facilitating for future reuse of building components. It also offers a critical view to the choice of hybrid solutions for increased strength and meeting acoustic and fire demands, which if not carefully designed, will potentially limit reuse and recycle potential.

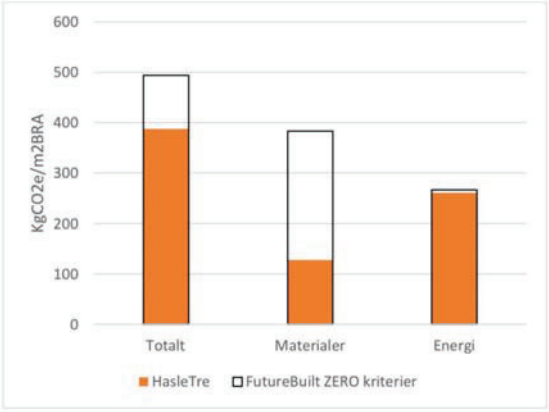

Figure 9: *GHG emissions compared with FutureBuilt ZERO cirteria.*

As built calculations show an overall 59% reduction in emissions from materials and energy use over a lifecycle of 60 years. Use of timber in post and beam structure, slabs and timber-to-timber joints have reduced the steel use in the building by 70% compared to a conventional office building [1].

TOWARDS ADAPTABILITY AND CIRCULARITY OF TIMBER BUILDINGS

Robert Jockwer[1], Vera Öberg[2], Lisa-Mareike Ottenhaus[3], Paola Leardini[4], Yutaka Goto[5]

ABSTRACT: The construction industry has been a major contributor to resource consumption and global greenhouse gas (GHG) emissions, owed to high demand for building construction and the rapid urbanization trend. Timber construction has gained traction globally due to environmental advantages, such as renewability and carbon sequestration. However, sustainably available wood resources are limited. Extension of service life of timber structures is key to prolong their carbon stock. This paper showcases research projects carried out in Australia and Sweden that aim to design adaptable timber buildings capable of accommodating functional and spatial changes over time, thereby extending the service life of buildings and their components, as well as optimising their life cycles through spatial variations and repair of local damages to structural elements. This approach, known as Design for Adaptation (DfA) is an important step of the roadmap towards circular design solutions for timber buildings, which provide many economic, social and environmental benefits to all stakeholders and key players related to the building process, including manufacturers, engineers, architects, end-users, municipalities, and others.

KEYWORDS: Timber Buildings, Circularity, Adaptability, Sustainability

1 INTRODUCTION

Urban population has dramatically increased since the 1950s, driving the need for more buildings in densely populated areas globally [1]. As the construction industry has been a major contributor to greenhouse gas (GHG) emissions and resource consumption [2], the recent global attempt to decarbonise the construction industry has boosted interest in timber buildings due to their inherent environmental benefits.

For example, the Swedish construction market has seen a rapid growth of multi-storey timber construction for both residential and commercial buildings. The share of wood in newly built multi-storey constructions grew to approx. 20% in 2020, while it was 0% until the legislative change in 1994 [3], which was made possible by advances in fire safety engineering and allows to build more than 2 storeys in timber. Likewise, the Australian government is encouraging timber buildings as a pathway to emission reduction through policies and incentives, which has led to a nationwide timber shortage [4]. Although Sweden currently has a sufficient supply of timber for the domestic market, the export of sawn timber may increase from 70% of the current production to a much higher share in the coming decades, as it is expected that the timber construction industry will continue to grow globally [3].

Wood shortage is aggravated by its use in other sectors; wood is an attractive alternative as a renewable energy source and has applications in the chemical industry and for packaging. It is obvious that there must be a more rational and efficient use of raw materials in the overall wood-consuming industry; therefore, it becomes crucial to maintain the value of wood-based products and building components for an extended time. The best way is to utilize larger elements made of solid timber or engineered wood products (EWPs) as long as possible before letting them be transformed (cascaded) into other less valuable products, such as wood chip, pellets or pulps, which are the most common options. By reusing timber building components, the material is kept at the highest levels of the value chain, also assuring the continued storage of carbon in wood products [5].

In practice, when damages and deterioration of timber elements occur in critical parts of a structure, the whole building might need to be demolished if local repairs are not feasible for technical and/or economic reasons. Often though, other reasons may lead to building demolition and replacement. Regardless of the construction material (wood, concrete etc.), buildings might face the end of their service life due to the functional changes and different user needs over time. According to Thormark [6], there is a tendency for buildings in Sweden to be demolished far too early in terms of their technical service life; approximately 25% of buildings which have been demolished after 1980 were 30 years old or younger. If the construction system of those buildings, had allowed for easy removal or replacement of structural elements and enclosure components, their service life could have been significantly extended.

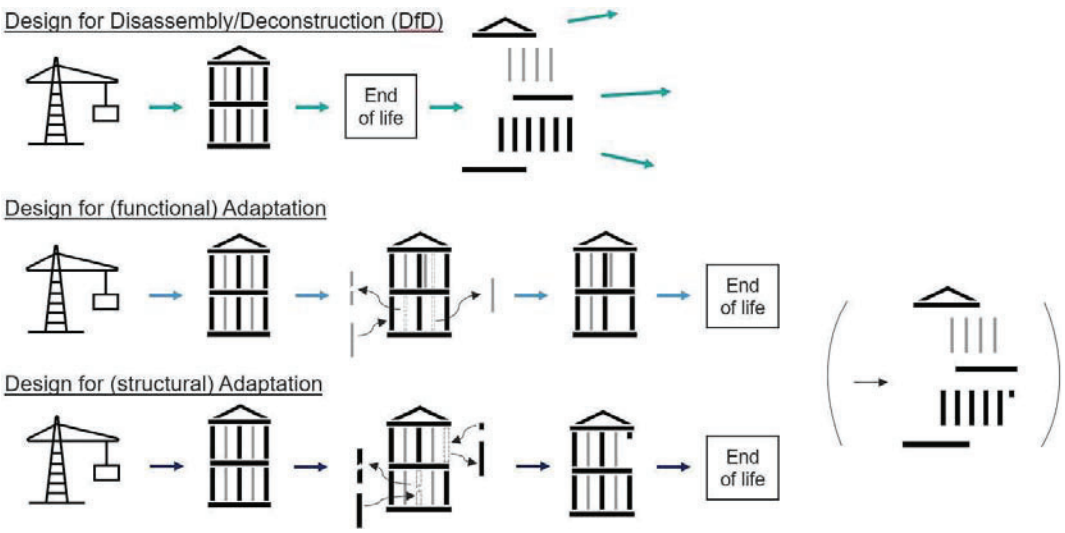

Figure 1: *Definitions and illustration of the concepts of DfD and DfA.*

To explore this potential, projects researching aspects related to adaptability and circular design of timber buildings have been initiated in parallel at Chalmers University of Technology (Chalmers) [7] in 2021 and at the University of Queensland (UQ) in 2022. They both focus on the numerous challenges still to be addressed in the circular design realm, such as a lack of adequate legal frameworks including standards, procurement requirements, regulations, and quality assurance, but also a lack of technical solutions for planners, engineers, and architects as well as a general lack of knowledge regarding the benefits of considering circularity and adaptability already in the design stage. Addressing these gaps requires the definition of a detailed and concrete roadmap towards the implementation of circularity and adaptability in timber buildings.

In this paper, we will critically present and discuss the concept and theory of design for adaptation (DfA), review the status of the timber and construction sector in Australia and propose the next steps to be taken for an effective implementation of DfA in timber construction.

2 CONCEPT AND THEORY

2.1 DfA and related concepts

Existing research on building adaptability has, to a large extent, focused on architectural and spatial changes. Definitions vary, but a common thread is the building's capacity to change in some way to meet new functional requirements or user demands, with the goal of extending its *useful life* [8]-[11] (for engineering aspects the term *service life* is used instead). DfA, in turn, has been described by Graham [12] as "a strategy used to avoid building obsolescence, and the associated environmental and cost impacts of resource consumption and material waste". While this could refer to the design for adaptability of both a building's structure and its non-load-bearing parts, this paper makes a distinction between the two, as designing adaptable non-load-bearing parts is dissimilar, both in execution and desired outcome, to doing the same for load-bearing parts. For example, designing non-load-bearing partition walls to be movable, removable, or replaceable enables the *functional* adaptation of indoor spaces without changing building structure and envelope, while designing parts of the structure, e.g., floors or load-bearing exterior walls, to be moveable, removable, or replaceable could instead defined as *structural* adaptation.

The concept Design for Disassembly or Deconstruction (DfD) is, in many ways, related to DfA, as it is a prerequisite for adaptability. DfD aims to limit waste production and raw material consumption by designing building elements (and the uncontaminated materials they are made of) to be disassembled and reused at the building's end of life [13],[14]. An important aspect of applying this concept to timber structures is the design of reversible connections [15], which are also crucial for designing timber structures for adaptation. It is indeed assumed that a timber structure designed for adaptation would also enable, or at least facilitate, deconstruction and reuse of its parts at its end of life. It should, however, be noted that the deconstruction and reuse of separate elements and materials at a building's end of life is not inherently a part of the DfA concept.

The concepts Design for Disassembly/Deconstruction, Design for (functional) Adaptation and Design for (structural) Adaptation are demonstrated in Figure 1.

2.2 Why do we demolish buildings?

If the purpose of implementing DfA is to prolong the service life of buildings, one should first consider why buildings are typically demolished. Any building, whether it is a single-family house or a multi-storey office building, is presumably at a low risk of demolition while it is considered useful and functional, i.e. if there is a need

https://doi.org/10.52202/069179-0203

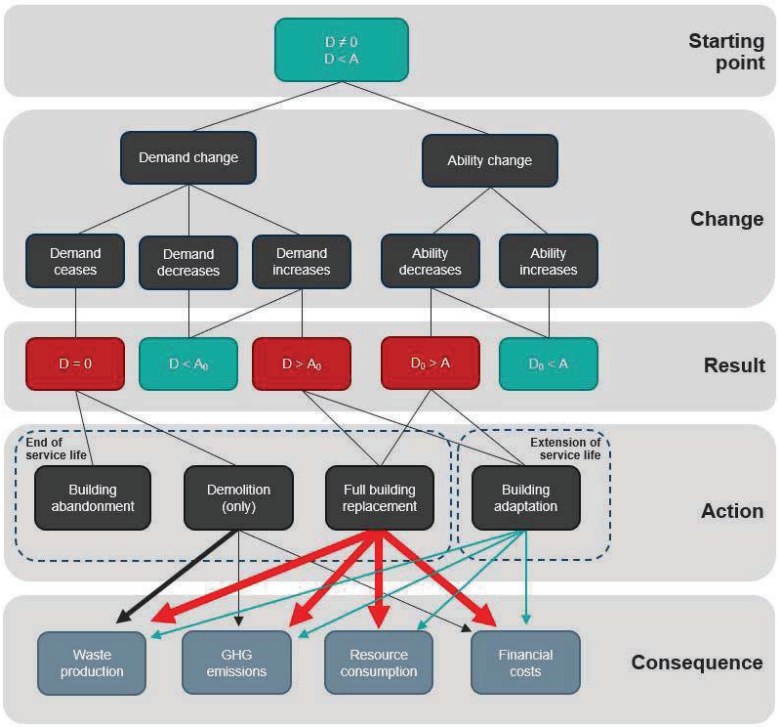

Figure 2: *Why do we demolish buildings?*

for the building in question and the building sufficiently fulfils specific functional and performance requirements. Consider the market **demand (D)** for a building type and its associated performance and functional requirements, versus its **ability (A)** to satisfy those requirements. This is illustrated in Figure 2. The demand is external; for example, the demand for office space at a given location and with its associated imposed structural loads. The ability, instead, is internal; for example, the building's ability to provide office space and carry certain loads. In a simplified model, one could set up two criteria for any given building. The first criterion is that there is a demand ($D \neq 0$), e.g., the demand for office space in the building's location. The second criterion is that the ability is greater than the demand ($D < A$); e.g., the building can sufficiently provide the demanded office space for its location.

If a building meets both criteria, it could be considered useful, which is normally the starting point for a newly constructed building. After some time, however, a change might occur – see Figure 2. In case of an external change, the demand could either cease, decrease, or increase. A complete cease of all demands would render the building in that specific location useless, and logically the owner could choose between abandoning the building or demolishing it. An example of this is a remote building connected to a mining operation, where a complete depletion of the mine might cease the operation and render the building useless. A decrease in demand, however, would still imply that both criteria are being met (economic implications of a significantly decreased demand could, however, still cause a decision to demolish or abandon the building). Lastly, when the demand increases, it might exceed the building's ability, in which case an action needs to be taken. Assuming no additional space is available on site for new construction, a whole building replacement or a building adaptation would be the relevant options. For example, a three-story multi-residential building in a city centre (where land value is high) might be replaced by a taller building as the area becomes more densely populated and the demand for housing is increased.

Regarding internal changes as defined above, the 'ability' of the building, as referred to its performance, typically decreases over time. An ability decrease could be caused by, for example, deterioration, long-term structural effects, or local damage. If the ability decrease falls below the demand, the relevant actions are yet again either fully replacing the building or adapting it to again meet the demand. In structural terms, a building's ability increase might be observed, e.g., if assessment is performed, and more beneficial member properties can be utilized through updated information; an example would be increased strength of concrete beams over time that exceeds 28-day strength used in design.

This model though, is clearly simplified; for example, a change might not be isolated, or a building might have a simultaneous demand and ability change. Furthermore, one demand could simply be replaced by another demand, e.g., a demand for office space being replaced by a demand for housing. In this case, the requirements for span length or floor height might decrease while those for

https://doi.org/10.52202/069179-0203

acoustics and fire safety might increase. Hence, the building might need to be adapted or even replaced to meet the demand for housing along with its associated performance and functional requirements. If some requirements exceed the building's ability, owners may need to consider building adaptation (retrofit) or replacement.

The detailed consequences of these four actions – building abandonment, demolition, replacement, and adaptation – vary on a case-by-case basis. Focusing on waste production, GHG emissions, resource consumption and financial costs, one could compare the assumed effect of each action to identify the most effective (overall or for specific targets). Building abandonment might be an option only if the economic loss of no longer using the building is negligible. Therefore, it is assumed to not cause any of the four consequences in a significant way. After some time and inevitable degradation, however, building abandonment could also lead to demolition. Demolition would presumably mainly cause waste production, along with related GHG emissions and financial costs for demolition and disposal. A whole building replacement, however, would cause all four of these consequences in a substantial way. Finally, a building adaptation would also cause all four consequences, but presumably to a much lesser extent than a building replacement, which must be evaluated on a case-by-case basis; different cases require different levels and intensities of adaptations in terms of cost and technical difficulty. When are the required alterations too complicated and costly, to justify building replacements as the more economical alternative? This is where design for adaptability and disassembly may shift owners' choices. Key to this approach is conceiving a building as an assembly of systems.

A popular way to illustrate a building's separate systems is Brand's [16] concept of 'shearing layers' of change. In this model, Brand identifies six building systems as layers, where the systems' varying lifespans causes shear between them. If relatively isolated, one system with a short lifespan can be changed without affecting the more 'permanent' layers [16]. The load-bearing structure, however, is the system layer with the longest planned lifespan; changes in the structure will likely affect some, or all, other building systems. Furthermore, altering a building's structure can be considered more technically complicated than altering its non-load-bearing parts. While lighter repairs are often favoured over demolition due to economic advantages, severe structural damages often cause a decision to demolish due to technical challenges and the repair costs exceeding the cost of a whole building replacement [17]. In the decision to demolish or rehabilitate a building, Bullen and Love [18] concluded that the leading determinant was the financial criterion, followed by asset condition and regulation. Economic, environmental, and social sustainability were all deemed important factors but given a lower priority in the decision [18],[19]. It is clear that, to make building adaptations a favourable alternative to demolition, it needs to be a cheaper and more technically feasible option, also supported by building regulations.

2.3 Expected benefits

So far, DfA has not been the prevalent concept neither for the design and conception of new buildings nor for the rehabilitation and adaption of existing buildings. It can be stated that the construction sector and building industry still follow a predominantly linear system, with a focus on the construction and development of new buildings. In previous years, the maintenance and rehabilitation of existing structures have contributed only minimally to the revenue of the actors involved in the construction process. Nevertheless, they are gaining importance (not least also in the infrastructure sector), and there is a clear trend to shift from a linear construction process to a more circular approach for the construction, use, and re-use of buildings and structures. In this process prefabrication is a natural way to implement DfA.

Amongst others, the following specific benefits are expected in the construction sector from a successful implementation of DfA for timber buildings:

- Contractors. Improved workflows on the construction site due to an increased use of standardized assemblies and the shift from on-site labour to offsite facilities, with associated benefits in terms of quality, cost, efficiency, and occupational health and safety.
- Manufacturers. Higher added value of building components will strengthen the producers' market position and create new business opportunities, e.g., leasing of components.
- Consultants, engineers, and architects. Best practice detailing and solutions that guarantee compatibility will allow to create more long-lasting solutions instead of individualized compromises.
- Developers. Buildings start to act as material banks, where the building retains a considerable material value. The value is retained after conventional 'end-of-life' through disassembly and reuse. At the same time benefits can be gained from the experience, repetition, and scaling effect of the successful circular concept and building system, hence, making the project development more cost-effective.
- Property owners. Long lasting, sustainable, and smart buildings that can react to changes in use and context conditions, thus maximising their value; this reduces maintenance costs and increases attractiveness of the property on the market.
- Users. Buildings that match user needs. For instance, tenants no longer need to adapt to the individual building; instead, the building adapts to their needs, requirements and wishes.
- Municipalities and society. Long lasting building stock that is able to adapt to changes in societal structure, such as demography or age distribution, to tackle new planning and building regulations, but also that can be used as a whole more effectively as buildings become material banks.

https://doi.org/10.52202/069179-0203

- Financers. Better estimation of economic risks and opportunities due to more sustainable buildings that can adapt to climate change; Thus, inherently lower risk in the light of an uncertain future, e.g., waterfront properties can be disassembled and relocated to respond to sea level rise.

3 REVIEW OF STAKEHOLDER STATUS AND DEMANDS

3.1 Overview

As part of the collaborative investigation carried out by UQ and Chalmers on DfA of timber buildings, the current stakeholder status, demands, and their development potential were evaluated in a study tour in Australia in October and November 2022. This tour was part of a project funded by the Swedish Research Council for Sustainable Development with the aim to establish a strong collaboration between the European and Australasian region with the focus on making timber buildings ever more sustainable by implementing the concepts of adaptability and circularity in their design.

The overall aim of the study tour comprised the following three objectives:

- Mapping the differences in use between new and reclaimed/reused wood-based building materials and elements from the perspectives of all stakeholders, such as producers, contractors, consultants, architects, engineers, and end-users.
- Analysing production, fabrication, design, use and re-use of timber building elements to identify opportunities and barriers to the transition to adaptability and circularity.
- Summarising barriers, challenges, and drivers, as well as possible means and technologies to overcome the differences between scales of applications, from construction products to building design.

By understanding the challenges and opportunities, it is possible to define the necessary steps for adaptability and circularity of timber buildings to be further developed, implemented, and utilised in Sweden and Australia, but also internationally. The following section presents the findings of the study tour, grouped by stakeholder type.

3.2 Stakeholder status, demands and development potential

3.2.1 Wood sector in Australia

Australia has a great diversity of wood species, however, only few softwood species are used to larger extent in the construction industry. In order to create sustainable development while maintaining and developing ecological diversity of forests, the utilisation of a more diverse range of wood species should be considered. Timber Queensland [20] is an association of wood industries in Queensland, which maintains an online tool to purchase Queensland timbers [21]. Finding a suitable application for each of the wood species in different applications will help enable a more sustainable utilisation of resources.

3.2.2 Forestry

Sustainable forestry is a prerequisite for achieving a thriving timber sector and implementing DfA. Timber plantations are a common solution for sustainable forestry and wood production in many parts of the world. For example, in Southern Queensland (Wide Bay Burnett, South East Queensland - SEQ, and Darling Downs South West) HQPlantations [22] manages 310,000 hectares of plantation forest in a 99-year lease contract; HQPlantations is both Forest Stewardship Council (FSC) and Responsible Wood (PEFC) certified, and their softwood supply is used to build 25,000 homes/year, covering most of the demand in the SEQ region.

Different wood species are grown in different locations, depending on the local climate and geographic conditions. For example, the hills around Imbil show great diversity in plantation and natural forests, with a variety of different hard- and softwood species. Natural hardwood forests cover the hilltops whereas diverse plantations stretch across the valleys. In contrast, the flat sandy landscape around Toolara provides soil conditions for large monocultural forests, from which the logs are directly transported to the nearby sawmills [23]. The different wood species at the various locations may offer different benefits for specific applications.

There are two important Southern Queensland wood species. Araucaria (Hoop Pine) is an endemic rainforest species mostly grown for visual grade veneers, baby cots (food grade timber) and musical instruments; its harvesting age is 50 years. The second one is Southern Pine, which is a hybrid of Slash and Caribbean Pine, harvested at 28 years, which supplies SEQ's structural timber demand, including engineered wood products.

Fire management is a crucial part of HQPlantations' activities: fire observation towers are installed in different locations to detect smoke plumes, all vehicles are equipped with firefighting equipment, and the staff consists of trained fire fighters. The active fire management of the forest, through prescribed burning and controlled burns in collaboration with adjacent landowners, is an effective means to control the fuel load.

The direct connection and vertical integration between the forest and the further processing steps in the wood value chain are important to create a more resource efficient wood value chain. An example of this efficiency is linking the growth data from the forest, including stem dimensions and qualities, to the production demands and capabilities of the sawmills, in order to manufacture higher value products and avoid unnecessary waste during production. Such an integration provides benefits both for forest and plantation owners, supplying higher value-added products to sawmills, which can then meet their customers' demands more efficiently. An important first step in this process is, for example, the delivery of full size (untrimmed) logs of Southern Pine from the Toolara plantations by HQPlantations to the Hyne sawmill in Tuan, Queensland [24]. For the plantation owners, this vertical integration includes selecting the most appropriate genetic resources and breeding seedlings in nurseries.

3.2.3 Producers and Sawmills

A variety of structural products are manufactured in different sawmills and production plants across Australia. As part of the study tour, a total of 6 sawmill, glulam, and CLT plants were visited. Depending on the location and the local raw material supply, the sawmills are specialized in different raw materials, timber products, production processes. Despite their individual differences, some commonalities and challenges can be identified:

- Grading and strength classes. The strength class system of machine graded pine (MGP) is rather strict and allows only for a limited range of adaptation to the feedstock. Almost all sawmills use machine grading to produce MGP10 lumber and partly higher qualities. Lower qualities than MGP10 result in F-grade timber, which is assessed based on bending strength rather than stiffness. Over the time, the market demand has adapted to these qualities. However, this strict and limited system of strength classes does not allow for a better and more efficient utilisation of the raw resources in the future. Vertical integration between the sawmill and the users in the construction industry can provide a solution here.
- Timber treatment against termite attack. Most of the timber products used in Australia require chemical treatment against termite attack. The effective and sustainable use of chemicals is a general challenge for the re-use of timber elements and circularisation of resources. Reliable and long-term specification of the treatment type is important. At the same time (private) users are familiar with certain colour codes for different applications and demand these colours without further questioning the performance.
- Optimisation of sawing patterns. The yield of the sawmill depends, to a large extent, on an optimal choice of the sawing pattern for the feedstock. Depending on locations and species of the feedstock, the log's cross-section, length, and straightness can vary quite considerably. E.g., Radiata and Southern Pine used by Associated Kiln Driers Pty Ltd (AKD) Softwood Mill Caboolture, Queensland [25] have a considerably smaller diameter compared to Radiata Pine used by TimberLink, Bell Bay, Tasmania [26]. Good interaction and communication between the forest owners, harvesters, sawmills, and consumers are crucial to achieve an efficient utilisation of resources. The vertical integration enables also to track the product Chain of Custody.
- Hardwood species are used to a much smaller extent in the construction industry compared to softwood. Several manufacturers work with hardwood in Australia and produce glulam or CLT. However, hardwood has not yet fully penetrated the market; some of the challenges of working with hardwoods are the different gluing requirements compared to softwoods and the more careful and slower drying processes to avoid wood matrix damages.
- Automation can help to upscale the production volume compared to elaborate production by hand. Automated glulam production from softwood of standardized sizes in the Hyne timber Glulam factory [24] (Maryborough, Queensland) is a good example. However, individual and customised timber members of other dimensions or bespoke shapes still require manual production.

  The trimming of full size CLT panels on CNC machines at XLam Australia, Wodonga [27][26], offers the possibility to prefabricate entire wall and floor elements and integrate the connection details in factory. This enables to integrate DfA solutions as standardized detailing solutions in the process.

Excellent examples of small innovative producers are CLTP and CUSP Building Solutions [28], in Wynyard, Tasmania, which have developed hardwood CLT and glulam for a better utilisation of local resources: they produce Eucalyptus Nitens and Eucalyptus Grandis composite Glulam beams and Eucalyptus Nitens CLT panels. At the same time, they utilise the finger jointing lines to re-use MGP10 cut-offs to produce structural finger jointed lumber of a similar quality. This is an excellent example of efficient resource utilisation and reuse, well aligned with circularity principles.

3.2.4 Architecture and Engineering

Common challenges for engineers and architects for the development of the mass timber industry where discussed with NexTimber [29], which is the Melbourne-based mass timber (Glulam and CLT) division of Timberlink [30]. These are the reuse of CLT panels, lack of a standardised connection details, repairability of structures, and classified material properties. These gaps impact the ability of engineers and architects to design for deconstruction, reuse, and recertification of timber components, as well as the carbon credits system, as it cannot be assured that timber remains in use and is well maintained.

Advancing education around the use of timber in architecture is in the focus of the Centre for Future Timber Structures at the University of Queensland's St Lucia campus, as well as the Centre for Sustainable Architecture (CSAW) at the University of Tasmania's Newnham campus. UQ projects include, amongst others, research on adaptable timber structures and innovative reversible connections [31][32], and hygrothermal performance of CLT in hot and humid climates [33]. UTas projects include, amongst others, the use of salvaged timber materials for innovative structures, and research on local hardwoods [34]-[36].

Innovative construction concepts are offered by ArKit, Sunshine, Victoria [37]. ArKit's projects range from bespoke architectural designs using volumetric and panelised offsite construction, to Passivhaus standard projects, and volumetric social housing. The use of modular, panelised, and volumetric prefabrication in their factory enables high-performance and quality solutions also for low budget social housing funded by the Australian government. The modularity enables the

refurbishment of existing modules in the factory after their initial lifetime for a second cycle.

3.2.5 Exemplar timber buildings

Structural timber is a common building material used in residential buildings and there are many historic examples of mid-rise timber buildings in Australia, such as the oldest surviving building in Albert Street, Brisbane [38]. The development of modern structural engineered wood products (EWP), namely glued laminated timber (GLT), laminated veneer lumber (LVL), and cross laminated timber (CLT) enabled to build also larger high-performance structures in timber instead of the other prevailing building materials steel and concrete.

One of the most celebrated modern, multi-storey buildings made of EWPs in Australia is the office building at 25 King Street in Brisbane [39]. Lendlease is the developer, Aurecon is the engineering consultant and Bates Smart the architecture firm who designed the building of the 9-storey mass timber office building using Stora Enso CLT. Despite attracting a 'timber premium', the lease worked out much cheaper than Aurecon's previous offices in the CBD. Furthermore, employees enjoy the timber feel of the building with the building winning design and wellbeing awards.

The following structural design features of this showcase building can be highlighted:

- Slotted in steel plates, concealed with timber covers, and timber plugs for bolts and screws to enhance fire performance also enable potential deconstruction.
- 5-layer CLT in the staircase, with the first two layers running vertically to improve load bearing resistance - the staircase has no lateral bracing function. This solution also improves fire resistance rating.
- Hardwood LVL banded Glulam beams to reinforce the beam around services penetrations.
- Large open floor plans offer functional and spatial flexibility.
- Durability and repairability of exposed timber elements improved by adequate protection from wetting and weathering; UV protection is crucial to avoid colour variations in different exposed members.

The timber building at 25 King Street is exemplar towards implementing DfA as, in principle, much of the building is deconstructable due to the fasteners and brackets chosen, and due to a clear and open member design, which applies circular design principles for.

Another exemplar building is the recently opened extension of the Maryborough Fire Station [40], designed by Baber Studio (architecture) [41] and Bligh Tanner (structural engineering), and realised by Hutchinson Builders. While the old brick façade of the existing fire station building was preserved, the whole new extension is made from Glulam and CLT supplied by Hyne Timber and XLam - manufactured from local softwoods from their Tuan mill. Design features of the fire station extension include CLT band beams and concrete ring beams in the fire engine area, to kept timber off the ground while fire engines are being washed down or when leaking water. This building is particularly relevant as it shows the potential of timber also in non-conventional applications.

Finally, the Inveresk UTas Library, in Tasmania, is an exemplar hardwood structure made of local Tasmanian Oak. Tasmanian oak is the name used for three eucalypt hardwoods: Eucalyptus delegatensis (alpine ash) can be found at higher altitudes, while E. regnans (mountain ash) is found in wetter sites; and Eucalyptus obliqua (messmate) has a wide distribution, growing in wet forests but also extending into drier areas. The timber members are used in bespoke roof trusses offering large open spaces and appealing architectural design, which is an excellent example for the use of local resources in a performant structure. The efficient large span truss structure offers a flexible usage of the building.

3.2.6 Research

Circularity of wood products

The circular use of wood requires strategies to maintain wood products at their highest value and then provide efficient solutions for a cascading application, at a lower value. This is one of the focus areas of the Advance Timber Hub, an Industrial Transformation Hub funded by the Australian Research Council (ARC) to advance timber in Australia's future built environment. Furthermore, researchers at Queensland's Department of Agriculture and Fisheries (QDAF) facilities at Salisbury are looking at engineered wood-based composites, kiln drying and sawmilling technology, timber grading,
wood product design, and performance testing, which all enhance timber recovery and durability throughout the value chain. Particularly significant towards the implementation of a circular timber construction sector is research led by A/Prof Benoit Gilbert, which addresses: high quality products from the raw material in form of sawn boards or veneers from different wood species [42] to be used in LVL, glulam, or CLT; recycling and reuse of different waste materials in value-added products, such as tyres and wood fibres in composite particle boards; and product durability to ensure a long and safe service life. Durability of EWPs is also at the centre of a collaborative research project by PhD candidate Marcus Strang, under the supervision of Dr Paola Leardini (UQ) and Dr Maryam Shirmohammadi (QDAF); the study investigates the hygrothermal performance of high-performance CLT construction in hot and humid climates, providing design guidance that, ultimately, also ensures structural durability across different Australian climates [43].

Construction strategies and solutions

Technical solutions for the application of DfA in construction are investigated by the research group of A/Prof Hamid Valipour at the University of New South Wales (UNSW), Sydney. Hybrid steel timber elements are being developed that offer a variety of benefits [44]; the combination of low-grade timber elements with steel rods in hybrid elements can provide high quality usage for low quality timber in standardized components, such as columns or beams. Standardisation facilitates the use and

https://doi.org/10.52202/069179-0203

re-use of these components in different applications. Constructing with standardized components instead of members with individualized geometry is common already e.g., in the steel or prefab-concrete industry and offers high circularity potential also in the timber field. The combination of these hybrid elements with conventional structural solutions in steel or concrete offers the easy implementation of more resource efficient components in the construction sector. Further implementation of specialized connections will facilitate construction and deconstruction, and it enables the implementation of fuse elements to achieve ductility for robustness or seismic purposes.

3.3 Necessary steps towards DfA

While significant research is currently carried out, further steps are necessary to ensure the transition of timber construction to circularity and the implementation of DfA, including:

- Vertical integration of processes, from the forest to the end-user.
- Utilisation of a wider range of wood resources.
- Effective use of all by- and side products of the wood value chain (e.g. structural finger jointed timber, scrimber)
- Production of standardized components instead of materials.
- Design and construction of flexible structures in terms of both floor plans and re-use and deconstruction.
- Use of offsite prefabrication and modularisation as mainstream practice.
- Mapping of differences in use between new and reclaimed/reused wood-based building materials and elements, from the perspective of all relevant stakeholders, such as manufacturers, contractors, consultants, architects, engineers, and end-users.
- Development of business concepts including the re-use of material, members, components, and entire structures for transitioning to adaptability and circularity.
- Translation and commercialisation of circularity and adaptability research in collaboration with industry stakeholders and research providers.
- Education of architecture, engineering and building professionals with respect to durable and circular design, better interdisciplinary networking, and collaboration between industry stakeholder to achieve common goals.

4 CONCLUSIONS

The results of the research and built projects described in this paper provide a greater understanding of the challenges and opportunities of DfA and, more broadly, circularity of timber buildings, with a special focus on the Australian and Swedish market. The concept and general benefits of DfA were explained. Then the current status and ongoing development of the stakeholders in the Australian timber construction industry and research environment were analysed. Following this evidence-based analysis of the Australian timber sector, the paper proposes some first but necessary steps for adaptability and circularity in the timber sector to be further developed, implemented, and utilised. This paper leverages results of government funded research projects on DfA currently being conducted at UQ and Chalmers, thus significant findings are expected in the future.

ACKNOWLEDGEMENT

The paper is based on the following research projects: “Roadmap towards adaptability of timber buildings” (project number 2021-02711) and “Design for adaption for resource efficient timber structures” (project number 2021-02499), both funded by FORMAS, the Swedish research council for sustainable development; and Linkage Project “Offsite manufacture reimagined for high-performance adaptable housing” (LP200301402), funded by the Australian Research Council. The researchers would like to thank Timber Queensland, HQPlantations, AKD, Hyne timber and XLam Australia, Timberlink and NexTimber, CLTP and CUSP, UTas, UNSW, QDAF, Baber Studio, ArKit and Aurecon for their input.

INVESTIGATION OF STRUCTURAL BEHAVIOR OF WOODEN TRADITIONAL JOINTS VIA FINITE ELEMENT ANALYSIS

Hafshah Salamah[1], Seung Heon Lee[2], and Thomas Kang[3]*

ABSTRACT: With timber buildings becoming increasingly popular, the study of timber structures and joints has gained great attention. As the weakest part of the building, it is fundamental to investigate joints, especially traditional ones. In this research, the structural behaviors of longitudinal joints from Korea and Indonesia were investigated using finite element modeling. *Maettugijjangbu* (Joint 1) and *jumeokangbu* (Joint 2) as Korean traditional joints and *sambungan bibir miring* (Joint 3) and *sambungan bibir lurus* (Joint 4) as Indonesian ones were analyzed. The four types of joints were compared in terms of deformation capacity, and the procedure for investigating their structural behaviors was thoroughly explained. Finite element analysis was performed using linear elastic analysis for orthotropic material. The boundary conditions, loads, and contact surface conditions were input based on design setup. From displacement analysis, it was found that Joint 1 has the smallest deformation in terms of tension and compression load than other joints. Meanwhile, Joint 4 and Joint 3 have the highest deformation under tension load and compression load, respectively. Even though the maximum stress at all joints might be higher than the strength factor (C_f), it is feasible to conclude that Joint 1 performs better than other joints.

KEYWORDS: Structural behavior, wooden traditional joint, finite element modeling

1 INTRODUCTION

Timber buildings have garnered large interest in recent years, due to their advantages of good carbon storage, heat preservation, and sustainability. Modern timber buildings started from the legacy of traditional wooden buildings. As a proven precedent of timber buildings, traditional wooden buildings have good earthquake resistance because of their unique architectural style and structural system. The Korean traditional building, Hanok, uses *ieum* and *machoom* construction method to create solid and durable house [1]. This method allows for wood joints to be assembled without nails. Similarly, Indonesian traditional buildings called Rumah Gadang use mortise tenon joints without metal fasteners [2].

Timber joints are usually the weakest point in timber structures [3]. Although joints or member connections are unavoidable in building structure, timber joints need extra consideration. As structural material, timber has limited size and length which require more joints than other materials. One of the most important traditional joints is in member along with the member direction to extend the length (post to post, beam to beam) or *ieum* in Korean joint classification. This joint is crucial to fulfil the required span of the timber structure. Thus, many studies of these joints have been conducted, especially its mechanical behavior.

Currently, finite element analysis (FEA) is one of the preferred methods to investigate timber joints due to its wide range of applications and type of elements. Even though the resulting capacity of the finite element method is usually lower than the actual value, the result is typically considered to be reliable compared to experimental results [3][4]. Typically, FEA could provide displacement and stress distributions of the structures which are enough to understand the mechanical behavior of joints in preliminary stage.

In this study, traditional joints from Korea and Indonesia were investigated to find their structural behavior using the finite element method. *Maettugijangbu* and *jumeokjangbu* from Korean traditional joints and *sambungan bibir miring* and *sambungan bibir lurus* from Indonesia were analyzed under tension and compression loads. Due to the complex shape of those traditional joints, finite element modeling was used via computer software. Friction and compressive strengths are the most influential factors in the flexural capacity of the joints [5] that are also used in modeling. Friction factor was used in the model setup and compressive strength was used for failure criteria. From the simulation result, the performance of the joints was compared based on joint

properties and deformation shape. In this study, stress distributions were not elaborated and expected to be further analysis in the future. Thus, only prediction of general failure of the joints was discussed.

2 FINITE ELEMENT MODELING

Four types of joints were examined within the same factors: material properties, boundary conditions, and forces. FEA was conducted using Dlubal RFEM software. Before starting the simulation, mechanics of material, joint models, and design setup are required to be inputted to the software. Then, after the simulation, the results are analyzed using failure criteria of wooden material.

2.1 MECHANICS OF MATERIALS

As an orthotropic material, wood exhibits a variety of mechanical characteristics along three mutually perpendicular axes (natural axes): longitudinal, radial, and tangential. The longitudinal axis X is parallel to wood grain (fiber); the radial axis Z is normal to the growth rings (perpendicular to grain in radial direction); and the tangential axis Y is perpendicular to grain but tangent to the growth rings (Figure 1).

Since this investigation is not directly performed in the experiment, the wood mechanical properties were chosen based on the availability of material library in Dlubal RFEM. Originally, Korean traditional buildings use softwood material while Indonesian traditional buildings use hardwood material. In this study, the material properties are generated to be the same as hardwood grade D30 (DIN 1052:2008-12) (Table 1).

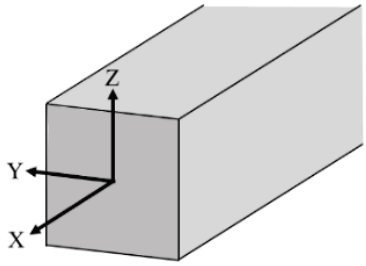

Figure 1: *Wood axis in finite element model*

Table 1: *Wood anisotropy parameters in finite element model*

E_x	$E_y = E_z$	v_{yz}	$v_{xz} = v_{xy}$	G_{yz}	$G_{xz} = G_{xz}$
10000	640	0.1	0.045	60	600

Note: E = modulus of Elasticity (MPa), v = Poisson's ratio, and G = shear modulus (MPa) are mean values. Subscripts xyz in the formula represent the direction of the properties.

The wood material is set as 'Orthotropic Elastic 3D'. This setting is for linear elastic analysis for 3-dimensional models. Following Hooke's law, the elasticity matrix of wood in the software is expressed as:

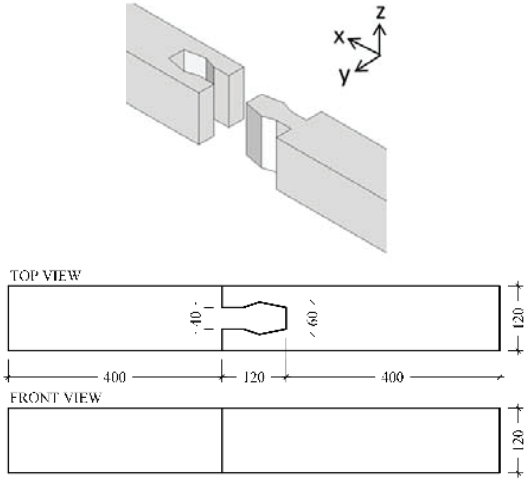
$$\begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \\ \gamma_{yz} \\ \gamma_{xz} \\ \gamma_{xy} \end{bmatrix} = \begin{bmatrix} \frac{1}{E_x} & -\frac{v_{yx}}{E_y} & -\frac{v_{zx}}{E_z} & 0 & 0 & 0 \\ -\frac{v_{xy}}{E_x} & \frac{1}{E_y} & -\frac{v_{zy}}{E_z} & 0 & 0 & 0 \\ -\frac{v_{xz}}{E_x} & -\frac{v_{xz}}{E_y} & \frac{1}{E_z} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G_{yz}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G_{xz}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{xy}} \end{bmatrix} \begin{bmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \tau_{yz} \\ \tau_{xz} \\ \tau_{xy} \end{bmatrix} \quad (1)$$

The following correlation exists between principal Poisson's ratio v_{xy} and secondary Poisson's ratio v_{yx}:

$$\frac{v_{zy}}{E_z} = \frac{v_{yz}}{E_y}; \frac{v_{zx}}{E_z} = \frac{v_{xz}}{E_x}; \frac{v_{yx}}{E_y} = \frac{v_{xy}}{E_x} \quad (2)$$

2.2 JOINT MODELS

Two Korean and two Indonesian traditional joints were chosen from actual traditional buildings: *maettugijangbu* (Korean), *jumeokjangbu* (Korean), *sambungan bibir miring* (Indonesia), and *sambungan bibir lurus* (Indonesia). These joints were analyzed under tension and compression loads. The joints originally come in different sizes and proportions but are adjusted to the same beam size for this investigation. The cross-section size of the beam is 120 x 120 mm. Details of the joints are shown in Figure 2.



(a) Joint 1. *Maettugijangbu* (Korea)

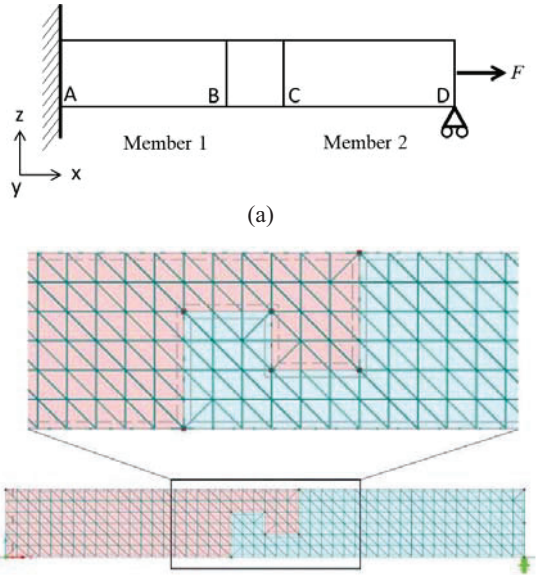
(d) Joint 4. *Sambungan Bibir Lurus Berkait* (Indonesia)

Figure 2-2: *Details of joints (size in millimeters)*

2.3 DESIGN SETUP

After modeling the joint shapes, the next step is to set up the boundary conditions, loads, and surface conditions. The boundary condition is set as a fixed joint on the yz-direction at Point A, and a roll joint at the base on Point D. Then, the joints were applied with nodal loads on the yz-surface of Point D with two conditions: 5 kN tensile force and 5 kN compression force. The length of Points A-B and C-D are 400 mm, whereas Point B-C varies depending on the type of joint (Figure 3a).

Each joint has two solid members, member 1 attached at Point A and member 2 with a roll joint at Point D. Because each member has contact with the other, the 'surface release' setting was used to create separation between the members. The contact surface can be released in this configuration based on the direction and the relationship between the surfaces. The shear between timber members is related to friction force. Based on the wood properties, the friction factor for the D30 wood grade is 0.1875. The finite element was set to 20 mm with a triangular shape element (Figure 3b).



(a)

(b)

Figure 3: *(a) Design setup and (b) FE mesh on Joint 3 from xy-plane*

2.4 FAILURE CRITERIA

Failure at wood connections is typically categorized as either ductile or brittle. The only type of ductile failure is a bearing failure, which occurs before brittle failure or fracture. Meanwhile, brittle failure has three types: splitting, shear failure, and tension failure. However, it is not easy to determine the type of failure in a computer analysis. Thus, the failure analysis of joints is commonly based on evaluating the stress distribution at the joint surface.

https://doi.org/10.52202/069179-0204

Failure criteria in plane stress [6] are adopted to this investigation. The criterion can be written as follows:

$$\left(\frac{\sigma_x}{X_1}\right)^2+\left(\frac{\sigma_y}{Y_1}\right)^2+\left(\frac{\tau_{xy}}{S}\right)^2 \le C_f \quad (3)$$

where σ_x is the limit stress parallel to wood grains, σ_y represents the limit stress perpendicular to wood grains, τ_{xy} is shear stress parallel to wood grains, X_1 represents the limit strength parallel to wood grains, Y_1 is the limit strength perpendicular to wood grains, S is the shear strength parallel to wood grains, and C_f is the strength factor. The limit stress can be a compressive or tension stress.

Failure occurs when the total strength exceeds the strength factor (C_f =1.0). Based on material properties in Dlubal RFEM, D30 wood grade has compressive strength parallel to wood grains, compressive strength perpendicular to wood grains, and shear strength parallel to wood grains of 23 N/mm^2, 8 N/mm^2, and 3 N/mm^2, respectively. Moreover, D30 wood grade has 18 N/mm^2 for tension stress parallel to wood grain and 0.5 N/mm^2 for tension stress perpendicular to wood grain.

3 RESULTS AND DISCUSSION

The performance of four traditional joints was analyzed in terms of joint properties and deformation. Joint properties were analyzed based on the joint shape and its impact on the structure. Deformation was analyzed based on the maximum value obtained from FEA.

3.1 JOINT PROPERTIES

In this study, the chosen joints are the joint between the timber members in the same direction which usually extends the beam or column length. This type of joint has many subtypes with various joint properties. The joint properties are divided into three aspects: orientation shape, shape complexity, and joint length.

Orientation shape is the direction where the unique shape of joints is created. Joints 1 and 2 have the orientation shape on the xy-plane while Joint 3 and 4 have the main joint shapes on the xz-plane. Despite not being covered in this study, this factor affects gravity loads and when wood properties of tangential (y-direction) and radial (z-direction) to wood grain have different values.

The number of formed contact surfaces between timber members determines the complexity of joint shapes. The joint surface in Joints 2, 3, and 4 have five surfaces, while Joint 1 has seven surfaces. The surface direction angle in the contact surface is another element of form complexity. Joints 1, 2, and 3 have diagonal surfaces besides horizontal and vertical contact surfaces. Meanwhile, Joint 4 has only horizontal and vertical contact surfaces. The diagonal surface creates more impacts on the friction force which increases the joint strength. The analysis of the joint is seen on Figure 4.

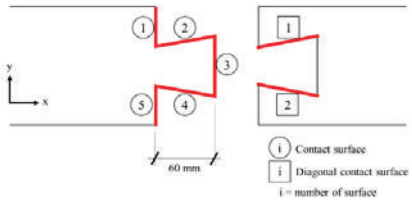


Figure 4: *Joint properties of Joint 2*

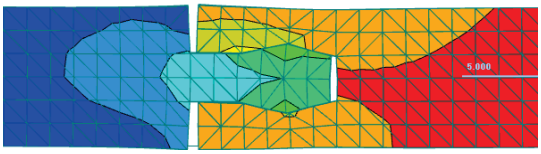
According to design setup, the length of the joints in Points A-B and C-D are the same, but the length of B-C depends on the length requirement of the joints. Carpentry joints are made by crafting the edge of the timber members into male and female shape. This process is related to material waste because crafting the joint reduces the beam length to the specified size of the joint. The length of Point B-C in Joint 1 must be the same as the beam width (120 mm), while Joint 2 is only half of the beam (60 mm). For Joint 3 and 4, the length of Point B-C is originally twice of the beam width (240 mm). However, only on Joint 4, the length of Point B-C is reduced to 120 mm. Thus, in terms of material waste, Joint 2 has less waste than Joints 1, 3, and 4.

Table 2: *Joint properties*

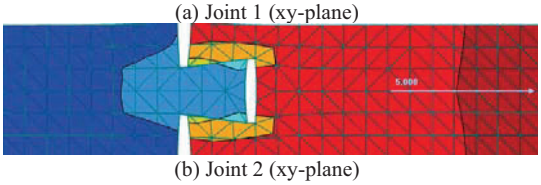
Criteria	**Joint 1**	**Joint 2**	**Joint 3**	**Joint 4**
Shape orientation	x-y	x-y	x-z	x-z
Complexity				
Total contact surface	7	5	5	5
Diagonal surface	4	2	2	0
Joint's length (mm)	120	60	240	120

3.2 DEFORMATION

Deformation on joints under tension and compression load are analyzed using global displacement. Joint 1 exhibits the smallest displacement (0.7 mm) of the four joints under tension load, and the maximum displacement on Joint 2 is close to Joint 1 (0.8 mm). The largest displacement occurred in Joint 4 (5.0 mm), while Joint 3 has a max displacement of 1.9 mm (Figure 7a)



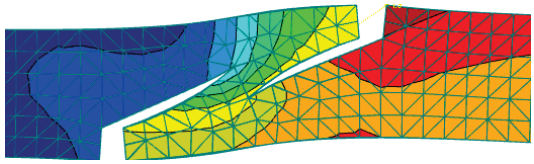
(a) Joint 1 (xy-plane)



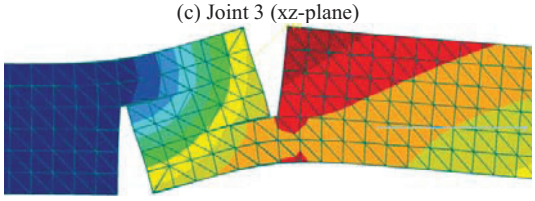
(b) Joint 2 (xy-plane)

Figure 5-1: *Deformation shape on joints under tension load*

https://doi.org/10.52202/069179-0204



(c) Joint 3 (xz-plane)

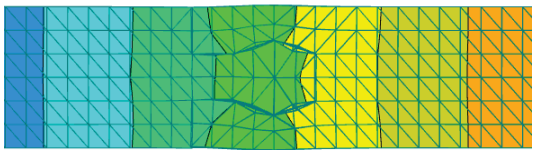


(d) Joint 4 (xz-plane)

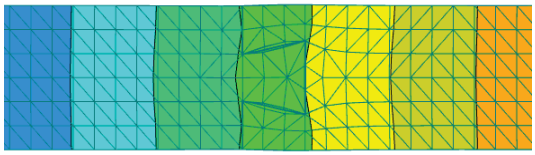
Figure 5-2: *Deformation shape on joints under tension load*

The maximum displacements on Joints 1 and 2 are located at point D, which indicates the higher probability of bearing or shear failure. However, the maximum displacements on Joints 3 and 4 are located at point C, which indicates a high probability of brittle failure such as tear-out failure (Figure 5).

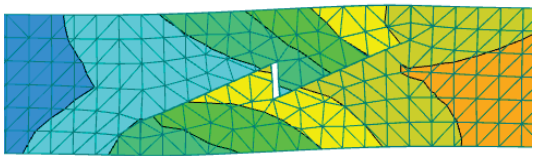
The joints under compression load exhibit unexpected results. Joints 1, 2, and 4 have the same maximum displacement (0.3 mm), as opposed to Joint 3 which has larger displacement (0.4 mm) (Figure 7b). From the deformation shape in Figure 6c, it can be seen that Point B-C on the Joint 3 is bending and shows a gap on the middle of the joint. Meanwhile, the rest of the joints look the same as the initial shape.



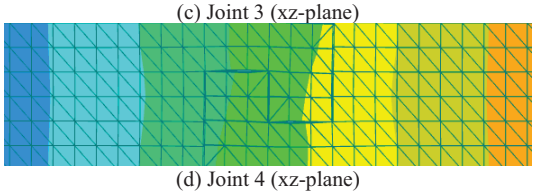
(a) Joint 1 (xy-plane)



(b) Joint 2 (xy-plane)



(c) Joint 3 (xz-plane)



(d) Joint 4 (xz-plane)

Figure 6: *Deformation shape on the joints under compression load*

From the global displacement, it can be concluded that all joints have smaller deformation under compression load than tension load, which alludes to the fact that wood has a higher compressive strength than tension strength. Meanwhile, the joint shape is the most important parameter for a timber joint's structural response under tension load. Yet, there are not many studies on the relationship between joint performance and its shape.

Figure 7: *Displacement on beam from Point A-D in (a) tension force and (b) compressive force.*

4 CONCLUSIONS

In this study, the four joints of traditional joints have been investigated using finite element analysis. Deformation capacity was obtained from simulation results using Dlubal RFEM software. For modeling and simulation,

https://doi.org/10.52202/069179-0204

several setups were adjusted to the capability of the software.

Based on simulation, Joint 1 and 2 have the smallest displacement compared to the other joints under tension load. It appears that the larger displacement occurred in Joint 4 under tension load while under compression load the larger displacement occurred in Joint 3. Meanwhile, under compression load, Joint 1, 2, and 4 have the same displacement.

Deformation is correlated to stress distribution on the joints. Large displacement has a higher possibility of member failure. Joint failure can be examined by validating the maximum stress on stress distribution to the strength factor (C_f) equation. Thus, the failure occurrence can be checked when the result is above C_f. The inadequate beam size in comparison to the assigned loads is one potential cause of joint failure. Thus, nonlinear analysis is expected in future studies. If the deformation and stress distribution result is connected to the joint properties, a joint with shorter joint length has better compromise than other joints. However, these results still need to be validated for further simulation and experiment.

BONDED-IN RODS IN BEECH GLULAM – EFFICIENCY OF A RECESS IN THE BONDLINE

Steffen Franke[1], Bettina Franke[2], Alexander Salenikovich[3]

ABSTRACT: The load-bearing behaviour of bonded-in steel threaded rods (BiR) in hardwood was investigated with special focus on the prevention of the splitting behaviour using a recess (not bonded zone) in the bondline. The main objective was to analyse the influence of the not-bonded length and the rod edge distance on the distribution of longitudinal shear and transverse tensile stresses in joints with bonded-in rods in beech glulam. Several BiR joint configurations were tested experimentally and a wide range of joint configurations with various combinations of recess and bonded lengths and edge distances were numerically investigated. According to the experimental and numerical analyses, a recess length of 2*d* (two times rod diameter) produced a significant positive effect on the stress distribution reducing the risk of splitting of beech glulam in the studied joint configurations.

KEYWORDS: Bonded-in rods, beech, splitting, not bonded length, numerical simulations, shear and tension interaction

1 INTRODUCTION

Discussions and ambition about the use of hardwood as construction material are currently present in Europe. On the one hand, hardwood provides excellent mechanical strength properties, but on the other hand, the strength parameters are less investigated and standardized for the design of connections with mechanical fasteners or bonded-in rods (BiR). The performance of connections in hardwood timber structures must be determined with high reliability to benefit from the naturally higher strength potential of hardwood. In Switzerland, 31 % of the entire wood stock is hardwood, where the biggest part with 18 % counts for beech wood [1]. Therefore, the research work concentrates on the European beech wood.

To use high-performing glued-laminated timber (glulam) from beech wood efficiently, high-performing connection systems must be available too. BiR connections are one of those. However, neither the Swiss standard SIA 265:2012 [2] nor the Eurocode 5 (EC 5) [3] currently include the design of BiR in softwood or hardwood glulam. The German national annex of EC 5 (DIN EN 1995-1-1/NA:2013-08) [4] provides a design method for axially loaded threaded steel rods glued in softwood. Research papers and publications have publicly discussed and proposed methods and approaches for the design of BiR, e.g., [5]. In EU, common rules for the assessment of BiR have been adopted in 2019 [6] and testing requirements for BiR in glued structural timber products have been adopted in 2021 [7]. Basic design provisions for GIR in timber connections are now given in EOTA TR 070 [8], and included in the Eurocode 5 draft [9].

The load-bearing capacity of BiR depends on the following main parameters [10]:

- Geometry; size and proportion of timber, adhesive and rod; slenderness; number and placement of rods (edge/end distances)
- Material stiffness and strength
- Fracture behaviour of timber and adhesive
- Variability of all properties
- Imperfections (quality control)
- Loading situation (forces, moisture, temperature)

For the best performance and robustness, it is preferable to prevent brittle failure modes, such as splitting, like shown in Figure 1, or bondline failures, and to target ductile steel failure. The maximum utilisation of timber (ratio of the connection capacity to the member cross-section capacity in tension) can be achieved by increasing the number of rods per unit area, which leads to smaller spacing and edge distances [11] and, in turn, may provoke

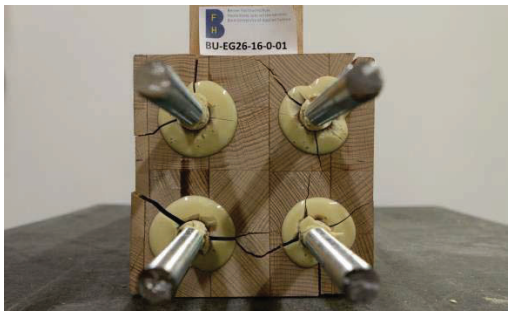

Figure 1: *Typical BiR failure in beech glulam – wood splitting due to transverse tension without a recess in the bondline*

the undesirable wood splitting unless special preventive measures are undertaken.

This study is focused on achieving an efficient and robust connection configuration with small edge distances $a_{2,c}$ by using a recess l_{recess} in the bondline, i.e., not-bonded zone in front of the bondline, as shown in Figure 2. Therefore, the load-bearing behaviour depending on the interaction of the longitudinal shear and transverse tensile stresses around the bondline is investigated numerically and experimentally for beech wood glulam.

2 STATE OF THE ART

2.1 EFFECT OF BIR PLACEMENT

The placement, i.e., spacing and edge distance, have a great impact on the load-bearing capacity and performance of BiR connections [12], [13], [14]. By using the standardized spacing of 5d and steel with the tensile strength of 800 MPa results in an equivalent timber stress of 19.6 MPa which is about 60 % utilization for a timber grade GL40, as shown in Figure 3. The maximum utilisation up to 100 % can be achieved with a much smaller wood cross-section a_2 per rod between 3.61 and 3.85 times the rod diameter (d) for the timber grades GL 48 and GL 40 respectively. However, BiR connections with these small spacing and edge distances are not permitted in standards, because of their propensity for wood splitting and reduced pull-out strength even in laboratory tests.

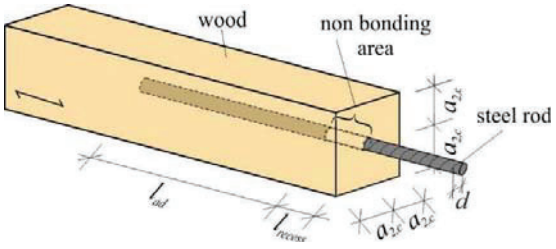

Figure 2: *Principal sketch of BiR and notation of variables and components*

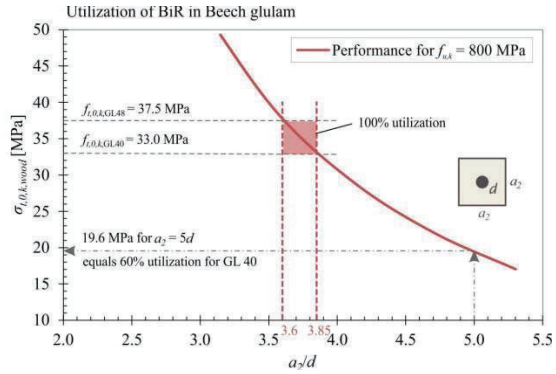

Figure 3: *Utilization of BiR in beech glulam for steel strength of 800 MPa and different timber grades*

For example, Figure 4 illustrates the influence of the edge distance on the pull-out resistance and failure mode of BiR connections in beech wood studied by Franke et al. [15]. Three levels of failure behaviour and capacity can be observed. At the edge distance $a_{2,c}$ (half of a_2) of 1.5d, the pull-out strength of rods, affected by the premature splitting, was about 20 % less than that of rods with 2.5d and 3.5d edge distance, for the same rod diameter, bonded length, and adhesive. Nevertheless, most of the joints with 2.5d edge distance experienced splitting and bondline failures at almost the same breaking loads. At 3.5d edge distance, there was no splitting observed and the strength of BiR joints reached the highest values with minimum variation. However, the cross-section utilisation of only less than 50 % can be achieved. All these tests were conducted on the BiR joints without a recess in the bondline.

2.2 EFFECT OF RECESS IN THE BONDLINE

It is well known that the stress distribution along the length of the BiR is not uniform, with stress concentrations near the ends of the bondline. Recently, Vallée et al. [16] studied the distribution of shear (τ_{RL}) and radial (σ_R) stresses along the bondline via numerical modelling of single BiR in CLT and glulam. Figure 5 illustrates the results for four different bonded lengths of a 12.7 mm (1/2-in) rod. The highest peaks of both shear and radial stresses are seen at the outer end of the bondline. These numerical simulations confirm that the longer the bondline, the greater is the difference between the peak stress and the mean stress, the less stress is transferred into the depth of the wood member, and, hence, the lower is the strength of the bondline.

The peaks of the shear and transverse tensile stresses near the end of the wood member negatively affect the pull-out resistance of BiR due to splitting. Fabris [12] studied the interaction of the stresses on the BiR performance and suggested that a recess of the bondline into the wood creating an unbonded zone near the outer end increases the stressed wood volume around the rod and hence improves the resistance to splitting, as shown in Figure 6.

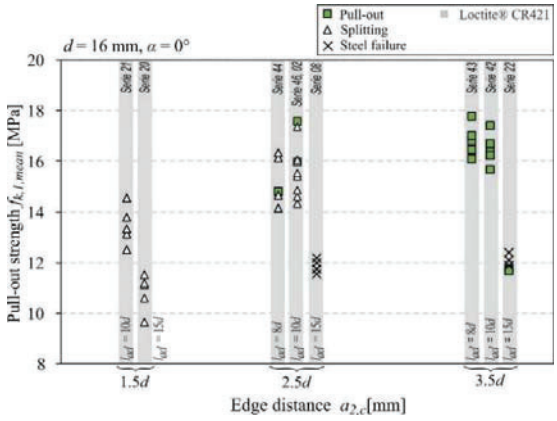

Figure 4: *Pull-out strength and failure modes of BiR in beech glulam for different edge distances [15]*

https://doi.org/10.52202/069179-0205

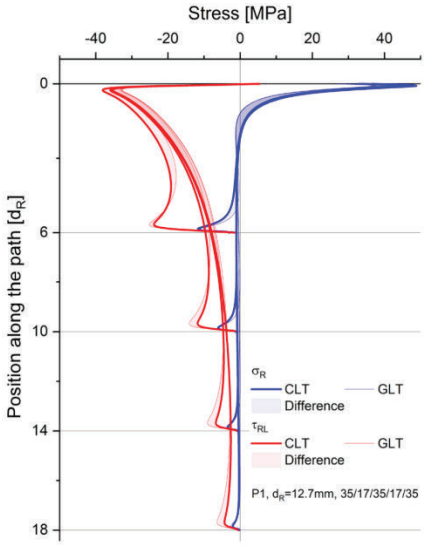

Figure 5: *Shear stresses, τ_{RL}, and radial stresses, σ_R, along the adhesive-wood interface, reference load F_0= 100 kN, from [16]*

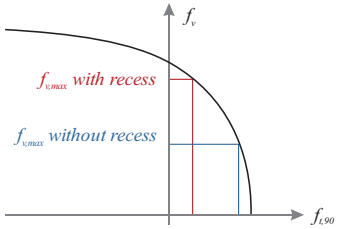

Figure 6: *Interaction of shear and transverse tensile stresses, modified from [12]*

The beneficial effects of a recess in the bondline on the pull-out resistance has been demonstrated experimentally by Salenikovich et al. for BiR in CLT [17] and in glulam [18]. It allowed achieving a higher load capacity and minimizing the risk of splitting and other brittle failure modes, such as plug shear in CLT for rods bonded perpendicular to the grain.

The effect of different recess lengths in beech glulam has not been investigated so far. Besides the increase of the stressed wood volume around the rod, it is assumed that a recess in bondline also changes the interaction of shear and transverse tensile stresses as indicated in Figure 6 and leads to higher capacities. Less transverse stress will exist at much higher shear stress for the case with a recess.

3 INVESTIGATION OF THE RECESS LENGTH

3.1 MATERIALS

All specimens for the investigation have been produced from Glulam GL 40h of European Beech (*Fagus sylvatica*) from Swiss forests with an average density of 710 kg/m³ and moisture content of 10.5 %. Threaded steel rods of M16 with a strength class of 8.8 and 10.9 were bonded-in using a two-component PUR adhesive

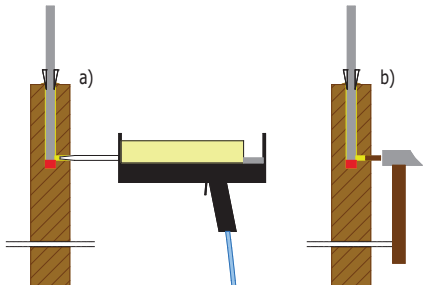

Figure 7: *Preparation of test samples, a) gluing injection from the bottom of the bondline, b) closing of the injection hole with wood dowel*

Loctite® CR421 or its newer version Loctite® CR821. Centering aids and upright position gluing was used, see Figure 7.

3.2 EXPERIMENTAL PROGRAMME

The investigation was carried out in two stages. The first stage started within a research project on efficient connections in hardwood [15], see Table 2. It focused on testing of known connection systems in hardwood to determine their performances. Within the test period from 2019 to 2021, the adhesive was changed from Loctite® CR421 to CR821 in line with current market developments at Henkel & Cie AG and the borehole diameter d_{hole} was reduced by half, from d_{BiR} + 4 mm to d_{BiR} + 2 mm. The experimental programme included a variation of the edge distance $a_{2,c}$ and the bonded length l_{ad} in combination with a recess length of 0d, 2d or 5d which reflected the known practice for softwood glulam.

The second stage stemmed from the first one and focused specifically on the influence of the recess length on the performance and comprised test series S0 to S5 with the recess length between 0d and 5d in increments of 1d. A constant edge distance of 1.75d and bonded length of 13d were used to provoke splitting failure and prevent pull out failure. In the second stage all rods were bonded-in with Loctite® CR821. Table 2 summarizes the configurations and variations of the experimental test programme.

3.3 NUMERICAL SIMULATIONS

The influence of the not-bonded length on the resistance of a BiR joint was also studied using numerical linear elastic simulations of the joint as shown in Figure 2, with a single rod with a varying bonded length l_{ad}, recess length l_{recess} and edge distance $a_{2,c}$. The numerical investigation focused on the analysis of the stress distributions along the bondline and especially at the beginning of the bondline of a single rod connection in beech glulam. A quarter of the specimen was modelled benefiting from the double symmetric conditions, as shown in Figure 8 for a connection with a bonded length of 13d, recess length of 1d and edge distance $a_{2,c}$ of 2.5d. The elastic material properties are summarized in Table 1. The rod was loaded in tension by 100 MPa for all simulations and presented results.

https://doi.org/10.52202/069179-0205

3.4 EXPERIMENTAL RESULTS

All failure modes, steel rupture (yielding of the rods), wood splitting and rod pull-out (bond rupture), were observed. The failure modes and pull-out strength values calculated from the maximum load divided by the circumference with the nominal rod diameter and the bonded length are summarised in Figure 9.

In general, the BiR joints glued with Loctite®CR821 demonstrated a lower pull-out strength compared to Loctite®CR421. Therefore, the results are analysed separately.

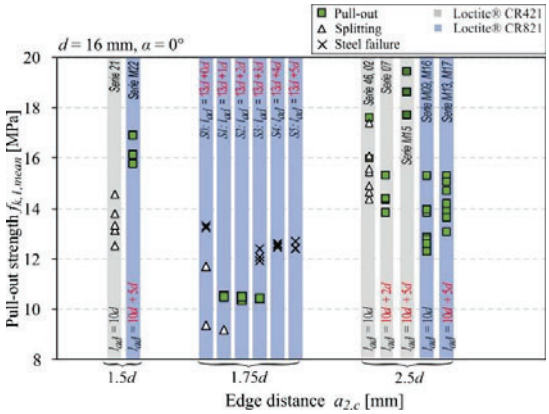

Figure 9: *Pull-out strength results depending on the edge distance, bonded length and recess length for two glues*

Focusing on Loctite®CR421 (columns highlighted in grey):

- Splitting was not observed in joints with the recess length of $2d$ (series 07) and $5d$ (series M15) and the edge distance of $2.5d$ as opposed to joints without a recess (series 46 and 02); the joints with the recess of $5d$ showed higher strength.

Focusing on Loctite®CR821 (columns highlighted in blue):

- Splitting was not observed in joints with the edge distance of $2.5d$ without a recess (series M09 and M16) and with a recess of $5d$ (series M13 and M17); however, less variation and higher mean values were observed for the series with recess.
- No splitting was observed even for the joints with the edge distance of $1.5d$ with the recess of $5d$ (series M22).
- All joints with the bonded length of $13d$ and the edge distance of $1.75d$ (series S0 to S5) showed lower pull-out strength values than those with the bonded length of $10d$ and the edge distance of $2.5d$ (due to the larger bondline circumference).

https://doi.org/10.52202/069179-0205

- Three distinct levels of pull-out strength and failure mode transition can be observed depending on the length of the recess:
  - Although two specimens without a recess (series S0) showed steel failure, two specimens failed by splitting, one of which occurred at a low load level; one specimen with the recess of 1*d* (series S1), failed by splitting at a similar load level.
  - Specimens with the recess length of 1*d*, 2*d* and 3*d* (Series S1, S2, S3) that failed by pull-out (bond failure) showed equal pull-out strength, which was higher than that due to splitting but less than that due to the rod rupture.
  - Starting with the recess length of 2*d* (Series S2), no splitting failures were observed.
  - Three specimens with the recess length of 3*d* (Series S3) reached the steel rod resistance.
  - All specimens with a recess length of 4*d* (Series S4) and 5*d* (Series S5) failed due to steel rod rupture.

3.5 NUMERICAL RESULTS

Figure 10 shows a BiR joint FE model in a deformed state and the deformation gradient in the longitudinal direction for the bonded length of 13*d* and the recess length of 1*d*. The resulting shear and transverse stress distributions along the bondline at the wood/glue interface are plotted for the same joint configuration in Figure 11 and Figure 12, respectively. The stress distributions for the recess length between 0*d* and 4*d* (no visible difference was observed for 5*d*) are summarized in Figure 13 and Figure 14.

The numerical simulations show a 19% increase of the longitudinal shear stress from 0*d* to 2*d* recess length and then a gradual increase up to 26.3% at 5*d* (see Figure 14 and Figure 15). At the same time, the transverse tensile stress at the beginning of the bondline drops down rapidly to 47.5% from 0*d* to 2*d*, and to 46.5% at 3*d* (see Figure 13 and Figure 15). No further reduction of the peak transverse stress is observed beyond $l_{recess} = 3d$.

Similar results were observed in simulations with a bonded length of 10*d* and for connections in softwood.

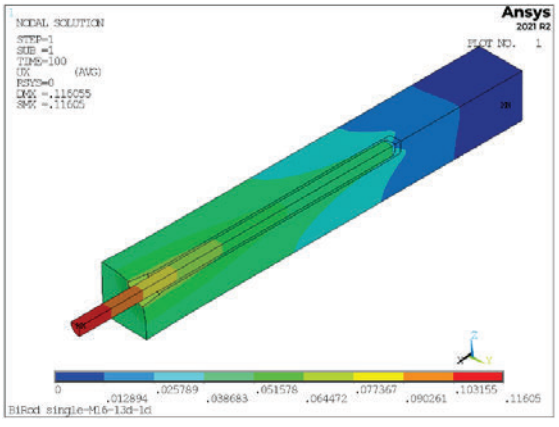

Figure 10: *Deformations of a BiR joint, l_{ad} =13d, l_{recess} = 1d*

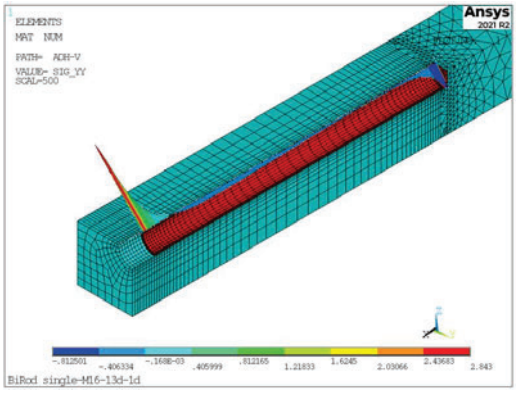

Figure 11: *Transverse stress distribution along the bondline, l_{ad} = 13d, l_{recess} = 1d*

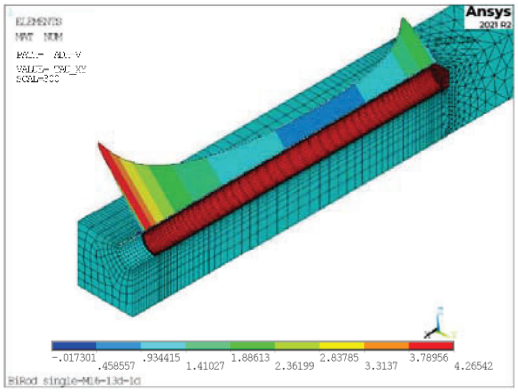

Figure 12: *Shear stress distribution along the bondline, l_{ad} = 13d, l_{recess} = 1d*

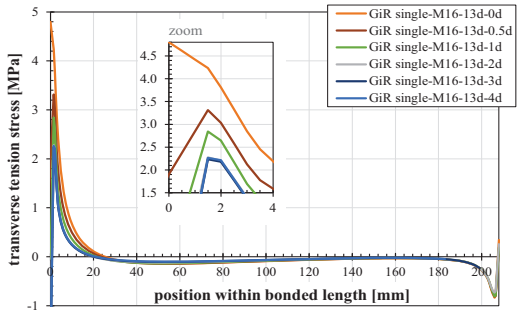

Figure 13: *Transverse stress distribution along the bondline depending on the recess length*

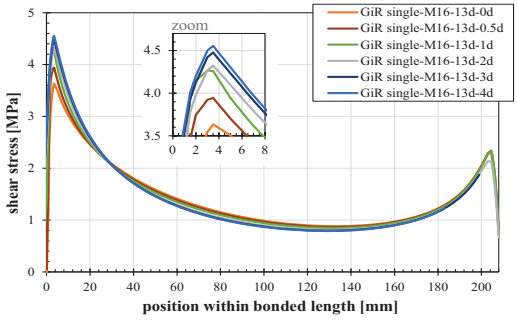

Figure 14: *Shear stress distribution along the bondline depending on the recess length*

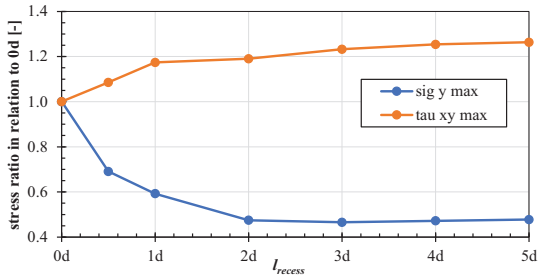

Figure 15: *Increase and decrease of the maximum transverse tensile and shear stresses at the beginning of bondline depending on the recess length*

4 DISCUSSION AND CONCLUSION

From the experimental results it can be concluded that without a recess or with a recess less than 2*d*, the risk of wood splitting in BiR joints with reduced spacing is very high. With a recess of 3*d* and more, the bondline strength increases to the extent that allows reaching the steel rod rupture, which is a preferred failure mode for BiR connections.

These experimental observations are well aligned and explained by the numerical simulations, which show a significant reduction of the peak transverse tensile stress at the recess length of 2*d*. It can also be concluded that no further gain in the splitting resistance is expected when the recess length is beyond 3*d*.

The relation assumed in Figure 6 can be confirmed by summarizing the stress relationship/interaction of shear and transverse tension depending on the recess length in Figure 16. The mean shear strength of 12 MPa and mean transverse tension strength of 7 MPa were assumed for beech wood according to [19]. Up to the recess length of 2*d*, higher shear stresses in combination with lower transverse tensile stresses can be achieved before failure with the increasing recess length. Therefore, the propensity for splitting is reduced and a higher axial load can be applied on the bonded-in rod. No further significant change is observed beyond $l_{recess} = 2d$.

These observations can be confirmed by using equation (1) for the stress verification, which is illustrated in Figure 17 for the GiR joint with bonded length of 13*d* under the same stress of 100 MPa. An optimal utilization starts at a recess length of 2*d*. However, a recess length of 3*d* is recommended for the safety reason before further confirmation with more experimental and numerical results including long-term load and moisture fluctuation effects.

$$\left(\frac{\tau_{yz}}{f_v}\right)^m + \left(\frac{\sigma_y}{f_{t,90}}\right)^n \leq 1 \qquad (1)$$

where

τ_{yz}	shear stress [MPa]
f_v	shear strength [MPa]
σ_y	transverse tensile stress [MPa]
$f_{t,90}$	transverse tension strength [MPa]
m	interaction parameter [-]
n	interaction parameter [-]

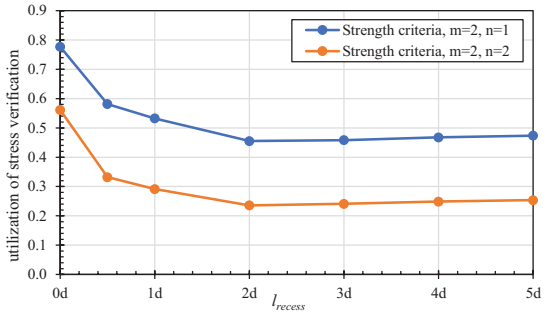

Figure 17: *Utilization of the shear and transverse tensile stress verification for two failure criterias curves (steel rod rupture is not included)*

Further investigations will be done towards

- Probabilistic verification of the timber stress interaction near the beginning of the bondline to analyse the contribution of the wood volume in front of the bondline;
- Implementation of fracture mechanics into the numerical simulations;
- Variations of material parameters as well as geometric parameters; and
- Experimental testing for more statistical values and validation.

USING X-RAY COMPUTED TOMOGRAPHY TO MEASURE FIRE DEGRADATION OF A TIMBER CONNECTION

Quentin Rodrigues[1], Johannes A. J. Huber[2], Lars Hansson[3], Rhoda Afriyie Mensah[4], Rostand Moutou Pitti[5]

ABSTRACT: The charring behaviour of timber elements under fire is well understood, however, the effects of fire and heat on connections are not equally well known. Timber connections often use steel fasteners, like screws or angle brackets, which conduct heat much better than wood. Moreover, these fasteners lose their mechanical resistance and capacity under elevated temperatures. X-ray computed tomography (CT) can be used to reconstruct the internal structure of wood non-destructively. It should therefore be possible to use this technology to also study the progressive degradation due to fire of a timber connection. The goal of the present study is to investigate how CT can be used to analyse the degradation of a timber connection due to fire. Samples of Norway spruce with self-tapping screws were scanned before and after a fire exposure, and mechanical tests were performed. The results indicate that the degradation due to fire in a timber connection can be observed in CT scans, but that certain measures need to be taken to minimise the effects of image artefacts due to X-ray scattering and photon starvation.

KEYWORDS: Steel-to-timber fastener, CT, Image artefacts, Image analysis, Density, Charring

1 INTRODUCTION

1.1 BACKGROUND

Connections are often the critical part of a building, since they establish structural continuity among the elements. Timber connections often use steel fasteners, like dowels or screws. The behaviour of timber elements under fire is well understood; charring occurs at a certain speed and the mechanical properties of unburnt timber close to the charring front remain unaffected [1]. Steel, however, behaves very differently under fire, due to its higher thermal conductivity and the tendency to soften under elevated temperatures. Timber connections using steel screws may therefore behave differently under fire than under normal conditions.

The Eurocode provides some recommendation to quantify timber resistance under fire and to passively improve the fire resistance of the connections [2]. It also provides us estimates about charring depth and the charring speed on fire exposed surfaces.

1.2 TIMBER CONNECTIONS UNDER FIRE EXPOSURE

Some studies have been conducted to investigate the mechanical resistance of timber connections using steel fasteners under a fire exposure. These experiments mainly focused on loaded samples. They provided insight on the impact of different parameters, like the position, dimension, and number of fasteners [3][4][5]. However, the conducted studies were only able to observe changes at the surfaces of the timber samples.

X-ray computed tomography (CT) enables non-destructive measurements of the internal density distribution of a scanned object. CT scanning has been used previously to investigate wood, e.g. to study density [6], shrinkage due to moisture changes [7] or for developing simulation models [8]. Since degradation of wood due to fire entails local reductions of density, CT scanning could provide insight on the evolution of this degradation. Furthermore, it could be used to study the degradation of wood in the proximity of a fastener *in situ*, from which the connection resistance could be estimated.

1.3 OBJECTIVE

The aim of the present study is to investigate how X-ray CT can be used to analyse the degradation of a timber connection due to a fire exposure. The results of this study provide insight in the possibilities and limitation of using CT to detect fire propagation in wood. The results can be used to prepare future studies using a designated combustions chamber, where timber charring will be studied *in situ* using a CT scanner.

2 CT SCANS AND ARTEFACTS

All CT scans in this study were acquired by a laboratory-adapted medical CT scanner (Siemens Somatom Emotion Duo) at the facilities of Luleå University of Technology in Skellefteå, Sweden. The images were acquired at locations spaced 1 mm apart and each slice contained a grid of 512 × 512 pixels, at a resolution of 0.68 × 0.68 mm^2.

An initial pre-study was conducted to evaluate the effects of metal connectors on the quality of the reconstructed images from CT scans.

2.1 METAL INDUCED ARTEFACTS

As shown in **Erreur ! Source du renvoi introuvable.**Figure 1, the quality of an image obtained from the scan of a sample made of a piece of wood and a metal fastener is deteriorated by artefacts.

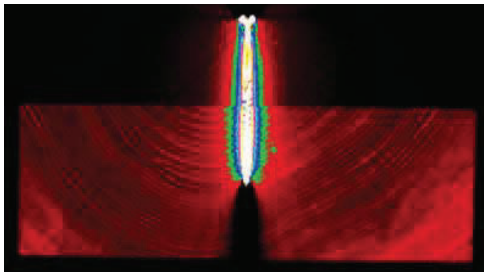

Figure 1: *CT image from of a piece of wooden piece with a screw inserted parallel to the scanning plane.*

We identified two main types of image artefacts. The first one causes the black part in **Figure 1** at the bottom of the screw and is due to photon starvation. It occurs when X-ray beams are attenuated after passing through material of too high density. The second artefact is visible in the proximity of the screw (blue and green on the figure) and is caused by photon deviation by the metal.

2.2 SETUP OPTIMIZATION TO REDUCE ARTEFACTS

Since photon starvation was caused by too large paths of metal in the emitter-sensor plane of the scanner, a first step to reduce artefacts without post-scan image correction was to scan the sample in a plane perpendicular to the screw axis. This way, the X-ray beams only need to pass through at most the diameter of the screw instead of its full length.

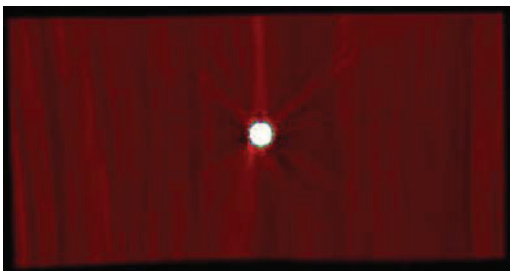

Figure 2: *CT image from a wooden piece with a screw perpendicular to the scanning plane.*

In Figure 2, much of the artefacts could be removed by a perpendicular screw orientation. Some bright streaks are still visible, but it does not affect the image quality substantially. In the proximity of the screw surface, some noise is also still visible, but substantially reduced compared to Figure 1.

2.3 SCAN WITH MORE METAL FASTENERS

Subsequently, scans have been performed on samples with a larger quantity of metal in the wooden sample to investigate the evolution of artefacts. In Figure 3 the effects of two screws in the sample are shown. It was found that both type of artefacts were more visible in both sample orientations. Again it was found, that having the screw axes aligned with the scanning plane deteriorated the image quality more than having the screw axis oriented perpendicular to the scanning plane.

It becomes obvious that “tilting” the sample for better image quality has its limitations with more fasteners involved. Furthermore, it seems difficult to investigate setups with larger metal connectors, e.g. angle brackets.

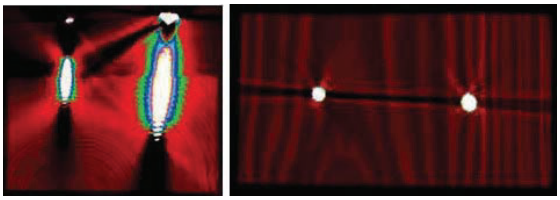

Figure 3**:** *Comparison of the influence of the screw’s positioning with two screws.*

3 SAMPLE PREPARATION AND TESTS

3.1 SAMPLE GEOMETRY AND CT SCANS

Two types of samples have been used for our experiments, as illustrated in Figure 4 one for tests in compression on a wood screw (5 × 120 mm²) perpendicular to the fibres (tagged C- in the text), and one for tests in tension on a wood screw (5 × 70 mm²) parallel to the fibres (T-).

Twelve samples were produced for both sample types; 4 pieces were used as a reference (tagged T-0 and C-0), 4 were fire exposed for 5 minutes (tagged T- or C-5), and 4 were fire exposed for 10 minutes (tagged T- or C-10).

All samples were CT scanned before and after an eventual fire exposure with the screw inserted in the wood. The screws were positioned perpendicular to the scanning

https://doi.org/10.52202/069179-0206

plane, following the reasoning of the pre-study. For those burnt samples where it was possible to remove the screw easily without disintegrating the sample, additional CT scans were conducted without the screw.

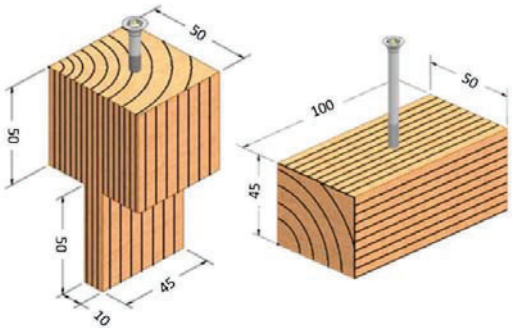

Figure 4: *Sample dimensions for tension (left) and compression (right)*

3.2 BURNING PROCESS

The samples were burnt in a cone calorimeter, according to the ISO 5660 standard [9]. The cone calorimeter is the most commonly used device to study small samples fire behaviour and is illustrated schematically in Figure 5. Samples are exposed to a one-dimensional radiative heat flux from a conical heater, with a constant surface heat flux of 35 kW/m² and a temperature of 722°C. These values have been chosen according to the fire exposition estimated in a real building fire.

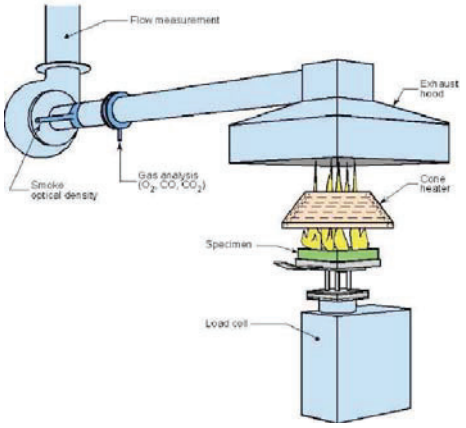

Figure 5: *Cone calorimeter*

To achieve a one-dimensional fire exposure, insulation layers of type Kaowool Blanket with a density of 64 kg/m^3 were wrapped around the wooden samples and fixed with staples, leaving only one surface exposed to the heat.

3.3 MECHANICAL TESTS

The samples were tested with a universal testing machine (MTS Criterion Series 40) for both compression and tension. A loading speed of 0.2 mm/s and a maximum load limit of 10 kN were applied. The setup is shown in Figure 6. For analysis, the mean values of respectively the tension and compression test series were used.

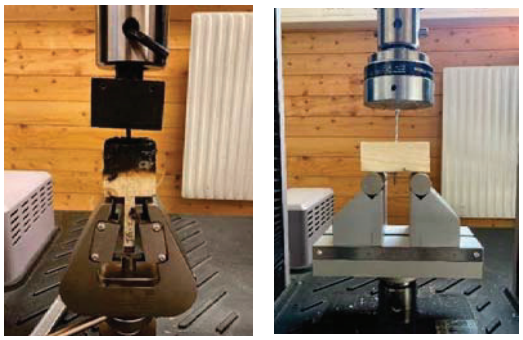

Figure 6: *Mechanical test setup for tension (left) and compression (right)*

4 IMAGE ANALYSIS

The CT images were analysed using Python code. Images of the same samples before and after the fire exposure were compared. The analyses were confined to 20 CT slices from the top of each sample, i.e. from the surface intended to be exposed to fire, which corresponded to 20 mm due to the 1 mm spacing between scans.

4.1 SINGLE IMAGE HISTOGRAMS

At first, the greyscale histograms of single image slices were analysed. Histograms from the same slice of a same sample before and after fire exposure were compared. For illustration, images of the same slice of a representative sample before and after a 10-minute heat exposure are shown in Figure 7.

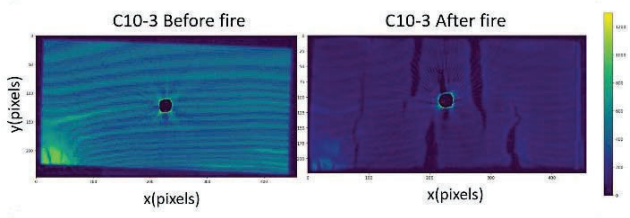

Figure 7: *CT images of the same slice of the same sample before (left) and after (right) a 10-minute fire exposure*

Figure 8 shows the histogram of the unburnt sample in Figure 7. The histogram was truncated at 1000 kg/m^3 for a better readability, but there was also an additional peak at 4000 kg/m^3 caused by the metal of the screw. The histogram was separated into four distinct zones (vertical lines in the figure). We can distinguish two density peaks in Figure 8, which were characteristic for unburnt wood: the first in zone 1 around 50 kg/m^3 representing air around the sample and covering approximately 13 % of the image, and the second in zone 3 between 400 and 550 kg/m^3 representing wood and covering approximately 73 % of the image. The flat area in zone 2 represents approximately 5 % of the image.

https://doi.org/10.52202/069179-0206

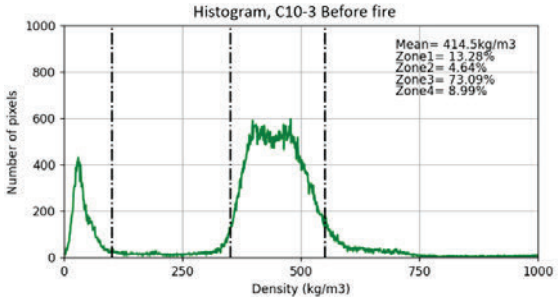

Figure 8: *Histogram of the image before fire exposition*

Figure 9 shows the histogram of the sample in Figure 7 that has been fire exposed for 10 minutes, again truncated for density. We are still able to distinguish two main peaks, however, they are now located in zone 1 (26 %) and zone 2 (73 %). The peak around 500 kg/m^3 in Figure 8 thus shifted to lower values due to the charring process and the resulting lower density of charcoal. The greyscale histogram can therefore be used to detect and quantify fire degradation.

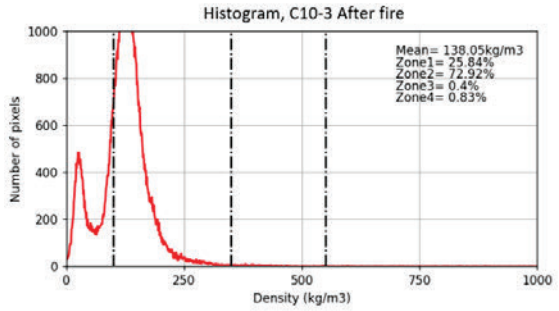

Figure 9: *Histogram of the image after a 10-minute fire exposure*

4.2 HISTOGRAM EVOLUTION THROUGH THE SAMPLE

The classification of the pixels according to the four density zones defined above can be used to study the evolution of the distribution in each class in consecutive slices along the CT scan of each sample.

Figure 10 shows this evolution for one representative sample before and after fire exposure along the top 20 mm from the surface exposed to fire. The figure clearly shows a shifting of the density from zone 3 (350-550 kg/m^3) to zones 1 and 2 (0-350 kg/m^3) when approaching the exposed surface. For the same sample before the fire exposition, we can notice that the zone classification remains constant when traversing the sample. Note also the rise of zone 1 (0-100 kg/m3) close to the top of the sample, which was due crack opening during the burning.

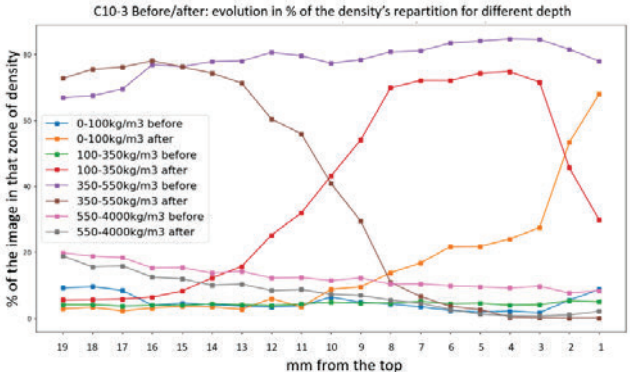

Figure 10: *Evolution of density zones on the top 20 mm of the sample, before and after fire exposure*

4.3 EVOLUTION OF DENSITY CLOSE TO THE SCREW

To study whether any particular degradation occurred due to increased heat conductivity of metal compared to wood, the following method was applied. For each CT slice, concentric circles with radii between 6-30 mm were created around the centre of the screw (Figure 11). Along the perimeter of each circle, the density was integrated, and average density was calculated.

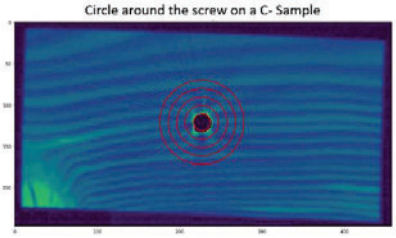

Figure 11: *Concentric circles around the screw for studying wood degradation in the proximity of the screw.*

The procedure was repeated for the CT slices representing the first 20 mm along the sample starting from the surface exposed to fire. The average density along each circle was then plotted for each slice to study its evolution at fixed distances from the centre of the screw.

In the subsequent figures, the density evolution profiles in the proximity of the screw are shown for representative compression and tension samples at 0, 5 and 10 minutes of fire exposure.

In Figure 12, we can see the mean density values on the circles before any fire degradation. The circle with the smallest radius is affected by the density of the screw and fluctuates due to noise from the metal. All the other values are approximately constant over the initial 20 mm from the top of the sample.

https://doi.org/10.52202/069179-0206

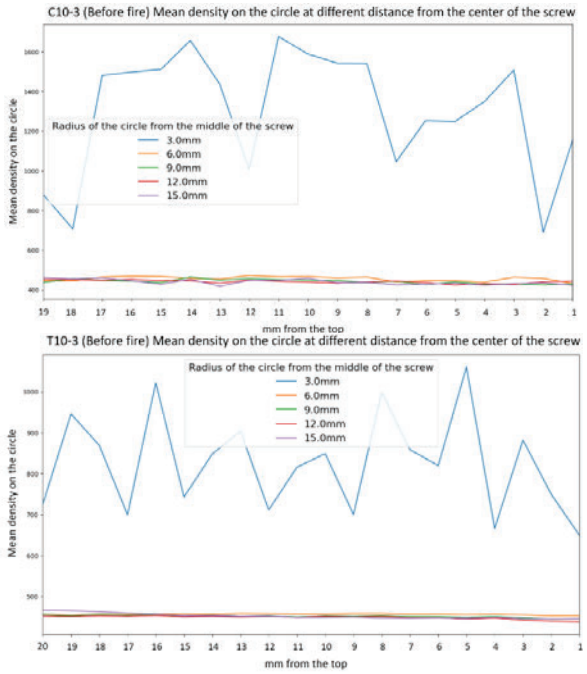

Figure 12: *Graph of density measured on circles for samples without fire exposure*

Figure 13 shows the evolution of the degradation around the screw on samples after a fire exposure of 5 minutes. The average density on all circles started to decrease approximately 7 mm from the top, which indicated the charring front, and it reached a lower constant value, indicating burnt wood. Although the density on the innermost circle again fluctuated due to noise, it followed the same decreasing trend.

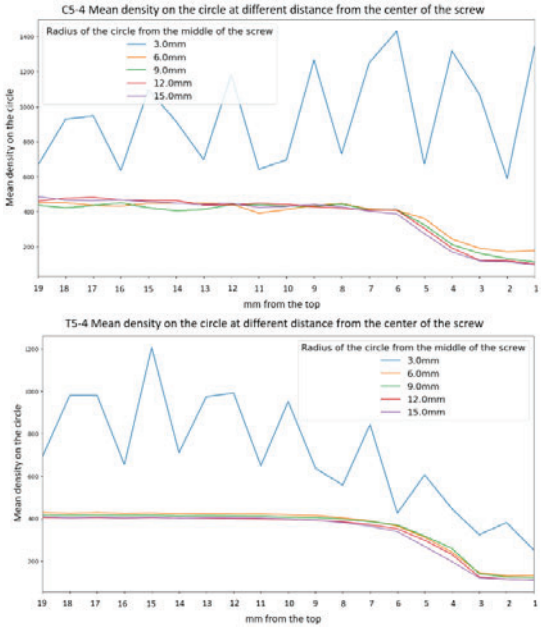

Figure 13: *Graph of density measured on circles for samples after 5 minutes fire exposure*

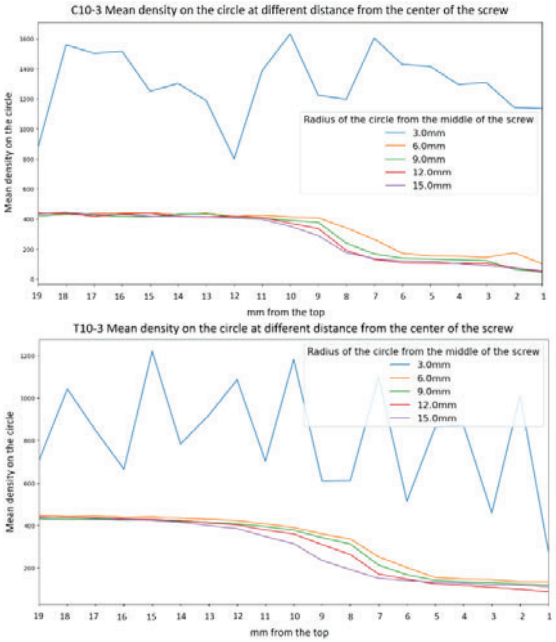

Figure 14: *Graph of density measured on circles for samples after 10 minutes fire exposure*

Figure 14 shows the evolution of the degradation around the screw on samples after a fire exposure of 10 minutes. Similarly to Figure 13, the density dropped to a lower constant value over a certain distance, but starting from a greater distance from the top of the samples due to increased charring.

In general, for all evolution graphs above, the mean density decreased for increasing circle radius, which was probably an effect of artefacts and noise around the screw which artificially increased the apparent density. With the screw still attached during the scans, we could therefore not observe a significant density loss close to the screw, which could have resulted from heat conduction

4.4 EVOLUTION OF DENSITY AFTER SCREW REMOVAL

The degradation of wood in the proximity of the screw was difficult to interpret in scans where the screws were present. The analysis procedure using concentric circles described above was thus repeated for CT scans of four fire-exposed samples in which the screws were carefully removed, instead of conducting destructive mechanical tests.

Figure 15 shows the evolution of the degradation around the screw hole on a representative sample after a fire exposure of 10 minutes and where the screw axis was perpendicular to the fibre direction. All curves follow the similar trend as with the screw inserted, and the noise affecting the innermost circle disappeared. Interestingly, the average density on the innermost circle was considerably higher than on circles further away from the hole. This higher density in the immediate proximity of the hole edge can be explained by compression of the wood during screw insertion, which can also be seen in the corresponding scan of the graph in Figure 16.

https://doi.org/10.52202/069179-0206

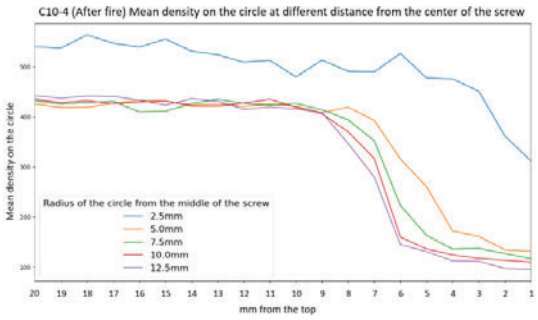

Figure 15: *Graph of density measured on circles around the screw hole for samples after 10 minutes fire exposure and where the screw axis was perpendicular to the fibre direction*

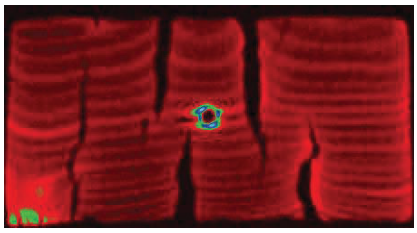

Figure 16: *CT image of the sample used for calculating the graph in Figure 15, blue and green colour indicate elevated and red lower density values.*

Figure 17**Erreur ! Source du renvoi introuvable.** shows the evolution of the degradation around the screw hole on a representative sample after a fire exposure of 10 minutes and where the screw axis was parallel to the fibre direction.

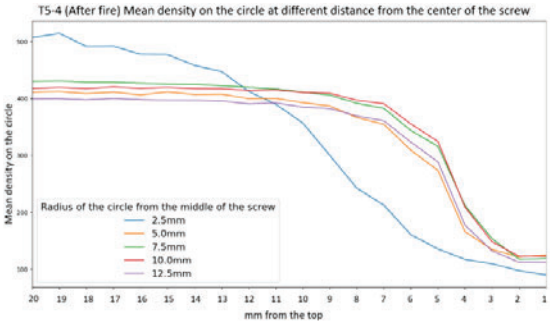

Figure 17: *Graph of density measured on circles around the screw hole for samples after 10 minutes fire exposure and where the screw axis was parallel to the fibre direction*

In contrast to the perpendicular case, the average density of the innermost circle clearly drops below the density of the areas further away from the hole when approaching the top (burnt) surface, which happens at around 10 mm from the top. This indicates that heat degradation in the screw hole has occurred. The lower density in the hole can also be observed in the corresponding scan in Figure 18.

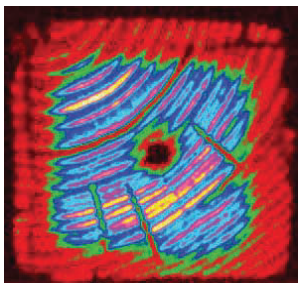

Figure 18: *CT image of the sample used for calculating the graph in* ***Figure 17****, blue and green colour indicate elevated and red lower density values.*

The observations indicate that the insertion direction of the screw with regards to the fibres could affect the fire resistance of the connection. When the screw is inserted, it densifies the wood around this as such should have a protective effect against charring in the hole. However, for the tests in this study, the charring progressed into the hole more easily if the screw was inserted parallel to the fibre directions. The effect could, however, also have been a result of the different sample geometries for the different insertion directions.

5 RESULTS OF MECHANICAL TESTS

Figure 19 shows box plots for the compression and tension tests on the samples. For both, loading parallel and perpendicular to the fibres, the load capacity reacts similarly to increasing length of fire exposure. There was almost no degradation of the load capacity during the five first minutes of fire exposure, but a noticeable degradation after 10 minutes exposure.

The degradation could be clearly linked to the observed charring depth in the image analysis of the CT images. The higher the indicated charring depth from the images, the lower the capacity of the connection.

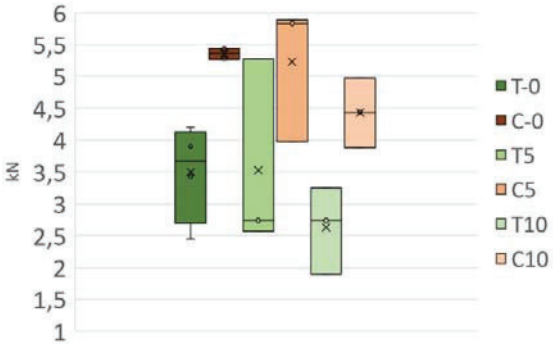

Figure 19: *Load capacity box plots of the tested samples*

Figure 20 shows the evolution of the load capacity of the connection as a function of the charring depth along the screw. Mean values were used for the figure. Compression and tension samples followed the same trend. Linear regression lines in the figure indicate a negative correlation between charring depth and load capacity.

https://doi.org/10.52202/069179-0206

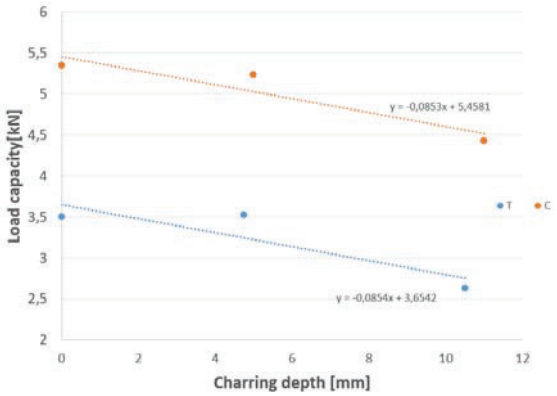

Figure 20: *Evolution of load capacity as a function of the charring depth*

6 CONCLUSIONS

This study has shown that it is possible to use CT images to observe fire degradation in wood with one fastener installed. It was concluded that

- the greyscale histogram of a CT image can be used to separate between wood, burnt wood and metal,
- the evolution of the histogram over increasing depth from a burnt surface can yield information about the charring depth,
- the evolution of the average density in the proximity of the screw hole can yield information about the degradation of the connection, and
- it is difficult to fully avoid artefacts due to metal, but the effect can be mitigated by minimising the amount of metal in the scanning plane, or potentially by using higher energy X-rays.

We developed a first approach to investigate wood degradation close to the screw using the average density of concentric circles around the screw. Noise and artefacts generated by the screw make measurements close to the screw surface difficult in CT images, however, if the screw is removed, the edge of the hole can be investigated more easily. The results indicate that the charring behaviour in the proximity of the screw differs, depending on the insertion direction with respect to the fibres.

In the future, it could be interesting to focus analyses on the charring around the hole after removal of the screw to clarify whether the insertion direction indeed affects the charring.

ANALYTICAL MODELLING OF POST-TENSIONED TIMBER BEAM-COLUMN CONNECTIONS IN FIRE

Paul D Horne[1], Anthony K Abu[2], Alessandro G Palermo[3]

ABSTRACT: Post-Tensioned Timber (PTT) is a structural system that has many advantages over conventional timber frames, particularly in high-seismic areas such as New Zealand. These include a low-damage, re-centring system and fast construction. Although PTT systems have been shown to perform well in ambient conditions, concerns remain about the performance of beam-column connections in fire. As part of a larger project to address these concerns, a full-scale loaded PTT beam-column subassembly was exposed to a Standard Fire. Connection moment resistance was lost when thread stripping at the anchorage nut. An analytical model was compared to the experimental results. The decompression moment decreased due to the reduced tendon force from heating, the tendon acting eccentrically and the reduced effective cross-section. The analytical connection rotation after decompression was a third of experimental rotation until thread stripping began. This analytical model can be improved by including more complex aspects such as softening of a heated rocking interface and determining the beam stiffness based on the reduced material properties beneath the char layer. A follow up study is being undertaken to address these improvements and to provide a method for designers to evaluate the performance of these connections in fire.

KEYWORDS: Post-Tensioned Timber, Frame, Connections, Fire

1 INTRODUCTION

In high-seismic areas such as New Zealand, building owners and occupiers are also becoming more aware of the downtime and costs of repair or demolition of a building after an earthquake. Instead of conventionally designed structures, they seek low-damage structures which can be reinstated more easily, faster and cheaper. In contrast to conventionally designed structures, where seismic energy is dissipated by plastic hinges in primary structural elements, the primary structure of a low-damage system responds elastically and seismic energy is absorbed by specially designed components, which can be replaced after an earthquake.

Post-Tensioned Timber (PTT) is a technology that meets the demands for both a low-damage structure and timber as the primary structural material. PTT frames utilise prestressed unbonded steel strands or high strength bars inside timber elements, running the length of the frame, with replaceable energy dissipaters at the top and bottom of each beam-column connection (see Figure 1a). Under a lateral load, a gap opens at the rocking beam-column interface and the dissipaters are stretched or compressed, dissipating the seismic energy (see Figure 1b). Moment resistance at the connections is provided by force-couples from the dissipaters in tension and compression and from the tendon and compression of the beam against the column. The stressed tendon re-centres the structure after the conclusion of the lateral action. This technology can also be applied in low seismic areas to achieve longer spans than typically possible with timber elements alone, by using draped tendons and omitting the energy dissipaters (see Figure 1c). The advantageous performance of this structural system is due to the ductile rocking connections which contain the rocking interface and energy dissipation devices (see Figure 1d). The performance of PTT structures under seismic and gravity actions at ambient temperature has been extensively researched at the University of Canterbury [1–7] [1, 2] and a design guide has been published [8]. Several PTT frame buildings have been built in New Zealand and overseas, for example, Trimble Building [9], Young Hunter House and Von Haast [10] in New Zealand and ETH Zurich House of Natural Resources, Zurich, Switzerland [11] (Figure 1e shows a PTT frame during construction).

Although the behaviour of Post-Tensioned Timber box beams in fire has been investigated [12–14], the response of PTT frames and their beam-column connections in fire has not been investigated. Design guidance [8], therefore, proposes two design approaches for PTT structures in fire: the protected and unprotected approach. In the protected approach (see Figure 2a) the tendon is protected from the effects of fire so that the tendon force is maintained. Even though the cross-sections of the timber elements are reduced by charring, the moment resisting connections and moment-frame are preserved. In the unprotected approach (see Figure 2b), the tendon is not explicitly

[3] Alessandro G Palermo, University of Canterbury, New Zealand, alessandro.palermo@canterbury.ac.nz

https://doi.org/10.52202/069179-0207

protected from the fire. On this basis, it is assumed the tendon force is zero and the beams are designed as simply supported with reduced cross-sections. All PTT buildings built in New Zealand so far have used the unprotected approach, because there is no additional costs to install protection and the design check is simple [12].

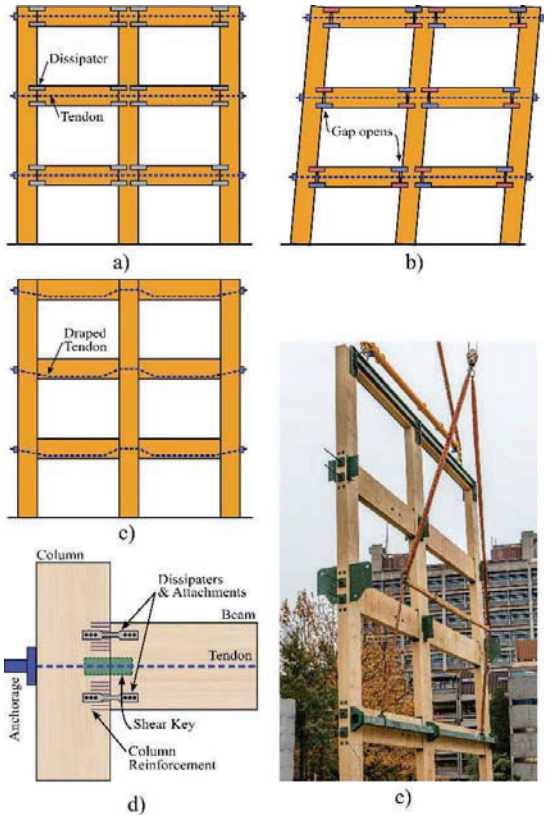

Figure 1. *Illustration of PTT frames a) in a high seismic area at rest and b) under a lateral load and c) in a low seismic area, d) a schematic of a PTT beam-column connection and e) a PTT frame during construction*

While these two design approaches are easily implemented by designers, they do not evaluate the actual response of the connection or structure in a fire. Even in the unprotected case, the tendon will take some time to be heated through an exposed tendon anchorage and for the force in the tendon to decrease. Furthermore, in structures designed for seismic loads, features may already be present that also provide advantageous performance in fire; e.g. larger column sizes for increased lateral stiffness can withstand greater charring in a fire. Although harnessing this advantageous fire performance is an opportunity for increased economy, increased performance in fire is not guaranteed by seismic design and detailing. A previous study has shown that PTT beam-column connections detailed for beneficial seismic performance does not necessarily also improve the connection performance in fire [15].

Previous study [16,17] modified the analytical model for PTT beam-column connections at ambient to the fire scenario and compared results from the analytical model to an experiment of a simple reduced-scale PTT beam-column connection (i.e. had a tendon, anchorage and internal corbel only). The analytical results compared favourably with those from the experiment; the studied connection did not have all the detailing features of a beam-column connection in a multi-storey PTT frame structure (e.g. interface stiffening, creep prevention or an external corbel which is more common) and was also at a reduced-scale. Therefore, questions remain about how representative the analytical model is of "fully" detailed PTT connections.

To address these questions, an experiment of a full-scale PTT beam-column connection is required given the complex thermal and mechanical response of PTT beam-column connections in fire. This paper presents the experimental results from a full-scale PTT connection that was detailed to current design practice in New Zealand and a comparison with an analytical model. Firstly, the components of a PTT beam-column connection and the analytical model are summarised. Secondly, the key results and observations from this experiment are reported and thirdly, the analytical and experimental results are compared.

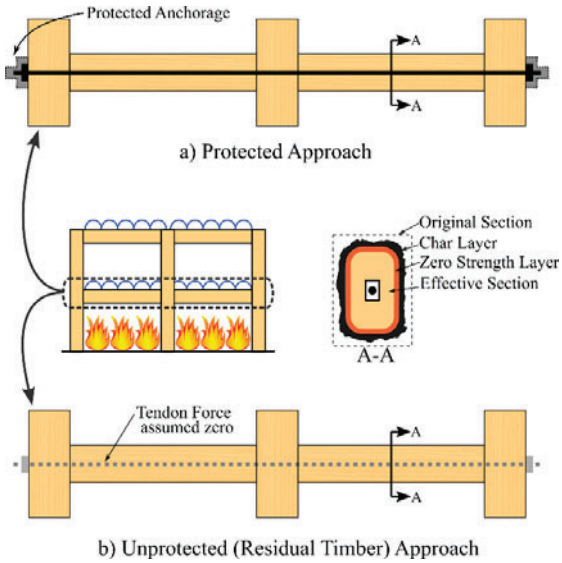

Figure 2. *Illustration of the a) Protected and b) Unprotected approaches to the design of PTT frames*

2 PTT BEAM-COLUMN CONNECTIONS

The advantageous response of PTT structures is directly attributable to the ductile rocking behaviour of the connections while the timber elements remain within their elastic limits. For a beam-column connection in a frame to have this beneficial behaviour, it must contain (see Figure 1d):

1. A tendon passing through ducts in the beam and column.
2. A tendon anchorage at the beam-column connections at each end of the frame.

https://doi.org/10.52202/069179-0207

3. Dissipaters and their attachments to the timber elements. Dissipaters can take several forms from buckling restrained necked bars to reduced cross-section angles.
4. Corbel or shear key to transfer shear from the beam to the column, which can be external or internal.

However, further detailing of the connection must be considered to ensure the desired stiffness and long-term performance is achieved:

1. The rocking interface must be sufficiently stiff so that drift limits under Serviceability Limit State (SLS) lateral actions are achieved. The interface stiffness depends on the material properties and size of the timber elements, and whether there is a steel interface plate.
2. Perpendicular-to-grain crushing of the timber column must be avoided under large gap angles when the bearing area is small.
3. Creep deformations from the compression of timber column perpendicular-to-grain must be limited so the required tendon force is maintained over the life of the building.

Connection detailing to address these considerations includes screw reinforcement in the column, a steel jacket around the column, steel compression elements inside the column or the column being fabricated with rotated timber blocks at the beam-column zone so the grain is parallel to the compressive forces (see [8]).

The mechanical behaviour of PTT beam-column connections in fire strongly depends on the thermal field established in the joint and the complex interaction between the many connection components. Therefore, the behaviour of PTT connections in fire will depend on their configuration and detailing choices by the designer. While different detailing options to achieve the same objective may result in similar ambient temperature performance, e.g. stiffening the interface with reinforcing screws or rotated timber blocks, they may perform differently in fire. This is particularly true where steel components are introduced which conduct much more than the surrounding timber.

3 ANALYTICAL MODELLING OF PTT CONNECTIONS

The presence of a gap at the beam-column interface violates the assumptions of the Euler-Bernoulli beam theory; therefore, it cannot be applied. The Monolithic Beam Analogy was developed to overcome the same limitation in controlled rocking joints from precast concrete elements during the Precast Seismic Structural Systems (PRESSS) project [18,19]. It was extended to timber elements and called the Modified Monolithic Beam Analogy) several additional complexities had to be addressed including initial joint stiffness and compression block [2,4,5,8]. The MMBA establishes a displacement equivalence between the rocking element and a "monolithic" analogue to determine the equivalent curvature in terms of the gap angle. This additional displacement compatibility equation combined with the two equations of equilibrium allows the calculation of the moment for each given rotation or gap angle. The extension of the MMBA into the fire case is summarised here but explained in more depth in [16] and [17].

The MMBA for an element exposed to fire, is derived by establishing displacement equivalence between the fire-exposed rocking and monolithic cantilever elements of length, ℓ, under axial load, N, (which is the tendon force including the additional force from stretching) and external horizontal load, P, as shown in Figure 3. When the element is exposed to fire on three sides, the centroid moves towards the unexposed side, and so the tendon force acts eccentrically (e), producing a uniform moment (Ne) along the element. This moment contributes to decompress the beam, so less external horizontal force is required to decompression the interface. At decompression, the stress at the extreme tension fibre is zero, so it can be expressed as:

$$\frac{N}{A} - \frac{M_{dec}}{Z} = \frac{N}{A} - \frac{Ne + P_{dec}\ell}{Z} = 0 \quad (1)$$

where P_{dec} is the external horizontal force required for decompression. The curvature at the base of the rocking element at decompression is ϕ_{dec}. From the two moments Ne and $P_{dec}\ell$, the sum of the curvatures produced by these moments is: $\phi_{dec} = \phi_{Ne} + \phi_{P_{dec}\ell}$.

The displacement at the top of the rocking and monolithic cantilever elements in terms of the curvature at the base of the element is (i.e., applying Equation 1):

$$\frac{\phi_{Ne}\ell}{2} + \frac{\phi_{P_{dec}\ell}\ell^2}{3} + \theta_{gap}\ell = \frac{\phi_{Ne}\ell}{2} + \frac{\phi_{P\ell}\ell^2}{3} \quad (2)$$

$$\frac{\phi_{P_{dec}\ell}\ell^2}{3} + \theta_{gap}\ell = \frac{\phi_{P\ell}\ell^2}{3} \quad (3)$$

$$\left(\frac{3\theta_{gap}}{\ell} + \phi_{P_{dec}\ell}\right) = \phi_{P\ell} \quad (4)$$

This is the same form as the ambient-temperature seismic MMBA formulation except the curvature required for decompression is reduced by the tendon acting eccentrically.

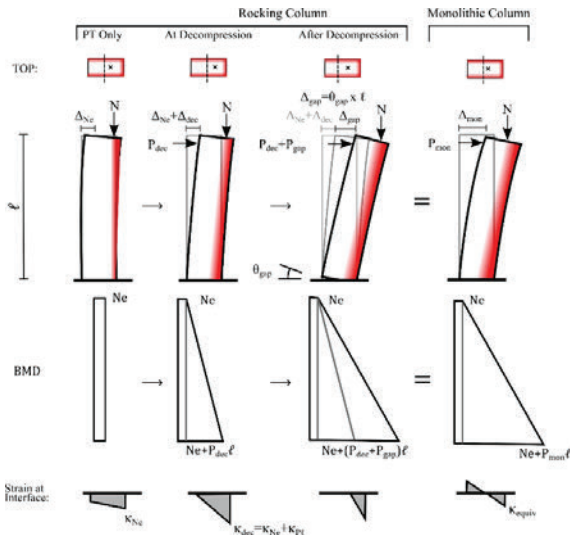

Figure 3: *MMBA for a cantilever element exposed to fire*

4 EXPERIMENT

4.1 SETUP

A 1:1 scale PTT beam-column subassembly, based on the connection detailing of recently constructed PTT framed structures [10] and published design guidance [8], was constructed, loaded and exposed to fire. The tested sub-assembly (shown in Figure 4) was constructed from LVL13 (E=13.2 GPa [20]) 700x310 mm beam and 800x310 mm column with two 75 mm square ducts for the tendons. These timber elements were fabricated from seven 45 mm thick LVL laminations glued to form the 310 mm thick elements. Bare wire K-Type thermocouples were laid in small grooves on the surface of the seven laminations prior to gluing. The two tendons were 26.5 mm diameter high-strength Macalloy 1030 bars [21] tensioned to 160 kN (28% of UTS) with 200 mm square, 40 mm thick anchorage plates. Two 75 mm square hollow steel sections (5 mm wall thickness) were installed inside the ducts to prevent long-term creep perpendicular to the grain of the column. Reinforcing screws were installed in the column at the top and bottom of the beam-column contact area to prevent crushing of the column perpendicular to the grain under large gap angles in seismic events. Vertical support of the beam at the connection was provided by a steel bracket with central stiffener fixed to the column with 10x M20 coach screws. Thermocouples were placed at the interface between the bracket and the beam and column.

The beam-column sub-assembly was placed in a purpose-built enclosure, so that the beam was exposed on three sides and the column was exposed on four sides below a floor level. The enclosure was made from 13 mm calcium silicate board lined internally with an alkaline earth silicate fibre blanket. The effect of a floor was simulated with a 100 mm thick slab of concrete on the beam. Two viewing windows were installed in the enclosure for visual observations. This enclosure was placed on a 3 x 4 m standard fire resistance testing furnace in its vertical orientation (see Figure 5). A point load of 16 kN was applied to the end of the beam to achieve a total connection moment of 29.6 kNm (90% of the decompression moment). An axial force of 50 kN was applied to the top of the column (limited by hydraulic jack capacity). The furnace was controlled to follow the ISO 834 Standard Fire [22] time-temperature curve (according to AS 1530.4 [23]) until failure of the connection.

4.2 OBSERVATIONS

Photos of the connection and the residual cross-section of the timber elements are shown in Figure 6. Corner rounding at the bottom of the beam had occurred and the contoured shape of the column near the connection zone indicates the thermal field was not the same as in the timber elements away from the connection, and charring of the bottom of the column interface which was promoted by conduction through the steel bracket.

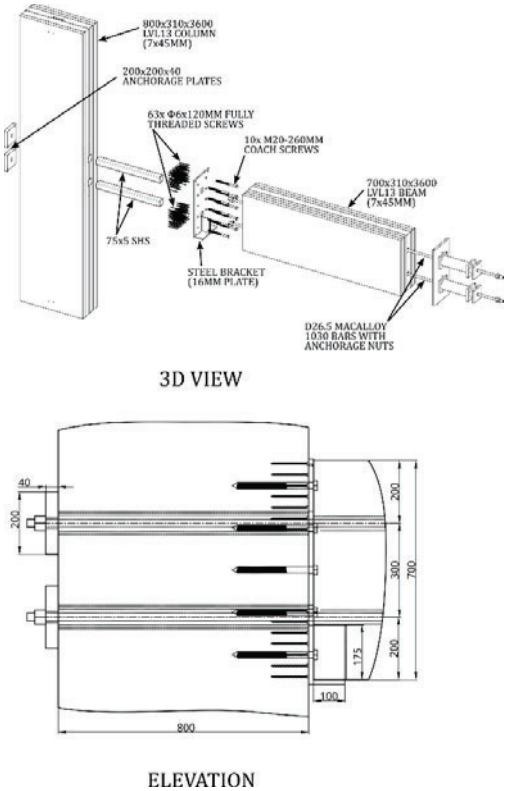

Figure 4: *3D and elevation views of the tested beam-column sub-assembly*

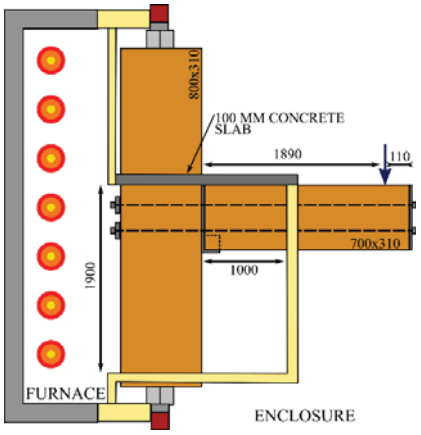

Figure 5: *Schematic of beam-column subassembly in enclosure on furnace*

Also evident in Figure 12 is the effect of anchorage reinforcement; in this case, the anchorage plates are held off the char surface. Although the 40 mm thick anchorage plates did delay the onset of charring underneath by approximately 15 minutes, without reinforcement under anchorage, the large bearing stress would result in crushing of the timber column perpendicular-to-grain at low temperatures. In this connection, the detailing to prevent long-term creep (the SHS tubes inside the column) formed an alternative load path and supported the anchorage plates as the timber underneath charred. Without anchorage reinforcement to resist the high

https://doi.org/10.52202/069179-0207

bearing stress from the anchorage, hot wood/char underneath and anchorage plates would be crushed, and the tendon force would decrease from shortening of the tendon. Therefore, if the moment resistance of connections and the frame is to be maintained, the exterior frame connections should be detailed to avoid this failure mechanism.

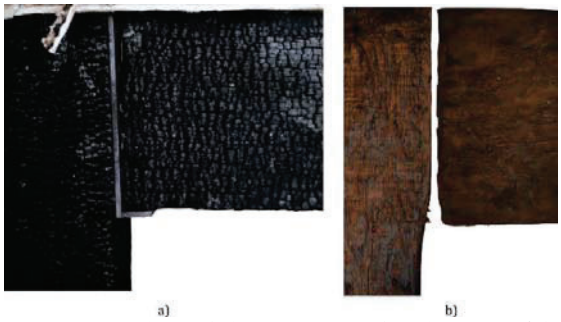

Figure 6: *a) Photo of the connection after the test and b) residual cross-sections*

4.3 TEMPERATURE RESULTS

The temperature of the furnace control thermocouple probes is shown in Figure 7. Char rates, determined from thermocouples in the beam and column away from the connection (using a 300 °C isotherm), ranged from 0.62 to 0.78 mm/min with a mean of 0.70 mm/min. A previous study of the charring of LVL elements in the Standard Fire reported a mean charring rate of 0.72 mm/min [24]. Only a selection of key thermal results are presented here.

The steel bracket, which supported the beam, was exposed to the fire on three sides and conducted heat through the interface. At 21 minutes, the temperature at the interface between the beam the bearing plate of the bracket exceeded 300 °C. Temperatures measured at the interface between the steel bracket and the column are shown in Figure 8. The temperature developments at locations A-D show that a 2D thermal field was established in the lower third of the interface. Heat was conducted up the interface from the exposed bearing plate and from the exposed sides of the interface plate. In the top two-thirds of the interface plate the thermal field was one-dimensional, decreasing in temperature from the exposed edges to the centre of the bracket.

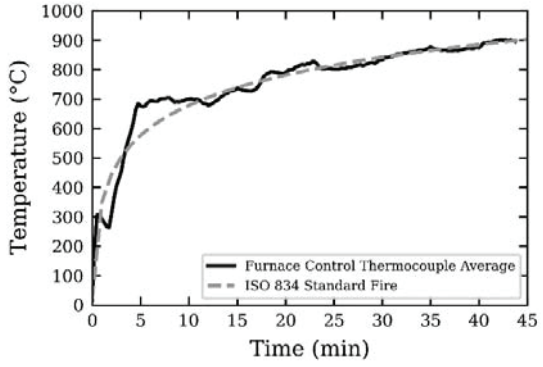

Figure 7: *Temperature of furnace control thermocouple probe*

A large thermal gradient was recorded along the tendon (see Figure 9). The temperature of the tendon underneath the anchorage nut increased quickly and reached a maximum temperature of over 700 °C at the end of the experiment. However, at the same time the temperature 100 mm into the column the tendon was 270 °C and less than 100 °C at 300 mm.

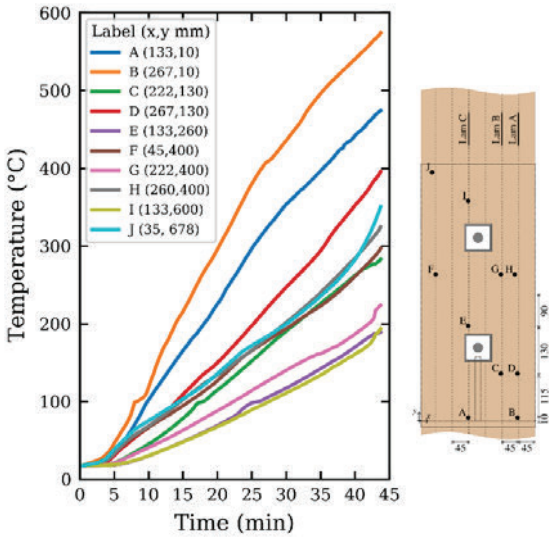

Figure 8. *Temperatures at the interface between the timber column and steel bracket*

The temperature of the tendon was also monitored at the beam-column interface to determine if the tendon was heated by the opening at the interface. The temperature of the bottom tendon did increase slightly (less than 100 °C) as it was heated from the hot steel bracket. The temperature of the top tendon was the same as the bottom tendon except for the final five minutes, when the temperature increased rapidly to 200 °C as hot gases penetrated the gap at the beam-column interface.

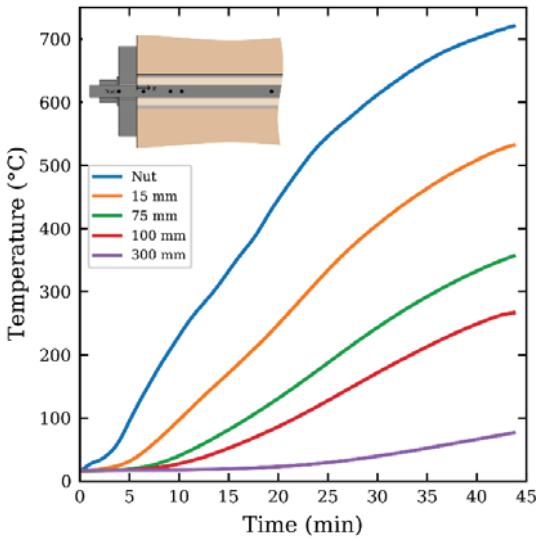

Figure 9: *Temperature of tendon*

https://doi.org/10.52202/069179-0207

4.4 MECHANICAL RESULTS

The connection decompressed after 5 minutes of fire exposure and increased linearly (approximately 0.0014 rad/min) until 37 minutes (a rotation of 0.005 rad). The connection rotation then increased rapidly, and the test was terminated at 44 minutes at a rotation of more than 0.05 rad.

The tendons were initially stressed to 160 kN each although the force in the top tendon increased by around 5 kN and the force in the bottom tendon decreased by the same amount as the beam was loaded. Between 5 and 10 minutes the tendon force in the top and bottom tendons decreased by 13% and 7% respectively. The force in the bottom tendon remained slightly greater than the top tendon until 27 minutes, at which time the force had decreased to 75% of its initial value. After this time, the forces in the tendons reduced at a greater rate. The force in the bottom tendon decreased to 25% of the initial force. The force in the top tendon decreased to 52% at 37 minutes and remained roughly constant for five minutes. In the final minutes of the test the top tendon was unable to sustain the applied force and the interface gap opened to the extent that the bottom tendon was stretched to provide additional moment resistance.

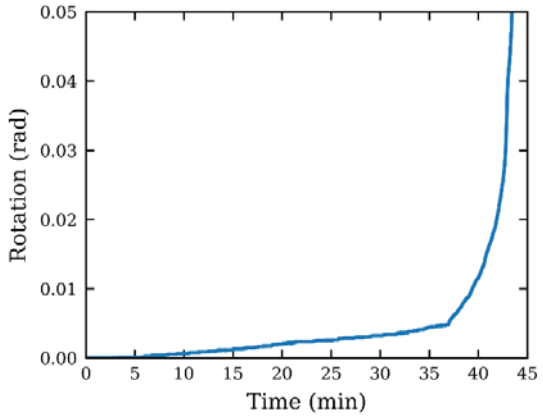

Figure 10: *Connection rotation*

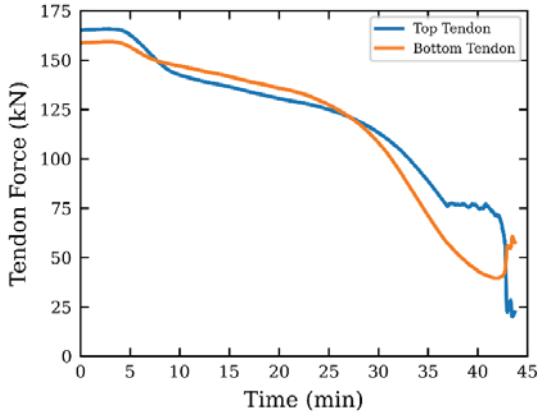

Figure 11: *Forces in the tendons*

The rapid increase in connection rotation (see Figure 10), that began at 37 minutes, coincided with the plateau in the force in the top tendon (see Figure 11). At the conclusion of the experiment, the top tendon had pulled through the anchorage nut (see Figure 12).

For a bar to be pulled a bar through a nut, the threads undergo large plastic deformations, which would explain the constant tendon force and the rapid increase in rotation.

Figure 12: *Tendon anchorages after test*

5 ANALYTICAL MODELLING

The response of the connection in the experiment was modelled using the MMBA procedure that has been modified for fire (see section 3). The effective cross-section of the timber elements was determined using two different implementations of Residual Cross-Section Methods because they are already familiar to practitioners. The two methods were:

1. Char rate of 0.65 mm/min with corner rounding explicitly calculated (radius equal to char depth). This is based on the residual cross-section method in NZS 3603 [25].
2. Char rate of 0.65 mm/min and a 7 mm zero-strength layer. This is based on AS/NZS 1720.4 [26] but the zero-strength layer is considered to develop over 20 minutes [13].

The cross-section was then transformed into an equivalent section with ambient elastic modulus (using modulus ratios) to be used in the MMBA procedure.

The tendon force was reduced by thermal expansion and reduced elastic modulus in the heated portion. For this analysis the temperature profile along the tendon was obtained by fitting a piece-wise linear curve to the tendon temperatures measured in the experiment (Figure 9). Thermal expansion and reduced material properties of prestressing steel were adopted from EN 1992-1-2. The ambient elastic modulus of the tendons was 170 GPa, the secant value provided by the manufacturer [21].

5.1 Decompression Response

The decompression moment is the moment at the connection that corresponds to the point of

https://doi.org/10.52202/069179-0207

decompression; i.e. stress at the extreme fibre is zero. The decompression moment decreases as the effective cross-section of the timber element and the tendon force reduce. The decrease in decompression moment as the connection was exposed to the Standard Fire is shown in Figure 13 for a constant tendon force case and a tendon relaxation case (thermal expansion and reduced elastic modulus as it is heated). After the first five minutes the decompression moment decreased in an almost linear manner. Following 45 minutes of Standard Fire exposure, a 5% reduction in decompression moment was attributable to the loss of cross-section area and approximately 18% was the result of the reduction in tendon force.

The decompression curvature (in the beam and at the interface) is an important parameter in the MMBA as it relates to the displacement prior to decompression. The reductions in decompression curvature for both the constant and relaxed tendon cases are shown in Figure 14. In the case of the constant tendon force, the decompression curvature continues to increase throughout the exposure, by a factor of 1.34 for Method 1 and 1.44 for Method 2 (at 45 minutes). However, when relaxation of the tendon was considered the decompression curvature increased for the first 30 minutes of the exposure, after which it remained relatively constant. The decompression curvature had increased by roughly half the amount, as in the constant tendon force case, to 1.10 for Method 1 and 1.19 for Method 2 (at 45 minutes).

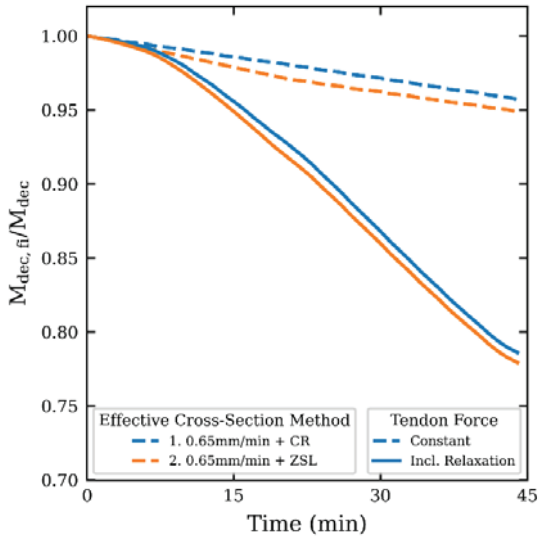

Figure 13: *Decompression Moment when exposed to a Standard Fire*

In seismic resisting PTT applications, the tendons are located so that the centroid of the tendon force and the neutral axis align. However, when the rocking element in a PTT system is exposed to fire on three sides, such as a beam supporting a floor, the neutral axis moves towards the unexposed face as the element is heated and chars. The tendon force then acts eccentrically so an additional moment acts to decompress the connection. Consequently, the moment required to decompress the connection decreases. The additional moment from the tendon acting eccentrically is shown in Figure 15 for both the constant and relaxed tendon cases. The additional moment reached 12-15% of the initial decompression moment after 45 minutes of exposure for the relaxed tendon case, which was about 80% of the additional moment from the constant tendon case.

Figure 16 shows the moment that must be applied to the connection to cause decompression (accounting for the additional moment from the tendon eccentricity and the decreasing decompression moment) as a proportion of the ambient decompression moment. This applied moment for decompression decreases by 17-20% of the ambient decompression moment for the constant tendon case and by a third for the relaxed tendon case.

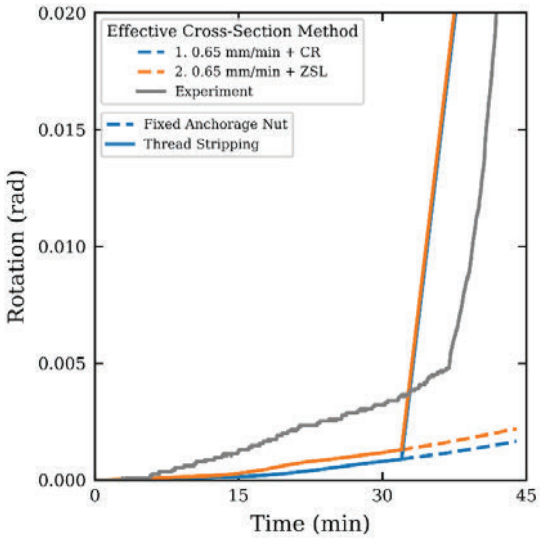

Figure 17: *Analytical and experimental connection rotation*

5.2 Post-Decompression Response

The softening of the interface from the heated interface plate was accounted for by taking the interface stiffness modification factor, k_{gap}, as 0.1 (the value for an unreinforced interface) [9]. Thread stripping of the anchorage nut that was observed in the experiment was included in the model by displacing the anchorage at a constant rate after the strength of the nut was exceeded (32 minutes). This rate assumed the anchorage nut deformation (measured at the end of the experiment) occurred at a constant rate.

Figure 17 compares the analytical connection rotation, with and without thread stripping at the anchorage nut, with the experimental rotation. The connection decompressed at similar times in the experiment and in the analytical models. Like the experimental response, the analytical response had two distinct stages – before and after thread stripping starts. The analytical model predicts only 30% of the experimental rotation before thread-stripping of the anchorage nut began. Thread stripping occurred a few minutes earlier in the analytical model than in the experiment. The thread stripping of the anchorage nut effectively lengthens the tendon and additional connection rotation is required to maintain the tendon force and moment resistance. The different responses of the analytical results with and without thread stripping at the anchorage nut shows that thread stripping dominated the connection response.

6 DISCUSSION

The 1:1 scale experiment of PTT beam-column sub-assembly showed that even when the tendon anchorage is not protected from the fire, the moment-resisting connection has some inherent fire resistance. The unprotected design approach neglects this beneficial performance. The edges and bottom of the steel bracket were exposed to the fire and conducted heat into the connection interface. The elastic modulus and strength of the adjacent wood decreased, softening the connection response. At 37 minutes the top tendon pulled through the anchorage nut. Insulating the anchorage and tendon from the fire will reduce the relaxation of the tendon and delay failure of the anchorage. The internal steel tubes resisted the force from the anchorage when the adjacent timber had charred. Without these tubes, the char and heated layers would have been crushed and the tendon force would have been lost earlier. Similarly, the screw reinforcing in the interface supported the steel bracket when the surrounding timber had charred. Without this screw reinforcement the connection response would have been a lot softer as this timber was crushed and the analytical model would have to be modified to take this into account.

The analytical modelling prior to decompression shows that the pre-decompression behaviour was reduced more by the decreased tendon force (due to thermal expansion and reduced elastic modulus) than the decrease in effective cross-section. Of the two Reduced Cross-Section Methods used to determine the effective cross-section, the method that considered a zero-strength layer always resulted in a softer connection response.

The response of the analytical models compared to the experimental results after decompression indicate that there is a softening phenomenon between 5 and 30 minutes that is missing from the analytical model. This is likely a result of the 3D thermal field in the bottom corner of the beam (due to the heated steel bracket), which is also

https://doi.org/10.52202/069179-0207

where the greatest bearing stresses would normally occur. Any additional deformation of the interface timber would also reduce the tendon force, so the analytical models would better represent the experimental tendon forces. To examine this further, the 3D thermal field at the connection and heat transfer between adjacent parts should be investigated then the analytical model can be modified to include these effects.

The MMBA is based on an additional displacement condition, so the stiffness of the rocking element (i.e. beam) is a key parameter. The stiffness of a timber element exposed to fire depends on the effective cross-section area, due to charring, and the reduced material properties in the heated layer underneath the char layer. Reduced Cross-Section Methods, such as those used in this analysis, are commonly used by designers to predict the failure times of loaded timber elements exposed to a Standard Fire. However, these methods are developed for a strength criterion, so may not be directly applicable to calculating the reduced stiffness. To alternative methods would be to consider a parabolic temperature distribution in the heated layer or determine the temperature distribution using a numerical technique e.g. finite element analysis. Reduced mechanical properties through the heated layer can be explicitly considered, e.g. using the reduced mechanical properties in EN 1995-1-2.

The thread stripping of the anchorage nut on the threaded bar tendon was not considered adequately in this analysis. Further study is required to develop an appropriate sub-model for this plastic deformation. One option would be to limit the tendon force to the shear yield strength of the threads reduced by the temperature-strength relationships of EN 1992-1-2 [27].

The analytical model presented here captured some of the response of realistically detailed PTT beam-column connections, however, the response is much softer than in the experiment and some important aspects are missing. While some detailing features can improve performance in fire (e.g. interface reinforcement screws), other features degrade connection performance (e.g. partially exposed steel bracket). Further study is required to modify the analytical method to account for the softer response of these connections and to refine how different types of detailing change the connection behaviour.

7 CONCLUSIONS

The performance of Post-Tensioned Timber frames is governed by the behaviour of the beam-column connections and their detailing. A loaded 1:1 scale PTT beam-column sub-assembly, with current seismic detailing, was exposed to the Standard Fire. The connection maintained its moment resistance for 40 minutes despite the tendon anchorages being exposed directly to the fire. This was in opposed to the Unprotected design approach, which neglects the tendon contribution from the start of the fire exposure. The internal SHS tubes in the column and the screw reinforcing at the interface, installed for long-term and seismic considerations, were important to obtaining this performance.

An analytical model for PTT beam-column connections in fire, previously used with medium-scale simple PTT connections, was used to evaluate the response of the connection that was tested. Reduced performance of the connection before decompression was primarily due to a reduced tendon force (thermal expansion and lower elastic modulus in the heated portion) and to a lesser extent, the reduced effective cross-section. The analytical model only rotated approximately a third of the experiment before thread stripping occurred. Once it began, thread stripping of the anchorage nut on the bar tendon dominated the connection behaviour.

The analytical model did not capture some behaviour that was observed in the experiments which this study has shown to be important to the connection response, e.g. softening of the rocking interface as it was heated. To address these shortcomings and improve the analytical model, a follow-up numerical study is being undertaken to investigate the connection's thermal field and the resulting structural response. This analytical model will enable designers to assess the actual response of PTT beam-column connections in fire.

ACKNOWLEDGEMENT

Logan Cooper and George Hare provided assistance in constructing the experimental specimen.

MECHANICAL PERFORMANCE AT ELEVATED TEMPERATURES OF NON-METALLIC DOWELS FOR MASS TIMBER STRUCTURES

Alexandra Boloux[1], Rafik Nizarali[2], Luke Bisby[3]

ABSTRACT: Connections between timber structural elements are normally accomplished using metallic bolts, pins, and rods whose high thermal conductivity typically generates undesirable in-depth heating and charring of timber in fire. Despite existing studies on the fire performance of non-metallic shear connections, knowledge of the isolated mechanical performance of non-metallic dowels at elevated temperatures is scarce. To address this knowledge gap, a bespoke experimental rig was developed to evaluate the performance of circular glass fibre reinforced polymer (GFRP) and oak dowels at elevated temperatures. A comparison between GFRP (E-glass with vinyl ester) and oak dowel strength and deformation with temperature is presented, with GFRP displaying superior performance given its higher strength at all temperatures considered. However, oak maintained its strength better than the E-glass vinyl ester dowels when normalised against ambient temperature capacity.

KEYWORDS: timber connections, elevated temperatures, non-metallic dowels, glass fibre reinforced polymer, oak.

1 INTRODUCTION

A major challenge in building taller and more complex mass timber buildings is the high-level consequences that may manifest in case of fire. In modern mass timber buildings, structural connections are commonly made using metallic plates and fasteners. However, this increases risks in fire due to the high thermal conductivity of metals, and in particular, steel.

If left unprotected in a building fire, steel connections will readily conduct heat into timber elements and may char the surrounding in-depth timber, possibly resulting in structural failure. Non-metallic connections may present possible solutions, due to the drastically lower thermal conductivity of some such fasteners. Despite limited existing research on the structural performance of non-metallic dowelled connections in timber, there is a paucity of literature on the performance of such connections at elevated temperatures. Additionally, there is a lack of data on the isolated mechanical performance of non-metallic shear fasteners at elevated temperatures. The project presented in this paper therefore investigated the mechanical performance (in shear) of non-metallic dowels, namely GFRP and oak, at elevated temperatures.

2 PREVIOUS RESEARCH

2.1 GFRP DOWELS

There is an existing body of literature on performance of non-metallic timber connections, which was pioneered by Drake and other colleagues [1]. Their aim was to show that non-metallic (GFRP) based timber connections can provide suitable alternatives to steel-based connections. Initial experimental programs conducted double-shear tests using GFRP and steel dowels embedded in a laminated veneer lumber (LVL) member [2]. Despite the GFRP dowel yielding at a lower load than its steel counterpart, it "absorbed at least two or three times more energy" [2]. This can typically be considered beneficial in the context of designing mechanical connections, as structural engineers tend to prefer connections that fail in a ductile manner. In addition, the high strength-to-weight ratio, compatible stiffness between GFRP and timber, and a relatively high resistance to corrosion make GFRP-based connections a compelling replacement to steel-based connections in timber structures [2].

GFRP also has a much lower thermal conductivity than steel, which is a key factor influencing the heat transfer and mechanical performance of a dowelled connection in a fire scenario.

Despite experiments and existing literature suggesting that GFRP can be a suitable alternative to steel mechanical fasteners, no design guidance for their application currently exists. Pedersen [3] proposed changes to timber connection design rules when using GFRP connectors, however Thomson et al. [4] argued that there is a discrepancy between Pedersen's proposed yield equations and the available experimental data.

Additionally, the behaviour of GFRP at elevated temperatures has been previously studied in the context of replacing steel bars in reinforced concrete. Despite having a low thermal conductivity compared to steel, most

polymers burn readily [5] and lose their mechanical properties (i.e., strength, stiffness, and bond) at much lower temperatures than steel, with some GFRP materials softening at temperatures below 100 °C [6].

As the polymer matrix resin in a GFRP softens with an increase in temperature, loss of bond with surrounding materials is typically observed; this has potential consequences where bond integrity is important, as in applications of reinforcing concrete with GFRP bars [7].

Kumahara et al. [8] and Hajiloo et al. [7] tested vinyl ester GFRP rods in tension at elevated temperature. Kumahara et al [8] tested GFRP rods in tension at 240 °C and 400 °C and reported losses of 40% and 60% of tensile strength, respectively. Hajiloo et al. [7] also observed a loss of 25% tensile strength at a temperature of about 150°C. In both cases, the loss in tensile strength was observed at temperatures near the glass transition temperature of the polymer matrix, which for vinyl esters is typically between 55 °C-145 °C [9]. Glass transition temperature may be highly variable within any class of polymers and corresponds to the temperature at which the polymer matrix enters a soft rubbery state and the stiffness and strength rapidly decrease [10].

Brandon [11] tested GFRP bars in torsion to measure shear properties at different temperatures; he observed a decrease in shear strength and modulus of specific GFRP bars with temperature. However, in full-scale testing of dowelled connections under a transient thermal regime, the time to failure of dowelled double shear timber connections was shorter for metallic connections as compared with non-metallic connections [11].

Another important factor to consider for GFRP dowel behaviour at elevated temperatures is creep, which can be expected to accelerate at elevated temperatures.

2.2 TIMBER DOWELS

Given its comparatively poor shear strength relative to either steel or GFRP, softwood timber has not been widely considered as a potential alternative mechanical fastener. Additionally, like GFRP, timber also loses its mechanical properties at relatively low temperatures in comparison to steel; this is potentially important in the context of fire performance. Given its limited shear strength, timber dowelling has mainly been used in furniture applications – with much lower loads than structural applications – and in mortice and tenon joints – which rely on a large section of timber to transfer loads.

Despite existing guidance on timber's thermomechanical properties in the Structural Eurocodes, the existing literature on such matters is comparatively scarce and inconsistent [12-14]. BS EN 1995-1, the Eurocode for Timber Structures, suggests a 60% loss of transverse shear strength at 100 °C.

Despite comparatively poor thermomechanical performance, the experimental program included mechanical tests on oak dowels in addition to GFRP dowels. This is in the interest of advancing understanding of the mechanical behaviour of fully timber connections at elevated temperature.

3 MATERIAL CHARACTERISTATION

Thermogravimetric analysis (TGA), Dynamic mechanical analysis (DMA) and moisture content tests were performed to assess the fundamental properties of the dowels, including the glass transition temperature, T_g, of the GFRP. The results from those characterisation tests were used to decide the testing temperatures in the double-shear tests.

3.1 MATERIAL PROPERTIES

The GFRP rods were manufactured by pultrusion from unidirectional E-glass fibres in a vinyl-ester polymer matrix. The diameter of the rods was 12 mm, so as to be representative of dowel sizes likely to be used in practice. The GFRP rods had a nominal tensile strength of 1000 MPa and a nominal fibre content of 80% by mass.

The timber dowels were made of hardwood oak, chosen for its increased strength, stiffness, and durability compared to typical softwoods [2]. Oak dowel rods were sourced from a local commercial supplier with a nominal diameter of 12 mm; no technical information could be obtained from the supplier on their mechanical properties.

3.2 THERMOGRAVIMETRIC ANALYSIS

Thermogravimetric analysis (TGA) was performed on the GFRP dowels to validate the fibre mass fraction provided by the manufacturer, and to determine the decomposition temperature, T_d, of the polymer matrix. The TGA tests were performed using a Mettler-Toledo TGA/DSC1. Two samples were tested in an oxidative (air) atmosphere, and two in an inert (nitrogen) atmosphere to assess the potential role of oxidation in accelerating decomposition. A temperature range between 25 °C and 800 °C, with a heating rate of 10 °C/min, was used for all samples in accordance with BS EN ISO 11358-1 [15].

The average fibre mass content, determined from a mass loss curve, from the 4 tests, was 79.4% which is in accordance with the value provided by the manufacturer (80%). The mass derivative (MLR) curves for all four samples are presented in Figure 1. These data suggest that no significant decomposition of the GFRP bars occurs below about 225 °C, as should be expected for a glass/vinyl ester polymer composite product. In addition, the mass derivative curves indicate decomposition temperatures of 371 °C and 386 °C in oxidative and inert atmospheres, respectively.

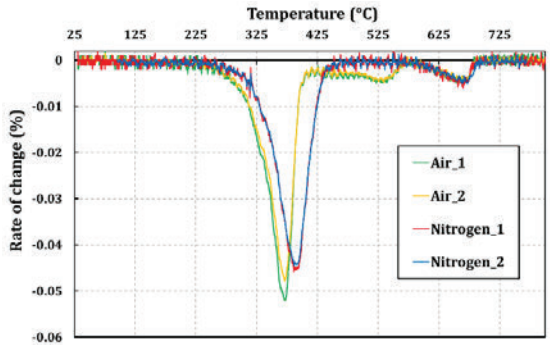

Figure 1: *Differential Thermogravimetry (DTG) results from TGA tests on GFRP dowels.*

3.3 DYNAMIC MECHANICAL ANALYSIS

Dynamic mechanical analysis (DMA) was used to define the glass transition temperature T_g of the polymer matrix and to characterise the elastic and viscous behaviour of the GFRP bars. Even though DMA is generally used to characterise polymers, analysis of oak from the timber dowels used in this study can also indicate changes in the behaviour of this material as temperature increases. The DMA tests were performed using a DMA850 testing device manufactured by TA Instruments. Samples of dimensions 50 mm x 12 mm x 2 mm were tested in three point bending mode and were subject to sinusoidal loading at 1 Hz. They were heated from 25 °C to 180 °C or 200 °C, for the GFRP and oak, respectively; at a heating rate of 3 °C/min.

The results from the DMA were analysed according to BS ISO 6721-11 [16] (see Figure 2). The glass transition temperature of the GFRP was obtained from the peak in the loss factor. From two tests, the T_g of the GFRP was determined to be 154 °C. In addition, the onset temperature, T_{onset}, was graphically determined from tangents to the storage modulus curve as can be seen in Figure 2. The mean onset temperature of the three tests was 130 °C. These TGA data suggest that considerable reductions in polymer matrix dominated mechanical properties (including shear strength and stiffness) can be expected in the temperature range of 130-154 °C.

The DMA results for the oak were not taken to a high enough temperature to determine a classical T_g value, but suggest that oak is less sensitive to elevated temperatures than GFRP (in terms of reductions in elastic modulus under cyclic flexural loading). This is shown in Figure 2, where the modulus values for oak decrease only mildly at temperatures below 180 °C. These TGA data suggest only minor reductions in flexural stiffness of oak at temperatures as high as 200 °C.

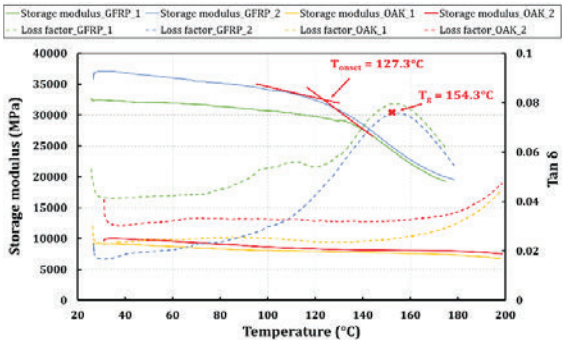

Figure 2: *Storage modulus and loss factor of GFRP and oak dowel materials.*

3.4 OAK MOISTURE CONTENT

Two 60 mm long oak samples were each enclosed in a metal container and dried in an oven at 60 °C for 48 hours. Their mass was measured every 24 hours using a high precision balance, until the change in weight measured was less than 5%. From the two samples, the moisture content of the oak was determined as about 9.0%.

4 MATERIALS AND METHOD

4.1 RIG DESIGN AND FABRICATION

The aim of the rig in this experiment was to load the dowel in shear, up until failure, whilst simulating the embedment of the dowel in timber (Figure 3). The rig was made from steel, due to its superior thermo-mechanical properties in comparison to timber and GFRP and loaded the dowels in double shear. The steel rig provides an embedding constraint and forces the dowel to fail at each of two interfaces [2].

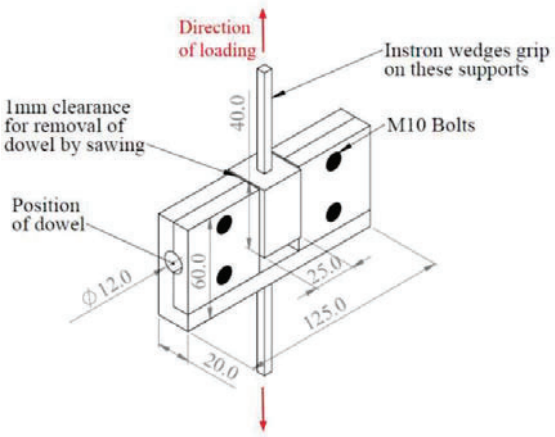

Figure 3: *Isometric view of the double shear steel rig. All dimensions are in millimetres.*

The rig was loaded in tension to help with alignment of the steel elements and dowels during loading. The hole in which the dowels placed was made 12 mm in diameter (later enlarged to fit the timber dowels), for a tight fit around the GFRP dowels.

4.2 TESTING PROCEDURE

The shear tests were performed using an Instron 600LX loading frame with a capacity of 600 kN (Figure 4 a.). The loading frame measures the crosshead displacement of the rig as opposed to the absolute displacement of the dowel. However, given a minimal stress is applied to the steel elements compared to the yield strength of the steel, the deformation of the steel rig and testing frame are assumed to be negligible (aside from seating effects). All results in this paper are presented in terms of displacement measured by crosshead stroke of the testing machine.

GFRP and oak rods were cut into 130 mm long dowels to fit within the rig with their ends protruding to allow observations during testing. All dowels tested at elevated temperature had a 3 mm diameter hole drilled 50 mm into them centroidally along their length so as to fit a T-type thermocouple to measure the dowel internal temperature. For ambient and steady-state tests, a vertical crosshead displacement rate of 2 mm/min was used based on similar experimental programs available within the literature [7,17].

For transient temperature tests, a heating rate of 5 °C/min was used; this facilitated comparatively homogeneous heating of the samples without leading to very long exposure times which may overestimate strength degradation [17]. Two temperatures were recorded (Figure 4 b.) during each test: first, a thermocouple was placed inside the oven to measure air temperature, while a second thermocouple measured the temperature inside the dowel adjacent to the shear failure plane. The second measurement was used to assess critical temperatures for the dowels themselves.

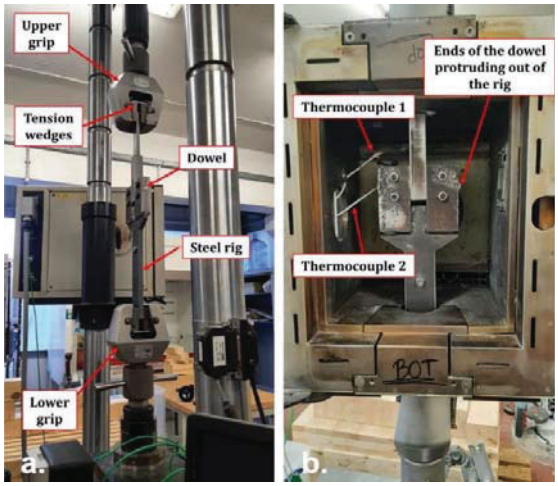

Figure 4: *Experimental set-up: a. rig in Instron frame without oven, b. close-up of the oven.*

4.2.1 Steady state tests

Steady state tests heated the sample to a target temperature before loading it to failure at constant temperature. Four steady state temperatures were selected for each material. For the GFRP, the aim was to study the behaviour of the dowel around the glass transition temperature, since there is a significant drop in mechanical properties around that temperature. A range of temperatures was chosen to observe how this physical change in the material could be correlated to a change in its shear properties at elevated temperatures. A temperature of 120 °C was selected to assess the behaviour just prior to the onset temperature, and a temperature of 140 °C was selected to assess the behaviour just prior to the glass transition temperature. Temperatures of 100 °C and 200 °C were selected since they were respectively well below and well above the glass transition temperature.

For the oak, the aim was to explore the behaviour of the dowel as it loses its moisture content, near to 100 °C. Thus, temperatures of 90 °C and 110 °C were selected. An additional two temperatures, at 140 °C and 200 °C were (semi-arbitrarily) selected to allow comparison between the oak and the GFRP.

4.2.2 Transient state tests

The transient tests loaded the specimens to a target sustained level, and then heated them up while the load remained constant. The critical temperature at failure, under sustained load, was recorded by a thermocouple inside the dowel (as already discussed).

The transient loads were taken (again, semi-arbitrarily) as 20% and 50% of the dowel capacity at ambient temperature. The lower load value was selected from literature as the suggested value to avoid creep-rupture failure in GFRP [18]. The higher loading value was set to allow for meaningful comparisons of the effects of applied stress at credible upper limit in-service levels. From the results presented in the next section, these loads translated to 9.6 kN and 23.9 kN for the GFRP, and 2.2 kN and 5.6 kN for the oak dowels, respectively.

Table 1: *Summary of testing programme.*

5 RESULTS

5.1 AMBIENT TESTS

Tests were performed at ambient temperature (i.e. approximately 20 °C) to establish a comparison baseline for the mechanical properties and behaviour of the dowels within the loading rig used in this study. Tensile load versus crosshead displacement curves are presented in Figures 5 and 6. The **GFRP dowels** (see Figure 5) exhibited a comparatively higher initial stiffness. A first drop load was observed at a crosshead displacement of around 5 mm, followed by a second shorter drop at around 9.5 mm. These drops, as suggested in previous experiments [19], can be attributed to sequential failures of shear planes within the GFRP material. The mean maximum load reached for the GFRP samples was 48.9 kN. To find the average shear strength of the dowel (within this loading rig), the maximum load was divided by two and then by the cross-sectional area of the dowel; this gave a mean shear strength of 219.6 MPa. Despite loading the dowels in shear, in the next section it is explained that that the calculated strength does not actually correspond to pure shear.

The **oak dowels** (see Figure 6) were much less stiff and much weaker and exhibited a more ductile failure. In both tests, the dowels failed at around 8 mm of crosshead stroke, as indicated by the sharp decrease in load. Compared to GFRP dowels, the oak dowels were much weaker. The mean peak load of oak dowels was 11.15 kN which represents only 23% of the peak shear load carried by the GFRP dowels of similar diameters.

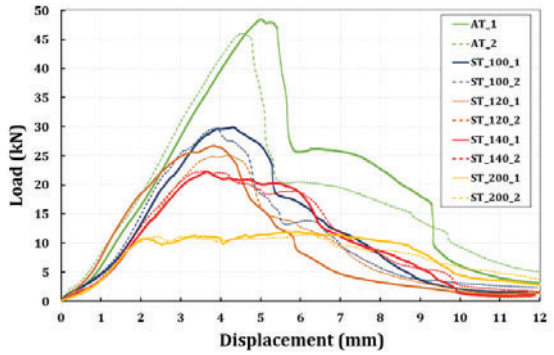

***Figure 5**: GFRP load-displacement curves for steady state tests.*

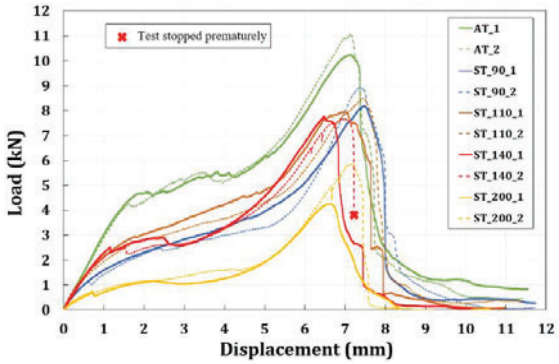

***Figure 6:** Oak load-displacement curves for steady state tests.*

5.2 STEADY STATE TESTS

Figure 5 shows the load versus crosshead displacement curves for GFRP dowels at different steady state temperatures. The reproducibility of the tests was generally reasonable, hence only 2 tests were performed under each condition. Up until 120 °C, and hence before entering the glass transition, the GFRP dowels showed an essentially elastic behaviour until failure, similar to their behaviour at ambient temperature. Furthermore, it can be seen from the slope of the load displacement curves, that the initial stiffness of the dowels remained relatively constant. At 140 °C and 200 °C, the dowels' stiffness drops and the ductility of the response increases. The GFRP dowels change from a comparatively high strength, high stiffness material at ambient temperatures to a lower strength, more ductile material at elevated temperatures.

The general trends for the load versus crosshead displacement curves for oak dowels did not significantly change with increasing temperature (Figure 6). Increases in temperature result in decreases of initial stiffness of the dowels. Failure displacements of the samples however remained unchanged, at around 8 mm at all temperatures.

The loss of strength for both GFRP and oak dowels is presented in Figure 7. Despite the smaller percentage loss of strength of oak dowels at elevated temperatures, comparison of absolute strengths shows that the oak dowels remained considerably weaker than the GFRP dowels for all steady state temperature conditions.

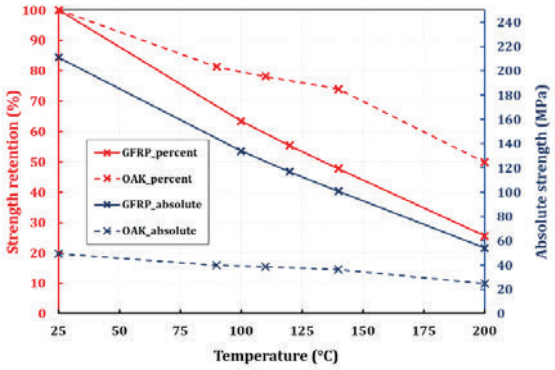

***Figure 7**: Absolute and relative strength of GFRP and oak dowels.*

5.3 TRANSIENT STATE TESTS

For each loading case, Figure 8 shows that the failure temperature was similar between the oak and GFRP dowels. Thus, dowels loaded at 20% of ambient peak strength failed on average at 224 °C. Dowels loaded at 50% failed on average at 105 °C. Despite this similarity, the temperature at failure of oak dowels was on average 14 °C higher than for GFRP dowels. This seems to corroborate findings from the steady state tests, which showed that oak dowels were better at retaining their strength at elevated temperature.

https://doi.org/10.52202/069179-0208

In the 20% loading case, the displacement rate of GFRP dowels increases from 0.13 mm/10°C, until 170 °C, to 1.28 mm/10°C in the rubbery phase of the material, after its glass transition. The oak dowels exhibit a relatively constant increase in displacement until failure, however, they both experience a jump in displacement at 100 °C, which is presumed to reflect the loss of moisture at these temperatures.

In the 50% loading case, the displacement rate of the GFRP dowels is maintained relatively constant until a sudden failure around 100 °C. The oak dowels exhibit a more progressive behaviour to failure. Indeed, between 30 °C and the failure temperature, the oak dowels show a crosshead displacement of 4.4 mm; this is versus a 2 mm displacement for the GFRP dowels.

In addition, between 30 °C and 80 °C, all dowels have similar displacement versus temperature traces, except the oak dowels in the 50% loading case which showed significantly higher deflections at temperatures well below 100 °C.

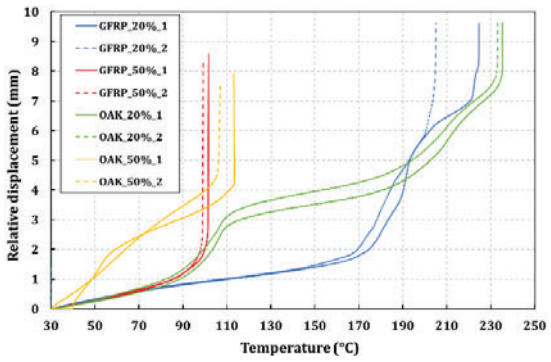

Figure 8: *Transient state analysis for oak and GFRP dowels.*

5.4 SAMPLE OBSERVATION

The GFRP and oak dowels tested in steady state conditions at 140 °C, are presented in Figure 9. The GFRP dowels exhibited signs of delamination at their edges, which is attributed to interlaminar shear failure. On the failure planes, on each side element, it can be seen that the fibres on the top half of the dowel were severed in the transverse axis, whilst the fibres in the bottom half were bent upwards. This behaviour suggests that, during loading, the dowels experienced both transverse shear and bending. Since GFRP is weaker in shear than in tension, it can be assumed that the top fibres in the dowel failed in shear, whilst the bottom fibres, loaded in tension, continued to carry some of the load until fibre failure. This test setup therefore fails to capture "pure" shear, and the true loading condition of the dowels is much more complex as the crosshead displacements grow.

The oak dowels also exhibited signs of a shear/bending behaviour: curvature of the central element, cracks in the bottom part of the side element, cracking of the top fibres and compression of the bottom fibres in the central element. In addition, oak dowels showed strong discolouring at 200 °C, possibly indicating the onset of pyrolysis reactions (Figure 9), as should be expected at these temperatures.

Figure 9: *Failed samples, from top to bottom: GFRP in steady state at 140 °C, oak in steady state at 140 °C, oak in steady state at 200 °C.*

6 DISCUSSION

6.1 INCREASE IN DUCTILITY AT ELEVATED TEMPERATURES

The steady state and transient results show a ductile failure mode at elevated temperatures for both the GFRP and oak dowels. For the GFRP dowels, this represents a net change of behaviour from ambient conditions, characterised by a high stiffness. Indeed, at 200 °C, the dowels maintained their peak load capacity until a crosshead displacement of 9 mm, which represents 3/4 of their nominal diameter. Ambient shear tests from the literature [20], report a maximum test load carried between a fibre displacement of 1/4 and 1/3 of the rebar diameter for GFRP dowels. This difference in deformations is evidence of the increased ductility (and reduced stiffness) of the GFRP at elevated temperatures.

Furthermore, due to the polymeric nature of the GFRP's matrix, the mechanical behaviour of the dowel is greatly influenced by its glass transition. However, the comparison of DMA and steady state results, suggests that the onset temperature is a better indicator of behaviour change than the glass transition temperature determined via peak loss factor. Figure 5 shows that, at 140 °C, the GFRP dowels had already transitioned to a more ductile failure mode at temperatures 14 °C below the glass transition temperature.

The oak dowels exhibited no significant change in their behavioural trends between 25 °C and 200 °C. However, the peak shear strength is notably reduced at 200 °C. In addition, at 200 °C, the oak dowels experienced a sharp increase in loss factor (see Figure 2). Further research is required to fully understand and explain the changes in properties of oak dowels at 200 °C.

https://doi.org/10.52202/069179-0208

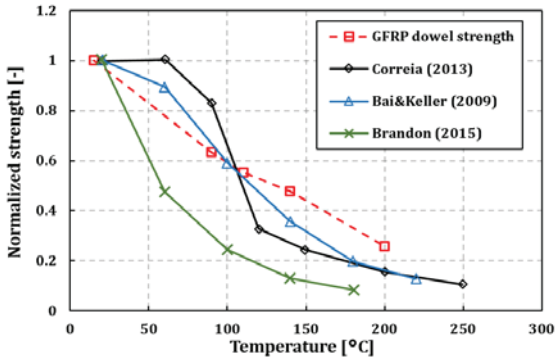

Figure 10: *GFRP dowel strength against literature values of interlaminar shear strength with temperature [17,21,11].*

6.2 SIGNIFICANCE OF BENDING IN DOWEL FAILURE

The study of the failed dowels, for both GFRP and oak, highlighted the significance of bending in their failure. In particular, curving of the fibres in the central oak element, and delamination of the top layers of the GFRP dowel are signs of a combined shear and bending mechanism. As such, results from this study are not in complete agreement with findings from the literature which test dowels in pure shear or pure bending.

From Figure 10, at higher temperatures, the GFRP dowels used in the current study appear to retain more of their strength at higher temperatures than values of interlaminar shear strength obtained for GFRP in studies found in the literature. It is considered likely that, upon loading at elevated temperatures, the dowels – both GFRP *and* oak – first failed essentially in shear, with fibres in the bottom part of the dowel on the tension side continuing to carry the load at larger crosshead displacements up until failure (i.e., a combined shear and flexural mechanism). The choice of testing rig is hence a determining parameter as it influences the amplitude of bending experienced by the fastener. Further, embedding tests of the dowel in a timber element are necessary to assess the degree of bending which non-metallic dowels are able to achieve. Indeed, the current study has not addressed whatsoever the interactions between dowels and timber elements that would undoubtedly be relevant in the elevated temperature performance of a dowelled timber connection (involving the use of any type of dowel, whether oak, GFRP, or indeed steel). Additional research is required to study such issues before GFRP dowels can be confidently applied in connections in timber structures requiring fire resistance.

6.3 COMPARISON OF METALLIC AND NON-METALLIC DOWELS

Figures 7 shows that both types of dowels experienced a loss of strength at elevated temperatures. At 200 °C, the GFRP and oak dowels retain 25% and 50% of their ambient strength, respectively. In comparison, steel shows no reduction of its effective yield strength until about 400 °C, according to EN 1991-1-5 [22]. However, the increased ductility of non-metallic fasteners, which leads to the more progressive failure of the dowel, may present significant advantages in timber connections.
In addition, at elevated temperature steel fasteners, which have a comparatively high thermal conductivity as compared with either oak or GFRP, will conduct heat into a connection and may lead to a loss in strength due to accelerated in depth heating and/or charring of the surrounding timber.

In a ductile failure, the fastener externalises strain energy by means of cracking or displacement, and transfers the energy to the surrounding timber. Since the stiffness of the non-metallic dowel is more compatible with timber than steel [2], the surrounding timber can absorb the energy released by the fastener and experience ductile deformations. Since the stiffness mismatch is reduced between the fastener and the timber, the likelihood of a brittle failure of the connection is thus reduced. It can thus be suggested that, with non-metallic dowels, the failure of the connection at elevated temperatures is a combined failure of the fastener and embedding timber instead of an inefficient and ultimately disadvantageous use of the strength of the metallic fastener.

6.4 DESIGN CONSIDERATIONS

Current timber fire protection strategies typically rely on encapsulation [23]; this aims to protect a connection by ensuring that heat does not reach the fasteners too quickly. However, this strategy leads to an increase in material and weight of the connection, as well as being aesthetically undesirable in many cases. Non-metallic connections, due to the low thermal conductivity of the fasteners, are less susceptible to elevated temperatures. By quantifying the performance of non-metallic dowels at elevated temperatures, design of connections using non-metallic dowels can become a more realistic option.

For GFRP dowels, if adequate protection is provided to the connection to minimise heat exposure of the fastener and ensure that the temperature in the dowel remains below the glass transition temperature of the material, conventional elastic design can perhaps be used, taking the strength of the dowel obtained at 120 °C, or before the onset of glass transition. This strength value represents 55% of the strength of the dowel at ambient temperature.

6.5 FUTURE WORK

The aim of the research presented in this paper was to study the shear behaviour of oak and GFRP dowels. However, in this process, the influence of the embedding timber on the failure of the connection was removed. Further embedding tests, including a direct measurement of the strain of the fastener within embedding timber should be conducted to assess the behaviour of full dowelled connections.

The steady state study should be complemented with more temperatures, especially between 150 °C and 180 °C for the GFRP, to observe the behaviour of the dowel just after its glass transition. In addition, different loading and heating rates should be explored. Finally, extensive modelling research is required to translate the behavioural observations presented in this thesis, into adequate design rules to improve the fire performance of non-metallic dowelled connections in timber structures.

7 CONCLUSION

This paper has explored the behaviour of GFRP and oak dowels at elevated temperatures to initially assess their potential as a replacement for steel in timber connections. The dowels were tested in a steel rig which was designed to simulate the behaviour of a connection. Through a series of steady state and transient state elevated temperature tests, the following preliminary conclusions were obtained:

- The failure of both oak and GFRP dowels was by a combination of bending and shear failure at elevated temperatures. This led to the loss of interlaminar shear strength for GFRP dowels, and failure of fibres in tension for oak dowels.
- At 200 °C, GFRP dowels retained only 25% of their ambient temperature shear strength, whereas oak dowels retained 50%. Despite this less severe loss in strength, oak dowels were significantly weaker than GFRP for all tested temperatures.
- Even though GFRP and oak dowels are significantly weaker than steel dowels, their progressive failure at elevated temperatures – as well as their lower stiffness even at ambient temperatures – increases their compatibility with embedding timber; this may lead to a beneficial more ductile failure of non-metallic dowelled connections.

The non-metallic dowels tested in this study appear to represent feasible alternatives to metallic dowels for some timber connections, and in particular appear to provide compelling advantages for architecturally expressed connections in mass timber structures (subject to considerable additional research).

FIRE PERFORMANCE OF PENETRATIONS IN GLULAM BEAMS: A PRELIMINARY STUDY

Laura Hasburgh[1], Keith Bourne[2], David Barber[3]

ABSTRACT: Glue laminated timber (glulam) is an engineered wood product composed of wood laminations bonded together with durable adhesives. Glulam is versatile ranging from simple, straight beams to complex, curved structural members and are used in a variety of applications including residential and commercial construction where they are often exposed due to the timeless aesthetic of wood. Glulam beams are also resource-efficient and offer designers highly predictable structural and fire performance when used in accordance with design specifications. However, factory-cut or field modifications to glulam beams, such as notching and drilling for routing piping and ductwork, has become common practice, which has the potential to impact structural integrity. There are prescriptive recommendations for these unplanned penetrations to ensure structural capacity remains intact but, in the event of a fire, the field modifications may enlarge and further reduce the beam's cross-section. Here, we present an experimental method to evaluate the char rate and growth of various standard-fire exposed penetrations in glulam beams.

KEYWORDS: Glulam, penetration, char depth, fire performance

1 INTRODUCTION

Structural glue-laminated timber (glulam) beams are engineered building components manufactured from specially identified and placed lumber laminations of varying strength and stiffness. Because of their strength and ability to be specified for unique situations, glulam beams are often highly stressed under design loads and alterations to the beams could result in failure to carry these loads.

Prior to or during construction and installation of glulam beams, it has become common practice to drill horizontal penetrations, also known as horizontal holes, to allow building services (e.g., pipes, ducts, cable trays, etc.) to run through glulam beams such as those shown in Figure 1. Whether factory-cut or field-modified, these penetrations remove wood fibre, reducing the cross-sectional area of the beam at that location. This results in strength reductions and localized stress concentrations [1]. Because of these potential issues, prescriptive recommendations based on a combination of practical experience and engineering analysis for in-field penetrations can be found in a Technical Note S560J published by APA – The Engineered Wood Association [2]. Several investigations have evaluated the fracture behaviour and design of glulam beams with both round and rectangular penetrations that support the recommendations by APA including [3 – 6]. Non-critical zones for simply supported beams are identified in Technical Note S560J as portions of a glulam beam where the stresses are less than 50% of the design bending stress and design shear stress. Additional design guidelines for penetrations that exceed the guidance provided in S560J, Technical Note V700B [7] provides an analytical tool and engineering equations to ensure the structural integrity is not compromised.

Methods for calculating the fire resistance ratings of structural building members are specified by building codes and require the member to endure a specified fire without loss of its loadbearing capabilities. The codified procedure to calculate the fire-resistance ratings for exposed mass timber, such as glulam beams have allowed their use in fire-rated buildings. This mechanistic approach, found within the National Design Specification for Wood Construction (NDS) [8] and the Fire Design Specification for Wood Construction [9], applies to all wood structural members designed per NDS including structural composite materials such as glulam. In this method, the engineering calculations of the ultimate load capacity are adjusted to take into consideration the reduced dimensions with time due to the formation of char. Nominally, a char depth of 38 mm at 1 hour is used for exposed (i.e., no fire protection applied) solid-sawn and structural glued-laminated softwood members with a 20% increase to account for rounding at the corners and loss of strength in the preheated zone located just beyond the char layer.

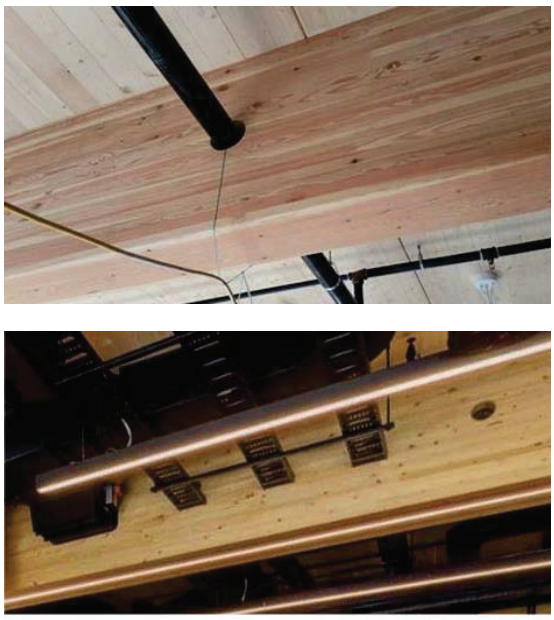

Figure 1: *Glulam beam with field penetrations for a pipe (top) and cable trays (bottom). Photos provided by Barber.*

Firestopping for through-systems do exist, but these systems are applicable to penetrations through fire-rated wall and floor assemblies and the fire testing is conducted from a single direction [10]. This fire testing is not applicable for glulam beams, which are typically exposed on three sides.

While the fire resistance of non-modified beams is well documented and the structural implications of penetrations in glulam beams have been addressed, the intersection of these issues has not been evaluated. The char rates used to calculate fire resistance are typically only applied to the exposed sides of a beam and do not account for penetrations through a beam that may widen due to charring during a fire event.

Here, the method used to expose glulam beams with various penetrations sizes and shapes to a standard fire is presented along with char depth analysis techniques. Additionally, preliminary results pertaining to the increase in penetration size due to charring are provided.

2 MATERIALS AND METHODS

2.1 MATERIALS

A total of six Douglas-fir (*Pseudotsuga menziesii*) glulam beams with dimensions of 343 mm deep (10-ply) by 175 mm wide and 3.66 m long were used. Two of the beams were laminated with a phenol-resorcinol-formaldehyde (PRF) adhesive while the other four were manufactured with a polyurethane (PUR) adhesive. Because the beams were unloaded, the differences in adhesives did not affect the charring around the top and sides of the penetrations.

Three beam configurations (A, B, and C) were designed with a range of penetration sizes and shapes. The dimensions and type of the penetrations for each beam configuration are provided in Table 1 and illustrated in Figure 2. There were three types of round penetrations (small, medium, and large pipes) and two rectangular penetrations (small cable tray and large duct) tested. These penetrations were cut along the centreline of the depth of the beam (x-y plane). It is important to note that the penetration configurations for these beams do not conform to the design guidelines for holes/notches for the beams used and, as such, this study focused on the expansion of the penetrations due to fire exposure and not structural integrity. The penetrations were strictly sized and placed such that the expansion of the holes would not interfere with each other and associated thermocouples. Additionally, the penetration configuration optimized the experimental space in the furnace while allowing replicates of each penetration type.

Table 1: *Beam penetration configurations*

Beam ID	Penetration Shape	Penetration Size (mm)	Insert or empty
A1	large round	Ø168	empty
A1	medium round	Ø 139.7	empty
A1	small rectangular	76 x 177.8	empty
A1	small round	Ø 88.9	empty
A2	large round	Ø 168	insert
A2	medium round	Ø 139.7	insert
A2	small rectangular	76 x 177.8	insert
A2	small round	Ø 88.9	insert
B1	large rectangular	127 x 330	insert
B1	large round	Ø 168	insert
B1	small round	Ø 88.9	insert
B2	large rectangular	127 x 330	empty
B2	large round	Ø 168	empty
B2	small round	Ø 88.9	empty
C1	large rectangular	127 x 330	insert
C1	medium round	Ø 139.7	insert
C1	small rectangular	76 x 177.8	insert
C2	large rectangular	127 x 330	empty
C2	medium round	Ø 139.7	empty
C2	small rectangular	76 x 177.8	empty

Each penetration type was separated by at least 305 mm (12 inches) to reduce potential interactions during the fire exposure, allowing for up to four penetrations per beam.

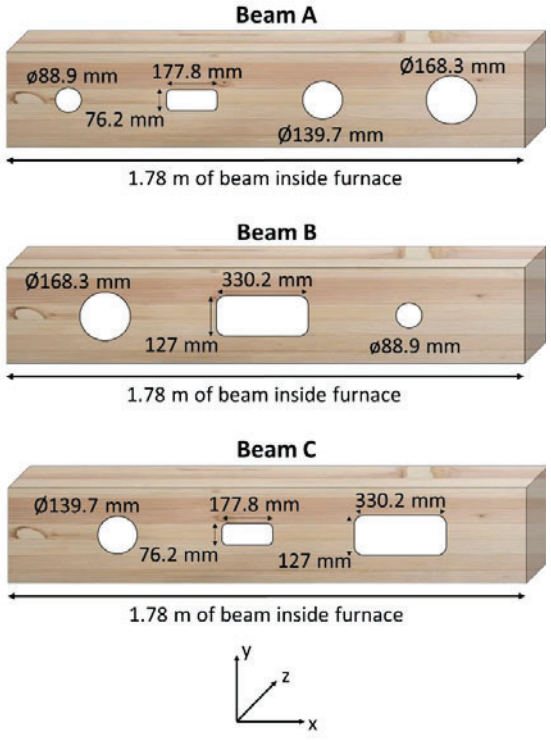

Figure 2: *Glulam beam types with penetration layout: A (top), B (middle) and C (bottom).*

To evaluate the effect of a penetration with equipment through it, two of each beam configuration were run: one with building service components inserted through the penetrations during the fire test and the second with empty penetrations. For the tests with building service components in-place the components were secured with chains as shown in Figure 3. When an insert was included through the beam, a gap of at least 12.7 mm (1/2 inch) around the insert was maintained with sizes of inserts provided in Table 2.

Figure 3: *Glulam beam (Type C) with penetrations for a pipe, cable tray and duct (left to right).*

Table 2: *Building service component details*

Hole Shape	Hole Size (mm)	Insert details	
		Material	Size
large round	Ø168	schedule 40 steel pipe	141 mm diameter with 6.5 mm wall (nominally 5-inch)
medium round	Ø 139.7	schedule 40 steel pipe	114 mm diameter by 6 mm wall (nominally 4-inch)
small round	Ø 88.9	schedule 40 steel pipe	60 mm diameter by 4 mm wall (nominally 2-inch)
large rectangular	127 x 330	galvanized steel duct	102 mm by 305 mm (4 by 12 inches) wall thickness of 0.4 mm (0.02 inches)
small rectangular	76 x 177.8	Cable tray with 5 mm (0.2 inch) steel wire on a 50 mm by 100 mm (2 by 4 inch) with an electro zinc finish	150 mm x 50 mm (6 by 2 inches)

2.2 METHODS

2.2.1 Instrumentation

To obtain the temperature profile around a penetration, 28 thermocouples made in-house from 30-gauge type K wire (Omega GG-K-30-SLE) were embedded in the glulam both above and on each side of every penetration. To install the thermocouples, 2.4 mm (3/32 inch) diameter holes were drilled from the top of the glulam beam to known depths and set distances from each penetration.

For the thermocouples installed on the side of a penetration, arrays of four thermocouples starting at 25.4 mm (1 in) from the penetration edge and spaced at 12.7 mm (1/2 inch) were installed along the centreline of the beam in the x-direction (Figure 4). Above the penetration, four thermocouples were installed along the centreline of the penetration in the z-direction. These four thermocouples started at the top edge of the penetration and were spaced at either 25.4 mm (1 inch) or 12.7 mm

https://doi.org/10.52202/069179-0209

(1/2 inch) in the y-direction and 12.7 mm (1/2 inch) in the z-direction. This installation pattern ensured that the thermocouples were parallel to the isotherm/char front for the side arrays, which has been shown to provide more accurate measurements of temperature. However, the thermocouples arrays above the penetrations were perpendicular to the isotherm. To reduce the impact of this on the data, the holes were filled with fire caulk after the thermocouples were inserted. In addition to the thermocouple data, after the specimens were exposed and cooled, they were sawn and physical measurements of the remaining cross-section were taken to determine the final char depth at 90 minutes.

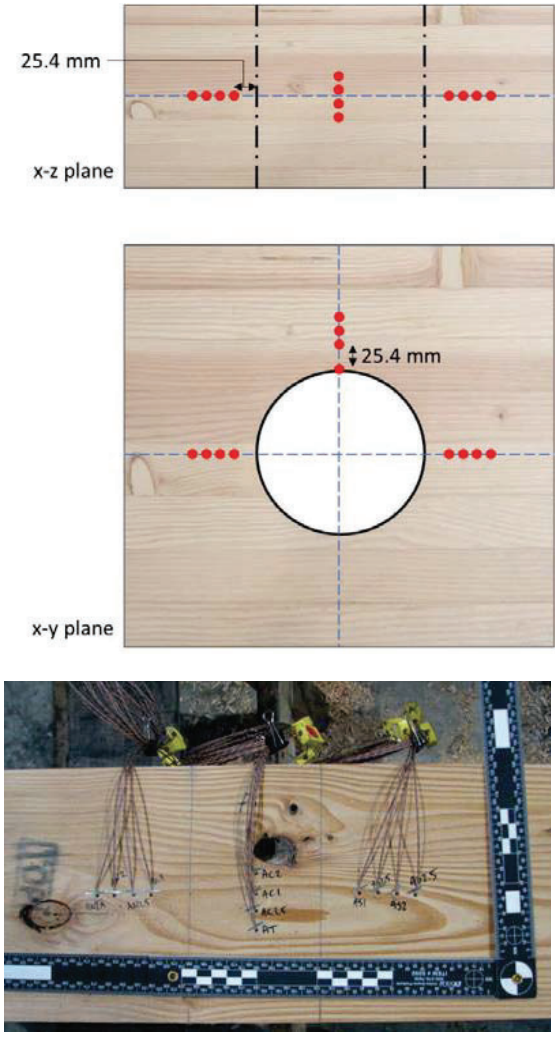

Figure 4: *Top: Schematic of thermocouple placement for a round penetration (not to scale) and Bottom: top of glulam specimen with thermocouples installed.*

2.2.2 Test Furnace

The glulam beams were tested in an intermediate-scale horizontal furnace and subjected to the standard time-temperature curve specified in ASTM E119 [11]. The furnace at the Forest Products Laboratory (FPL) has interior dimensions of 1.8 m long, 1.1 m wide, and 1.3 m high. The furnace has eight diffusion-flame natural gas burners on the floor and all air for combustion was provided by natural draft through vents at the bottom of the furnace. The furnace was controlled via six capped furnace thermocouples located 305 mm from the furnace lid. Approximately 1.78 m of the beam length was exposed to fire within the furnace with 0.94 m on each side of the beam not exposed to the fire. To avoid uneven exposure near the furnace walls, all penetrations were located within the middle 1.5 m of a beam as illustrated in Figure 3. A non-combustible lid was designed such that the top of the beam was not exposed to the fire (Figure 5).

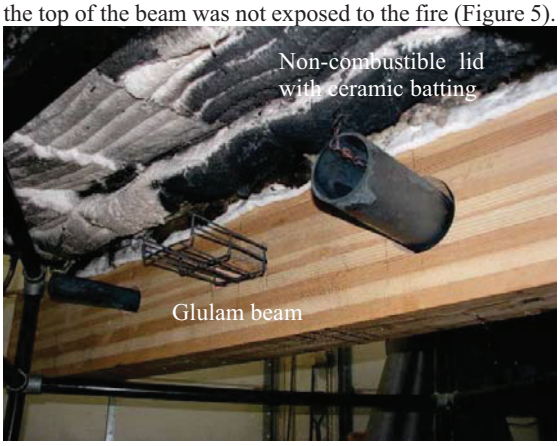

Figure 5: *Glulam beam with non-combustible lid protecting the top of the specimen prior to being placed in the furnace.*

Each beam was exposed for a duration of 90 minutes. The tests were terminated by removing the specimen, extinguishing the fire with water, and scraping all char off to halt smouldering combustion. Figure 6 illustrates these steps through the removal of a burning glulam beam from the furnace, an extinguished beam, and a beam with the char removed for a 127 mm by 330 mm rectangular penetration in beam B that had a duct in place during the fire test.

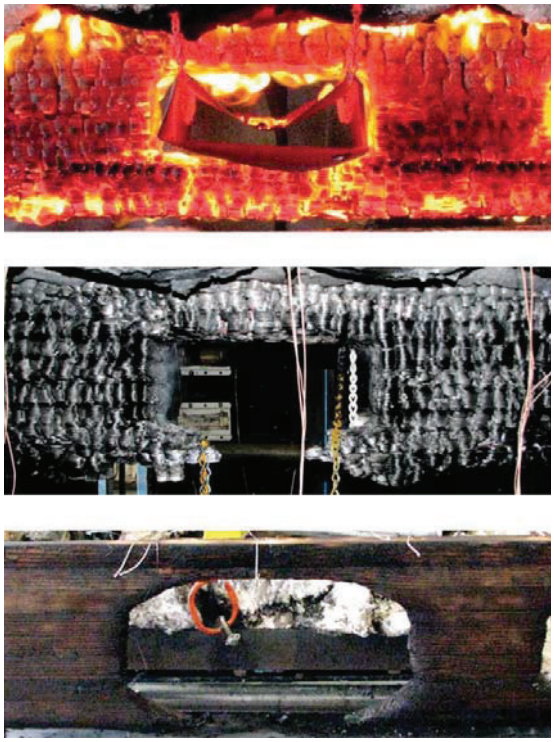

Figure 6: *Image of duct penetration immediately after removal from the furnace (top), once extinguished/cooled (middle), and with the char layer scrapped off (bottom).*

3 RESULTS

During the experiments, the thermocouple data allowed the char front to be monitored by using the commonly-accepted 300°C isotherm as the temperature when wood converts to char [12]. The thermal profile in the glulam beam around a penetration will increase in both temperature and depth with time. As an example, the results collected around one of the penetrations in beam C2 (no building services installed) are provided in Figure 7 with the ASTM E119 standard time-temperature curve provided for reference. The alpha characters identify the penetration type (D = 139.7 mm (5.5 inch) diameter penetration). The side thermocouple arrays are denoted with either N for North or S for South while C indicates the thermocouple array centred above the penetration. The numbers indicate the depth (in mm) of the thermocouple from the exposed interior surface of the penetration.

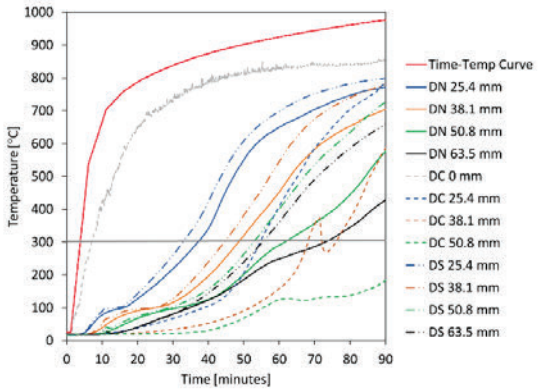

Figure 7: *Thermocouple data around a penetration with a diameter of 139.7 mm (5.5 inch) in beam C2.*

The data in Figure 8 shows that the increase in temperature and the increase in depth at which higher temperatures are measured occurred slightly faster on the side of a penetration versus above the penetration for the specific specimen/penetration configuration. This same trend appears to hold true when evaluating the linear char rates, taken as depth over time (mm/min), for each type of penetration, both with and without pipes/ducts/cable trays in place. Table 3 provides the linear char rates around the perimeter of the various penetrations and with or without a pipe or duct in the penetration. These char rates were calculated for each individual beam/penetration and then averaged for each penetration type at 60 minutes.

Table 3: *Average linear char rates in mm/min for each penetration type.*

Penetration Type	Insert or empty	Char rate at 60 minutes (mm/min)	
		Side	Top[a]
large rectangular	insert	0.65	-
large rectangular	empty	0.92	0.92
large round	insert	0.68	-
large round	empty	0.74	0.47
medium round	insert	0.58	-
medium round	empty	0.99	0.54
small rectangular	insert	0.66	0.48
small rectangular	empty	0.67	0.62
small round	insert	0.51	-
small round	empty	0.69	-

[a] For five tests, the thermocouples above the penetration did not reach a temperature of 300°C at 60 minutes. As such, no data is available.

The results in Table 2 can be compared to the standard nominal char rate of 0.635 mm/min at 60 minutes. Most

https://doi.org/10.52202/069179-0209

of the penetrations were comparable to the standard char rate. However, the medium to large penetrations without building component inserts have much faster char rates between 0.74 mm/min and 0.99 mm/min.

4 CONCLUSIONS

The perimeter of horizontal glulam beam penetrations will increase during a fire, further reducing the effective cross-section of the member. These preliminary results show the char rate at and around penetrations with building services components installed are near the standard nominal char rate of 0.635 mm/min for glulam beams. Therefore, when designing a structural member, in addition to reducing the overall cross section, an effective penetration size that includes an increase for charring should be considered. The results also indicate that if a horizontal penetration is made for a building service component that is later abandoned, the penetration should be filled with a non-combustible material to avoid rapid increase of the penetration during a fire.

ACKNOWLEDGEMENT

The authors would thank Eleanor Q. Lazarcik for her assistance with conducting the experiments.

CALCULATION METHOD OF COLLAPSE TIME OF WOOD MEMBERS EXPOSED TO FIRE HEATING WITH HEAT AND WATER TRANSFER ANALYSIS: INFLUENCE OF INITIAL MOISTURE CONTENT ON CHARRING RATE AND MECHANICAL PROPERTIES OF REMAINING SECTION OF WOOD MEMBERS

Tatsuro Suzuki[1], Yuji Hasemi[2]

ABSTRACT: This study formulates a method to calculate the collapse time of wood members exposed to fire heating by considering the influence of temperature and moisture content. Moisture content affects the mechanical properties of wood members adversely during fire heating because of an increase in moisture content by water transfer and thermal softening at high temperature; however, the impact on mechanical properties of wood members during fire heating has been previously evaluated with respect to temperature alone. Consequently, this study formulates the calculation of the buckling time of a Japanese zelkova column under two conditions of initial moisture content (13.4% and 30.4%) and compares it with previous experimental results. This study showed that moisture content increased from 13.4% to 20.0% and from 30.4% to 39.1% at most for the two conditions, respectively, during fire heating. The buckling time could be predicted with good accuracy considering the moisture content dependence of Young's modulus. Although the moment of inertia was 1.67 times at 82 minutes when the column buckled in the experiment when the moisture content was high, the buckling time was only 3.5 min later than at low moisture content. Therefore, this calculation results show high initial moisture content increased in the remaining cross-sectional area and decreased Young's modulus significantly.

KEYWORDS: Fire Heating, Wood Members, Moisture Content, Mechanical Properties, Heat and Water Transfer

1 INTRODUCTION

In recent years, large wooden buildings have been constructed worldwide for the purpose of low-carbon construction or utilisation of forest resources. In Japan, high-rise and large-scale wooden buildings have been constructed due to supportive legislation and technological development. Therefore, the prediction of fire resistance of wood members exposed to fire heating has gained importance to improve the credibility of wooden buildings during fire and design appropriately sized members.

Regarding parameters affecting the mechanical properties of wood members during fire heating, not only temperature but also moisture content is important. Moisture content is significant because an increase in moisture content caused by vapourisation, transfer, and re-condensation of water in the remaining cross-sectional area required to bear load. The experiments in [1-3] showed that fire heating caused an increase in the moisture content of the specimens. Such an increase decreases the mechanical properties of wood members even at room temperature. Second, temperature dependence of mechanical properties of wood members increases significantly under the condition of high moisture content due to the thermal softening of lignin and hemicellulose, as shown in [4,5]. Hence, water transfer and moisture content increase by re-condensation, causing a probable decrease in mechanical properties.

Consequently, this study formulates a method to calculate the mechanical properties of wood members exposed to fire heating by considering the influence of temperature and moisture content. First, this study conducts heat and water transfer analysis, which calculates heat conduction and mass transfer. Second, the mechanical properties of wood members were calculated with distributions of temperature and moisture content given by heat and water transfer. Finally, the validity of the calculation was verified by comparing the calculation results and previous experiments' results.

2 METHOD

2.1 OUTLINE

Fig.1 shows the outline of the calculation method of the mechanical properties of wood members with heat and water transfer analysis.

[1] Tatsuro Suzuki, Adjunct Researcher, Waseda University, Japan, tatsuro@suzukikoumuten.com
[2]Yuji Hasemi, Professor Emeritus, Waseda University, Japan, hasemi@waseda.jp

https://doi.org/10.52202/069179-0210

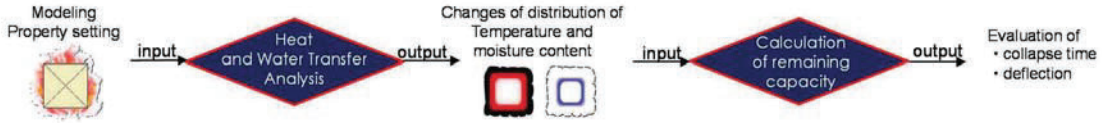

***Figure 1**: The outline of the evaluation method of the mechanical properties of wood members with heat and water transfer analysis*

First, the cross-sectional area of a wood member is divided into finite elements. Moreover, the time variation of the distribution of temperature and moisture content are calculated with heat and water transfer analysis. Second, the remaining ratio of mechanical properties of each element is calculated with those temperature and moisture content. Finally, collapse time or deflection is calculated by adding all remaining

2.2 CALCULATION OBJECT

2.2.1 EXPERIMENTS TO COMPARE

In this study, we compare calculation results with the experimental results in [6] to clarify the influence of initial moisture content on the charring rate and mechanical properties of wood members during fire heating. If the initial moisture content is high, On the on hand, the increase in the latent heat of water causes a decrease in the charring rate. On the other hand, the mechanical properties of wood members decrease under conditions of high moisture content and high temperature. Thereby, high initial moisture content has both positive and negative influences as it causes a decrease in the charring rate and decrease in the mechanical properties of wood members, respectively. In the experiments in [6], specimens in an air-dry state and with high moisture content were heated. Therefore, in this study, we use the initial moisture content as a parameter to calculate the collapse time of wood members due to fire heating and compare the results with the experiments in [6].

Table 1 shows the results of the two experiments in [6]. The buckling time of a full-scale Japanese zelkova cylindrical column was measured during the load heating experiment under the ISO 834 fire heating curve conditions. Before the load heating experiment, the charring rate of a short column was measured during the non-load heating experiment to predict the buckling time in the load heating experiment. Meanwhile, the difference in the initial moisture content levels between the two experiments caused a difference in the charring rate of specimens. Japanese zelkova (Zelkova serrata) is hardwood often used for constructing Japanese shrines and temples.

If the cross-section of a wooden member is large, the interior may continue to remain with a high moisture content because of the difficulty of drying the interior.

2.2.2 CALCULATION CONDITONS

Table 1 shows the calculation conditions with experimental conditions. The initial moisture content in the calculation was set to the same value for each experiment. In the two cases, the mechanical properties of the specimen were calculated by considering and not-considering moisture content dependence, respectively. The diameter of the wood member used in the calculation was the same in both cases, despite the difference in the experiments.

2.3 CALCULATION METHOD

2.3.1 MODEL

Fig.2 shows the calculation model. Heat and water transfer analysis was conducted with a one-dimensional model because the section in the experiment was a circle. The length of the calculation model was half of the experimental diameter since the side of the centre was under adiabatic conditions. Mechanical properties of the specimen were calculated with the assumption that each element has a doughnut-shaped cross-sectional area.

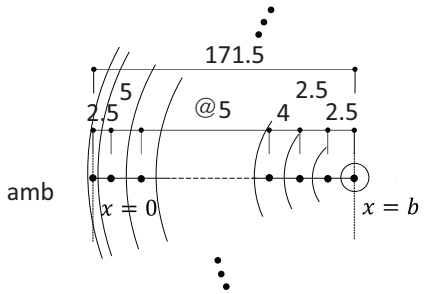

***Figure 2:** Calculation model (Unit: mm)*

2.3.2 HEAT AND WATER TRANSFER ANALYSIS

Time variation of temperature and moisture content are calculated with heat and water transfer analysis developed in [9]. In the calculation method in [9], temperature, moisture content, vapour pressure, and total pressure are assumed to be the four main variables, and their time variations are calculated.

Equations (1) ~ (4) show the basic formulas for calculating the four variables.

Temperature is calculated by considering the influences of latent heat of water evaporation, thermal decomposition, water adsorption/desorption, and heat generation by oxidation. In this study, heat generation is restricted to 0.4 times the volume to represent the time variation of temperature in the experiment. Consequently, this calculation method has the task of accurate temperature prediction.

Moisture content is calculated with the transfer of liquid water and adsorption/desorption. As a matter of fact, the influence of liquid water transfer is insignificant because the transfer speed of liquid water is slow as compared to gas transfer.

The basic formula of vapour and total gas represents mass conservation. Transfer speeds of gases depend on Darcy's row. In Darcy's row, specific permeability differs for each tree species.

(a) Heat transfer

$$\rho_{wood} c \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(\lambda \frac{\partial T}{\partial x}\right) - Q_{desorp} - Q_{evap} - Q_{decomp} + Q_{ox} \quad (1)$$

(b) Water transfer

$$\rho_{wood\ dry} \frac{\partial M}{\partial t} = \frac{\partial}{\partial x}\left(\rho_{wood\ dry} D_w \frac{\partial M}{\partial x}\right) - R_{desorp} - R_{evap} \quad (2)$$

(c) Mixture gas conservation

$$\frac{\partial \varepsilon \rho_g}{\partial t} + \frac{\partial \rho_g u}{\partial x} = R_{desorp} + R_{evap} \quad (3)$$

(d) Vapour conservation

$$\frac{\partial \varepsilon \rho_v}{\partial t} + \frac{\partial \rho_v u}{\partial x} = \frac{\partial}{\partial x}\left(D_v \frac{\partial \rho_v}{\partial x}\right) + R_{desorp} + R_{evap} \quad (4)$$

An increase in the moisture content is represented by the following algorisms: water evaporation in a higher temperature area, vapour transfer, increase in vapour pressure in a lower temperature area, increase in relative humidity, increase in equilibrium moisture content, and increase in adsorption rate. Thereby, moisture content does not increase above the equilibrium moisture content with the calculation method in [9]. However, if the initial moisture content is higher than the equilibrium moisture content, moisture content increases above the equilibrium moisture content possibly.

In this study, the algorism of water condensation was changed based on Equations (5,6).

(i) Adsorption ($P_v \geq P_{v,max}$)

$$R_{desorp} = \frac{\rho_v - \rho_{v,max}}{\Delta t} = \frac{M_v (P_v - P_{v,max})}{R\bar{T}\,\Delta t} \quad (5)$$

(ii) Desorption ($P_v < P_{v,max}$)

$$R_{desorp} = 0 \quad (6)$$

Table 2 shows the boundary conditions. Boundary conditions of every four variables on the unheated surface were set to adiabatic. On the heated surface, the temperature was calculated by considering conduction and radiation. The boundary condition of moisture content was adiabatic because liquid water was not exchanged. For total pressure, ambient total pressure was set to constant. The exchange of vapour pressure was calculated with the vapour transfer coefficient and the difference in vapour pressure via conductive heat transfer.

Table 3 shows the setting of properties for the calculation. Specific humidity was set to 3.96 [10^{-17} m^2/(Pa・sec)], which is the value of Japanese Elm in [16]. This is hardwood and rings porous wood similar to Japanese zelkova.

2.3.3 CALCULATION OF MECHANICAL PROPERTIES

Buckling time was calculated and compared with previous experimental results because the column collapsed due to buckling in the experiment. Buckling time was regarded as the period after which the load-bearing capacity fell below the load. Load-bearing capacity was calculated with Equation (7), and the load was 640 [kN].

$$P_k = \frac{\pi E I}{L_k^2} \quad (7)$$

Young's modulus is calculated with initial moisture content and Young's modulus remaining ratio. Young's modulus remaining ratio is calculated via the equation in

Table 2: *The boundary condition of the calculation (Words in [ ] mean types of boundary conditions)*

[5], which considers the decrease caused by both temperature and moisture content. For instance, Young's modulus remaining ratio of Cryptomeria japonica at 95°C and high moisture content was 0.59, equivalent to that at 200°C and bone-dried state.

Initial Young's modulus was set to 9500 N/mm², which is the same value as the experiments in Case A, and 11020 N/mm², which is calculated by considering the increase by drying as 2% at 1% moisture content increase.

3 RESULTS

3.1 HEAT AND WATER TRANSFER ANALYSIS

3.1.1 TEMPERATURE AND MOISTURE CONTENT

Figs.3,4 show the calculation results of temperature and moisture content at the initial moisture content of 13.7% and 30.4%, respectively.

Regarding temperature, temperature rise stagnates due to the latent heat of water evaporation and thermal decomposition. The temperature fluctuations at high temperatures result from temperature falls when the heat generation of each element stops. In other words, the fluctuation results from the discretisation of the space. Thus, the temperature transition is smooth if the elements are made finer, or in reality.

The influence of the initial moisture content on the charring rate of wooden members due to fire heating can be represented in the calculation. Comparing the temperature transitions under the two cases, the temperature increase was fast at low initial moisture content. Fig.5 shows that the charring rate calculated with temperature reached 260° C. The charring rate was determined as the gradient of the charring depth with respect to the time to reach 260°C when the intercept was set to 0. These values of the charring rate are also shown in Table 1. The difference in the charring rate was caused by the difference in the latent heat of water evaporation. Comparing the charring rate derived from the calculation

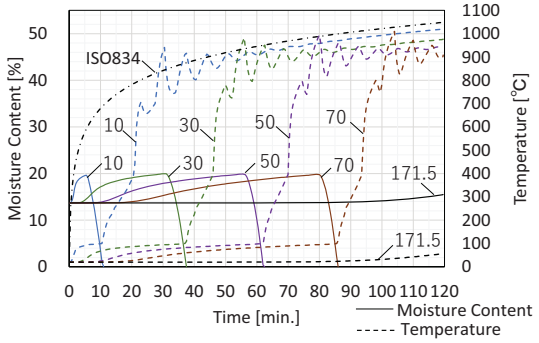

Figure 3: *Results of the calculation of temperature and moisture content at the initial moisture content of 13.7%*
(The values indicate distance from the heated surface)

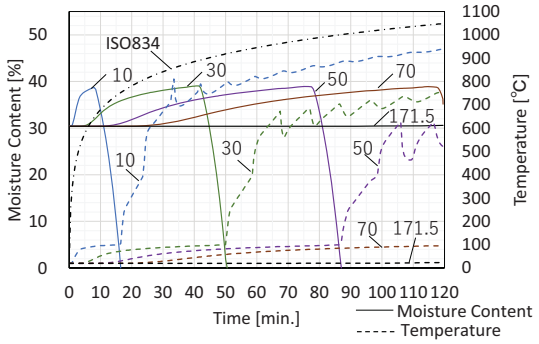

Figure 4: *Results of the calculation of temperature and moisture content at the initial moisture content of 30.4%*
(The values indicate distance from the heated surface)

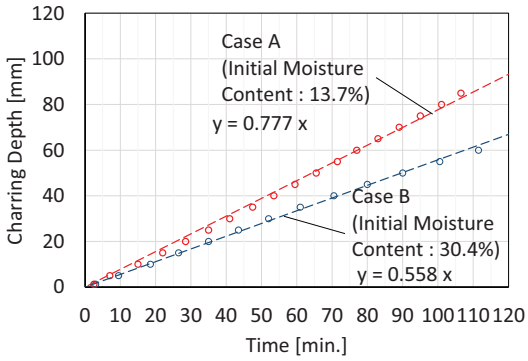

Figure 5: *Calculation results of the charring rates*

and the experiments, the agreement of the results was good. In the two cases, the charring rate was a little higher than the value of the charring rate in the experiments. However, this calculation method should be improved in the future because limits of the heat oxidation made agreement of the charring rate.

Moisture content was increased with temperature increase in the two cases. Maximum moisture content was 20.0% and 39.1%, for the initial moisture content of 13.7% and 30.4%, respectively.

Moisture content of the elements 10, 30, 50, and 70mm from the heated surface increased once and subsequently decreased due to evaporation. Moisture content increased of the elements near the heated surface and, with a

https://doi.org/10.52202/069179-0210

relatively large moment of inertia, decreased the overall bending stiffness. Conversely, the moisture content of the element closest to the non-heated surface also increased gently. Moisture content increased in the area away from the heated surface and at a relatively low temperature, indicating a decrease in the mechanical properties due to moisture content in the areas bearing the load during and after fire heating.

In the calculation method formulated in this study, the maximum moisture content of each element immediately before evaporation was almost constant for each initial moisture content. The amount of increase in moisture content was 19.6 ~ 20.0% and 38.6 ~ 39.1% by the end of evaporation for initial moisture content of 13.7% and 30.4%, respectively. These upper limits of moisture content increase were determined by water adsorption, temperature increase, vapour pressure increase, and difference in vapour pressure decrease. Specifically, when water adsorbs, the latent heat gradually increases the temperature until just before evaporation. Vapour does not flow into the element itself when vapour pressure becomes higher just before evaporation. Moisture content increases only by a small extent at the temperature just before evaporation. As evaporation begins, moisture content starts decreasing. Since it takes a long time for evaporation to start, the amount of increase in moisture content was greater with higher initial moisture content.

These time variations of moisture content should be compared and verified with experimental results. However, the method that can measure local moisture content with electric resistance cannot accurately measure at conditions of high moisture content. For instance, the upper measurement limit in [2] is shown as 30%. Thus, the measurement method at high moisture content conditions should be developed in the future.

3.1.2 TOTAL PRESSURE AND VAPOUR PRESSURE

Figs.6,7 show the calculation results of total pressure and vapour pressure at the initial moisture content of 13.7% and 30.4%, respectively. The stepped transitions resulted from sudden falls of vapour pressure when evaporation in each element was over. Since these discontinuous behaviours are due to the discretisation of the space, vapour transitions are smooth if the elements are made finer or in reality.

Vapour pressure is the highest in the element where evaporation occurs, and the vapour transfer is caused by the difference in vapour pressure. Vapour transferring to a heated surface is released to ambient air. Vapour transferring to an unheated surface causes an increase in the relative humidity to 100% and water adsorption.

Total pressure is the same as the atmospheric pressure at initial moisture content conditions and increases with vapour pressure. Total pressure of the element closest to the unheated surface gradually increases because the boundary condition of the unheated surface was similar to the adiabatic condition.

Comparing the two cases, the maximum values of vapour pressure are almost equal because vapour pressure is limited by saturated vapour pressure, and saturated vapour pressure is calculated with temperature and evaporation

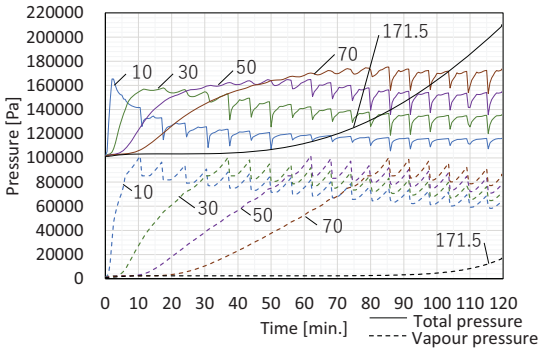

Figure 6: *Results of the calculation of total pressure and vapour pressure at the initial moisture content of 13.7%*
(The values indicate distance from the heated surface)

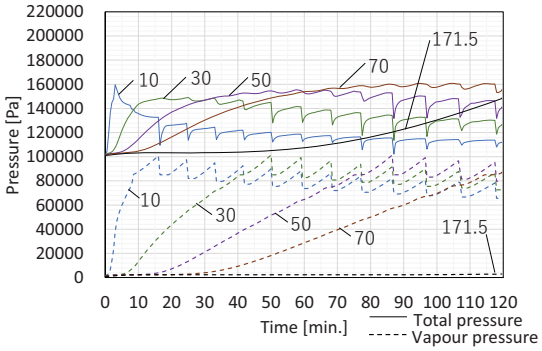

Figure 7: *Results of the calculation of total pressure and vapour pressure at the initial moisture content of 30.4%*
(The values indicate distance from the heated surface)

temperature, which is the same in the two cases. Total pressure of the element closest to the unheated surface at the initial moisture content of 13.7% is higher because temperature and saturated vapour pressure are higher.

3.2 MECHANICAL PROPERTIES

3.2.1 MOMENT OF INERTIA

Fig.8 shows the time variation of the moment of inertia in the two cases. Sudden falls of the moment of inertia occur because mechanical properties are considered 0 when the temperature of each element reaches 260°C.

The moment of inertia remains low as the initial moisture content is low. Comparing the moment of inertia at 82 minutes when the column buckled in the experiment, Case

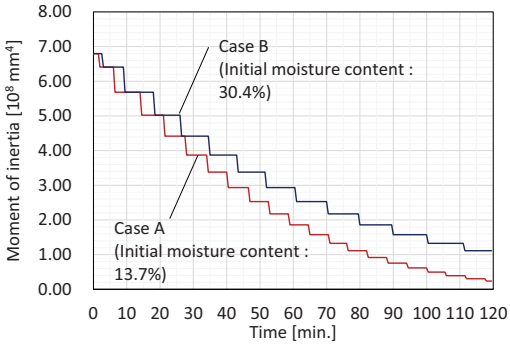

Figure 8: *Calculation Results of time variation of the moment of inertia*

https://doi.org/10.52202/069179-0210

B has 1.67 times more remaining than Case A.

3.2.2 BUCKLING TIME

Figs.9,10 shows the calculation results of buckling time at the initial moisture content of 13.7% and 30.4%, respectively. Buckling time is also shown in Table 1. Buckling time in the calculation was regarded as the period after which the smoothed curves of the load-bearing capacity fell below the load. The smoothed curves were drawn in order to estimate buckling time accurately. The smoothed curves were the result of averaging the calculation results of a total of 11 points every 30 seconds, adding 5 points before and after. Not-smoothed calculation results fell suddenly with changes in the moment of inertia. Additionally, elements close to the heated surface may temporarily recover Young's modulus due to evaporation. If the space is not discretised, the load-bearing capacity of the entire cross-section will not recover temporarily but will gradually decline.

There are two calculation results in Figs.9,10. The blue plots were calculated by considering temperature and moisture content dependence on Young's modulus.

Conversely, the red plots considered only temperature dependence in such a way as to evaluate the influences of moisture content. These temperature and moisture content are derived from the calculations of heat and water transfer in Section 3.1.

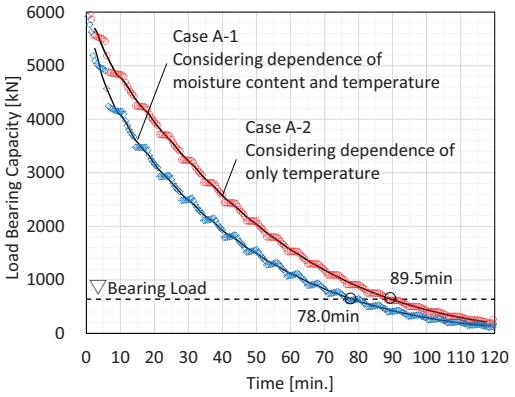

Figure 9: *Calculation results of buckling time at the initial moisture content of 13.7%*
(The plots indicate calculation results every 30 seconds, and the solid lines indicate calculation results after smoothing)

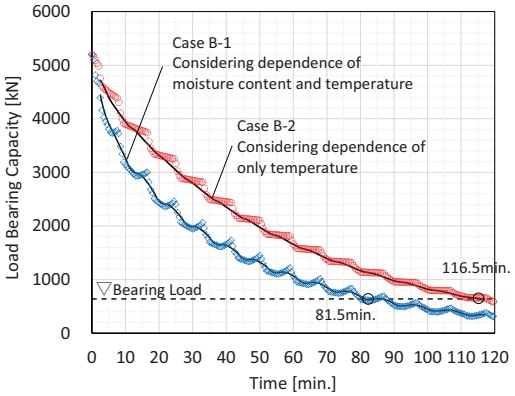

Figure 10: *Calculation results of buckling time at the initial moisture content of 30.4%*
(The plots indicate calculation results every 30 seconds, and the solid lines indicate calculation results after smoothing)

In both cases, the load-bearing capacity decreased when moisture content dependence was considered. The longest buckling time was 116.5 min in Case B-2 because the moment of inertia was greater, and moisture content dependence was not considered. Comparing the case with and without consideration of moisture content (Cases A-1 vs A-2 and B-1 vs B-2), the difference in the buckling time was 11.5 min and 35 min at the initial moisture content of 13.7% and 30.4%, respectively. The load-bearing capacity was further reduced at a high temperature and high moisture content; hence the difference in the buckling time was larger when the initial water content was higher.

In Table 1, comparing the buckling time derived from the experimental results and the calculation in this study (Cases B-1,2 vs the experiment), the buckling time was estimated to be almost the same or slightly earlier with consideration of moisture content. Conversely, for the condition of no consideration of moisture content, the buckling time was evaluated much to be later than that derived from the previous experiments. Therefore, when the initial moisture content is high, the buckling time is assumed to be long except for the condition of consideration of moisture content dependence.

In Fig.10, comparing the buckling time in the case with and without consideration of moisture content (Cases B-1 vs B-2), the difference in buckling time was 35 minutes, and both evaluated the buckling time to be earlier than that derived from previous experiments. The load-bearing capacity was 562kN and 627kN at 82 minutes when the column buckled in the experiment in Cases B-1 and B-2, respectively. This difference is insignificant compared to the difference in the moment of inertia (1.67 times). Although the cross-section remains large due to the high initial moisture content, the decrease in Young's modulus due to the high moisture content is large. Therefore, buckling time does not change significantly.

In conclusion, buckling time can be predicted with heat and water transfer analysis and consideration for moisture content dependence of Young's modulus. Moreover, as a result of the calculation considering the positive and negative influence of moisture content on charring rate and Young's modulus, both effects largely cancelled out in these cases. However, the balance of both effects will change if the calculation conditions change. Considering that Young's modulus decreases as the moisture content increases at room temperature, we conclude that initial moisture content is desired to be controlled in an air-dry state as before.

In the future, the study of other tree species is desired because the behaviour of heat and water transfer and the influence of moisture content differ among tree species. Furthermore, the study of collapse for reasons other than buckling is important to predict the collapse time of wood members other than columns.

https://doi.org/10.52202/069179-0210

4 CONCLUSIONS

This study predicted the buckling time of a Japanese zelkova column exposed to fire heating using heat and water transfer analysis. The results were compared with those of a previous study [6]. The calculations were conducted under two conditions, at the initial moisture content of 13.7% and 30.4%, to evaluate the following positive and negative effects of high initial moisture content: decrease in the charring rate and decreasing of the mechanical properties at a high temperature and high moisture content.

(1) An increase in the moisture content caused by water evaporation, transfer, and re-condensation was represented. Moisture content increased from 13.4% to 20.0% and from 30.4% to 39.1% at most, respectively.

(2) The phenomenon that the higher the initial moisture content, the slower the carbonisation rate was represented by calculation. The agreement between the calculated charring rate and that derived from the previous experiment was good; however, the heat oxidation was intentionally limited so as to reproduce the remaining sectional area.

(3) The buckling time was predicted by considering the dependence of mechanical properties not only on temperature but also on moisture content. Considering the dependence of the mechanical properties of wood members on temperature and moisture content, the calculated buckling times were similar to or slightly faster than the experimental results. Conversely, considering the dependence of the mechanical properties of wood members on temperature alone, the calculated buckling times were longer. Thus, the buckling time should be calculated by considering the moisture content dependence at high initial moisture content.

(4) Under this calculation condition, the effect of the high initial moisture content on slowing down the charring rate and decrease in the mechanical properties of the remaining cross-sectional area of wood members were largely cancelled out by the following results: although the moment of inertia was 1.67 times at 82 minutes when the column buckled in the experiment, buckling time changed by only 3.5 minutes.

In the future, the behaviour of water transfer at high initial moisture content should be measured, compared, and verified after the development of the measurement method. Furthermore, there is a need to conduct this study by considering other tree species; additionally, researchers should also study the collapse of wood members due to reasons other than buckling.

HEAT DELAMINATION IN CROSS LAMINATED TIMBER: INTERMEDIATE SCALE TEST BASED UPON THE NORTH AMERICAN STANDARDS

Samuel L. Zelinka[1], Keith J. Bourne[2], Laura E. Hasburgh[3], Kara Yedinak[4]

ABSTRACT: Currently, the North American standard, ANSI/APA PRG 320: *Standard for Performance-Rated Cross-Laminated Timber*, requires a full-scale compartment fire test to qualify adhesives for use in cross laminated timber (CLT) for structural applications. This test is necessary to determine whether the adhesives will experience heat delamination - a premature adhesive failure during fire that can lead to sudden fire regrowth during the decay phase of a fire commonly referred to as a secondary flashover.

The required full-scale test is cost-prohibitive to adhesive manufacturers when developing new adhesive formulations. This paper presents work performed at the Forest Products Laboratory (FPL) focused on developing a low-cost intermediate scale test used to predict if a new adhesive formulation is likely to delaminate and, therefore, fail the full-scale PRG 320 test. In the FPL method, a 2.44 m long by 610 mm wide CLT panel is exposed to a time-temperature profile in a furnace designed to match the PRG 320 test. Additionally, the mechanical loads are scaled to target the bending moment in the PRG 320 test standard. New findings presented in this conference paper include measurements of the oxygen concentration within the furnace during the test.

KEYWORDS: fire performance of CLT, adhesives for CLT, PRG 320

1 INTRODUCTION

Cross laminated timber (CLT) is being rapidly adopted in North American buildings [1-3]. Changes to the International Building Code (IBC) have allowed increases to the height and area limits for CLT buildings [4-6]. The IBC requires that the CLT complies with the ANSI/APA PRG 320: *Standard for Performance-Rated Cross-Laminated Timber* [7] (hereafter referred to as PRG 320) which specifies test methods and minimum performance requirements for CLT panels.

One unique aspect of the PRG 320 standard that was added in the 2018 Edition is the requirement for a full-scale compartment fire test to demonstrate that the adhesive between laminations does not fail during a fire scenario.

Heat delamination, hereafter shortened to delamination, occurs when the adhesive fails as the bond line is exposed to higher temperatures prior to the char front reaching the adhesive bond line during a fire scenario. In 2017, a series of full-scale fire tests on CLT compartments was conducted. During this test series, delamination occurred in unprotected (exposed) CLT surfaces in four of the 6 tests [8-11]. Based on data from thermocouples embedded in the CLT walls, delamination occurred prior to the char front reaching the bond line. In these tests, delamination resulted in a "second flashover"; a rapid increase in temperature that occurred during the decay phase of the fire after delamination exposed fresh, uncharred wood.

Since a second flashover creates unpredictable conditions during a compartment fire, it was decided that North American CLT must not delaminate during fire scenarios [12]. A test to evaluate adhesive performance at elevated temperatures was developed and adopted as Annex B test of the PRG 320 standard. The Annex B fire test involves a full-scale, non-combustible room with a CLT ceiling in which a natural gas burner creates conditions such that the ceiling temperatures closely match those observed in early CLT compartment fires where delamination was observed [8]. An external mechanical load is applied to the CLT ceiling and an adhesive is considered to pass the Annex B test if delamination is not observed during the 4-hour test. Following the development of the Annex B test, more large-scale fire testing has been conducted with adhesives that passed the Annex B test and delamination resulting in secondary flashover was not observed[13,14].

Despite the straightforward nature of the PRG 320 Annex B test, the test method does have some drawbacks. The biggest drawback of the method is the cost. The test is costly to run because it requires a full-scale compartment

to be constructed for each test. Furthermore, since the test geometry is different from ASTM/ISO standards, it requires laboratories to build a unique set up prior to testing. These costs have made it difficult to screen new adhesive formulations.

Previous work by the authors introduced an intermediate furnace scale test that could be used to screen new adhesives or CLT panel layouts [15]. (See Section 2 for more details on this method). The previous work evaluated CLT panels constructed with identical adhesives and layups at two scales (intermediate- and full-scale). The intermediate-scale tests had approximately 1 m^2 of exposed CLT whereas the full-scale tests conducted in accordance with PRG 320 has approximately 12 m^2 of exposed CLT [16]. In these tests, panels that delaminated at the full-scale were also observed to delaminate at the intermediate-scale. Likewise, no delamination events were observed in intermediate-scale panels that passed the full-scale test. Finally, temperatures measured within the furnace closely followed temperature profiles measured in the full-scale PRG 320 compartment fire tests.

While the previous work of Zelinka and Bourne [15] showed comparable results between the intermediate- and full-scale tests, several important questions remain regarding the utility of the method and its correlation to full-scale tests. In this paper, we examine the oxygen concentration within the furnace during the intermediate-scale tests and compare it to data collected in full scale compartment fire testing. It is part of a larger effort to develop a low-cost intermediate scale test used to predict if a new adhesive formulation is likely to fail the full-scale PRG 320 test.

2 MATERIALS AND METHODS

2.1 Materials

Several different types of CLT were tested. The adhesives used, lumber species, lumber grade, and performance in the full-scale test are included in Table 1. All specimens were 5-ply with a nominal thickness of 175 mm. The specimens were cut to 610 mm wide by 2.44 m long. Specimens were placed on top of a 1.83 m long furnace such that approximately 1.11 m^2 of mass timber was exposed to the fire in the test. Three replicates were tested for each panel configuration.

Table 1: *Panel information for the mass timber panels tested in both the intermediate and full-scale delamination test.*

Adhesive[1]	Species/grade[2]	Pass full-scale test?
MF	Douglas fir/larch V1	Y
PUR-1	SPF/E1	N
PUR-2	SPF/E1	Y
PUR-3	SPF/V2	Y

[1]MF= melamine formaldehyde, PUR=polyurethane
[2]SPF=spruce, pine, fir species group. Grades E1 and V2 are defined in the PRG 320 standard [7].

2.2 Specimen Instrumentation

Thermocouples were installed in most of the specimens to monitor the thermal profile during the exposure. From the fire-exposed side of the specimen, thermocouples were typically installed halfway through the first ply, at the first bond line, halfway through the second ply, and at the third bond line. Similar arrays were located near the center of the specimen and on each side approximately 0.61 m from the center.

Because many of the CLT specimens were commercially produced, installation of thermocouples during layup was not possible, so they were installed through 2.4-mm-diameter holes drilled from the unexposed side of the CLT. These thermocouples were made in-house from 30-gauge type K thermocouple wire (Omega Engineering GG-K-30-SLE) with welded junctions.

2.3 Panel mechanical loading

According to PRG 320 Annex B, section B9, 'The superimposed load on the CLT floor-ceiling slab shall result in 25% of the effective Allowable Stress Design (ASD) reference flatwise bending moment.' To achieve this, a scenario with two symmetrical and equal load points 0.813 m apart was implemented. For that loading scenario, the maximum bending moment occurs at the point of application of each load and the maximum shear stress is equal to the load at each actuator. With the end supports located just outside the furnace the clear span is 2.34 m with a heated length of 0.99 m. The overall specimen length of 2.44 m allows for a bearing area beyond the contact point.

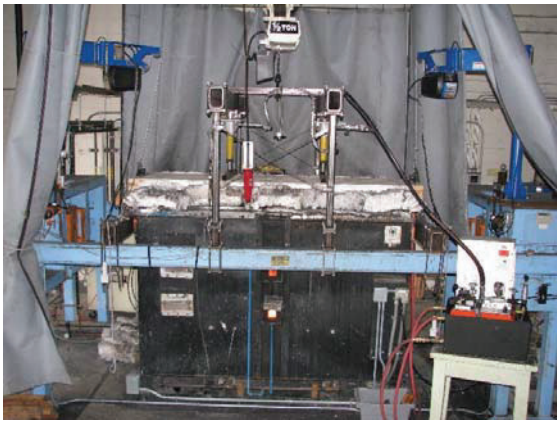

Figure 1: *Photograph of a panel being tested with the Forest Products Laboratory (FPL) intermediate-scale test method. The panel is loaded on a test frame built around a furnace. Two hydraulic actuators apply a mechanical load to match the bending moment prescribed in the standard.*

2.4 Thermal profile

An intermediate scale furnace located at FPL was used to conduct the experiments (Figure 1). The furnace is a metal box lined with ceramic fiber batting and has interior dimensions of 1.83 m long, 1.09 m wide and 1.27 m high.

Eight diffusion flame burners are located on the floor of the furnace and the top of the furnace is open to accommodate a variety of specimen and lid configurations. Suspended 102 mm below the bottom of the specimen face are 3 thermocouples made from 20-gauge type K thermocouple wire (Omega Engineering GG-K-20-SLE). The thermocouples are insulated with ceramic beads with the junction left exposed. These thermocouples approximate the measurement taken by the 5 ceiling thermocouples in the full scale PRG-320 test. Additional furnace details can be found in [13].

In the PRG 320 fire test, a calibration to determine the fuel flow rate necessary to achieve a specified hot gas layer temperature in the compartment is conducted prior to the qualification test. The calibration is run using a diffusion burner in the test compartment and the CLT ceiling is covered with 3-layers of gypsum wall board to create an essentially non-combustible room. While recording the gas flow rate, the burner is used to achieve an average ceiling temperature that matches the ceiling temperature profile measured in the 2017 compartment fire test series where delamination occurred. Upon completion of this 4-hour calibration run, the gypsum wallboard is removed to expose the CLT ceiling and the qualification test is conducted by running the diffusion burner with the same gas flow rate as the calibration run.

The thermal profile for the FPL intermediate scale test method was created using the same approach as the full-scale PRG fire test. First, for the calibration run, a non-combustible lid was placed on the furnace and was controlled so that the thermocouple temperatures within the furnace matched the temperature profile within the PRG 320 standard. Subsequent tests, with CLT samples were run by controlling the gas flow to match the gas consumed in the non-combustible control test. Figure 2 compares the temperatures measured in the intermediate scale furnace against the specified temperatures in the PRG-320 standard.

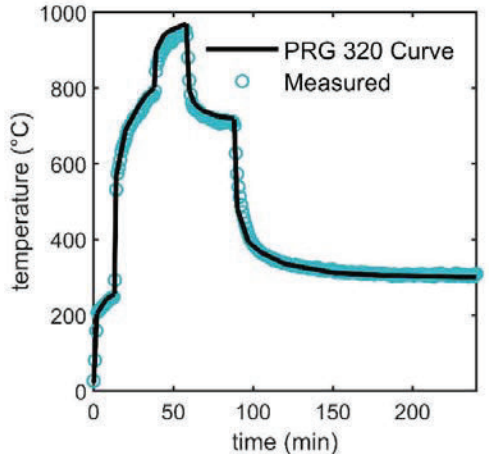

Figure 2: *PRG 320 specified temperature profile plotted against the measured temperature within the furnace with an inert lid.*

2.5 Oxygen measurements

To learn how oxygen concentrations may be affecting combustion within the furnace, measurements were taken in two locations: the exhaust duct and at 100 mm below the centre of the CLT specimen, location A and B in Figure 3, respectively. It is cost-prohibitive to sample multiple points simultaneously, so samples were taken in repeated experiments.

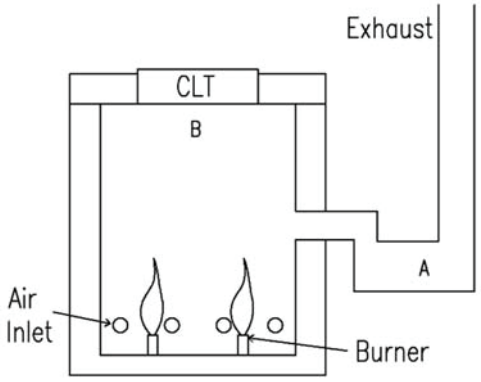

Figure 3: *Schematic of cross section of furnace showing oxygen sample location in exhaust stream (A) and 100 mm below CLT sample (B).*

A sample is continuously drawn from the sample point, either below the CLT specimen or in the exhaust stream. The sample is then passed through a glass wool pre-filter, a heat exchanger, a filter and a drier (Sable Systems ND2 Gas Sample Drier) before being measured. Oxygen measurements were made using a paramagnetic oxygen analyser (Sable Systems PA-10). A pump is located downstream of the oxygen analyser driving the flow. The flow rate is less than 200 ml/min, which is not expected to have significant effect on the temperature or flow inside the furnace.

3 RESULTS

3.1 Temperature Results

Figure 4 shows how the temperature within the furnace during each test compares against the full-scale PRG 320 test results. In Figure 4, the full-scale results are plotted as a blue line, and the intermediate-scale results are shown as a dashed grey line. Three replicates were tested for each adhesive type; all three replicates are plotted as separate grey dashed lines. The solid black curve is the time-temperature curve from the calibration with no-exposed CLT. The figure illustrates the increase in temperature in the furnace due to the fuel contribution from the exposed CLT.

https://doi.org/10.52202/069179-0211

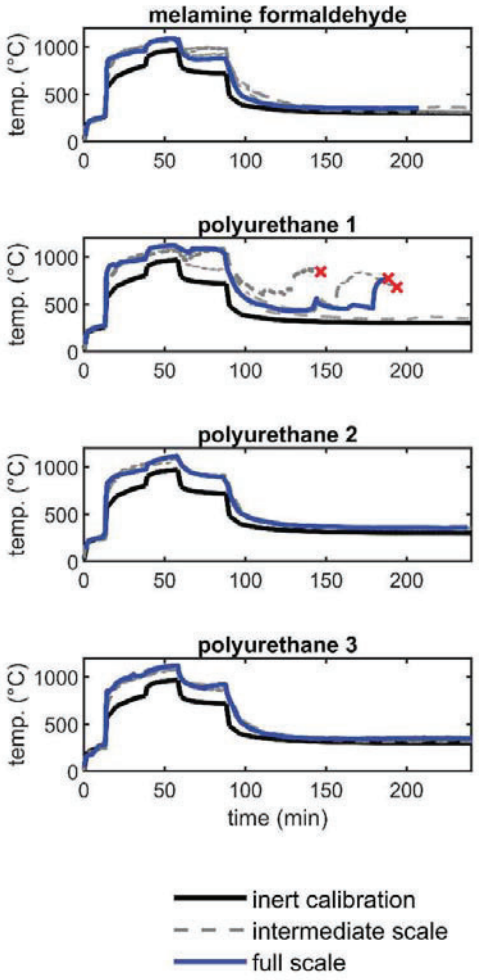

Figure 4: *Comparison of the furnace/compartment ceiling temperatures in the full-scale PRG 320 testing (blue) and intermediate scale test (dashed grey line). The black curve represents the temperature curve with no exposed CLT. The red "x" represents a test terminated due to failure.*

Delamination was observed for the panels constructed with PUR-1 in both the intermediate- and full-scale tests. In these tests, the temperature exhibits an increase during the final phase of the test when the furnace/compartment is cooling. Further evidence of delamination was visually observed from the camera pointed at the furnace floor (Figure 5). For the panels with PUR-1, a significant amount of charred wood material was observed on the furnace floor at 90 and 120 minutes when compared to the other panels types. The furnace tests on CLT with PUR-1 were terminated before the full 240-minute limit to avoid flame through the CLT panel that could cause damage to the loading actuators.

Good correlation was observed between the intermediate- and full-scale temperature results, especially for the panels made with PUR-2 and PUR-3. In two of the three panels with PUR-1 tested at the intermediate-scale, delamination occurred which caused a rapid rise in temperature between 120 and 200 minutes. In the third replicate, the temperature in the furnace increased after 200 minutes, but did was not a full delamination event.

The correlation between the intermediate- and full-scale tests can be most easily seen in Figure 6, which plots the residual of the temperature between the intermediate- and full-scale tests. The data show that the furnace temperature was very close to the compartment temperature for the panels made with PUR-2 and PUR-3. However, for the MF panels, the temperature in the furnace test was higher than in the compartment which was most prominent between 50-120 minutes.

3.2 Oxygen Results

Initial oxygen measurements were taken with inert insulation blocks in place of the CLT specimen. The reduction of oxygen, illustrated in Figure 7, compared to atmospheric levels corresponds to the amount of gas being consumed by the burners. In both measurement locations the lowest concentration is measured during the high temperature portion of the curve between 48 and 58 minutes. It is during this portion of the test that the biggest difference between the measurement locations is observed as well. In location A in the exhaust, the oxygen concentration went as low as 10.5%. At location B near the center of the exposed specimen surface the oxygen concentration was briefly observed to go below 1%. The oxygen concentration curves between each location are very similar before 15 minutes into the test and again after 58 minutes.

https://doi.org/10.52202/069179-0211

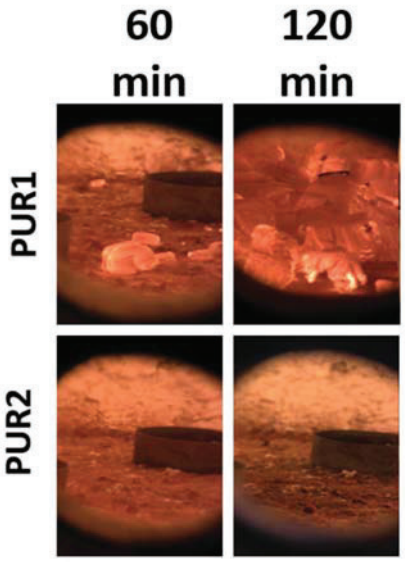

Figure 5: *Images of the furnace floor at 60 and 120 minutes into the test for polyurethane 1 (PUR1) and polyurethane 2 (PUR2).*

The low oxygen concentrations measured in the furnace are expected. Brandon and Dagenais [17] reported that it is important to match the oxygen concentrations within a furnace and compartment when developing a furnace test. They reported that in the 2017 compartment fire tests where delamination was observed, the oxygen concentration was nearly zero during the peak heat release period of the test and worked to mimic that in their furnace test by limiting the oxygen concentration between 15-80 minutes of their 180 minute test [8,17].

This data suggests that there may be adequate oxygen supply in the furnace to support combustion of wood specimens in all but the hottest portions of the test. Furthermore, it shows that there is a large difference in oxygen concentration throughout the furnace. It is measured quite low near the sample surface, the exhaust measurement is essentially an average, so the concentration must be higher somewhere else in the furnace.

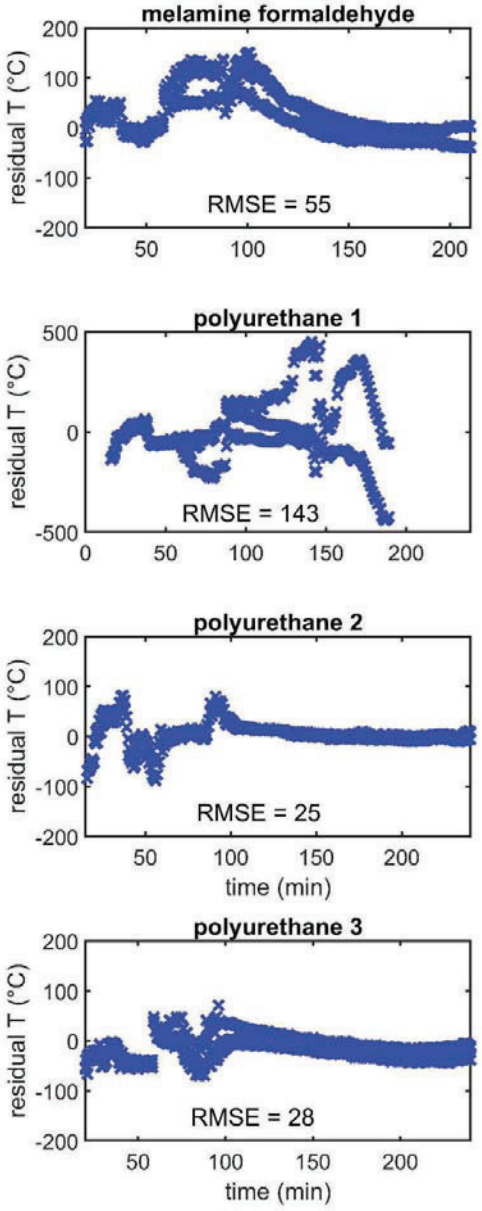

Figure 6: Plots of the temperature residuals calculated by subtracting the *full-scale* test temperature from the intermediate scale test temperature. RMSE = root mean square error calculated from the entirety of the test.

https://doi.org/10.52202/069179-0211

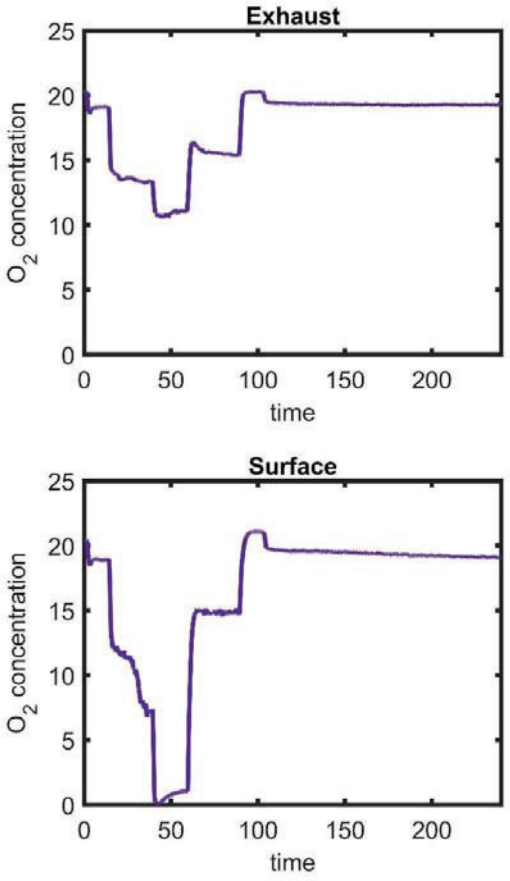

Figure 7: *Comparison of oxygen concentration in exhaust (labelled "Exhaust") versus 100 mm below specimen (labelled "Surface") when experiment is run with inert specimen in place of CLT specimen.*

The low oxygen concentrations measured in the furnace are expected. Brandon and Dagenais [17] reported that it is important to match the oxygen concentrations within a furnace and compartment when developing a furnace test. They reported that in the 2017 compartment fire tests where delamination was observed, the oxygen concentration was nearly zero during the peak heat release period of the test and worked to mimic that in their furnace test by limiting the oxygen concentration between 15-80 minutes of their 180 minute test [8,17].

This data suggests that there may be adequate oxygen supply in the furnace to support combustion of wood specimens in all but the hottest portions of the test. Furthermore, it shows that there is a large difference in oxygen concentration throughout the furnace. It is measured quite low near the sample surface, the exhaust measurement is essentially an average, so the concentration must be higher somewhere else in the furnace.

It is useful to compare the oxygen concentrations measured in this experiment to previous work where oxygen concentrations were measured in furnace tests. Schmid et al. [18] also examined the oxygen concentrations within a furnace during the testing of a CLT panel, although with a standard fire curve [19] rather than the PRG 320 fire curve. Schmid et al. also noted differences between the concentration of oxygen near the panel surface (which was near zero) and the exhaust of the furnace, which was found to vary between 5 and 10% [18]. Future work (See Section 4) will examine how these measured oxygen concentrations change when a wood panel is exposed to the PRG 320 time-temperature curve and how delamination affects the oxygen concentration both near the panel surface and in the furnace exhaust.

4 FUTURE WORK

In the future we intend to repeat the oxygen measurements with CLT specimens made with two different adhesives; one that we have previously observed to delaminate and one that has not. We will then be able to observe what effect the presence of a wood specimen has on the oxygen environment as well as the effect delamination has on the oxygen concentration.

5 CONCLUSIONS

This research aims to develop an intermediate scale test method that can be used to predict adhesive delamination under fire scenarios. The results demonstrate a good correlation between measured furnace temperatures and temperature measured near the ceiling in the full-scale PRG 320 tests that have been conducted.

Additionally, panels made with adhesives that passed the full-scale test also passed the intermediate scale test. Panels made with adhesives that failed the full-scale tests also failed in the intermediate-scale test with the exception of one replicate.

Oxygen measurements taken during the intermediate scale test show very low oxygen concentrations near the burning CLT specimen, which is similar to the oxygen concentrations measured in full-scale CLT compartment fire tests.

A NEW METHOD FOR MODELLING TEMPERATURE WITHIN STEEL BAR - TIMBER COMPOSITE BEAM USING DATA BY BURNING TEST

Shizuka Matsushita[1], Shinichi Shioya[2]

ABSTRACT: In light of the current climate crisis, there has been much recent interest in using timber structural members in large buildings, since timber is as renewable natural resource, and moreover, in severe earthquake prone zones, such as Japan, they are more desired on the grounds of light weight of timber members. We are developing a frame system formed by hybrid timber members reinforced with deformed steel bars (i.e. rebars) using epoxy resin adhesive. In order to practice the system, it is necessary to investigate fire resistance performance of the members. We conducted a 60-minute burning test of one specimen of the composite beam. The results will be reported in this WCTE2023[1]. This paper proposes a method for modelling temperature within beam specimen by using finite data obtained by the burning test.

KEYWORDS: Fire, Burning margin, Hybrid timber, Deformed steel bar, Beam

1 INTRODUCTION [3 4 5]

S.Shioya, (author [2]), has proposed a structural system for building construction, adopting Hybrid Glulam Timber members using Steel bars (HGTSB, nicknamed "Samurai" in Japan) [2]. Three-buildings were built with the system. One of them adapted two HGTSB beams, for a trial, at 11th floor of high-rise building, with a refractory coating authorized as two-hour fireproof timber for HGTSB beam, constructed in Tokyo, Japan, in February 2020.

On the other hand, semi-fireproof design method using burning marginal layer (charring layer) for HGTSB is strongly desired for low-rise and middle-rise buildings. In Japan, HGTSB member is defined as a new kind of structural member; Japan Building Standards Law does not allow application of general semi-fireproof design method using burning marginal layer to HGTSB member; several burning tests of beam and column, which are loaded with maximum weight of long-term design, are requested. However, difficulties of practice of the burning test pose at the point of test machine capacity and selection of failure mode of beam during its burning, because bending capacity of HGTSB beam is approximately 3-4 times as much as that of conventional Glulam beam.

The key to the solution of the difficulties is to develop new method for modelling temperature distribution within beam using several finite data of temperature measured during the burning test. The position and the number of the measuring points need to be selected so as to prevent bending capacity and shearing capacity of the beam from deteriorating. Thus, the new method is need. Moreover, verification of the capacity calculated using the modelled temperature distribution and reduction ratio of strength and elasticity of wood of beam is necessary to be conducted by using capacities obtained by loading during the beam burning test.

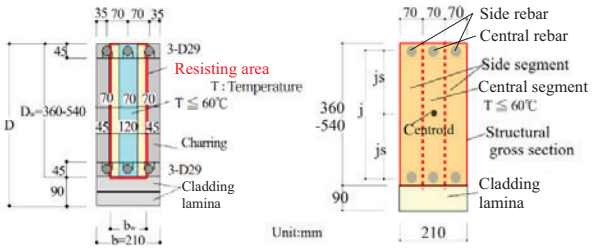
We conducted 60-minute-burning test of a timber-steel rebar composite beam and will report its outline and experimental results in WCTE2023[1]. This paper reports results of temperature variation inside the glulam timber and a new concept of modelling of temperature within the beam with finite measured temperature data.

2 OUTLINE OF BURNNING TEST

Details of burning test will be described in Literature 2 in this WCTE2023. Please refer to it. Outline of the test is described below.

2.1 SPECIMEN

Figure 1 illustrates measured cross-sections of specimen and a resisting area in the section expected after 60-minute burning. Figure 2 (in next page) illustrates a side view of the specimen and positions of foil strain gauge and thermocouple. Figure 3 illustrates 4 cross-sections of the specimen and positions of thermocouples in each cross-section. Main cross-section of beam is section II-IV with



(a) Cross-Section (b) Resisting portion

one tier rebar lamina, in which 3 rebars were embedded, on upper and lower of beam cross-section. The left-hand section I was prepared to investigate effects of the amount and the number of rebars on elevated temperature of wood during burning. The lamina is Cryptomeria Japonica; lamina composition of beam is adhered to Japanese Agricultural Standard E65-F225. Rebar diameter is D29(diameter=29mm) and its grade is SD390(Nominal yielding strength: 390N/mm^2). Adhesive is typical resorcinol resin adhesive for laminating laminas.

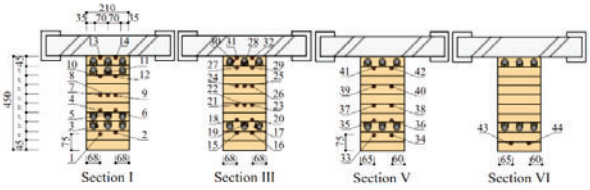

Figure 3 : *Cross-section measured in specimen and positions of thermocouple*

2.2 STRAIN AND TEMPERATURE MEASUREMENT

In Figure 2, locations of thermocouples are shown. Strain in wood and temperature of rebar were measured. Numbering of mark "No." is for thermocouple.

2.3 LOADING

Loading employed four-point bending such as the side view of specimen shown in Figure 2; magnitude of bending moment at mid-span of the specimen was selected to be value of allowable moment for long-term selected to be value under long-term loading design. Value of shearing force of both side shear spans was 10% higher than its allowable shear force for long-term loading design. Force/F.

2.4 HISTORY OF TEMPERATURE

The burning test was conducted on September 28, 2021 at 13:00 (its room temperature: 25.6℃) in a combustion furnace (ISO843-1 compliant furnace) at the Japan Testing Center for Construction Materials. During introducing initial force, deflections and strains in the elastic range were measured. Temperature during 60-minute burning test was controlled to adhere to ISO-fire exposure temperature curve. To capture capacity of the specimen by loading to fracture, a burning time of 5 minutes and 20 seconds after 60-minute burning passed was added; temperature of furnace was maintained at a constant temperature (945℃) by combustion.

3 CHANGE IN TEMPERATURE OF WOOD AND REBAR WITHIN GLULAM TIMBER DURING BURNING

Figure 4, Figure 5, and Figure 6 in the next page show the temperature variation of each measuring point. Figure 6(g) shows the variations of all measuring points for each section; Figure 4 shows that of section I and Figure 5 shows that of section III. The number on curves refers to the number of the measuring point in Figure 6(g); RC refers to the center rebar; RS dose to the side rebar; Va dose to a measured point at which temperature was presumed to increase due to water vapor generated by burning of wood.

Cal.1, Cal.2, and Cal.3 are curves based on an estimation method proposed in Chapter 4. Timber is a natural material, and thicknesses and densities of spring woods and autumn wood are not the same. Timber is not a uniform material to begin with. As the temperatures were measured at one point, it is necessary to analyse trend of temperature variation based on the assumption that the conditions of the material around the measuring point will be slightly different even at same depth from surface of timber, and that there will be some variation in the measured data.

3.1 UPPER LAMINA ENBEDDED WITH REBAR

Figure 4 (b) and Figure 5(b) show temperature variation of the upper lamina.

31V_a and 32V_a in Figure 5(b) show that the temperatures increased rapidly in 20-30 min, maintained about 90°C for 30-50 min, and increased slowly thereafter.

The cause is assumed to be that deflection at mid-span increased space between the upper surface of beam and the ALC board over beam, allowing hot air and flame to penetrate, causing the temperature there to rise quickly and water vapor from the burning of the timber to be suspended. Although RC28V_a was in the same lamina, the temperature rise was extremely slow, but according to Figure 5(f), the rate of rise was faster than that of RC19, i.e., the central rebar at the lower. That time was almost the same as the time when 31Va and 32Va rose rapidly and reached about 90°C.

https://doi.org/10.52202/069179-0212

A similar trend was observed for $13V_a$ and $14V_a$ in Figure 4(b), but it is less pronounced than for $31V_a$ and $32V_a$ in Figure 5(b). The reason may be that section I had a resulting in a slower rate of temperature increase. $27V_a$ and $29V_a$ in Figure 5(d), 41Va in Figure 6(a), and $42V_a$ in Figure 6(b) are also considered to be affected by the same effect.

3.2 LOWER REBAR LAMINA

Figure 4(c) and Figure 5(c) show temperature variation of the lower rebar lamina. Temperatures of the side rebars/RS3 and RS17 increased rapidly after 6 minutes. In Figure 4(g), temperature of 2 at section I was 72°C at 60 minutes. In Figure 6(e), temperatures of wood (4,6,15,16,18,20) at border of lower rebar lamina of the central segment of except for the 2 were below 60°C. This demonstrates that the lower border of the central column segment in Figure 1(b) is almost suppressed below 60°C.

3.3 WEB

The points have a horizontal depth/t_s (see Figure 6(f)) of 68.5 mm. t_s is horizontal depth from the side surface of beam to the width of the groove (3 mm) where the thermocouple is placed. Figure 6(a) shows the temperature variation at the border with t_s of 63.5 mm in cross-section V and Figure 6(b) shows the temperature variation at the border with t_s of 58.5 mm in the same cross-section. As t_s decreased, temperature increased in 60 minutes, and except for 36 at 58.5 mm in Fig. 6(b), the temperatures were above 70°C. Figure 5(d) shows temperature variation from 21 to 26 in cross- section III. In contrast to the temperatures at t_s of 68.5 mm (21, 23, 24, 26), temperature at center of the width (22, 25) in Figure 5(e) hardly increases at all. Even if there is some difference in the temperature variation at the border of the central segment width 70 mm, temperature near the center of the width decreases rapidly, and effect of the variation on the center rebar is considered to be small.

From the above discussion, it can be judged acceptable to calculate the capacity of the center segment as less than 60°C, except for upper surface of the rebar lamina at top of beam as mentioned in Section 3.1.

3.4 EFFECT OF THICKNESS OF CLADDING LAMINAS TO THE LOWER PORTION

Figure 6(c) shows temperature variation of the cladding lamina. The vertical depth /t_L (Figure 6(f)) of 43 and 44 in cross-section VI from the lower surface was 43.0 mm, thus reaching 150°C in 60 min; t_L of 33 and 34 in cross-section V was 73.0 mm, thus 69 ° C and 79°C, respectively; t_L of 15 and 16 in section III was 88.0 mm, thus both were 57°C. The t_L of 15 and 16 in cross-section III was 88.0 mm, so they were both suppressed to 57°C. RC19, the central rebar near the lower of cross-section III, was 27.6°C, hardly increasing from the initial 25.6°C. The center of the rebar in RC19 was almost 105 mm deep from both the lower surface and side surface of beam, and it can be concluded that that depth suppressed the temperature increase.

Figure 6(d) shows temperature variation of 21-26 of web of the cross-section III. 21, 23, 24, and 26 at the boundaries of the central segment were 56-68°C in 60-minute, while 22 and 25 in the middle of the beam width were both 28 ° C, hardly any increase in temperature. Considering this, the same depth from the lower at the width-middle position may be also quite low, close to 28°C, because 33 and 34 in cross-section V were 69°C and 79°C, respectively as mentioned above. These results suggest that even with a thickness of 75 mm of cladding laminas, the increase in temperature of the central rebar at the bottom of beam is suppressed in a 60-minute burn. However, from the viewpoint of providing extra strength for 60-minute burning, it is desirable to keep the depth from the lower surface to the central rebar close to 105 mm, which is the same depth from the side surfaces.

3.5 EFFECT OF HEAT CAPACITY OF TWO-TIER REBAR

Because the large heat capacity of the two-tier rebar in cross-section I, 10 and 12 in Figure 4(b) were less affected by water vapor than $31V_a$, $32V_a$ in cross-section III in Figure 5(b), and the temperature of 10 and 12 is considered to have remained below 60°C after 60 minutes. On the other hand, the rebar lamina at the lower is not affected by water vapor, and Figure 6(e) shows the temperature variation of the lower lamina, comparing the two-tier/RS3 and one-tier rebar/RS17. The data for the two-tier rebar are shown as blue thick solid lines, while the data for the one-tier rebar are shown as blue dotted lines. The positions close to each other in both cross-sections are shown in the same colour. In some cases, the temperature increase is slightly slower in the cross-section of the two-tier rebar. In the side rebar shown in Figure 6(f), RS3 of the two-tier rebars rose more slowly than RS17 of the one-tier rebars, but the effect of the two-tier rebar in suppressing the temperature was not very promising.

4 CONCEPT FOR MODELLING TEMPERATURE WITHIN BEAM

The portion of wood contributing to bending capacity and shearing capacity of beam is uncharred portion. In this study, the scope limits the uncharred portion and the aim is to formulate the amount of variation in wood temperature/T from room temperature/T_r before the burning test to wood char temperature/T_c, using data of temperature measured during the burning on test.

https://doi.org/10.52202/069179-0212

4.1 FORMULATION OF TEMPERATURE-RELATIVE DISTANCE CURVE FROM CHARRING-BORDER TO A MEASURING POINT

As shown in Figure 7(a), we assume that charring border is proceeding at a constant charring rate/v_c and that measuring point/m is in the direction of the border progressing. In reality, the charring border approaches the point/m, but from the perspective of the charring border, the point/m can be considered to be approaching with a relative velocity/v_c toward. The distance/S between the point/m and the charring border is expressed by Equation (1).

$$S=d_m-v_c\cdot t \tag{1}$$

where d_m is distance between surface of beam and the measuring point/m *in mm*; v_c is charring rate *in mm/minute*; t is time of fire exposure *in minute*.

Figure 7(b) illustrates schematically relationship between temperature/T and distance/S at the measuring point/m after burning time/t passing. The distance/S decreases with the time/t, and the distance/S and the temperature/T can be plotted, yielding a T-S curve. Temperature/T of wood at the start of burning is assumed to be room temperature/T_r, which increases with the progress of charring and reaches charring temperature/T_c. The distance/S is equal to distance/d_m, at the start of burning and to zero, at reaching the charring temperature/T_c.

These two points are designated as x= d_m, y= T_r and x=0, y= T_c in Figure 7(b). These points are to be boundary points at both ends of the T-S curve, which rises linearly with decreasing S for the measuring point closer to the charring border, and rises more slowly at the beginning of burning and rises more rapidly as the charring border approaches for the more apart points.

The T-S curve can be approximated by normalizing the distance/$v_c\cdot t$ of charring progression by the distance d_m of each measuring point and by normalizing the temperature increase/ (T- T_r) by (T_c - T_r); normalizing the coordinate axes as shown in Figure 8. As results, the T-S curve is represented by Equation (2). Substituting x and y in Equation (3) into Equation (2), T is represented by Equation (4).

$$y=x^n \tag{2}$$

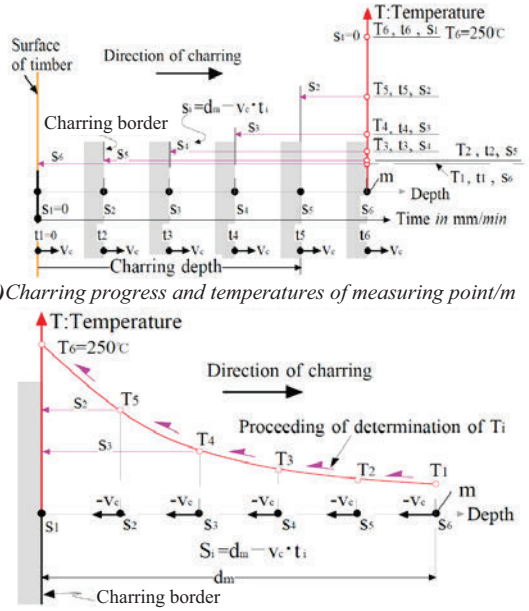
$$\text{where, } x=(v_c\cdot t/d_m),\quad y=(T-T_r)/(T_c-T_r) \tag{3}$$

$$T=T_r+(T_c-T_r)\cdot(v_c\cdot t/d_m)^n \tag{4}$$

4.2 EXPONENT/*n* BASED ON HARADA'S DATA

Harada et al. [3] reported a 45-minute loaded burning test on Abies sachalinensis Glulam timber beam to investigate the fire resistance performance of them, and measured temperature of the beam in detail. The model proposed above is applied to the temperature-time curves measured on the beam specimen PRF-b in the literature [3].

Specimen/PRF-b was glued with the same phenol-resorcinol resin adhesive. Figure 10(a) in the next page shows the temperature-time curve measured on PRF-b. The beam cross section and temperature measuring points



(a)Charring progress and temperatures of measuring point/m

(b)T-S curve of measuring point 'm'

Figure 7: *A new concept for estimation of temperature distribution in uncharred region of wood in timber*

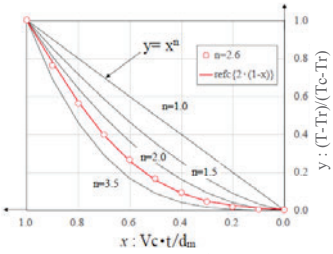


Figure 8: *Curves by Eq.(2)*

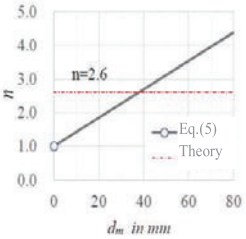

Figure 9: *Changing by Eq.(5)*

are shown in the upper left corner of Figure 10(a). The dotted line in the Figure represents experimentally measured temperature curve.

The T-S curve drawn using S by Equation (1) is shown by coloured thin solid line in Figure 10 (a)and(b). The exponent/n was determined so that the calculated value of temperature in Equation (4) conforms to the experimental curve. The charring temperature/T_c was assumed to be 300°C and the charring rate/v_c was set at 0.65 mm/min. The results are shown as ○ in Figure 10(c).

The y-axis is the exponent/n, and the horizontal axis is the depth/d_m. The exponent/n approaches 1.0 at zero for d_m and tends to change linearly with increasing d_m. Approximating the change with Equation (5), the coefficient/k was 0.0323.

$$n=1.0+k\cdot d_m \tag{5}$$

where k is assumed to be 0.0425 in 1/ mm

As dimensions of beam cross-section increase, exponent/n may differ from the straight line in Equation (5). It is expected to converge to a coefficient based on

https://doi.org/10.52202/069179-0212

temperature distribution during combustion of semi-infinite solid.

However, as the burning test for performance evaluation constrains cross-section dimension to be safe for burning and focus on the measured temperature data, it is out of the scope of this study to identify the convergence value.

In this study, it is enough if the exponent/n can be estimated in a form that allows the change in temperature measured in the burning test to be estimated. The T-S curve calculated with the coefficient/k in Equation (5) as 0.0323 as described above is shown in Figure 10(b) as a thin solid curve. The temperature/T - time/t curve is also shown in Figure 10(a) as a thin solid curve. The curves are coloured by the same colour for each measuring point. The rate of increase of the dotted curve was slower than the rate of the calculated curve at the temperature of 100℃, because moisture in wood becomes water vapour. In the temperature range above 120-140 °C and up to a charring temperature of 300 °C, the temperature of the calculated curves is on the safe side in terms of evaluating beam's resistance during burning, although in some ranges they are estimated to be higher than the experimental temperatures. The correspondence between measured and calculated T-S curves in Figure 10(b) is similar to that in Figure 10(a). The same study also reported the measured data of the test specimen PRF-a, which was glued together using the same adhesive with a lamina thickness of 22 mm in the cross-section in Figure 10(a), and the calculated curve for that was also confirmed to be a similar correspondence with the measured curve.

Although the coefficient/k is likely to depend on dimensions of specimen and its wood species, it can be concluded that the proposed method can be applied to historical data of temperature of burning test to model its temperature variation.

4.3 EXPONENT "*n*" BASED ON THE TEST

Figure 11 shows T-S curves based on data from each measuring point in this test. It is shown up to the end of the burning test; Figure 11(e1) shows the T-S curve for rebars. In this study, amount of loading was selected for the cross-section of the one-tier rebar at the middle of the span, so the exponent/n in Equation (4) was determined to fit the temperature data for cross-sections III, V and VI. The result adopted 0.0425 (1/mm) of n.

The charring temperature/T_c was assumed to be 250°C, T_r was assumed to be 25.6°C, the internal temperature before the burning test, and the charring rate v_c was assumed to be 0.65 mm/min with reference to Eurocode 5.

On the basis of the above approach, various constants were specified.

Figure 8 in the previous page shows the curves for varying n in Equation (2). Symbol '○' indicates the calculated value when n was assumed to be constant value of 2.6. Red curve in Figure 8 is the curve of the complementary error function (y=erfc(2-(1-x)) of the equation for the theoretical solution of temperature inside the semi-infinite solid during burning.

The ○ and red curves are almost identical, which means that Equation (2) can also approximate the curve of the equation of its theoretical solution, within the range of application. Figure 9 shows the variation of the exponent n according to Equation (5) with k of 0.0425. When d_m is close to zero, the shape of the T-S curve becomes steeper as surface of timber charrs at the initial burning, so approximating temperature with a straight line is not a major problem.

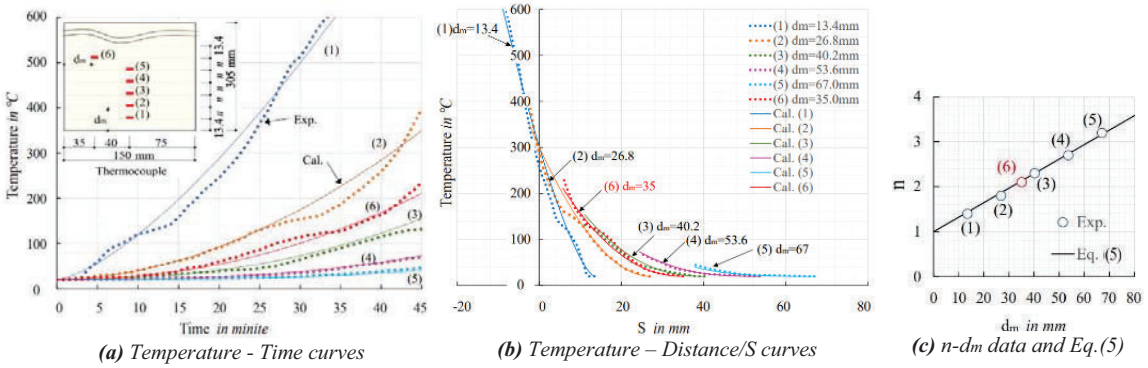
4.4 TEMPERATURE VARIATION AND COEFFICIENT/ *k*

Value of the coefficient k in Equation (5) was selected to minimize the standard error between the temperature measured at each position and the value calculated using Equation (4) for Figure 11 (b1), (c1), (c2) and (d1) of the cross section of the one-tier rebar during 60-minute burning.

In this case, the value that minimizes the standard error for the data of cross-section III where the temperature closest to the border of the central segment in Figure 1(b) was measured, was found to be 0.0425.

The d_m of each measuring point in wood was assumed to be the smaller distance between the horizontal depth/t_s and the vertical depth/t_L shown in Figure 11(a1), taking into account dimensions of the thermocouple groove.

Table 1 in the next page lists measured temperatures, their standard deviation/SD, calculated values, and their standard error/SE of the calculated values relative to the measured values for Figure 11 (b1), (c1), and (c2), where t_s (here equal to d_m) is the same for each position.



(a) *Temperature - Time curves* ***(b)*** *Temperature – Distance/S curves* ***(c)*** *n-dm data and Eq.(5)*

Figure 10: *Temperature – Time relationship of specimen/PRF-b of Harada's burning test for Japanese Abies* [3]

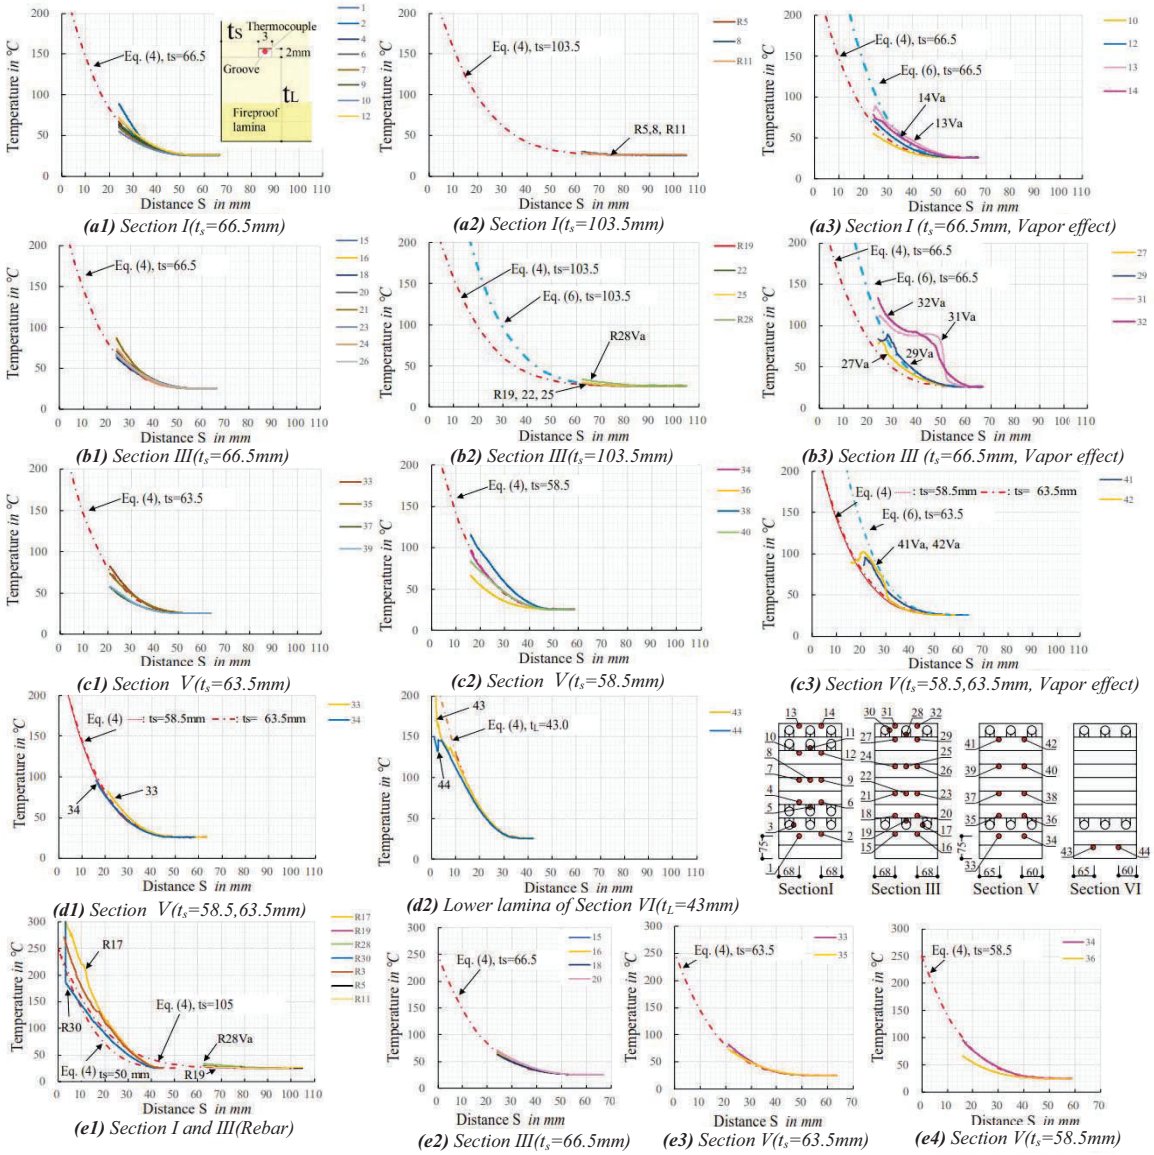
https://doi.org/10.52202/069179-0212

The position closest to the border of the central segment is Figure 11(b1), i.e., t_s=66.5mm, and the calculation error/SE for Equation (4) is 2.21°C. As temperature within the central segment is lower, its standard error is small.

Figure 11(d1) shows two positions (t_s=58.5, 63.5mm, t_L=75mm) of the cladding lamina in cross-section V. The measured values are almost the same change, which is almost estimated by the red calculated curve. Figure 11(d2) shows a cross-section VI with a depth t_L of 43 mm from the bottom surface, which is the position where charring will take place and where the temperature becomes high, as can be seen in Figure 12(b). Above 100°C, the temperature calculated by the curve is higher than the measured value. However, above 100°C, the reduction in the strength of wood is extremely large [4], and estimating the capacity of beam on the safe side is not a problem.

4.5 TEMPERATURE OF UPPER LAMINAS

Figure 11(a3), (b3) and (c3) show variation of temperature of upper surface of beam and wood on the underside of the rebar lamina immediately below it. Temperatures at the upper surface of beam/13V_a, 14V_a, 31V_a, 32V_a, indicate the temperature affected by water vapor, as thermocouples at the measuring points were in direct contact with the water vapor that might be stayed as mentioned above. Wood temperatures are estimated to be close to the temperature directly below the rebar lamina, i.e., 27V_a, 28V_a, 29V_a, 41V_a, 42V_a. Red one-dot curve in the Figures is curve of the calculated value according to Equation (4). The curve underestimates temperature of the wood directly below the rebar lamina (e.g., 27V_a as



(a1) Section I(t_s=66.5mm) (a2) Section I(t_s=103.5mm) (a3) Section I (t_s=66.5mm, Vapor effect)

Figure 11: *Temperature/T-Distance/S relationship in wood by experiment and curves calculated by Eq.(4) and Eq.(6)*

https://doi.org/10.52202/069179-0212

described above). In this study, it was assumed to approximate the temperature variations in the upper rebar lamina with the following Equation (6), in which the temperature increase in the second term on the right side of Equation (4) is multiplied by 2.0 to obtain a relatively accurate estimate of the temperature variations.

$$T=T_r+2.0\cdot(T_c-T_r)\cdot(V_c\cdot t/d_m)^n \quad (6)$$

Curve based on Equation (6) is shown as light blue dotted line. In Figure 11(a3), (b3), and (c3), the light blue curves roughly estimate the variation in temperature, i.e., $27V_a$, $29V_a$, $41V_a$, $42V_a$ of wood below the upper rebar lamina. In Figure 11(b3), temperatures of $31V_a$ and $32V_a$ on the upper surface of beam approach the temperature in the light blue curve after 60-minute burning. In terms of estimating the temperatures of this 60-minute burn, it is seemed that they can be estimated using Equation (6). The value of 2.0 needs to be verified by adding data from other burning tests in the future.

4.6 TEMPERATURE OF WOOD AROUND SIDE REBAR

Figure 11(e1) shows curves of rebars in cross-sections I and III. The curves by red one dot line were calculated by Equation (4), where d_m was assumed to be 50 mm (=35+15) for the side rebar as the side position near the central rebar, and d_m was assumed to be 105 mm for the central rebar as the center of the rebar. As temperature of the central rebar hardly rises, the difference of the calculated value to experimental value is almost negligible. However, temperature of the side rebar reached the charring temperature early because wood cover thickness on the side of the side rebar was 20 mm, and measured temperature of the rebar was larger than the calculated temperature because the thermal conductivity of rebar is larger than that of wood.

Figure 11(e2), (e3), and (e4) show variations of temperature of wood around the rebar lamina at the lower. Figure 13(a) and (b) show positions of thermocouples around the lower rebar lamina. Except for thermocouple 36 in Figure 11(e4), all positions follow the curve of the calculation. In Figure 12(b), wood around the side rebar was deeply charred, but as seen in Figure 11(e2), no increase up to the charring temperature was measured at the location near central side of the side rebar. However, considering charring condition in Figure 12(b), it is safe to assume that wood around the side rebar which is surrounded by pink line in Figure 13(c), cannot resist in burning for 60 minutes.

Table 1: *Depth/t_s of measurement point, distance/S and temperature after 60-minute burning, and temperature/T calculated by Eq.(4)*

4.7 RELATIONSHIP BETWEEN TEMPERATURE AND BURNING TIME AT EACH MEASURING POINT

Given the charring rate/v_c and the time of burning/t, the temperature at each point can be calculated using Equation (4) or Equation (6) to obtain a T-t curve of relationship between temperature and burning time. Here, the coefficient/k was assumed to be 0.0425 as mentioned above, charring temperature T_c of cedar wood was assumed to be 250°C [5], T_r was assumed to be room temperature of 25.6°C before the burning test, and the charring rate v_c was assumed to be 0.65 mm/min. d_m follows Section 4.4. The calculation results are shown as curves as Cal.1-Cal.3 in Figure 4-Figure 6. Cal.1 is the curve calculated for the measuring points close to the border of the central segment and Cal.2 is the curve calculated for the central position of beam width, i.e., the central rebar position. Cal. 3 is the curve calculated using Equation (6), which takes into account the effect of water vapor on the upper rebar lamina. The variation of calculated temperature is in good agreement with the experimental variation.

https://doi.org/10.52202/069179-0212

5 TEMPERATURE DISTRIBUTION OF UNCARBONIZED CROSS-SECTION WITHIN GLULAM TIMBER DURING 60-MINUTE BURNING

The beam section is divided into charred area and uncharred area as shown in Figure 14; the shortest depth of dy, dx_1, dx_2 is assumed to be d_m, where dy is depth from the lower surface and dx_1 and dx_2 are depth both sides of the beam respectively. The charring border of the outward corner of the lower surface of the beam is circular as shown in Figure 12(b), due to the burning of the lower surface and the side faces; in Eurocord 5[4], a point O is assumed to be inside from those faces at a distance twice the charring depth/$v_c \cdot t$, as shown in Figure 14, and the arc was assumed to be as 1/4 of a circle with the charring depth/$v_c \cdot t$ as radius. Here, in the uncharred area at its outward corner, temperature/T of wood at the position of the arc of concentric circles of radius/r_o centred at point O was assumed to be isothermal and equal to temperature due to burning in one direction on the bottom or side surface. Figure 15 shows temperature distribution in the uncharred area within the cross-section of this beam calculated for a 60-minute burning. The cross-section was divided into 84 sections in the beam width direction and 180 sections in the beam height direction. In future calculations of capacity of beam, it is assumed that wood in the pink range in Figure 13(c) do not resist, and effect of the rebar on temperature of the wood area is ignored.

Figure 15(a) shows the 3-dimensional distribution of isotherms in the right half of the beam cross-section in Figure 15(b). It is shown in the view from the top surface of the beam to the bottom surface. Temperature in the charred area is shown as 250°C. The temperature decreases rapidly as its position moves toward the interior. The x-y co-ordinate axes in the cross-section are indicated in Figure 15(b). The origin of x and y is assumed to be the centre of the beam width at the border between the lower surface of the structural section and the cladding lamina. The y is positive upwards, whereas the negative range of y means the range of the cladding lamina.

Figure 15(c) shows curves of temperature along the beam height. The curves indicate the center of the beam width (x=0 mm), the 50°C border (x=±36 mm), the 60°C border (x=±40.5 mm) and the centre of the side rebar (x=±70 mm). The temperature at the center of the width (x=0mm), where the central rebar is located, is 26.9°C, almost

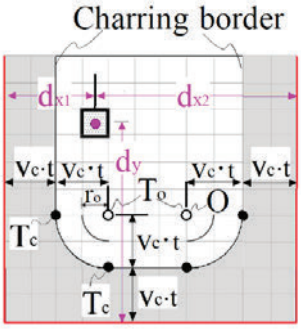

Figure14: *Distance /$d_{x1,x2,y}$ and T at the corner*

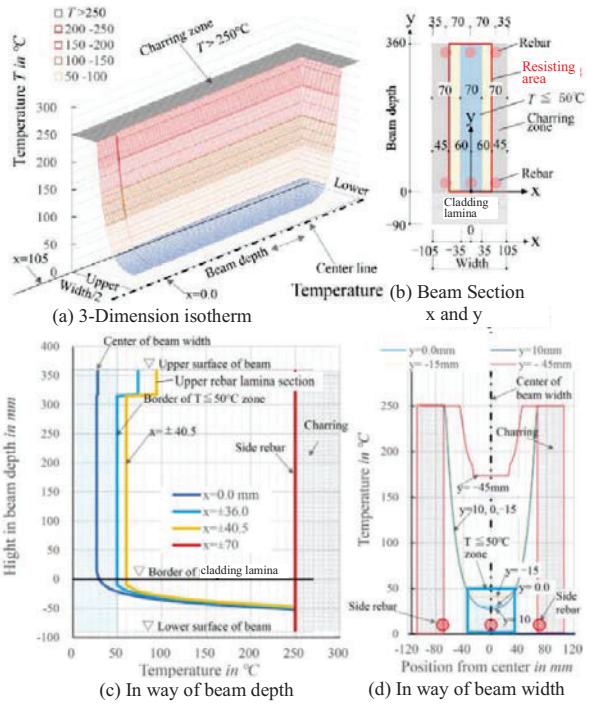

Figure 15: Temperature distribution of wood in beam cross-section after 60-minute burning calculated by the new concept

unaffected by the 60-minute burning in the structural section area ($0 \leq y$), whereas the temperature increases rapidly in the cladding lamina range ($-90 \leq y \leq 0$). This temperature distribution confirms the importance of the 90 mm thickness of cladding lamina.

Figure 15(d) shows curves of temperature in the beam width direction. The curves are for y=-15 mm in the cladding lamina, y=0 mm on the underside of the structural section area and y=10 mm in the structural section area. x=±35 mm is the width border of the central segment. Temperature in the area of the central segment within the structural section area enclosed by the blue line, i.e., $-35 \leq x \leq 35$ and $0 \leq y$, is below 50 °C, of which the area $-25 \leq x \leq 25$ is below 30 °C, resulting in the vicinity of the central rebar D29 being unaffected by burning.

From the above, it can be expected that in the case of a beam width of 210 mm, the central segment will be less than 50 °C and the temperature of the central rebar will hardly increase, even after 60-minute burning, if the thickness of the cladding lamina is 90 mm, and that the central rebar will demonstrate capacity as steel bar - timber composite beam resisting at room temperature.

https://doi.org/10.52202/069179-0212

6 SUMMARY

A method was proposed for estimating the temperature distribution inside steel bar - timber composite beam from experimental data by analysing the historical data of temperatures obtained during a 60-minute-burning test of the beam. The results are summarized as the followings:

i) A method was proposed to estimate temperature distribution in uncharred area of wood in glulam timber for any burning time within 60 minutes from the measured data of wood temperatures at limited locations in glulam timber, which reproduces the curve of the relationship between temperature at measuring point and burning time, showing temperature distribution in the cross-section during 60-minute burning.

ii) Based on the temperature distribution, beam width of 210 mm was divided into three equal sections, and the central segment of them was less than 50 °C even after 60 minutes burning, while central rebar and its vicinity were less than 30 °C (at room temperature of 25.6 °C) and were hardly affected by burning. The central segment can be expected to exhibit resistance as steel bar - timber composite beam. However, this assumes that 90-mm-thick cladding lamina are bonded to the underside of the beam.

iii) Around the side rebar, charring progresses quickly inwards in 60-minute burning, thus effect of this should be taken into account in the calculation of the capacity of beam.

iv) In 60-minute burning, the large heat capacity of the two-tier rebar in the cross-section had a small effect on the suppression of the temperature rise of wood in the glulam timber.

Note that to generalize the proposed modelling of the temperature distribution, it is necessary to generalize the method of setting the value of k for the coefficient in Equation (5).

TRAVELLING FIRES IN COMPARTMENTS WITH EXPOSED CROSS-LAMINATED TIMBER SURFACES

Andreas Sæter Bøe[1], Kathinka Leikanger Friquin[2]

ABSTRACT: This paper presents results from two large-scale experiments where the fire spread in large open-plan compartments with exposed cross-laminated timber (CLT) was studied. In the first experiment, #FRIC-01, the ceiling was exposed, and in the second, #FRIC-02, both the ceiling and the back wall was exposed. The charring rates of the CLT, the mass loss rates and heat release rates of the CLT and wood crib were measured. In addition, the fire spread was studied visually by recording the development of the fire with several cameras. The experiments provide unique information about how exposed surfaces affects the fire dynamics and fire spread in a modern wooden compartment. Both experiments showed that the presence of exposed CLT surfaces significantly affect the fire spread rate and fire dynamics of a compartment fire.

KEYWORDS: Cross-Laminated Timber, Compartment fire, Fire spread, Travelling fire

1 INTRODUCTION

Cross-laminated timber (CLT) has in recent years become very popular due to its many advantages; possibility of prefabrication, low carbon footprint, easy handling and mounting of wood, it's aesthetic look, and high strength and stiffness properties. With the increased popularity, CLT is now used in large apartment buildings, public buildings and office buildings.

Through a number of experiments, it has been found that the fire dynamics of a compartment is significantly changed when exposed surfaces of CLT are present. Examples of such changes are: higher heat release rate (HRR), increased duration of the fire, higher temperatures, and larger external flames [1, 2].

However, most experiments with CLT have been conducted in small compartments with nearly quadratic floor areas, and with small window openings, resulting mainly in ventilation-controlled fires [3-5]. Modern buildings, on the other hand, have large open-plan spaces and large window openings to allow for natural light. Fire dynamics of large, and sometimes long, open-plan spaces with large window openings is often characterized as travelling fires [6]. Travelling fires are recognized with a clear leading and trailing edge which propagates through the space.

Several full-scale experiments with travelling fires have been conducted over the last years, but mostly in compartments with non-combustible surroundings [7]. However, recently experiments have also been carried out with an exposed CLT ceiling. These experiments have provided new knowledge about how an exposed CLT surface affects the fire dynamic and fire spread rate.

In a small scale test, Nothard et al.[8] studied the effect of exposing CLT in the ceiling, and reported a more rapid fire spread with an exposed ceiling. In the Malveira fire experiments, the fire spread slowly for ~4 hours, until the fire spread to a location of the compartment where the ceiling was combustible. The burning ceiling significantly increased the fire spread in the rest of the compartment.

In the CodeRed-experiments [9, 10], the fire spread across a ~380 m^2 compartment with an exposed CLT-ceiling in 5 and 8 minutes. After ignition of the exposed CLT in the ceiling, the fire spread rapidly across the ceiling. This triggered the spread across the wood crib due to the strong radiation heat flux from the ceiling towards the wood crib. The impact of the exposed ceiling could clearly be demonstrated when compared against the X-ONE [11] and X-TWO [12] fire experiments, which were almost identical to the CodeRed-tests [10], but without exposed CLT in the ceiling. In these tests, the fire spread across the room in 25 and 32 minutes, respectively.

Through the few tests performed with a combustible ceiling, it is evident that there is a need for more knowledge on how different exposed CLT surfaces affects the fire spread and fire safety in large compartments. The rate at which a fire spreads is highly relevant for several aspects within fire safety, for example available time for people in the compartment to evacuate safely or be rescued, and efforts needed to contain and

suppress the fire, extinguishing tactics, spread to other parts of the building, etc.

To better understand how an exposed CLT-surface affects the fire spread in a large open-plan compartment with large window openings, two large-scale experiments have been conducted. This paper is a short summary of some of the results. Additional results will be published in separate articles.

2 METHOD

Two experiments were conducted. The first, #FRIC-01, had an exposed CLT ceiling, while in the second, #FRIC-02, the CLT was exposed in both the ceiling and the back wall. The compartment is shown in Figure 1-Figure 3.

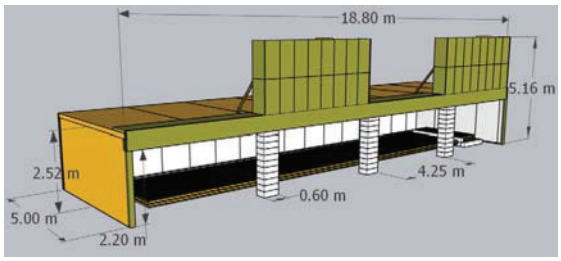

Figure 1 Sketch of compartment with dimensions.

Compartment

The compartment was built of a CLT roof and three CLT walls, while the front wall with large openings was made of a glue-laminated timber beam and three Siporex columns. The CLT in the roof and back wall was 140 mm thick, with 5 layers (40-20-20-20-40 mm), made of Norwegian spruce, and glued together with a regular polyurethane (PUR) adhesive. The CLT in the end walls were 80 mm thick with 3 layers (30-20-30 mm).

The inner geometry of the compartment was 18.8 m x 5.0 m x 2.52 m (l x w x h). The compartment was well ventilated with four large window openings in the front wall, with a total opening of 17.0 m x 2.2 m (l x h). This corresponds to an opening factor of 0.18 $m^{1/2}$. A 2.45 m high inert façade wall was mounted above two of the windows to study the external flame. The beam in the front wall protruded 350 mm below the ceiling.

The unexposed CLT surfaces were protected with 2 layers of 15 mm fire rated gypsum boards (type F) [13] to prevent any contribution from them. The edges of the CLT and the beam in the front wall were protected with a ceramic insulation.

Fuel load

The fuel load density was 373 MJ/m^2 per floor area and was chosen to represent a typical office building. The fuel load was represented by a 2.8 m x 15.5 x 0.2 m continuous wood crib and a 2.8 m x 1.0 m x 0.2 m wood crib positioned on a scale. The wood crib was made of four alternating layers with wood sticks with a 50 mm x 50 mm cross-section. The wood crib is shown in Figure 2 and Figure 3.

Figure 2 Compartment with exposed ceiling and back wall in #FRIC-02.

Figure 3 Inside compartment before ignition in #FRIC-02, with exposed CLT in ceiling and on back wall. Wood crib on the floor, TC-trees hanging from the ceiling. #FRIC-01 was identical except for gypsum boards covering the CLT back wall.

The fire was ignited at one end of the wood crib, the left end. Ten aluminium trays with heptane were evenly distributed under the end of the wood crib. In #FRIC-01 a total of 5.0 litres of heptane was used, and in #FRIC-02 a total of 9.8 litres.

Instrumentation

The compartment was instrumented with thermocouples (TC) and plate thermometers (PT) distributed inside and outside the compartment. The sensors measured the temperature and heat fluxes, and gave valuable data on fire spread rate, temperature distributions, charring rates, and heat flux towards the façade.

Charring rates of the CLT were determined based on temperature measurements. Embedded TCs were installed into the CLT elements from the sides, parallel to the isotherm, at depths 0, 10, 20, 30 and 40 mm into the CLT (Figure 4), at three different locations in the compartment.

https://doi.org/10.52202/069179-0213

Figure 4 TCs were embedded into the CLT from the rebate joint.

Determination of heat release rate

The determination of the heat release rate (HRR) of the wood crib was inspired by the method of Rackausakaite et al. [11], which determined the HRR per unit (here: 50 mm of crib length) and then integrated over the entire wood crib. In contrast to the method of Rackausakaite et al., the HRR per unit was determined from the mass loss rate (MLR) of the small wood crib positioned on a scale, instead of just an average value between start and end of burning.

The HRR contribution from the CLT was derived based on the charring rates, the density, and the area of the exposed CLT. Charring rates of the CLT were determined based on the development of the 300°C isotherm inside the timber [14].

3 RESULTS AND DISCUSSION

3.1 Fire development

In #FRIC-01, the heptane fire did not cause the ceiling to ignite, and the wood crib fire almost extinguished when the heptane burned out after 4 minutes. After ca. 20 minutes the wood crib fire had developed to cover an area of about 1 m x 2.8 m of the crib. The flame height was 0.5-2.2 m above the floor, i.e. not impinging the ceiling. During the next 13 minutes the flames travelled 0.5 m of the wood crib, but the base area and flame height was almost unchanged as the flames at the left end of the crib were dying out.

After ca. 33 minutes the CLT in the ceiling ignited. This occurred from a combination of radiation and convection, as the flames did not impinge the ceiling After this the fire spread across the entire room in approximately 12 minutes. Within these 12 minutes, the fire travelled back and forth in four distinct waves or cycles (Figure 5). We have chosen to call them *flashing waves* in this article.

The flashing waves were recognized by a rapid flash fire along the ceiling, followed by a spread along the top layer of the wood crib, triggered by the radiation from the ceiling. Each wave caused external flaming from the window openings. After a short intense fire of 30-60 seconds, the flames gradually reduced in the ceiling, and the radiation-controlled fire in the top layer of the wood crib was reduced or even extinguished. The wood crib fire grew in size after each wave, and spread to the right end of the compartment in the the 3rd and 4th wave, in which the full flashover occurred at the end of the 4th wave at 45:30 (mm:ss).

Figure 5 #FRIC-01: Fire spread and retraction of 3rd flashing wave. Time (hh:mm:ss).

https://doi.org/10.52202/069179-0213

Figure 6 #FRIC-01: Most intense phase of burning shortly after flashover.

After the flashover, the fire burned intensely for about a minute (Figure 6), and then gradually decreased in intensity. From 49 minutes, the fire was clearly most intense at the far end from ignition, and external flames were only present from the far end window. Self-extinguishment of flames in the CLT ceiling started at around 50 minutes, from the left end of the compartment towards the right end over the next 10 minutes. The wood crib fire was continuous until about 60 minutes into the fire. From 60 to 95 minutes, the wood crib fire became increasingly discontinuous, starting from the left end of the compartment and moving towards the right end. Visible flames in the wood crib self-extinguished at 95 minutes. The compartment was observed for a total of 4 hours. At this point, very little of the wood crib was left. A few lamellae of the outer layer of the CLT in the centre of the compartment were hanging down from the ceiling. Hot spots were present around these loose lamellae. Manual extinguishing was then conducted. No reignition occurred after the manual extinguishment.

In #FRIC-02, the amount of heptane used to ignite the wood crib was increased to avoid the risk of self-extinguishment, based on the experience from #FRIC-01. The extra heptane caused both the ceiling and the wall to ignite at 2 minutes. From this point on, the fire spread extremely fast, and flashover occurred at 3 minutes and 15 seconds (Figure 7).

After flashover, the fire burned intensely with large external flames for about 8 minutes. The flames in the CLT wall and ceiling gradually extinguished from the left end of the compartment after ca. 14 minutes. At around 16 minutes all flames in the wall and ceiling had self-extinguished, and only the wood crib was still burning.

From around 25 minutes, the crib was burning with discontinuous flames, and the last flames extinguished after 40 minutes. However, after 75 minutes a 2nd flashover was seen with flames on the entire back wall and the ceiling (Figure 8). The fire continued until 175 minutes (Figure 9), when it was manually extinguished.

3.2 Mass loss rate and heat release rate

#FRIC-01

The HRR of the CLT was estimated to be 21 MW at maximum, while the estimated HRR of the wood crib was 20 MW. Combined the total HRR was estimated to 41 MW, see Figure 10.

#FRIC-02

The HRR of the CLT was at maximum 24.5 MW for the ceiling, and 13 MW for the wall. The estimated HRR of the wood crib was 35 MW at maximum. The total HRR was at maximum approximately 73 MW. This is 32 MW (78 %) higher than in #FRIC-01.

However, the contribution from the CLT wall was only 13 MW. The additional 19 MW, compared to #FRIC-01, is due to an increased HRR from the wood crib, which was 15 MW higher than in #FRIC-01, and from the CLT ceiling, which was ca. 4 MW higher.

4 CONCLUSIONS

The experiments #FRIC-01 and -02 were conducted to increase the knowledge about fire spread and fire dynamics in large open-plan compartments with large ventilation openings. Both #FRIC-01 and -02 showed, in line with previous experiments, that the presence of exposed CLT surfaces significantly affect the fire spread rate and fire dynamics of a compartment fire.

In #FRIC-01, however, the time until ignition of the CLT ceiling occurred later than in previous experiments. This can be explained by the flame height of the wood crib fire, which were not impinging the ceiling.

In #FRIC-02 the ignition of the ceiling occurred earlier due to the increased amount of heptane in the start fire. However, the flame spread after ignition of the ceiling was much faster in #FRIC-01, which can be explained by the additional exposed surfaces on the CLT wall.

Both tests, but in particular #FRIC-02, show clearly that the presence of exposed CLT could cause a rapid fire development. A rapid fire development affects fire safety in several ways, for example available time for safe evacuation and rescue, and the size of the fire when the fire brigade enters the building.

CHARACTERIZING THE FIRE PERFORMANCE OF ADHESIVES USED IN GLUED-IN RODS CONNECTIONS

Diego Flores[1], Christian Dagenais[2], Pierre Blanchet[3]

ABSTRACT: Glued-in rods are an aesthetically and performant type of connection that has seen its usage increase in the last few years. However, there is still a lack of data concerning the fire performance of glued-in rods, limiting its integration in standards. Recent studies suggest that the adhesive is critical to the fire performance of glued-in rods, since its capacity is greatly reduced when the temperature exceeds its glass transition temperature (T_g), ranging between 45-65 °C for most structural adhesives. To validate these findings, dynamic mechanical analysis (DMA) tests were performed to better assess the T_g and other thermomechanical properties of the adhesives used in this research. Axial tension tests at stabilized temperature were performed on 67 glued-in rods specimens using five different adhesives (three epoxies and two polyurethanes) and various sets of temperatures at the glue line interface. Most of these specimens have shown a ductile failure mode for temperatures below the T_g of the adhesive and a brittle failure mode for temperatures above the T_g. This research helps determine guidelines for the fire design of glued-in rods and related testing, and ultimately leading to a design method for providing fire resistance to connections made of glued-in rods.

KEYWORDS: Girods, Fire behaviour, Adhesive, Glass transition temperature, Thermal resistance

1 INTRODUCTION

Glued-in rods, a connection system in which a metal rod is glued inside a wood element by means of a structural adhesive, are gaining in popularity in the construction industry due to their high bearing capacity, good slip stiffness, and great aesthetic. Since the metal rod is concealed inside the wood element, the connection is naturally protected in a fire situation. Wood has a predictable behavior under high temperatures, with a char depth given by Equation 1 [1] where $x_{c,n}$ is the notional char depth (mm), β_n is the notional char rate (0.70 mm/min for glulam) and t is the time (min). Wood also has a high thermal gradient that can be determined through Equation 2 [2], where T is the temperature (°C), T_o is the initial temperature (typically taken as 20°C), T_p is the temperature at the base of the char layer (300°C), x is the position within the thermal penetration depth (mm) and α is the thermal penetration depth (35 mm).

$$x_{c,n} = \beta_n \times t \quad (1)$$

$$T = T_0 + (T_p - T_0)(1 - \frac{x}{\alpha})^2 \quad (2)$$

However, in North America there is no consensus between experts on the design of glued-in rods, and existing standards does not cover all adhesive types, limiting its use in the construction industry [3]. While glued-in rod connections have been well characterized at ambient temperature, their thermomechanical behavior at elevated temperatures using different adhesives has been understudied.

Previous research suggests that the adhesive is the critical element in glued-in rod connections when exposed to elevated temperatures since its capacity decreases drastically when the glass transition temperature (T_g) is exceeded [4-7]. The latter is defined as the temperature where permanent modifications occur in the molecular structure of the polymer, leading to a transition of a solid to rubberlike state of the adhesive [8-11]. At temperatures above the T_g, this results in a considerable loss of adhesion and cohesion in the adhesive layer, translating to a poor performance of the connection with an undesirable brittle failure mode [7, 12-15].

The T_g of an adhesive strongly depends on its type, formulation, curing time, curing temperatures and thermal history [16, 17]. The latter refers to the effect of post-cure, which can increase the T_g by creating additional crosslinks in the adhesive. Furthermore, the T_g is not a fixed temperature, but is rather a range of temperatures that can vary between different test methods, and even within the same test method [16]. For this reason, it is a difficult task to accurately assess the temperature at which the thermomechanical performance of glued-in rods starts to deteriorate. The Dynamic Mechanical Analysis (DMA) is a sensitive method commonly used to determine the range of the T_g for all adhesives tested according to three curves: 1) storage modulus, 2) loss modulus and 3) tan δ. The storage modulus, which is a quantification of the

[3] Pierre Blanchet, Université Laval, Canada, pierre.blanchet@sbf.ulaval.ca

https://doi.org/10.52202/069179-0214

adhesive's stored energy [18], is an indication that the mechanical properties of the adhesive start decreasing at this temperature [19]. The thermomechanical behavior of glued-in rods can be determined through axial tension tests at stabilized temperatures [20], which informs the researcher on the stiffness, capacity, and failure modes of the connections at specific temperatures.

This research aims to characterize the performance of adhesives used in glued-in rods connections at elevated temperature. To do so, the effect of temperatures below the storage modulus, above the storage modulus and above the loss modulus on the resistance, stiffness and failure mode of the connection have been evaluated. The only variables in this research were the nature of the adhesive and the temperature of exposure. The findings will help determine guidelines for the fire design of glued-in rods and related testing.

2 EXPERIMENTAL

2.1 MATERIALS AND DIMENSIONS

Glued-laminated timber (glulam) made from Spruce-Pine of grade 12c-E per CSA O122 [21] provided by Art Massif were used in the fabrication of all glued-in rod specimens. The timber was conditioned at a temperature of 20°C and 65% relative humidity (RH) until their masses were at a constant value, meaning an equilibrium moisture content of ±12%. Each glulam specimen had dimensions of 80 x 104 x 686 mm (length of 1372 mm when fully assembled), with holes of 19 mm in diameter and 402 mm in length drilled in the middle lamella by a computer numerical control (CNC). Threaded steel rods of 16 mm nominal diameter and 800 mm length of grade ASTM A307 [22] with minimal strength of 414 MPa were used. An example of a glued-in rod specimen is shown in Figure 1.

A total of five structural adhesives were used in the fabrication of glued-in rods connections: three epoxies (EPX1, EPX2 and EPX3) and two polyurethanes (PUR1 and PUR2) which were deemed, per the adhesive suppliers, suitable for glued-in rods application. The identity of each adhesive is not provided due to non-disclosure agreements. Once injected into the connection, the adhesive had a 1.5 mm thickness around the steel rod.

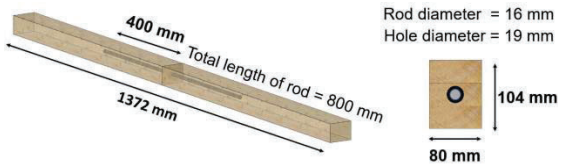

Figure 1: *Glued-in rod specimen*

2.2 FABRICATION OF GLUED-IN RODS

Two 9.5 mm diameter injection/ejection holes were drilled perpendicular to grain at 380 mm from the middle of the glued-in rod specimen. A threaded steel rod was inserted inside the 19 mm drilled hole of a glulam specimen. Prior to concealing the connection with a second glulam, butyl tape was added between both timber elements to limit the spread of the adhesive at this butt joint and have a preliminary bonding. A tight contact between the connection was ensured by two clamps. The adhesive was then continuously inserted through the injection hole until it ejected through the ejection hole. Both holes were closed by 9.5 mm diameter timber dowels to seal the assembly and limit heat flow during the heating of the specimens. The fabrication process is shown in Figure 2. Once fabricated, the glued-in rod specimens were untouched for 48h to allow the cure of adhesive at room temperature. The latter were then transferred to a conditioning room at 20°C and 65% RH for a minimum of 10 days, ensuring the same conditions for all specimens. A total of 67 glued-in rod specimens, consisting of 13 specimens per adhesive plus two additional samples for the EPX3 adhesive, with final dimensions of 80 x 104 x 1372 mm was fabricated.

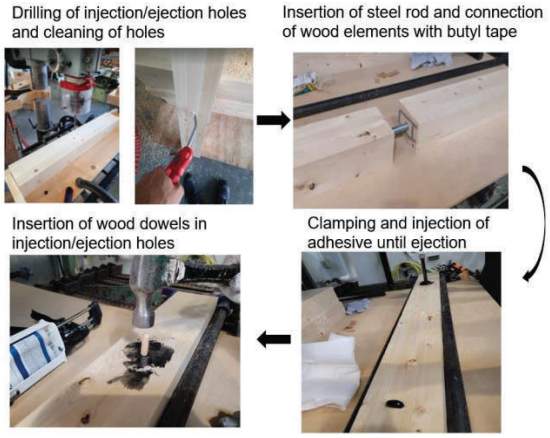

Figure 2: *Fabrication process of glued-in rods*

2.3 CHARACTERIZING ADHESIVES

To better assess the T_g and other thermomechanical properties of the adhesives used in this experimentation, DMA tests were performed. A DMA Q800 machine from TA Instruments was used, with a heating rate of 3ºC/min until 150ºC and a strain of 0.1%. The T_g obtained from these tests were used to determine the various sets of target temperature at which the glued-in rods were exposed for the mechanical testing. A total of 30 DMA tests were performed, meaning each adhesive was tested six times.

A second DMA run was performed on all adhesive samples previously tested, therefore fully crosslinked, to evaluate the effect of post-cure on the T_g from the storage modulus and loss modulus.

2.4 EXPERIMENTAL SET-UP AND INSTRUMENTATION

Four steel plates were fastened to the glued-in rod specimens using 16 self-tapping screws of 120 mm in length fixed at a 45° angle of the longitudinal direction at

https://doi.org/10.52202/069179-0214

each extremity. The number, length and angle of screws were determined to offer a greater resistance than the steel rod at ambient conditions. They have been calculated according to the withdrawal resistance equation from the Canadian Construction Materials Centre (CCMC) Evaluation report 13677-R [23]. To limit the heat transfer at both ends from the high thermal conductivity of the steel plates, the latter were wrapped into ceramic fiber blankets, as shown in Figure 3a.

A total of 8 type K thermocouples (TC) were positioned inside and outside the specimen to monitor the temperature in real time: two TC at the glue line interface (1 and 4), four TC at 15 mm around the glue line interface (2, 3, 5 and 6), one TC on the surface (7) and one TC in the oven (8), as shown in Figure 3b and 3c. A firestop caulking was used to seal the holes drilled for the insertion of each TC.

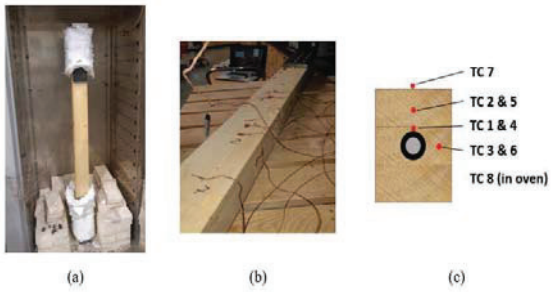

Figure 3: *Heating experimental set-up*

2.4 AXIAL TENSION TEST AT STABILIZED TEMPERATURE

The glued-in rod specimen was inserted inside an oven preheated at 200°C, regardless of the target temperature, to expose each specimen to the same heating conditions. The oven temperature was set to be below the auto-ignition temperature of the glulam, while being sufficiently high for an adequate heat transfer. The target temperatures used in this research were: 1) 21°C (ambient), 2) just below the T_g found through the storage modulus, 3) between the storage and loss modulus, and 4) above the loss modulus specific to each adhesive. Once the average of both TC at the glue line interface (1 and 4) reached the predetermined target temperatures, the specimen was transferred and fixed to the axial tension test bench within 10 minutes.

Four 25 mm Linear Variable Differential Transformer (LVDT) lasers were installed (two on each side of the large face) at 12.5 mm from the center of the specimen, as shown in Figure 4a. The LVDT lasers allowed to adequately measure the slip of the connection from all sides when axially loaded. Each specimen was subjected to an axial displacement rate of 0.5 mm/min until failure of the connection. Pin-pin end conditions were used to connect the specimen to minimize additional bending moment applied on the glued-in rod (Figure 4b). The temperature within the specimens was constantly monitored throughout the entire duration of the axial tension test to ensure that the glue line's temperature remained near the target.

Upon the failure of the specimen during the axial tension test, the failure mode was determined, and load-slip curves were generated, giving information on the strength of the connection (F_{max}), i.e. the peak of the load slip curves, and the stiffness of the connection (k_i). The latter was calculated following Equation (3) provided by EN 26891 [24] standard, where v_i is the slip at $0.4F_{max}$.

$$k_i = \frac{0.4F_{max}}{v_i} \tag{3}$$

Two additional tests were performed on the EPX3 specimen (EPX3-14 and EPX3-15) to determine the effect, if any, of post-cure on the thermomechanical behavior of glued-in rods. The latter were previously heated at the T_g of the fully crosslink adhesive (65°C) for three hours. These specimens rested for 12 hours at ambient conditions before heating in the oven for a second time and performing the axial tension test.

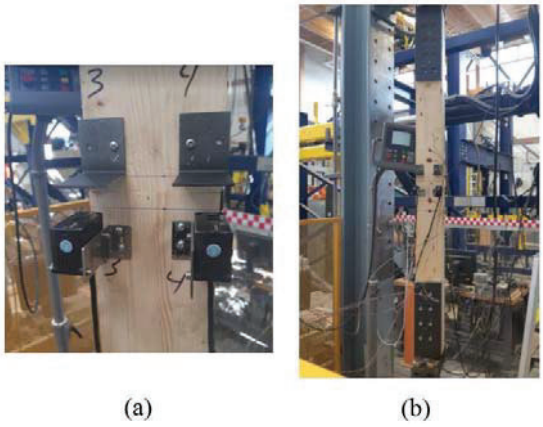

Figure 4: *Axial tension test set-up*

3 RESULTS

3.1 DMA TESTS

A total of six DMA tests were performed for each adhesive to determine the T_g through the storage modulus, loss modulus and tan δ. The former was identified by the intersecting the tangent at the top of the curve and at its inflection point, while the loss modulus and tan δ were valued at the peak of their respective curves, as show in Figure 5.

https://doi.org/10.52202/069179-0214

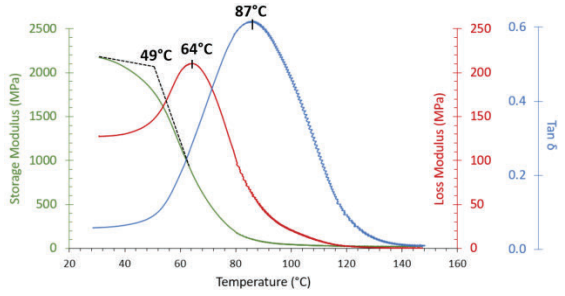

Figure 5: *DMA test of EPX1-3 specimen*

Table 1 displays the average T_g values of the storage modulus and loss modulus of each adhesive tested. Since the mechanical and physical properties of adhesives are already significantly affected at temperatures above the loss modulus, results for the T_g found through the tan δ are not displayed and will not be considered hereafter.

Table 1*: T_g values based on storage and loss modulus*

Specimen	Storage modulus (°C)	Loss modulus (°C)
EPX1	52	67
EPX2	48	59
EPX3	51	60
PUR1	56	71
PUR2	24	34

Table 1 shows that the storage modulus of all epoxies (EPX) samples was similar, with a difference of less than 4°C between each other. A greater dissimilarity was found for the loss modulus of the latter, with an 8°C difference at most. The polyurethane (PUR) specimen 1 had the highest Tg found through the storage modulus and loss modulus, while the PUR2 specimen demonstrated the poorest values of all adhesives. In addition to the reference specimen tested at ambient conditions, these results were used to determine the target temperatures each glued-in rod specimen was exposed during the axial tension test at stabilized temperature.

The post-cure effect did not have the same influence on the T_g of all adhesives. The EPX1, PUR1 and PUR2 adhesive specimens showed a decrease in the average T_g found through the storage modulus compared to the first heating cycle. The EPX2 and EPX3 adhesives demonstrated a considerable positive impact in their storage modulus, with an increase of +7°C and +15°C, respectively. As for the T_g found through the loss modulus, the EPX1 specimen showed a reduction while the EPX2, EPX3, PUR1 and PUR2 specimen had an increase ranging from +5°C to +19°C. Figure 6 displays the difference in the T_g between the first and second heating cycle for all adhesives. Since the EPX3 was the most positively affected by the post-cure, it was chosen to determine the effect on the thermomechanical properties of previously heated glued-in rod connections.

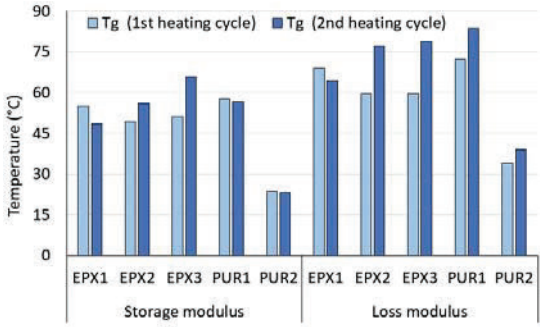

Figure 6: *Influence of post-cure on T_g*

3.2 MECHANICAL BEHAVIOR OF GLUED-IN RODS AT DIFFERENT TEMPERATURES

The reference values and failure mode for each glued-in rod specimens fabricated with a different adhesive were determined from an average of three specimens per adhesive tested at ambient temperatures. The average resistance and stiffness at 21°C for the EPX1, EPX2 and EPX3 specimen were respectively 75 kN and 177 kN/mm, 72 kN and 161 kN/mm, as well as 74 kN and 180 kN/mm. While the PUR1 specimen had a similar average resistance and stiffness than the EPX specimens, i.e. 74 kN and 178 kN/mm respectively, the PUR2 specimen had average values of 73 kN and 62 kN/mm. Most specimens had a ductile failure mode in the steel rod (Figure 7a), except for the PUR2 specimens which all failed in a brittle manner in the adhesive layer (Figure 7b).

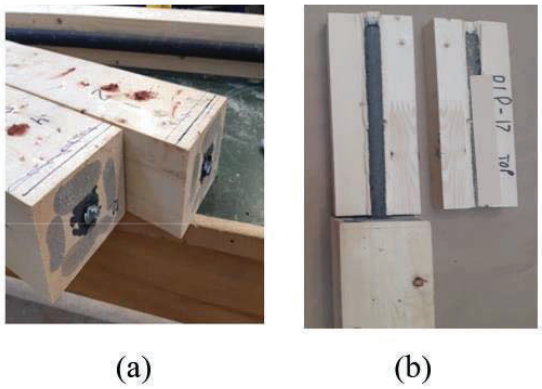

Figure 7: *(a) Ductile failure and (b) brittle failure mode*

When tested at temperatures just below the storage modulus specific to each adhesive, the resistance of almost all specimens dropped by less than 4%, regardless of the adhesive. However, the specimens tested closest to the storage modulus showed a decrease of between 23% and 29% for the EPX1, EPX3 and PUR1 adhesive, while the EPX2 adhesive demonstrated a reduction of 17%. At this temperature the failure mode remained ductile in most cases, while a brittle failure mode in the wood component

https://doi.org/10.52202/069179-0214

occurred for in the EPX2 specimen. Given that the T_g found through the storage modulus of the PUR2 was relatively low, no tests were performed at this temperature for the latter.

When tested at temperatures just above the storage modulus, the capacity of the glued-in rod specimens remained similar than the reference values, with a reduction of less than 5%. As for the stiffness, a reduction of between 59% and 70% was observed in the EPX1, EPX2, EPX3 and PUR1 specimen when compared to their respective reference value. The PUR2 specimens showed a stiffness reduction of 23%. A ductile failure mode occurred for all EPX1 and EPX3 specimen, while the adhesive failed in all EPX2, PUR1 and PUR2 specimens.

As the temperature increased closer to the T_g based on the loss modulus, the capacity of the EPX1, EPX2 and EPX3 decreased by 28%, 22% and 4%, respectively when compared to the reference values. The PUR1 specimen showed the largest decrease with 41%. The stiffness of those specimens decreased by between 66% and 77%. The PUR2 specimen had a reduction in its capacity and stiffness by 14% and 36%, respectively. All specimens demonstrated a brittle failure mode in the adhesive layer.

The mechanical properties of all specimens further decreased when tested at temperatures above the loss modulus, which was around 79°C. Almost all specimens had lost more than 50% of their initial strength, and more than 74% of their initial stiffness. In the case of the PUR2 specimens, it lost 65% of its initial strength and 57% of its initial stiffness. A brittle failure in the adhesive layer occurred in all specimens. The temperature (T) in °C, capacity (cap) in kN and stiffness (stiff) in kN/mm are displayed in Table 2 and 3 for the EPX and PUR, respectively. Figures 8 to 12 shows the evolution of the capacity, stiffness and failure modes of all specimens as the temperature increases.

When evaluating the effect of post-cure, i.e. the thermomechanical behavior of a glued-in rod specimen with a fully crosslinked adhesive, the EPX3-14 specimen had an increase of 14% in the resistance and an increase of 99% in the stiffness compared to the EPX3-13 specimen which did not go through two heating cycles. Both specimens were tested with a glueline temperature of 65°C. The EPX3-15 specimen also demonstrated an increase in the capacity and stiffness even when compared to specimens tested with a lower glueline temperature, as shown in Figure 13.

4 DISCUSSION

The DMA tests revealed that the T_g of all adhesives, except that of the PUR2, was similar. Therefore, the thermomechanical behavior of each glued-in rod specimens could be easily compared, and correlations can be drawn. A significant increase in the capacity and stiffness occurred in both specimens that were exposed to two heating cycles, i.e. where a post-cure effect was intentionally evaluated. The latter suggest that the method chosen to evaluate the thermomechanical properties of the glued-in rods did not enable the adhesive to fully crosslink, leading to representative results.

The results of the axial tension test suggest that the mechanical properties of the adhesive, thus the glued-in rod connections, are considerably affected when the glueline interface is exposed to elevated temperatures. As it can be observed in this research, the Tg found through the storage modulus of a DMA test is a good indication that the connection will not have the same mechanical behavior, regardless of the adhesive. In fact, all specimens have shown that when exposed to temperatures below the storage modulus, only a small decrease of the capacity occurred (≤4%) while a more noticeable decrease in the stiffness was observed (≤29%). However, the failure mode remained ductile in most specimens.

When the glueline temperature exceeded its T_g found through the storage modulus, the stiffness of all adhesives dropped by up to 70% compared to their initial stiffness. The failure mode occurred in the adhesive layer rather than the steel rod in three adhesive specimens, while it remained ductile in the other two adhesives tested. As the temperature at the glueline interface increased closer to the Tg of the loss modulus specific to each adhesive, all specimens had a brittle failure mode in the adhesive layer. This suggests that the thermomechanical behavior glued-in rods at this temperature is dependent on the nature of the adhesive.

The loss of capacity and stiffness of glued-in rods at elevated temperatures can be attributed to the increased mobility of molecules in the internal structure of the adhesive, leading to a rubbery state of the latter. This also translated into an undesired failure in the adhesive layer.

These observations align with the results of Verdet *et al.* [7], Lahouar *et al.* [8], Lartigau *et al.* [9], Di Maria *et al.* [12] and Luo *et al.* [15]. However, the findings of this research have determined that the Tg found through the storage modulus of a DMA test would be a reliable limit to impose for the temperature at the adhesive interface. These observations could pave the way for provisions and guidelines for the fire design of glued-in rods.

For example, to design a glued-in rod with the EPX1 adhesive (i.e. with a Tg from storage modulus of 52°C) required to provide a fire resistance rating of 1h without using protective materials, the designer would:

1. Determine the depth of the char layer from Eq.1:

$$x_{c,n} = 0.7 \times 60 = 42\ mm$$

2. Determine the position at which the temperature would reach the Tg from the storage modulus after 1h of fire from an adaptation of Eq.2:

$$x = \frac{35}{\sqrt{\frac{52-20}{300-20}}} = 103.5\ mm$$

3. Add both values:

$$Min.dimension = 42 + 103.5 = 145.5\ mm$$

Therefore, a glued-in rod fabricated with the EPX1 and a cross-sectional dimension greater than 146 x 146 mm would be adequate to resist a 1h fire scenario. This would assume that the butt-joint between the glulam elements would be properly fire-stopped to prevent fire penetrating and directly affect the steel rod.

5 CONCLUSION

Even though glued-in rods are a type of connection that is gaining in popularity, their thermomechanical behavior has been understudied, thus limiting its inclusion in standards around the world. Many researchers have suggested that the Tg of the adhesive used was the critical temperature at which the mechanical properties of the glued-in rods will deteriorate. Yet, the Tg is a range of temperature that can vary according to the method of determination chosen or the parameters used within a method. The results suggest that a Dynamic Mechanical

https://doi.org/10.52202/069179-0214

Analysis is an accurate method to inform on the properties of adhesives at different temperatures by determining the Tg through the storage modulus, loss modulus and tan δ. The objective of this research was to characterize the performance of adhesives used in glued-in rod connections at elevated temperatures. The following key observations have been found throughout this research for different temperatures at the connection's glueline interface:

1. All glued-in rod specimens had over 95% of their initial load-carrying capacity when the temperature at the bondline was lower than their respective Tg found through the storage modulus of a DMA test;
2. Except for the PUR2 specimen, no failure occurred in the adhesive layer below their respective storage modulus, while 3/5 adhesive specimens failed at temperatures just above the storage modulus;
3. All glued-in rod specimens had a brittle failure in the adhesive layer when the latter reached temperatures close to their respective loss modulus;
4. The stiffness of glued-in rods is most affected by elevated temperatures, with a decrease of up to 70% at temperatures just above the storage modulus;
5. The axial tension test at stabilized temperature did not enable a considerable post-cure effect, thus providing representative results on the thermomechanical properties of glued-in rods.

Therefore, the Tg determined through the storage modulus of a DMA test would be a reliable limit to impose for the temperature at the adhesive layer. Above the latter, the thermomechanical behavior of the connection is dependent on the nature of the adhesive, which could lead to unsafe connections. It is recommended to take precautions, i.e. protect with gypsum board, fire protective coatings or increase the section dimension, to limit a temperature rise above the Tg found through the storage modulus of a DMA test at the bondline.

Future research on the fire performance of glued-in rods should include an exposure to a standard fire curve, more repeatability at temperatures between the storage modulus and loss modulus, and/or evaluate the fire performance of glued-in rods subjected to a bending moment.

Some limits of this research include the grade of the ASTM A307 rod, since only a minimal tensile strength of 414 MPa is required by the standard. Furthermore, the charring at the butt joint of the connection, which could expose the steel rod to high temperature and increase the heat conductivity along the rod was not considered.

NUMERICAL MODELLING OF CONTEMPORARY MASS TIMBER CONNECTIONS IN FIRE

Bronwyn Chorlton[1], Mathieu Létourneau-Gagnon[2], Christian Dagenais[3], Marc-André Langevin[4]

ABSTRACT: Timber buildings are becoming increasingly popular due to their sustainability and aesthetic appeal. There remains however, a need to fully understand the fire performance of mass timber construction, including the fire performance of the connection. Beam-column connections can be complex to assess in fire, due to the proprietary and custom nature of many connection designs. The purpose of this study is to create a numerical model that can assess the residual fire resistance capacity of mass timber connections exposed to fire. This endeavour was completed using finite element modelling considering heat transfer of mass timber connections. Two approaches were taken, first, the heat flux through the fastener's shank establishes the reduction factors that predict the residual thermal capacity of fasteners, and the second establishes the residual length of penetration that provide adequate structural capacity into timber elements. These thermal analyses work towards developing a simplified design method for evaluating mass timber connections exposed up to two hours of standard fire exposures. By providing additional information related to the expected temperatures and strengths of timber connections in fire, novel designs become more accessible for innovative timber structures.

KEYWORDS: fire, connections, mass timber, numerical modelling

1 INTRODUCTION

Fire design of connections in timber buildings faces unique challenges due to the interaction of combustible structural elements and noncombustible metallic fasteners that perform differently in fire conditions. Given that there are a multitude of possibilities for how mass timber connections might be designed, with trends for connection configurations continuing to be developed, design tools are needed for timber connections to understand the effect of parameters such as the number and size of fasteners used, as well as the spacing in between fasteners. While standard fire tests are always an option, this type of testing can be costly and time consuming when only a small change is made to a design in attempt to optimize either the thermal or the thermomechanical performance of the mass timber connection.

Traditionally, heavy timber construction used steel or iron caps, as well as large metallic hangers and plates (Figure 1). These were used on buildings where little to no fire-resistance rating was prescribed in building codes. When such a connection is used, the metallic cap directly transfers the gravity loads to the column below and the beams are directly supported on top of that column. As such, even if this cap heats and loses strength, it will most likely not result in structural collapse. Based on their good historical performance, it is usually agreed that this type of construction provides an acceptable level of fire safety.

Figure 1: *Traditional heavy timber construction using iron/steel connections.*

With the recent advances in mass timber construction and products, construction and design techniques have also evolved. Taller buildings are also typically required to provide greater fire-resistance ratings, up to 2 and 3-hours, which is much beyond the deemed performance of traditional timber construction. Innovative fasteners such as self-tapping screws are gaining lots of popularity due to their ease of use and high capacity, while being aesthetically pleasant. While there has been a shift towards shear-type connection (i.e., similar to steel

construction), modern connection design is going back to traditional timber engineering method – that is to use as much of the timber embedment and compression strength and conceal all metallic components. Figure 2 shows a modern version of the same type of connection shown in Figure 1. Gravity loads are being transferred directly to the column underneath and beams are also supported by that column. Little to no forces are being transferred in the metallic (concealed) fasteners. While the engineering behind these designs are sound, there is a need to better understand the underlying thermomechanical properties and performance of modern mass timber connections.

Figure 2: *Modern timber construction using concealed connection.*

The objective of this study is to develop a numerical model using finite element analysis software that can predict the thermomechanical behaviour of contemporary mass timber connection configurations, for exposure durations longer than one hour. The development of these models will provide information to designers regarding the distribution of the temperatures in different connection configurations, allowing for an understanding of the heating rate through the fastener's shank into timber element for a standard fire exposure. The results will ultimately be used to validate an analytical model to predict the structural fire resistance of connections in design standards.

2 BOLTED CONNECTIONS

Herein, a series of experimental studies will be discussed to assess the developed numerical model. Many of these tests consider the timber assembly loaded in tension parallel to grain, and for a relatively short duration.

From the University of Canterbury, Chuo [1] considered the fire performance of Hyspan laminated veneer lumber connections. The connections were loaded to either a factor of the characteristic strength of the bolts used, and exposed to the ISO 834 [2] standard fire. The fire resistance of the connections was found to be less than 25 minutes.

In 2010 from Carleton University, Peng [3] published an experimental test series looking at the performance of wood-steel-wood and steel-wood-steel bolted connections using 20f-EX S-P glulam (test groups 2 through 5) and No. 2 SPF dimensional lumber (test group 1), loaded in axial tension and exposed to the CAN/ULC-S101 [4] standard fire, where it was found that the fire resistance of the bolted connections was less than 45 minutes. The tests were loaded to a fraction of their calculated ultimate load capacity. The experimental component of the study was followed by the creation of a finite element model which agreed well with the experimental data.

Also from Carleton University were test series completed by Alam [5] and Ali [6]. Alam tested four wood-steel-wood connections in tension, exposed to the CAN/ULC-S101 standard fire. The wood members in Alam's study were 24F/NPG glulam while Ali used 24F/ES12 glulam. Alam's assemblies were loaded to their calculated faxtored axial tensile strengths, and times to failure ranged from 12 to 32 minutes. Ali performed bending tests of beam-to-column timber connections, with either concealed, seated, or exposed steel plates. The glulam beams were 140 × 191 × 1 900 mm, and were loaded using third point loading configuration. The specimens were exposed to the CAN/ULC-S101 standard fire. Only Tests 1.1 and 1.2 by Ali are considered herein, both concealed steel connections (e.g., knifeplate connections).

Select connections from the above experimental tests from literature are considered in analysing the model results in Section 2.2 of this study. The connections considered herein are outlined in Table 1.

2.1 METHOD

A numerical model was created using ABAQUS to carry out transient heat transfer modelling of metallic fasteners into the timber. The purpose of this model was to determine the temperature profiles of the metallic fasteners, in order to understand how much strength could potentially be lost during heating that occurs during the thermal exposure. Bolted connections were considered due to experimental data regarding these connection types being widely available in literature.

In developing the ABAQUS model, bolts were assumed to have a hole 2 mm greater than the diameter of the bolt, as per CSA O86 [7]. Thus for this analysis, a 1 mm air space was assumed to be evenly surrounding the bolt. In reality, a portion of the bolt would be in contact with the surrounding wood, and a portion will have an air gap larger than 1 mm, however, previous studies have found that the size of air gap has little effect on heat transfer when the size of the gap is less than 4 mm [3]. Washers were assumed to be located between the bolt head and the top surface of the timber, and were taken as the maximum washer size as permitted by CSA O86. Fastener threads have been neglected in this model, as previous studies have found that neglecting threads can reduce computational time without significantly affecting the heat transfer of the model [8].

1 – Side member thickness
2 – Centre member thickness – all steel; except Chuo 1 and 2
3 - Fastener diameter
4 – Row number
5 - Number of fasteners in a row
6 – Two rows of 2 fasteners, 1 row of 1 fastener
7 – Concealed beam-column connection

Connections were subjected to the CAN/ULC-S101 from one side, and the distribution of temperatures through the fastener's shank into timber element were observed. A schematic of the ABAQUS model is seen in Figure 3. The transient heat transfer modelling was compared to temperatures as reported in existing literature.

Based on the interaction of timber and steel, the residual capacity of the connections exposed to the CAN/ULC-S101 standard fire was estimated. This was done by assessing the temperature at the interface of the shank of the bolt with the timber, and reducing the strength of the bolt according to temperature, as per the steel reductions outlined in CSA S16 [9]. Though the temperature on the outside of the bolt may not be quite as hot as at the centre of the bolt, assessing temperature along the side will allow for comparison with any future experimental testing in which a thermocouple could be placed at the interface of the timber and the bolt. The degradation of the timber followed the reduced cross section method as outlined by Annex B of CSA O86. A schematic of the ABAQUS model for a 12.7 mm bolt after 15 minutes of standard fire exposure is seen in Figure 4.

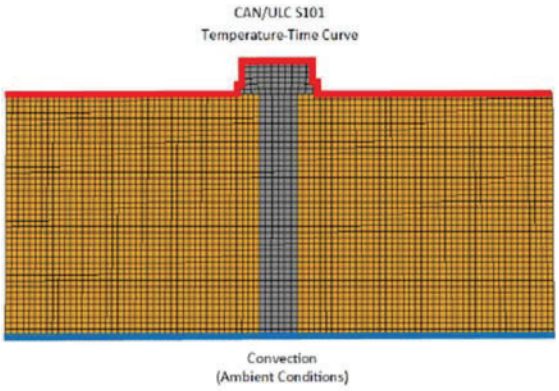

Figure 3: *Schematic of ABAQUS model (15 min exposure).*

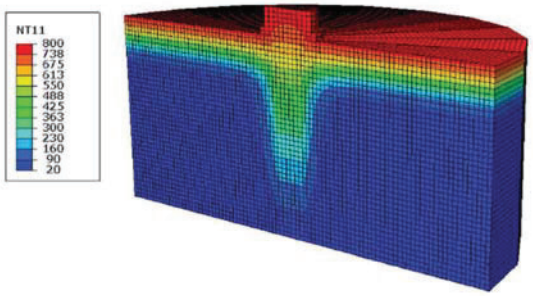

Figure 4 : *Schematic of ABAQUS model (15 min exposure).*

It is noted that only thermal degradation of the timber and the metallic bolt are considered herein. Strength loss of any steel plates used in the connection is not considered. This assumption was made as the ABAQUS model only considers heat transfer in one dimension. Thus, the steel plates largely remained at ambient temperature throughout the duration of the thermal exposure. However, for longer thermal exposures and more severe thermal exposures, strength loss of the steel plate due to fire should be explicitly considered.

2.2 RESULTS

Figure 5 presents a comparison of the experimental fire resistance as reported in the literature, the calculated fire resistance time considering only the degradation of the timber (the bolt is considered to retain full strength), and the calculated failure resistance time considering both the degradation of the timber, as well as a reduction of strength of the bolt using temperatures extracted from the ABAQUS model and reduced per Annex K of CSA S16. The temperature of the bolt was taken at the intersection of the bolt and the timber, along the top surface of the timber (immediately below the washer). Through the analysis, temperature of the bolt was taken at other locations along the shank for consideration and analysis into the optimal depth to read bolt temperature – these

depths included at set depths (e.g., 10 mm from the face of the timber), and as a function of the final char depth (e.g, 10% the depth of the char). It was found that using the temperature directly beneath the washer resulted in greater temperature (thus greater steel strength reduction), and ultimately better predictions of the failure times.

For the most part, the calculated results were more closely aligned with the experimental results when considering a strength reduction for the steel bolt, correlated with temperature. The exception to this would be the experiments performed by Alam [5], where the specimens were loaded to the CSA O86 predicted ambient factored failure load. Thus, any additional reduction in strength, either via the charring of the timber cross-section or the reduction in steel strengths only shortened the calculated fire resistance time. The experimental fire resistance time was therefore much greater than predicted.

The test series by Ali [6] considering beam-column connections in bending were also analysed using the method outlined above. It can be seen in Figure 5, in the case of Ali, that the modelling used to reduce the strength of the fastener did not affect the predicted fire resistance of the assembly. This is because the failure mode, considering only the timber's reduction in cross-sectional area, was found to be bending at the connection, which is not dependant on the strength of the fastener. Nevertheless, considering the degradation of the timber only, the calculated results had relatively good agreement with the experimental tests (with a calculated failure at 38 min, compared to 33 min for Test 1.1, and 40.3 for Test 2.1).

The calculated results, as seen in Figure 5, still had some deviation from the experimental results. However, considering the reduction in steel fastener strength at high temperature in addition to reduction of timber cross section did make a considerable difference in more closely aligning the experimental and calculated fire resistance times. Considering the degradation of the timber only, the average percent difference between the experimental and calculated fire resistances was 87%, whereas considering the degradation of the timber in addition to the strength reduction of the bolt, the average percent difference between experimental and calculated fire resistances was 37%.

2.3 DEVELOPMENT OF REDUCTION FACTORS FOR BOLTS

As it was found that the calculated fire resistance times were better aligned to the experimental results when the strength reduction of the bolts at high temperatures are considered, a series of reduction factors are proposed herein. From the temperature of the bolt at a given time – either 15 or 30 mins – a reduction factor was determined per the reduction factors outlined in CSA S16-19 Annex K [9] which is applied to the ultimate and yield strengths of the steel fastener. The reduction factors are in relation to the initial strength of the material (i.e., the strength at 20 °C). The resulting reductions for each fastener type are summarized in Table 2. It should be noted that the results of this study are, at this point in time, limited to the tests available in literature. Thus, the results are limited to 12.7 and 19.1 mm bolts, tested for up to a maximum of 31 minutes. Model development also relied on experimental tests of tension connections, with a bending test also considered as a point of comparison (however the calculated failure mode of the bending test was independent of bolt temperature). Thus, the results of Table 2 apply to short duration fires where the members are loaded in tension.

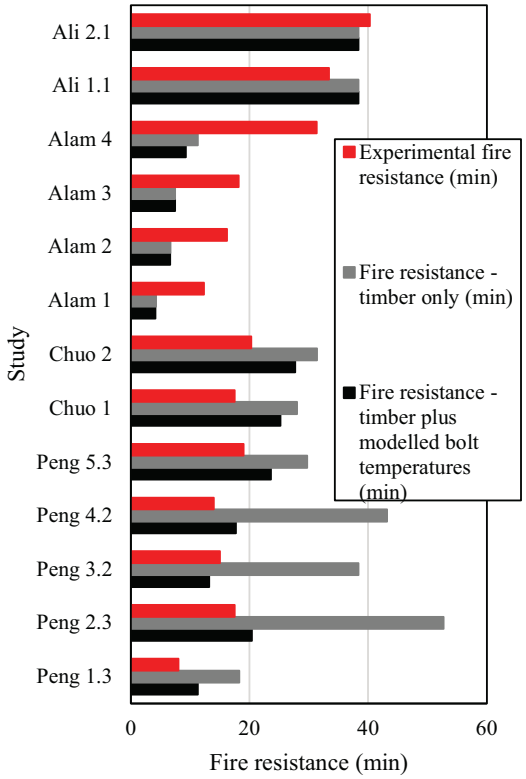

Figure 5: *Experimental and calculated fire resistance times for the tensile tests.*

The reduction factors were applied to the steel strengths within the connection equations of CSA O86-19. In essence, the reduction factors would be applied to the steel fastener strengths, and the capacity evaluation of the connection would be combined with a reduced cross-section approach for the timber portion of the connection (i.e., the dimensions of the timber will reduce with the time of fire duration, accounting for the charring rate and zero-strength layer set out by Annex B of CSA O86-19 [7]).

While the outcomes detailed herein provide a basis towards a calculation method in which the connection of timber structures can be considered at high temperature, further research and testing are needed to expand the applicability of these results. With additional testing of longer durations and testing of other connection configurations, the method presented in this study of deducing a reduction factor from the expected thermal

https://doi.org/10.52202/069179-0215

profile of a fastener can be extended to scenarios beyond short duration fires on tension connections.

Table 2: *Proposed reduction factors*

Bolt size (mm)	Standard Fire Exposure (min)	Steel Reduction Factor
12.7	15	0.22
	30	0.13
19.1	15	0.26
	30	0.15

3 SELF-TAPPING SCREWS

The fire performance of the self-tapping screw (STS) is mainly influenced by the residual capacity of the wood surrounding the fastener, i.e., the residual penetration length. This residual penetration length is affected by the heat conduction through the fastener shank which depend on its thermal capacity and fire exposure [10].

To evaluate the conductive heating rate of different mass timber fasteners, another transient heat transfer model using the finite element (FEM) method was developed to compare the effects of geometric parameters on the thermal behaviour of the fastener, such as the length, the size of the head, and the shank diameter.

3.1 MATERIALS AND METHODS

Six full-thread screws with self-drilling tip and countersunk head (SWG ASSY®3.0 VG CSK) and one full-thread screw with self-drilling tip and cylinder head (SWG ASSY®3.0 VG CYL) were examined with the head exposed to CAN/ULC-S101 standard fire. The STS are made of carbon steel and have a bending yield strength of 1015 to 1147 MPa and a shear strength of 341 to 533 MPa, depending on the types of STS [11]. Three high-strength structural bolt diameters (Ø12.7 mm, Ø19.1 mm and Ø25.4 mm) were examined. A length of penetration of 200 mm was assumed for all bolt-type fasteners. In attempt to evaluate the impact of bolt head, one dowel diameter of Ø12.7 mm were also examined. The dimensions of fasteners are presented in Table 3 and Table 4.

Table 3 : *Dimensions of self-tapping screws in accordance with CCMC 13377-R [11]*

Outside Thread Diameter (d_F) (mm)	Head Diameter (d_{head}) (mm)	Shank Diameter (d_{min}) (mm)	Length (L)/ Threaded length (L_F) (mm)	Penetration (mm)

[1] Dowel

Each fastener was inserted in a glulam of the 20f-EX spruce-pine stress grade conforming to CSA O122 [12]. The exposed top surface of timber element was 100 mm diameter with 8-ply of 35 mm, as shown in Figure 6. For the STS with a length of 400 mm and 800 mm, the STS was inserted in a 17-ply glulam and a 24-ply glulam to fully surrounding the STS with wood fibres.

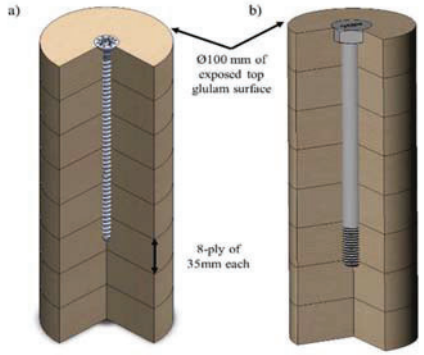

Figure 6 : *Geometrical configurations: a) Ø10 × 200 mm SWG ASSY®3.0 VG CSK inserted in 8-ply glulam; b) Ø12.7 × 179 mm A325 bolt inserted in 8-ply glulam.*

The three-dimensional transient heat transfer model through a solid timber using ANSYS was developed with a fastener inserted at the geometric center of the glulam element in attempt to characterize the thermal penetration depth of fasteners. The top surface of the glulam specimen and the head of the fastener were exposed to the CAN/ULC S101 standard fire for two hours. Eleven (11) heat transfer models were developed, i.e. one for each fastener type. The same boundary conditions were applied, as previously discussed in Section 2.1. Due to symmetry, the transient thermal model was performed only for one quarter of the specimen and cylindrical shank of the fastener (i.e., no threads), as shown in Figure 7a). The 3D temperature fields were also divided into elements with a length of 3 mm using 3D hexahedral elements.

To compare the temperature distribution between the simulation and the fire tests, five (5) coordinate systems and five (5) thermocouples were created in the heat transfer model at the exposed surface (0 mm), 1st glueline (35 mm), 2nd glueline (70 mm), Mid-length of the fastener, 3rd glueline (105 mm), and the tip of the fastener as presented in Figure 7b).

3.2 RESULTS

3.2.1 Influence of STS fastener diameter

Exposing the cylinder head (CYL) and the countersunk head (CSK) of Ø10 × 200 mm STS had some influence on the temperature distribution along the fastener. For similar temperatures at the fasteners' head, the thermocouples at the mid-length (100 mm), and at the tip (200 mm) of the STS estimated temperatures of 402 °C and 143 °C for CYL, whereas the temperatures reached 413 °C and 151 °C for CSK after two hours of fire exposure, as shows in Figure 8. The variation of temperatures between the two STS was due to the larger head diameter at the exposed surface, which was 19.6 mm for the CSK compared to 13.4 mm for the CYL. While little differences were observed, the results suggest that the larger heated area of CSK increases the amount of heat conduction along the shank inside the timber.

Moreover, the shank diameter of the fastener was also influencing the temperature distribution along the fastener when comparing the different diameter shank of CSK fastener. For instance, the temperature of the Ø8 mm CSK at the tip (200 mm) was around 110 °C, compared to 133 °C at the tip (200 mm) of the Ø12 mm CSK after two hours, as shown in Figure 8.

The same results are being observed with bolts and dowel where the temperature through the fastener increases with the diameter of the head and shank. Figure 9 shows the measured temperatures of the bolts and dowels analyzed. As expected, the bolt and dowel fasteners reached much higher temperatures along the fastener shank due to the larger thermal capacity.

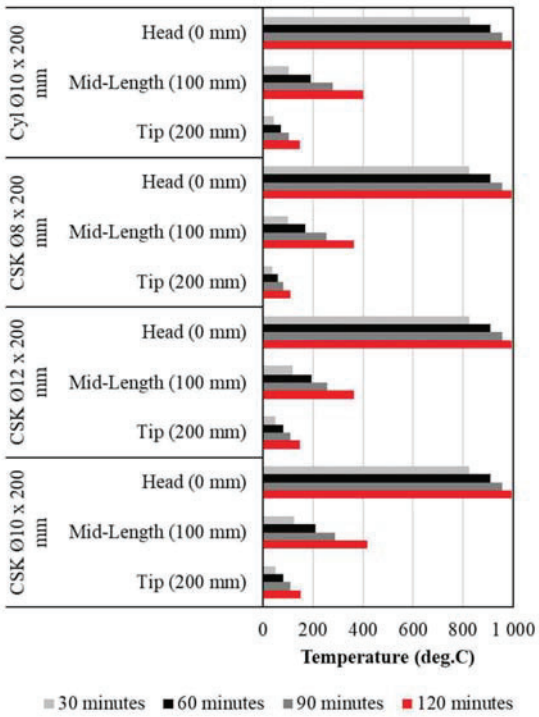

Figure 8 : *Distribution of temperatures on unprotected STS head using three (3) various STS outside diameters under the CAN/ULC-S101 [4] standard fire .*

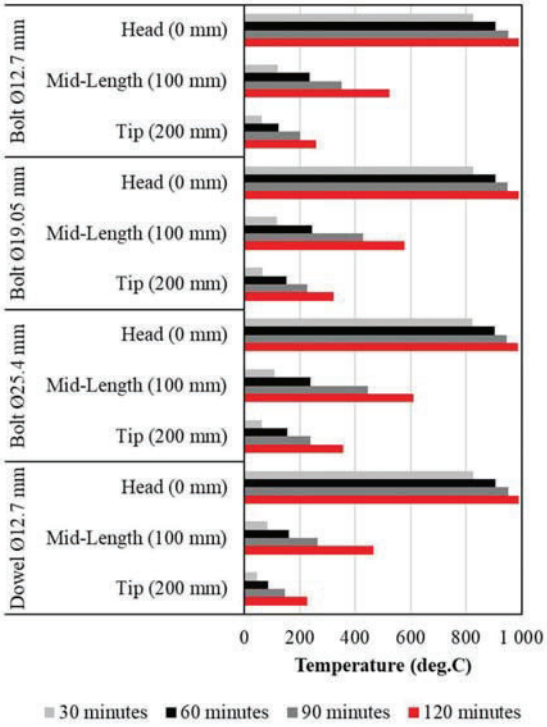

Figure 9 : *Distribution of temperatures on unprotected bolt and dowel head using (3) various shank diameters under the CAN/ULC-S101 [4] standard fire .*

https://doi.org/10.52202/069179-0215

In attempt to evaluate the impact of the shank diameter on the temperature distribution along the fastener, Figure 10 presents the temperatures at the mid-length (i.e., depth of 100 mm) of the screw-type and bolt-type of 200 mm long fasteners when exposed to the standard fire of CAN/ULC S101 for one and two hours. Three (3) shank diameter of screw-type fasteners (i.e., Ø5 mm, Ø6.2 mm, and Ø7.1 mm) and three (3) shank diameter of bolt-type fasteners (i.e., Ø12.7 mm, Ø19.05 mm, and Ø25.4 mm) were analyzed to compare the heat transfer through the fastener's shank.

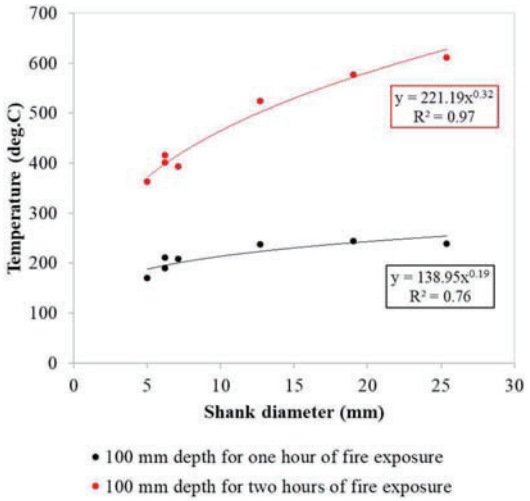

Figure 10 : *Temperatures on different fastener shanks exposed to the CAN/ULC-S101 [4] standard fire .*

The temperature distribution seems to increase as a power function with the shank diameter of the fastener, as illustrated in Figure 10. Influenced by the duration of fire exposure with higher temperatures for longer exposure, the power functions generated from the temperature data predicted by the FEM model shows high coefficients of determination R^2, suggesting that the natural power fitting curve is adequate (which is somewhat expected given that the standard fire exposure is characterized using a power curve). This effect demonstrates that the temperature along the fastener seems to increase as a power function with the shank diameter of the fastener, regardless of fastener types. Therefore, the results support the assumption that the conductive heating rate through the fastener shank is proportional to the amount of exposed area and thereby increasing as a power form with the shank diameter of the fastener, regardless of fastener types.

3.2.2 Influence of fastener length

The length of fasteners showed the greatest influence on the temperature distribution along the fastener shank. The ability of STS to penetrate the timber further away from the exposed surface allows the timber thermal capacity to limit heat transfer along the fastener. This effect was observed by increasing the length of Ø10 mm STS exposed to two hours of fire exposures, as shown in Figure 11.

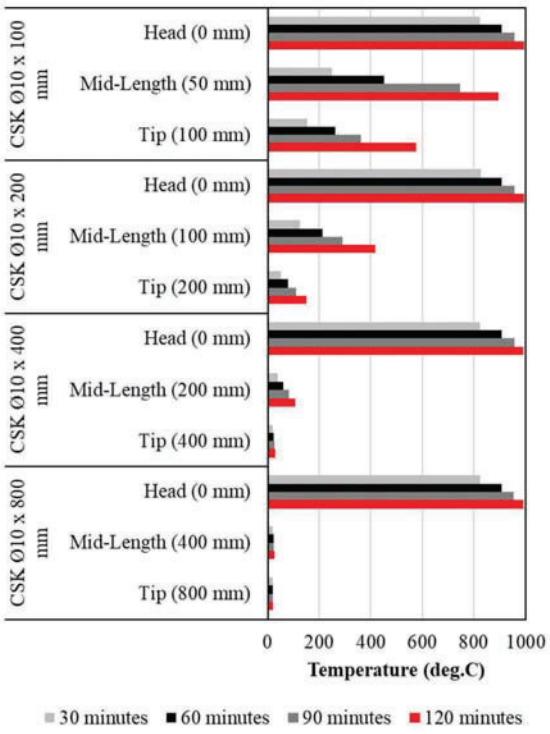

Figure 11 : *Distribution of temperatures on unprotected STS head using three (3) various STS lengths exposed to under the CAN/ULC-S101 [4] standard fire.*

For similar diameter at the head and the shank, using longer STS decreases the temperature along the fastener. For instance, the tip temperature of a 100 mm long STS (i.e., depth of 100 mm) is 154 °C, while a mid-length temperature of 200 mm long STS reached of 124 °C at the same distance from the exposed surface after 30 min, as shows in Figure 11. In addition, the 400 mm and 800 mm long STS maintain temperatures under 100°C along the screw at its mid-length and tip for up to two hours of fire exposure.

In attempt to evaluate the impact of the length of the fastener on the temperature distribution along the fastener, Figure 12 presents the temperatures at a depth of 100 mm and at a depth of 200 mm for a Ø10 mm STS by increasing the length of STS between 100 mm to 800 mm. The temperature distribution by increasing the length of fastener did not have a substantial influence on the heat transfer through the fastener, as similar temperatures were noted at the same depth from the exposed surface under one and two hour of fire exposures. Although the temperatures were very high for the screw length of 100 mm, the temperatures were similar for all screws at a depth of 100 mm and 200 mm, as illustrated in Figure 12. This effect demonstrates that longer STS did not substantially influence the temperatures through the fastener shank under longer fire exposure. The insulation effect of timber limits the thermal penetration along the fastener by the high slenderness of the STS (i.e., the ratio of their diameter to their length). It should be noted that higher temperatures for the screw length of 100 mm are

likely because the tip of the STS was not deep enough to limit the thermal penetration than those at a depth of 200 mm. Therefore, the temperature profiles through fasteners depend mainly on the diameter of the fastener rather than its length.

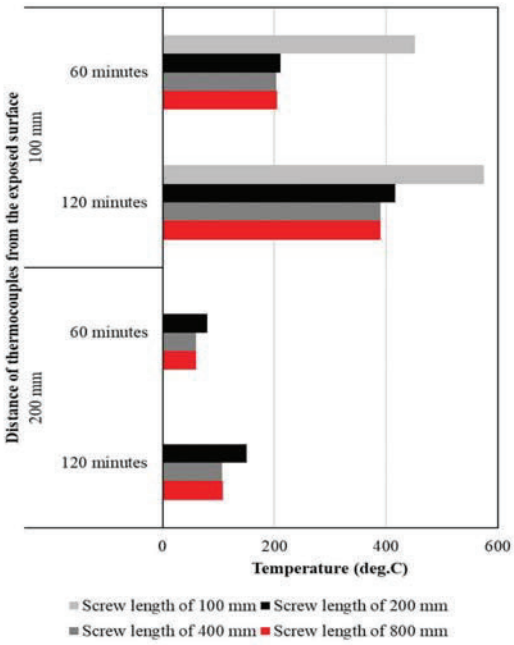

Figure 12 : *Temperatures on different lengths of Ø10 mm STS exposed to the CAN/ULC-S101 [4] standard fire.*

3.2.3 Effect of Fasteners on the Timber Charring Rate

The heat transfer model after two hours of standard fire exposure is presented in Figure 13 and Figure 14. These results were obtained by applying the 300 °C isotherm of the heat transfer model and measuring the distance between the char line to the exposed surface after one and two hours of standard fire exposures.

The fastener contributes by increasing the charring depth due to the larger thermal capacity. Due to the high conductivity of the steel, the heat transmitted through the fastener shank leads to higher temperatures into the timber. This effect was observed when comparing the heat transfer model of the bolt and the STS after two hours of fire exposures. For instance, the char depth was limited along the STS shank while the bolt shank created a notable char depth. This difference was caused by the larger heated area of the bolt shank that conducted heat faster and affected the timber surrounding the steel shank, whereas smaller screws had limited the temperature into the timber.

Although the diameter was found to be the major geometric parameter on the heating rate along the STS, longer fastener will increase the STS's effective length of penetration with more threads fully secured in unaltered wood fibers, which are still at ambient conditions (i.e., full capacity). When considering the mechanical properties of the wood fibers at a maximum of 100°C to retain sufficient residual strength, Létourneau-Gagnon et al. [10] demonstrated that the capacity of a STS was not influenced with an increase of fire exposure duration. While CSK Ø10 × 100 mm and CSK Ø10 × 200 mm have wood fibers above 100 °C along the entire shanks, CSK Ø10 × 400 mm and CSK Ø10 × 800 mm have wood fibers of 100 °C at a depth of 218 mm from the exposed surface. In fact, the residual penetration length for the 400 mm and 800 mm STS is 182 mm and 582 mm, respectively, after two hours of standard fire exposure, which can be defined as the length of penetration that will provide adequate structural capacity [10]. Therefore, longer screws would provide longer fire-resistance than shorter screws.

4 CONCLUSION

With the recent advances in mass timber construction and products, construction and design techniques have also evolved. Taller buildings are also typically required to provide greater fire-resistance rating, up to 2 and 3-hours, which is much beyond the deemed performance of traditional heavy timber construction. There is a need to better understand the underlying thermomechanical performance of the mass timber connection.

This study continues the development of a numerical model that aims to comprehensively simulate the thermal-structural performance of mass timber connections. The results of the novel developments towards this endeavour include the determination of reduction factors reflective of a simplified method for calculating the strength of a connection subject to a standard fire (e.g., CAN/ULC S101). The existing model was also expanded to consider contemporary connection types including those that use self-tapping screws.

Results from the numerical modelling suggest that for connections using bolts, using the steel strength reduction factors from CSA S16 as a function of the fastener temperature at the surface of the timber (i.e., underneath the washer) combined to the reduced cross-section of the timber components, provides reasonable agreements when compared to actual fire test data.

For connections using self-tapping screws (STS), the modelling predictions suggest that the STS shank diameter has an impact on the heat transfer, although minimal. Head of STS seems to have more impact on the heat conduction along the shank than the STS length. However, the length allows to slower heat conduction along the shank, and thus prevent undesired charring of the wood fibres surrounding the STS. Using longer STS will allow to maintain the connection capacity longer in fire conditions, when compared to using shorter screws.

Although this study provides valuable insight on the thermal performance of modern timber connections, their structural fire-resistance has not yet been evaluated through full-scale fire tests. Additional fire testing are currently planned at FPInnovations to further validate these assumptions and develop design guidelines for future implementation in CSA O86 wood design standard.

BURNING TEST OF STEEL BAR - TIMBER COMPOSITE BEAM

Shizuka Matsushita[1], Shinichi Shioya[2]

ABSTRACT: From a viewpoint of the current climate crisis, there has been much recent interest in using timber structural members in large buildings because timber can be used as renewable natural resource, and moreover, in severe earthquake prone zones, such as Japan, they are more desired on the grounds of light weight of timber members. We are developing a frame system consisting of hybrid timber members reinforced with deformed steel bar using epoxy resin adhesive. In order to practice the system, it is necessary to investigate fire resistance performance of the members. This paper reports a burning test of a beam burned for 60-minute semi-fireproof using burning marginal layer ,i.e., charring layer.

KEYWORDS: Fire, Burning marginal layer, Hybrid timber, Deformed steel bar, Beam

1 INTRODUCTION [3][4][5]

When constructing a large rigid-frame building with timber construction, the low bending stiffness and the low bending strength of timber become a serious problem.
S.Shioya, (author[2]) proposed a structural system for building construction, adopting Hybrid Glulam Timber members using Steel bar (HGTSB, nicknamed as "Samurai" in Japan) and has developed the structural design methodology, and constructed the first prototype building, a two-way frame structure using the structural system as seen in Figure 1 [1]. Three buildings were built with the system. One of them adapted two HGTSB beams, for a trial, at the 11th floor of a high-rise building, with a refractory coating authorized as two-hour fireproof timber for HGTSB, constructed in Tokyo, Japan, in February 2020. On the other hand, fireproof design method for using burning marginal layer (i.e. charring layer) for HGTSB is strongly desired for low-rise and middle-rise buildings. We scheduled to establish the semi-fireproof design method for HGTSB and conducted a fire resistance test of a beam.
The purpose of this study is to propose a method for estimating capacity of HGTSB beam that follows the semi-fireproof design method. A 60-minute burning test of a real-size beam was conducted. The safety factor, ratio of residual capacity of the beam after 60-minute burning divided by the loading expected under long-term loading, has not been sufficiently clarified. The safety factor is very important in the development of a new timber composite beam such as HGTSB. In the case of HGTSB, its bending strength is 3.0 to 4.0 times greater than that of timber beams, which means that the larger the cross-section, the greater the load on the beam, making it impossible to load the beam with Japanese burning test equipment. In such cases, if a method is established to estimate the safety factor of bearing resistance of the beam on the safe side, the burning test of the beam with its maximum cross-section is possibly eliminated.
Several studies [2,3] on fireproofing of carbon fibre-timber composite beam in which wood is used as main material, were conducted but there are no studies on fireproofing of steel bar-timber composite beam that use steel bar (i.e., rebar) as reinforcement against bending.
This paper reports the calculation concept for capacity of the beam during its burning, and the test to testify the concept and its results. Also, in another paper in WCTE2023, a new concept of modelling of temperature within beam with temperature data of only several measurement points is proposed [4].

2) The resistance of the bonded laminas is not expected in the structural design.
3) Depth of charring layer is assumed to be 45mm after 60-minute burning.
4) Portion of area ($b_w \cdot D_w$) enveloped by red line is assumed to resist as wood.
5) The residual wood portion is assumed to resist at the allowable stress level for short-term loading.
6) Central segment of three segments equally divided in beam width as Figure 2(b) is assumed to resist as HGTSB because of its being cooler than allowable limit temperature (60°C) for HGTSB.

3 EXPERIMENT

3.1 SPECIMEN

Figure 6 in the next page illustrates cross-sections of specimen. Main cross section of the beam is Section II-IV with one-tier rebar lamina, which 3-rebars were embedded on the upper and the lower lamina of beam cross-section. Figure 5 illustrates a side view of the specimen and positions of strain gauge and thermocouple. The left-hand Section I is prepared to investigate effects of the amount and the numbers of rebars on elevated temperature of wood during burning.

The rebar laminas were prepared in the same way as in our previous paper [5]. The lamina was Cryptomeria Japonica; lamina composition of beam was adhered to Japanese Agricultural Standard E65-F225. Rebar diameter is D29(29mm) and its grade is SD390(Nominal yielding strength: $390N/mm^2$). Adhesive was typical resorcinol resin adhesive for laminating the laminas and epoxy resin adhesive for rebar, of which allowable upper limit temperature is 110°C.

3.2 YOUNG'S MODULUS, STRENGTH, AND MOISTURE CONTENT OF LAMINA

Table 2 lists mechanical properties of laminas by bending test, compression test, tensile test and block shear tests. Figure 3 shows applied force of the bending test. Compression tests were performed using specimens with cross section of 25 x 25 mm and height of 100 mm. Figure 4 shows configuration of the tensile test. The center length of 75mm was shaved down to 10 mm in width. Table 2 lists moisture content of lamina testpiece (45 x 210 x 20 mm), of which the numbers was three for each lamina. The shear plane for the block shear test were 26 x 36 mm. The numbers of specimens for these tests were 10 for each lamina.

3.3 THE CENTER OF GRAVITY OF THE CROSS-SECTION AND SECTIONAL SECONDARY MOMENT OF BEAM

Using Young's modulus in bending for each lamina, distance/y_o from lower surface to the center of gravity of the cross-section and the cross-sectional secondary moment/I_e were calculated using Equation (1) and Equation (2) below.

$$y_o=(\Sigma n_{wi}\cdot a_{wi}\cdot y_{woi}+\Sigma(n_r-1)\cdot a_{ri}\cdot y_{roi}) /(\Sigma n_{wi}\cdot a_{wi}+\Sigma(n_r-1)\cdot a_{ri}) \quad (1)$$

$$I=\Sigma n_{wi}\cdot a_{wi}\cdot y_{woi}^2+\Sigma n_i\cdot I_{wi}+\Sigma(n_r-1)\cdot a_{ri}\cdot y_{roi}^2+\Sigma(n_r-1)\cdot I_{ri} \quad (2)$$

where, $n_{wi}=E_{wi}/E_{wo}$, $n_r=E_r/E_{wo}$, E_{wi} : Young's modulus in bending for each lamina, E_{wo}: Average value of all laminas, E_r: Young's modulus for rebar, a_{wi}, y_{woi} : Cross-sectional area of each lamina and distance from lower surface to the center of cross-section area of each lamina to origin, a_{ri}, y_{roi}: Cross-section area of each rebar and distance from lower surface to the center of cross-section of each rebar, I_{wi}: cross-sectional secondary moment of each lamina only ($=b\cdot t^3/12$), b: Lamina width, t: Lamina thickness, I_{ri}: Cross-sectional secondary moment of rebar ($Pi\text{-}d^4/64$), d: Diameter of rebar

Table 3 lists calculated values of the cross-sectional secondary moment/I_e, with and without considering fireproof laminas. I_e was 2.32 times greater than I_0 in the former case and 3.51 times greater in the latter case. Young's modulus/E_r and cross-sectional area/a_{r0} of the rebar were set to standard value ($E_r=2.05\text{x}10^5$ N/mm^2).

3.4 STRAIN AND TEMPERATURE MEASUREMENT

Figure 5(b) illustrates a side view of the beam specimen and positions of foil strain gauges and thermocouples. Figure 5(a) illustrates locations and names of the measured cross sections. It shows the locations where strain of wood and strain of rebar were measured. Numbering of mark "No." is for thermocouple; "W" is for uniaxial strain of wood in direction of beam axis, "R" is strain for rebar in the same direction. Figure 7(a) illustrates the gluing of foil gauge for wood. Before gluing laminas as beam, grooves were processed into laminas and the foil gauges were attached with adhesive for long-term measurement. The surface of the gauges was then coated with wax and was overwrapped with vinyl tape. Foil gauges were 3-wire type with lead wire temperature compensation. Thermocouples were used to measure temperature. Lead wire of the foil gauge and the thermocouple was pulled out from left or right end of the beam.

3.5 LOADING

Loading employed the four-point bending in Figure 8; magnitude of bending moment at mid-span of the specimen was selected to be value of allowable moment under long-term loading design. Value of shearing force of both side shear spans was 10% higher than its allowable shear force for long-term loading design. Force/F, vertical displacement, temperature, and strains of wood and rebar were measured. Deflections were measured for mid-span, two loading points, and both support points.

4 RESULT

4.1 HISTORY OF FORCE, TEMPERATURE, AND FRACTURES

The burning test was conducted on September 28, 2021 at 13:00 (its room temperature: 25.6°C) in a combustion furnace (ISO843-1 compliant furnace) at the Japan

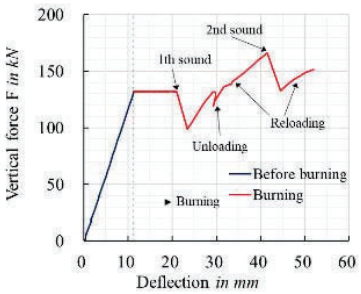

Figure 10: Force-deflection relationship

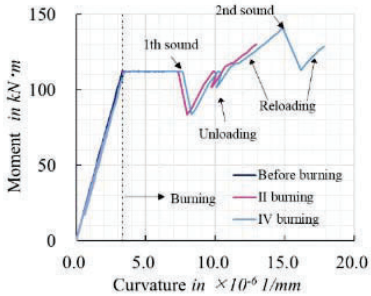

Figure 11: Bending moment-curvature relationship

Testing Center for Construction Materials. During introducing initial force, deflections and strains in the elastic range were measured. Figure 9 shows the heating temperature history of the air inside the furnace. After five minutes after completion of the loading, burning test was initiated. Temperature during 60-minute burning test was controlled to adhere to ISO-fire exposure temperature curve. Figure 12 shows changing of deflection at mid-span until the end of additional loading to investigate capacity after the burning. As burning proceeding, the deflection increases gradually, but an impact sound occurred suddenly just before 60-minutes passed, degrading the deflection stiffness, and ALC board over top of the specimen was found to be leaning.

At this time, it was confirmed that the capacity calculated by the concept mentioned in Chapter 2 was supported and the deflection of the mid-span was less than several thresholds for deflection required as semi-fireproof construction of the beam in Japan.

By reloading to the specimen at time of the impact sound before 60-minutes passed, the force F could again recover the initial applied force value, and then the additional loading was continued to be conducted. When the second impact sound occurred, the test was terminated because of the ALC board leaning largely. This additional time after the 60-minute burning passed was 5 minutes and 20 seconds; Temperature of the furnace was maintained at a constant temperature (945°C) by burning.

4.2 DEFLECTION - LOAD RELATIONSHIP DURING THE BURNING TEST

Figure 10 shows force-deflection relationship and Figure 11 shows bending moment–curvature relationship until the end of the burning test. The curvature is the same as that of the cross-section II and IV of Figure 15 mentioned later. Immediately after the first impact sound, the force decreased by 33.5kN; the deflection and curvature increased. The force increased to 166.2kN after 60-minute burning and decreased by 29.6kN at the second impact sound. The maximum force was 166.2kN, which was 26% higher than the initial force(F=132kN). The similar magnitude of the load drop immediately after the impact sounds is part of the evidence supporting the buckling of the upper two side rebar, which will be discussed in Section 4.6.

4.3 PERFORMANCE IN ELASTIC RANGE DURING INTRODUCTING INITIAL LOAD

Figure 13 shows strain distribution of wood and rebar of cross sections of II and IV during introduction the initial

load. Strains of rebar are seen to be located on the line connecting the strain of wood, proving that rebar and wood in the same position within beam distort with same strain value. Figure 14 shows changing in the strain of the wood and rebar near lower or upper surface of beam, which are compared to those calculated using the plane section assumption in response to bending moment. The calculated values have approximately estimated the experimental values. Therefore, the assumption of the

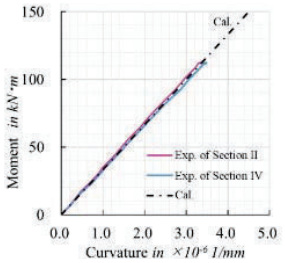

Figure 15: *Bending moment – curvature relationship*

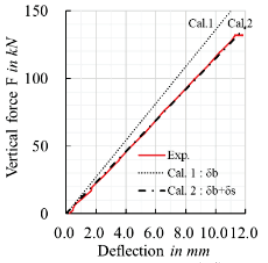

Figure 16: *Force-deflection relationship*

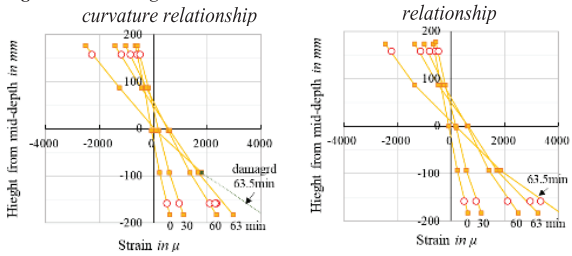

(a) Section II (b) Section IV

Figure 17: *Bending strain profiles during burning*

plane section is, also for RGTSB beam, confirmed to be allowed.

Figure 15 shows bending moment-curvature relationship for the cross-section II and IV. The curvature was assumed to be equal to average slope of strain distribution of wood cross section. The calculated bending stiffness is represented by a black one-dot chain line. The stiffness was calculated by I_e and E_{wba} in Table 3. Young's modulus of rebar was assumed to be its standard value. The bending moment-curvature relationships are almost same to the calculation line.

Figure 16 shows force-deflection relationship (red line) at the mid-span and relationships calculated using elastic stiffness. In the calculations, the fire cladding lamina was taken into account. Cal. 1 is deflection taking only bending deformation component/δ_b into account; Cal. 2 includes shear deformation component/δ_s. The coefficient of shear deformation /κ_d was assumed to be the value of 1.23 calculated by Eq. (10) in Reference [6]. The shear modulus of elasticity was not measured in this experiment, so the average value (824 N/mm^2) of the average value (15 pieces) of the center height of the beam web in Figure 24 of Reference [5]. In Figure 16, Cal. 2, which considers bending and shear deformation components, estimates the experimental relationship with high accuracy.

4.4 STRAIN DISTRIBUTION OF WOOD AND REBAR WITHIN BEAM DURING BURNING

Figure 17 shows strain distribution of wood and rebar at the cross section II and IV during burning. Amounts of strain increased with combustion proceeding resulted from decrease in resistance area within the beam as the combustion proceeding. In the Section II, at 63.5 min, strain value of rebar near the lower at 63.5min is small against wood strain distribution, i.e., black dotted line which was estimated on the basis of the trend of change up to that point because the wooden gauge at the lower could no longer be used for measurement. At the point of yielding in rebar, mill scale of rebar surface locally peels off and the adhesive around the rebar delaminates, resulting in stress relaxation in the rebar. This leads to variation in the strain of the rebar after the start of yielding. Excluding the variation of the effect, even after 60-minute burning, these results suggest that the assumption of plane in the cross section within the beam is reasonable.

4.5 DAMAGES AND CHARRING CONFIGURATION AFTER BURNING TEST

Photo 1(b) shows the specimen immediately after the burning test. The side rebars were supposed to be curved because of their buckling caused by thermal expansion in its axial direction during burning. When water was then poured on the specimen, temperature of the rebars decreased to room temperature and the rebars approached a straight line due to decay of thermal expansion, as shown in Photo 1(c). The specimen was applied to reveal capacity of the burnt specimen as mentioned later in Chapter 4. Figure 18(b), (c) shows cross-sections of residual wood portion over which its charring layer was removed after the additional loading test. Figure 18(d) shows lines of charring border of experiment and according to Eurocode 5 with a charring rate of 0.65 mm/min: red line is one of experimental results; blue line is line calculated assuming the combustion time reaching 60 minutes, and green line is line calculated assuming the combustion time reaching 65 minutes and 20 seconds.

https://doi.org/10.52202/069179-0216

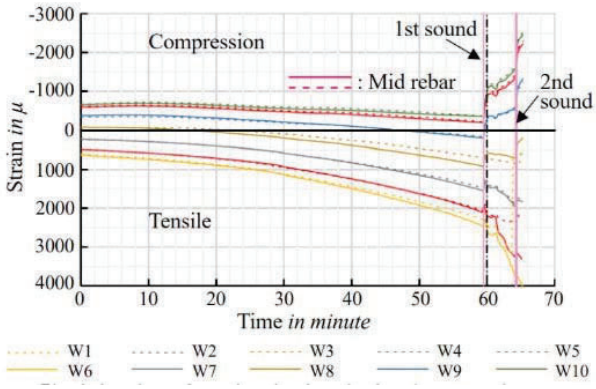

Figure 19: *Strains of wood and rebar Section II and IV*

Charring depth around the side rebar is larger than that of portion apart from the rebar. The reason may be that the side rebars buckled and some space generated between the rebar and wood by its curving. The side rebar is found to accelerate charring of wood in the case of 60-minute burning. The wood portion around the side rebar is necessary to be assumed not to contribute the capacity of beam at 60-minite burning on the safe side.

4.6 INFERENCE OF MECHANISM FOR THE IMPACT SOUND

Figure 19 shows changing in strains of wood and central rebar in the Section II and IV during burning: the dotted line indicates that of the Section II; the solid line indicates that of the Section IV; red line indicates that of the rebar. At the first impact sound, strain of the lower central rebar suddenly exceeded yielding strain (2075μ) of rebar, while the upper mid rebar reversed its trend of decreasing in compression and suddenly increased, exceeding the yielding strain (-2075μ) at the second impact sound. These suggest buckling of the upper side rebar, which is accompanied by impact sound.

Figure 20(a) shows schematically change in resistance of the upper rebars during burning. The upper rebar resists a greater compressive force due to bending moment of beam than that of the lower side rebar because it tries to extend axially during burning, whereas compressive force of the upper central rebar, which is lower in temperature than the side rebar, decreases. At the stage before the first impact sound, as seen in Figure 19, the strain of the upper central rebar (red solid and dotted lines) decreases in compression. Immediately after the first impact sound, the upper central rebar suddenly increased in compression strain and the reversal of velocity of strain changing can be seen to have occurred. These phenomena can be reasonably explained by the buckling of the side rebar. The reversal of strain velocity implies that the acceleration is great, which can be interpreted as a greater movement resulting in the impact sound; the similar amount of load drop after the two impact sounds, as discussed in Section 4.2, suggests that the load drop due to buckling of those two bars was of the same magnitude.

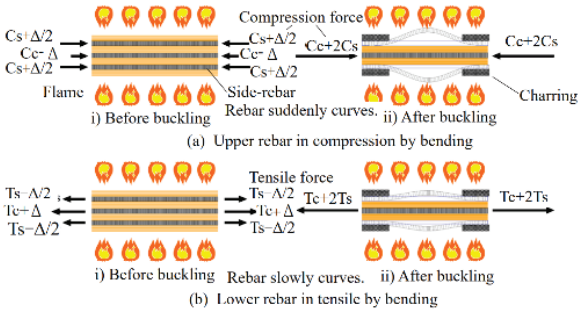

Figure 20: *Behavior of side-rebar curved during burning test*

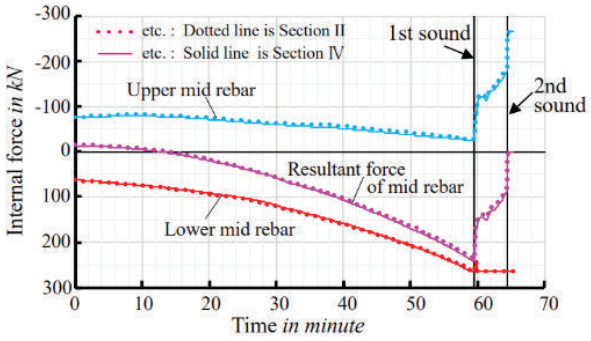

Figure 21: *Internal forces of mid rebar in Section II and IV*

On the other hand, as the lower side rebar was subjected to tensile strain by bending, tensile force of the side rebar was gradually transferred to the lower central rebar from the start of burning, and even if the lower side rebar buckled due to axial extension, the velocity of movement of buckling is supposed to have been slow to the extend such that its acceleration was slow and did not lead to the motion that produced the impact sound.

4.7 EXTINCTION OF TEMPERATURE STRESS IN REBAR

Figure 21 shows changing of axial force of the upper (light blue line) and lower (red line) central rebar and resultant force (pink line) by sum of the axial forces. Dotted line indicates that of the Section II and thin line indicates that of the Section IV. The axial force was calculated by multiplying value of axial strain of the central rebar by nominal Young's modulus and cross-section. The resultant force (pink line) increases in tension from the start of burning but decreases at the first impact sound and reaches zero immediately after the second impact sound.

The reason for its becoming zero is that the lower central rebar yields in tension and the upper central rebar yields in compression, cross-section area of the rebars is identical, and the forces cancel each other. Because the side rebars have already buckled and are not resisting, the resultant force by rebars on the cross section of the timber will be zero at the section that fractures in bending. In other words, the component of bending moment resisted by the timber can be estimated using the properties of only wood taking into account the temperature increase,

https://doi.org/10.52202/069179-0216

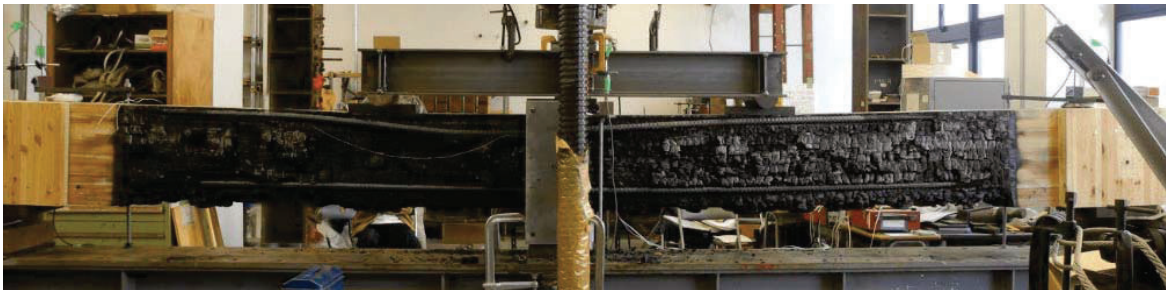

Photo 2: *Specimen before additional loading test burning test*

without the effect of the rebar. On the other hand, the component of bending moment resisted by the central rebar can also be estimated using on yield stress and sectional-area of rebar.

Bending capacity of the composite beam can be considered as the sum of these components. Rebar yields at approximately 0.2% of strain; then plastic flow occurs; the yield stress level is constant up to the start of strain hardening (about 2.0%). Assuming that the timber will fracture in bending, bending capacity of the beam can be estimated as the sum of both.

As can be seen in Figure 19, the rebars (red solid and dashed lines) almost strains in unison with wood portion (W1, W5, W6, and W10) around rebar until the rebar yielding. If yielding strain of rebar is smaller than rupture strain of wood at lower surface of beam and rebar is placed close to the surface, the assumption is satisfied. In this respect, HGSTB meets the requirements.

On the other hand, yield strain of rebar is about 0.2%, and fracture strain of wood in tensile by bending is expected to be approximately 0.4%, even if the wood ruptures at the finger joint of lamina.

However, the rupture strain is the value at room temperature. It may decrease at high temperatures. It is necessary to discuss the estimation of capacity at high temperature by considering the rupture strain of wood at high temperature.

4.8 LOADING TEST AFTER BURNING TEST

Because the additional loading immediately after the burning test did not reveal capacity of the specimen owing to the limitation of the loading apparatus, loading test was conducted to reveal the capacity as shown Photo 2 at Kagoshima University laboratory on February 15, 2022, i.e., 4.5 months after the burning test.

The force was the same as those of the burning test. Figure 22 shows the force-deflection relationship with a black curve. Figure 23 shows the bending moment-curvature relationship at the mid-span as yellow and black curves.

Those are overlaid on Figure10 and Figure 11. Yellow curve is with curvature by strain of wood; black curve is curvature by strain of rebar. In Figure 23, the stiffness of the curvature of rebar was reduced at the point indicated by '○'. In Figure 22, the point is also indicated with the same symbol, where the deflection stiffness also decreases.

Photo 3 shows failure of the upper of beam. When the capacity of beam decreased, wood portion at the force

Photo 3: *Partial compressive deformation around loading plat*

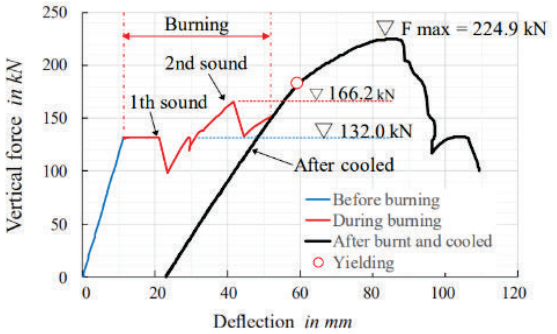

Figure 22: *Force-deflection relationship after cooled*

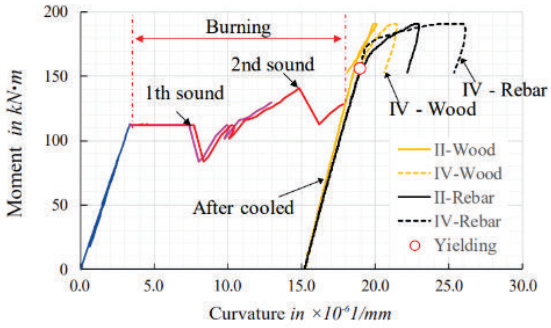

Figure 23: *Bending moment-curvature relationship after cooled*

position became more dented, causing the left side of the upper portion to bounce up.

In Figure 22, the maximum force of 166.2kN in the burning test is indicated with red dotted horizontal line. The force value was 73.9% of the maximum force in this test (F=224.9kN); this means that bending capacity of the specimen could not have been measured by during additional loading just after the 60-minute burning test.

The maximum capacity was 170.4% of the long-term loading load (132kN); this means that the capacity of specimen was sufficient against the collapse of the specimen in the 60-minute burning test.

https://doi.org/10.52202/069179-0216

These experimental results suggest that the approach for calculation of capacity proposed in Chapter 2 has sufficient potential to estimate bending and shear capacity of steel bar - timber composite beam just after 60-minute burning on the safe side.

5 SUMMARIES

In order to establish a design method for semi-fireproof for steel bar-timber composite beam, a 60-minute burning test was conducted, clarifying temperature [4] and strain behaviour inside the beams. The following i) to ii) were found during loading before the burning test, and iii) to vi) were found by the 60-minute combustion test and additional loading test to its specimen cooled after the burning test.

i) Detailed strain measurements of the wood and rebar within the specimen showed that rebar and wood in the same position within beam subjected bending distort with same strain value, providing a basis for the assumption of plane section within the composite beam's cross-section.

ii) Bending stiffness calculated based on assumption of the plane section within beam subjected to bending and using Young's modulus in bending of each lamina within beam specimen could estimate accurately moment-curvature relationship of the beam and changes in strain of wood and steel bars within the beam. Deflection stiffness of the composite beam was also accurately estimated by adding shear deformation to bending deformation component.

iii) Burning tests confirmed that a steel rebar-timber composite beam specimen bonded with two laminas (sum thickness of 90 mm) at the lower surface of beam exhibited bending and shear capacities calculated using the proposed resistance section model even after 60 minutes of burning.

iv) After 60 minutes of burning, load was increased with continuing the burning, and it was confirmed that the specimen could withstand up to 126% of the long-term allowable load. Furthermore, the specimen was cooled and subjected to loading test, and it was confirmed that load reached a maximum of 170.4% of the allowable long-term load and then collapsed. It was confirmed that the proposed estimation method for capacity of the beam after 60-minute burning is sufficient to estimate load capacity of timber-rebar composite beam on the safe side.

v) Although during 60-minute burning test, a component of elongation was added to upper central rebar and lower central rebar within beam width owing to the difference in temperature between surface portion and interior portion within beam, and with buckling of the upper side-rebar, the addition changed abruptly, causing the central rebars to yield before reaching the bending capacity and the thermal stress in the wood and rebar beam extinct.

vi) Charring depth for 60-minute burning wood was in approximately close agreement with the Eurocord 5 value. However, it should be taken into account that the depth is greater around the side rebar.

ACKNOWLEDGEMENT

This project was funded as Grants-in-Aid for Scientific Research-B by Japan Society for the Promotion of Science.

ADVANCED FIRE MODELLING IN SUPPORT OF PERFORMANCE-BASED FIRE DESIGN OF TIMBER BUILDINGS

Christian Dagenais[1], Zhiyong Chen[2]

ABSTRACT: The wood products industry is growing, as evidenced by the desire to build larger and taller buildings with timber and the start-up of new manufacturers. Despite the benefits of timber, projects are still experiencing approval resistance, namely when performance-based design is proposed to demonstrate code compliance. To gain approval, testing is often required to confirm the performance of a given product or design. While large-scale testing can always be performed, it tends to be very costly and time consuming, and can be argued to be valid only for the scenarios being tested. Fortunately, greater knowledge in fire safety engineering now allows for advanced/sophisticated fire modelling techniques, including models using the computational fluid dynamic and finite element method. This paper presents a number of advanced modelling tools and an ongoing effort to develop and harmonize a material database to be used in these models. Given the complexity of advanced modelling and the variety of input parameters and properties, an initiative is being launched at FPInnovations to generate a centralized material properties database, with the intent of making it available to the design community. Guidance on the proper use of advanced models in support of performance-based design with timber elements is also being developed.

KEYWORDS: Fire safety engineering, modelling, fire dynamics, timber buildings, performance-based design.

1 INTRODUCTION

The wood products industry is growing, as evidenced by the desire to build larger and taller buildings with timber and the start-up of new manufacturers. Some of the benefits that are fuelling renewed interest in timber construction include sustainability, prefabrication, reduced construction times, and the creation of more reliable timber products suitable for larger and taller applications. This has led to a resurgence of wood-based products in markets that have been historically dominated by steel and concrete mainly due to prescriptive limitations for using wood in larger and taller buildings, as well as non-residential construction.

Despite the benefits of timber, projects are still experiencing approval resistance, namely when performance-based design (PBD), i.e., alternative solutions, are proposed to demonstrate code compliance. To gain approval, testing is often required to confirm the performance of a given product or design.

While large-scale testing can always be performed, it tends to be very costly and time consuming, and can be argued to be valid only for the scenarios being tested. Fortunately, greater knowledge in fire safety engineering now allows for much more advanced/sophisticated fire modelling techniques, including models using the computational fluid dynamic and finite element method. These modelling techniques are gaining popularity in lieu of large-scale testing to extrapolate results and support PBD, provided the input parameters and results are verified and validated appropriately.

The purpose of this paper is to outline some available tools and ongoing efforts related to PBD, such that continued developments needed towards PBD can be identified. The need for a centralized material database to be used in these models is also discussed.

2 TIMBER CONTRIBUTION

When conducting a performance-based fire design, the contribution of combustible materials to the fire growth, intensity and duration is an important behaviour that need to be properly assessed. Combustion properties such as heat release rate, ignition temperature and mass loss rate as a function of the incident heat flux, among others, are used to predict the effect of combustible components to the fire dynamics. Charring rate dictates the rate at which timber is converted to char and is typically used to evaluate the structural fire-resistance of building elements. Each of these factors is pertinent in understanding the potential fire dynamics of a compartment in which structural timber is used, essentially for a PBD.

2.1 COMBUSTION PROPERTIES

The hazard related to exposing mass timber surfaces is due to the potential fire contribution of these surfaces.

[1] Christian Dagenais, FPInnovations, Canada, christian.dagenais@fpinnovations.ca
[2] Zhiyong Chen, FPInnovations, Canada, zhiyong.chen@fpinnovations.ca

https://doi.org/10.52202/069179-0217

When exposed to appropriate conditions, mass timber elements will ignite, release heat and flames, and ultimately reach self-extinction, should appropriate conditions be reached. Fire effluents, such as smoke and fractional effective dose, are also hazards to consider, namely as it relates to life safety of occupants and evacuation.

Advances in fire science and engineering have allowed for rapid progression in fire and smoke modelling. As such, the traditional prescriptive design is no longer the only compliance method for designing a fire-safe buildings [1]. Parametric modelling, zone models and field models using computational fluid dynamics (CFD) are among the most used in the fire engineering community. CFD models divide a given space into numerous control volumes where mass, momentum and energy conservation are numerically solved for each control volume.

Fire Dynamics Simulator (FDS), developed by NIST, is a commonly used CFD model. Modelling a fire source or a combustible material in FDS can be done from various methods. The most common methods, as described in FDS User Guide [2], are to use:

1) the pyrolysis model embedded in FDS following an Arrhenius function; or,
2) the use a of defined heat release rate (HRR) curve.

Both approaches require test data as input parameters.

2.1.1 Pyrolysis Kinetic Properties

Pyrolysis kinetic properties can easily and rapidly be obtained through a series of micro-scale thermogravimetric analysis (TGA). The mass change of a material as a function of time or temperature is measurement with high accuracy. The specimen is placed in either an inert environment (e.g. nitrogen) or in an oxidative environment (e.g. air). Through a series of data processing, it is relatively easy to determine the kinetic properties.

Several timber decomposition models can be found in the literature, ranging from simple models to more complex and sophisticated models. The level of accuracy, computational time and intended use of a given model is to be carefully evaluated when selecting the type of decomposition scheme. Using a simpler model helps at minimizing the uncertainties that may arise from each additional input parameter (i.e., level of complexity) to the total model uncertainty [3]. The simplest model consists at converting a solid material (wood) into char, volatiles and residues following an Arrhenius function consecutively, as shown in Equations (1) and (2). FDS User Guide [2] presents a detailed methodology for determining the activation energy (E) and pre-exponential constant (A) for use in the Arrhenius function.

$$Wood(\%MC) \xrightarrow{r_1} Dry\ Wood + Water\ Vapour$$

$$Dry\ Wood \xrightarrow{r_2} Char + Volatiles \quad (1)$$

$$Char \xrightarrow{r_3} Residues + Volatiles$$

$$r_i = Y_i^{n_{s,i}} A_i e^{\left(\frac{-E_i}{R\,T}\right)} \quad (2)$$

Where r is the reaction rate (s^{-1}), $n_{s,i}$ is the reaction order, Y_i is the mass fraction, A is the pre-exponential factor (s^{-1}), E is the activation energy (kJ / mol), R is the universal gas constant (8.314 x 10^3 kJ / mol·K) and T is the temperature (K).

Figure 1 shows the results from a TGA analysis performed at a heating rate of 20 K/min. A first reaction (r_1) is observed between 20 and 100°C, which is the wood at a given moisture content being converted into dry wood. The second reaction (r_2) occurs between 200 and 400°C, which is the wood being converted into char and volatiles and is clearly the most important reaction. The char oxidation (r_3) then occurs up to approximatively 600°C. Beyond 600°C, the specimen is entirely converted to residues. It is noted that Figure 1 shows the reaction rate as a function of temperature rather than as a function of time. This representation is typically used to better understand the effect of temperature on the reaction rates.

It is noted that conducting TGA under an inert environment (nitrogen) or an oxidative environment (air) does not provide the same trend towards the end of the decomposition. As reported and observed in [4, 5, 6], TGA performed in an oxidative environment provides more complex and detailed results than those done in an inert environment. The char oxidation occurring towards the end of the second reaction is not well captured when done in an inert environment, as shown in Figure 1. The maximum reaction rates are also greater when evaluated in an oxidative environment. The heating rate in a TGA is also affecting the decomposition, where a low heating rate typically increases the yield of char and a fast heating rate increases the yield of volatiles. As such, performing TGA in an oxidative environment should be favoured, as well as using a fast heating rate to evaluate the yield of volatiles, which would essentially be the pyrolysis gazes fueling the flaming combustion of wood.

Another method embedded in FDS is to directly enter the TGA test parameters and some data processing. Only, the TGA heating rate (K/min), the reference temperature (°C or K) and the pyrolysis range (°C or K) can be provided and FDS will calculate the E and A. The pyrolysis range can be estimated as the width of the reaction rate curve, assuming it to be of a triangular shape (pyrolysis range would be about ±120°C in Figure 1).

2.1.2 Heat Release Rate Curve

Heat release rate (HRR) of a material is among the most important combustion parameter to assess its potential contribution to fire growth. Heat release rate of materials or components can be evaluated using oxygen calorimetry, such as a small-scale cone calorimeter conforming to ISO 5660 standard [7], to a large-scale calorimeter, which was used to measure the HRR of mass timber compartments during a study in 2018 [8]. Intermediate-scale calorimeter can also be used to evaluate smaller components and assemblies, such as office cubicles, upholstered furniture, etc.

When the HRR of a given material or component is known, it can be implemented into FDS so that its fire development will follow that of the calorimeter test. The HRR values can be adjusted as a function of time using the RAMP function in FDS. It is noted that the RAMP values are to be determined after ignition occurs (i.e., RAMP time increment starts at the ignition time and not at the test/modelling time – thus once the material ignites). Other parameters can also be used to determine more realistic behaviour, such as ignition and extinction temperatures, as well as the recently implemented FDS function CONE_HEAT_FLUX. This function allows to scale up or down the HRR of a material exposed to a given constant or transient incident heat flux, based on its reference heat flux value (e.g., at 50 kW/m²). As reported by Hernouet *et al.* [9], a combustible material exposed to a radiant heat flux will be subjected to a greater incident heat flux due to flame irradiance generated from the combustion. As such, this increases in incident heat flux should be explicitly considered when determining the RAMP values in FDS.

However, at the time of writing this paper and based on discussion on the online Google FDS-SMV forum, the FDS developers confirmed that the CONE_HEAT_FLUX function is still under development and not yet ready for proper use. As such, the option of using a HRR curve will not be further detailed herein.

2.2 CHARRING RATE

When exposed to an adequate heat source (e.g., fire), timber will experience pyrolysis and ultimately charring. Charring is a fundamental property for timber and is the main parameter used to estimate the structural capacity of timber elements in fire (i.e., residual cross-section method). A thorough review of factors affecting the charring rate of timber was recently done by Bartlett et al. [10]. Among others, charring is influenced by various factors, such as wood density, moisture content, oxygen concentration and exposure conditions (fire severity).

Butler [11] reported charring rates as a function of radiant heat fluxes varying from 20 to 3000 kW/m² using a linear regression. The data were obtained using timber slabs having sufficient thickness to behave as a thermally-thick solid. Babrauskas [12] reported that this linear regression is however arguable given that some of the charring data was indirectly obtained from mass loss data and assumed that the residual char density as being nil. It was also mentioned that the linear regression over-estimates the charring rate when exposed to high levels of heat flux, suggesting that charring rate is not linearly proportional to the heat flux level. White & Tran [13] found a similar relationship whereas the charring rate is proportional to the ratio of external heat flux ($\dot{q}$) over wood density (ρ) based on oven-dry mass and volume, per Equation (3).

$$\beta = 5\left(\frac{\dot{q}_{rad}}{\rho}\right) + 0.374 \quad (3)$$

Mikkola [14] evaluated the parameters affecting charring of timber, such as density, moisture content, external heat flux and oxygen concentration of the surrounding air. Spruce specimens with a density of 490 kg/m³ and a 10% moisture content were subjected to external heat fluxes of 25, 50 and 75 kW/m² and exhibited charring rates of 0.56, 0.80 and 1.02 mm/min, respectively. The author suggested that a linear relationship exists between the charring rate and the external heat flux in the early phase of charring (first 20 minutes after ignition) when the protective char layer is in its growing phase. When the char layer reaches its maximum thickness, the effect of the external heat flux is less pronounced, and the charring rate decreases considerably. Experiments that used white pine specimens exposed to a constant heat flux and oxygen concentrations of 21%, 10.5%, and 0% showed that the mass loss rate decreased by 50% when the oxygen concentration decreased from 21% to 0%. It is noted that typical cone calorimeter tests are conducted in normal oxygen concentration (ambient, thus 21%), while it can drastically reduce to less than 5% in a standard furnace test and in compartment fire tests, as mentioned by Schmid & Frangi [15]. This suggests that as a fire grows within a compartment and the oxygen concentration declines, the charring rate is expected to decrease and should be determined accordingly.

https://doi.org/10.52202/069179-0217

2.3 STRUCTURAL FIRE-RESISTANCE

Modelling structural fire-resistance involves three fundamental components. It includes 1) a fire model, 2) a heat transfer model, and 3) a structural model, as illustrated in Figure 2. The fire model generates a specific fire exposure (temperature boundary conditions) for the thermal simulation using the heat transfer model which in turn develops thermal gradients in the structural components / connections. The structural model will calculate the response of the components / connections under fire and loads (mechanical boundary conditions).

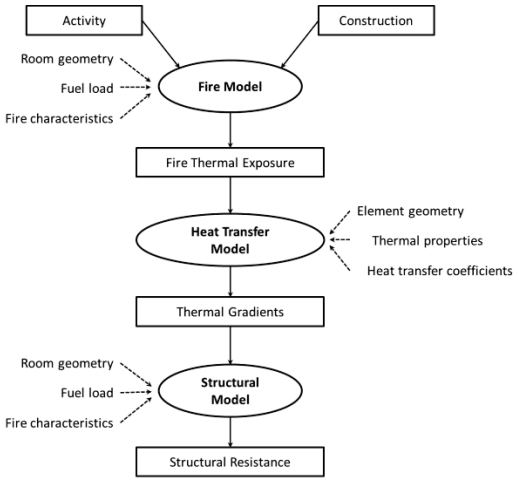

Figure 2: *Flow chart for calculating structural fire-resistance, redrawn from Buchanan & Abu* ***[16]***

The performance of structures exposed to fire can be evaluated from models that are using the finite element method, in which the results of a transient heat transfer are typically sequentially imported into a structural model (i.e., a 1-way coupling). A fully coupled analysis (i.e., 2-way coupling) should however be used when the thermal and mechanical solutions affect each other, as with timber.

A fully-coupled constitutive model, called WoodST, was developed at FPInnovations for assessing the structural fire-resistance of timber elements and connections. "S" means "Structural" and "T" is for "Thermal". This unique finite element model (FEM) combines several mechanics-based submodels, as detailed in Chen et al. [17]. The model has been verified and validated against a number of fire tests. It has also been used in support of PBD for evaluating the performance of timber structures in fire.

Additional guidance for advanced modelling of timber structures can be found in a recently published modelling guide for timber structures [18].

3 ADVANCED FIRE MODELLING

Several validation scenarios are presented herein. Additional information and details of the modelling parameters can be found in [17, 19].

3.1 FIRE DYNAMICS

With the main objective to develop and to validate fire dynamics combustion properties and CFD models in support of performance-based fire design, several verification and validation scenarios were conducted. The modelling properties were implemented in Fire Dynamic Simulator (FDS) version 6.7.9. Simple models (TGA) were easily run on a personal computer with an Intel® Core™ i5-8265U CPU @ 1.60GHz. The more complex models (cone calorimeter, wood cribs and mass timber fires) were run using high-performance computers from the Digital Research Alliance of Canada.

3.1.1 Validation of pyrolysis kinetic properties

With the desire to increase the amount of exposed mass timber in buildings, specimens of commercially-available mass timber products have been used. Specimens from Douglas fir lumber used in the manufacturing of glue-laminated (glulam) timber beams and columns, as well as specimens of the Spruce-Pine-Fir (SPF) species group used in glulam and CLT elements were evaluated. These products have been selected given their wide use in North American mass timber construction and that they are among the two main wood species group used for structural applications.

Thermogravimetric analysis (TGA) was modelled in FDS at the same heating rates as the actual TGA tests, i.e., 5, 10, 20, 50 and 100 K/min. The FDS model used to replicate a TGA analysis was adapted from [20], with the pyrolysis kinetic properties detailed in [19]. The thermal properties from EN1995-1-2 [21] were assumed. The density relationship given in EN1995-1-2 is ignored as it is explicitly being considered by the pyrolysis kinetic properties obtained from TGA. Moreover, the sharp peak in specific heat at a temperature of 100°C is neglected, also due to the explicit consideration of water evaporation through the 1st reaction kinetics.

During the verification and validation of the pyrolysis kinetic properties, it was found that the 1st reaction (moisture evaporation) was best modelled using the alternative method embedded in FDS – that is to input the TGA heating rate, the reference temperature and the pyrolysis range (taken as 100°C) – rather than explicitly using the E and A of that reaction. The 2nd and 3rd reactions were modelled using their respective E and A.

Table 1 summarizes the pyrolysis kinetic properties obtained from TGA performed at 50 K/min. The mass fraction and reaction rate predicted by FDS are shown in Figure 3 and Figure 4 for Douglas fir and SPF, respectively, at a heating rate of 50 K/min and in an oxidative environment (air). It can be observed that the

https://doi.org/10.52202/069179-0217

pyrolysis properties provide reasonable predictions of the mass fraction and reaction rate when compared to test data. Although not shown herein, it was also found that faster heating rate (e.g., TGA at 50 and 100 K/min) provides better predictions in FDS when compared to slower heating rates (e.g., 5, 10 and 20 K/min).

Table 1: *Pyrolysis kinetic properties for Douglas fir and Spruce-Pine-Fir from TGA at 50 K/min*

Property	Douglas fir	Spruce-Pine-Fir
1st reaction (r_1)		
T_{ref} (°C)	54	55
Pyrolysis range (°C)	100	
Heating rate (K/min)	50	
2nd reaction (r_2)		
E_2	1.142×10^5	9.923×10^4
A_2	3.692×10^7	1.479×10^6
3rd reaction (r_3)		
E_3	2.525×10^4	3.042×10^4
A_3	1.344×10^{-1}	3.602×10^{-1}

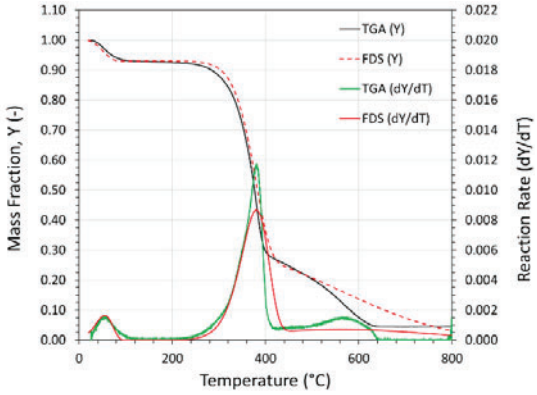

Figure 3: *TGA predictions from FDS compared to test data – Douglas fir at 50 K/min in oxidative environment (air)*

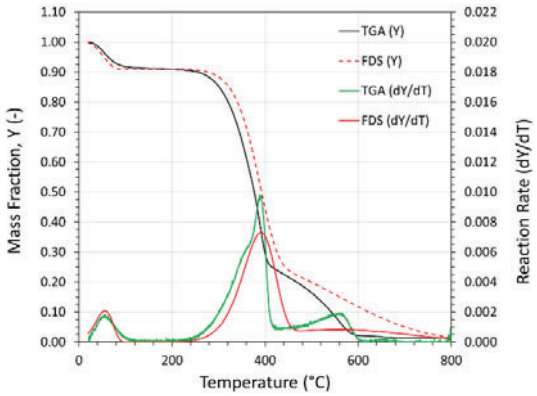

Figure 4: *TGA predictions from FDS compared to test data – Spruce-Pine-Fir at 50 K/min in oxidative environment (air)*

During the verification and validation, it was found that all pyrolysis kinetic properties showed a strong relationship with the heating rate, which was also found by Bakar [20]. Figure 5 shows the relationship for the reaction rate of SPF specimens.

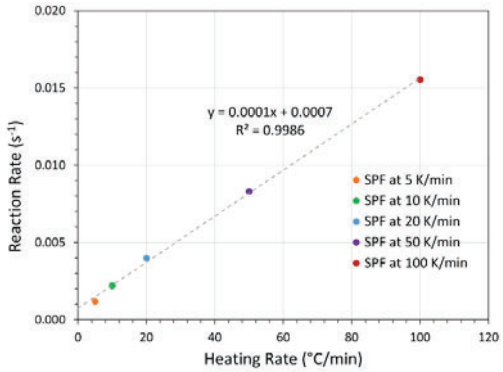

Figure 5: *Reaction rates as a function of the heating rate for Spruce-Pine-Fir specimens (2nd reaction)*

Currently, FDS does not allow to adjust the pyrolysis properties as a function of the heating rate. A single set of properties can only be used (e.g., those from 50 K/min) for modelling. However, given that the pyrolysis properties are sensitive to the thermal conditions, there would be a merit for FDS to allow such adjustments using a specific function (i.e., as with the RAMP function used for HRRPUA). This would be more realistic of a transient exposure from a fire exhibiting a growth, steady-state and decay phases.

3.1.2 Validation of combustion properties

Cone calorimeter conforming to ISO 5660 were also modelled in FDS, using the same radiant heat levels as the actual tests, i.e., 25, 50 and 75 kW/m². The FDS model used to replicate a cone calorimeter consists in a simplified domain where the specimen properties are assigned as a simple surface (called VENT in FDS). The specimen is then subjected to an external heat flux of the required magnitude. The surface properties (specimen) consisted of a fraction of water (moisture content) and dry wood. The specimen surface was 100 x 100 mm with a thickness set to 25 mm, with its back being set to "insulated" to replicate a cone calorimeter test. Due to equipment malfunctioning, the heat of reaction used in this study is taken from the literature [3]. Values of reaction of 355 kJ/kg and 205 kJ/kg were assumed for the Douglas fir and SPF, respectively. Based on cone calorimeter tests, an average effective heat of combustion of 12.35 MJ/kg and 13.30 MJ/kg is used for Douglas fir and SPF, respectively.

Table 2 summarizes the HRR obtained from test data and FDS modelling. It can be observed that FDS provides reasonable HRR when compared to test data (taken over an 1800 s burning period), while being slightly lower. The results suggest that using the properties from TGA tests done at a fast heating rate (e.g., 50 and 100 K/min)

https://doi.org/10.52202/069179-0217

provides better HRR predictions when compared to actual test data. Lastly, it was found that for both wood species, the modelling predictions were in much better agreements with the test data when exposed to greater heat flux levels (50 and 75 kW/m²). At 25 kW/m², the ignition time is always predicted too early.

Table 2: *Heat release rate – Test data compared to FDS for Spruce-Pine-Fire specimens of 25 mm in thickness*

Cone calorimeter tests		FDS Predictions	
Heat flux (kw/m²)	**$HRR_{tig+1800s}$ (kW/m²)**	**Heating Rate (K/min)**	**$HRR_{tig+1800s}$ (kW/m²)**
		5	25.25
	45.23	10	27.46
25	49.92	20	34.45
	52.99	50	32.52
		100	40.94
		5	71.63
	77.76	10	76.94
50	90.56	20	81.33
	77.89	50	78.33
		100	80.30
		5	80.67
	87.05	10	80.64
75	91.25	20	81.83
	93.28	50	80.66
		100	80.61

Figure 6 illustrates the heat release rate (HRR) profile obtained by the numerical modelling for the 25 mm Douglas fir exposed to 50 kW/m². The modelling provides consistent results when compared to actual test results, while being slightly underpredicting.

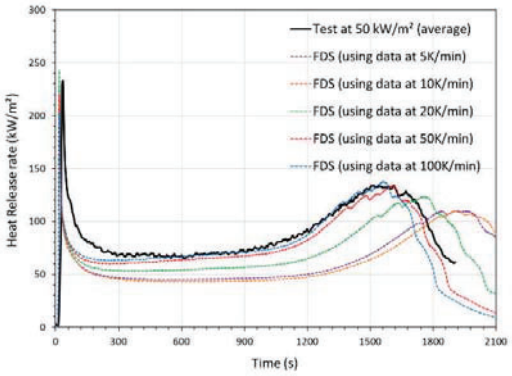

Figure 6: *Heat release rate predictions from FDS compared to test data – Douglas fir at 50 kW/m²*

For all 3 heat flux levels (i.e., 25, 50 and 75 kW/m²), TGA data from heating rates of 50 and 100 K/min provided the best profiles with respect to HRR and THR. These faster heating rates support the assumption where faster heating rates should be favoured in attempt to better predict the yield of volatiles (i.e., pyrolysis gazes). The mass loss was evaluated by calculating the consumed mass of reacting fuel (i.e., dry wood) and water vapor, and compared to actual tests. As shown in Figure 7, the mass losses obtained in FDS are in good agreement when compared to test data.

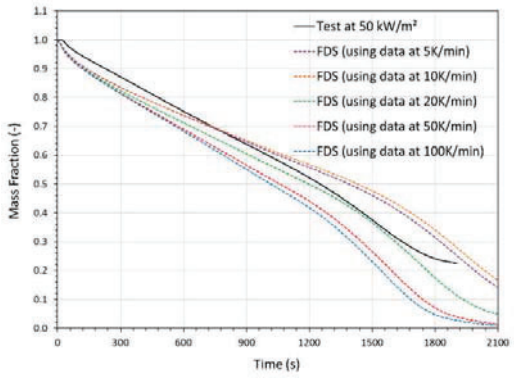

Figure 7: *Mass loss predictions from FDS compared to test data – Douglas fir at 50 kW/m²*

3.1.3 Wood crib packages

In attempt to develop fuel packages for use in advanced modelling in support of performance-based fire design, wood cribs were also modelled in FDS using the pyrolysis kinetic properties presented herein and detailed in [19]. Wood cribs are widely used in large-scale fire tests to simulate moveable fuel load.

HRR and THR were calculated using the analytical model presented in the SFPE Handbook of Fire Protection Engineering [22]. FDS predictions were compared to the calculations as well as test data by Bwalya *et al.* [23]. Figure 8 illustrates the total heat release (THR) for a large wood crib (8 layers). Interestingly, the mesh size used in FDS influenced the HRR and THR. A mesh size of 5 cm was found to provide the best predictions (vs. 10 cm). In addition to the recommendations about mesh resolution in the FDS User Guide [2], it is strongly suggested to conduct a sensitivity analysis when trying to use fuel packages in advanced modelling.

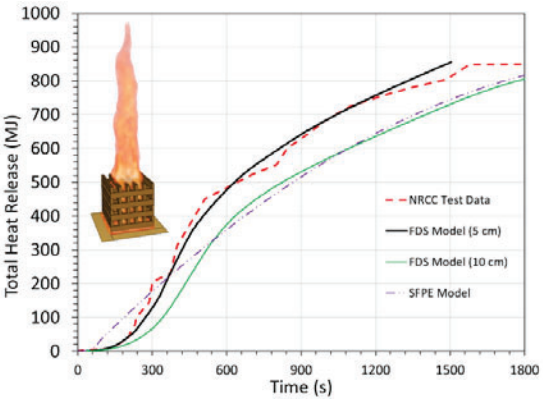

Figure 8: *Total heat release rate of a large wood crib*

https://doi.org/10.52202/069179-0217

3.2 CHARRING AND CHAR DEPTH

During a series of demonstration fires in Canada, large-scale mass timber constructions were subjected to various fire scenarios (https://firetests.cwc.ca/). Among those, pilot-scale tests were conducted in Richmond (BC) in June 2021 to demonstrate the fire performance of mass timber construction during the construction phase, thus when not protected or encapsulated.

3.2.1 Mass timber 1

Mass timber 1 (MT1) was constructed using glulam and CLT elements. The cube was 3 m x 3 m x 3 m (10' x 10' x 10') and subjected to a fire developed by two (2) large wood cribs (8 layers of wood sticks). All timber elements, including the CLT back wall, were fully exposed to fire. A partition protected by gypsum board was installed to simulate a corner effect. Four (4) thermocouples were positioned in each quadrant underneath the ceiling.

Wood cribs and mass timber elements were modelled in FDS using the pyrolysis properties presented herein (Figure 9). In the modelling, in addition to monitoring the temperature underneath the CLT ceiling, devices were added to monitor the oxygen concentration and incident heat flux at each quadrant. Figure 10 shows the temperature profiles obtained from the test data and those from FDS. When combining the charring rate, calculated per Equation (3), to the reduction effect due to the oxygen concentration, a char depth of 13 mm is obtained. When not considering oxygen concentration, a char depth of 17 mm is obtained. A char depth varying between 10 and 15 mm was obtained from hand measurements after the demonstration fire (Figure 12).

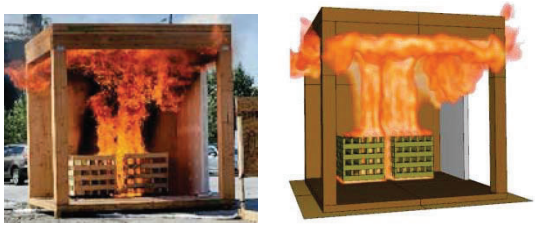

Figure 9: *MT1 – left is the actual test, right is FDS modelling*

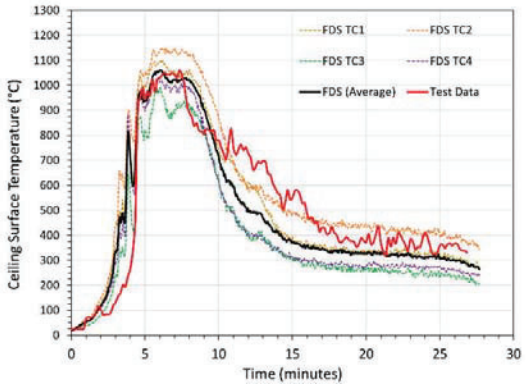

Figure 10: *Temperature at the MT1 ceiling – Test data compared to FDS predictions*

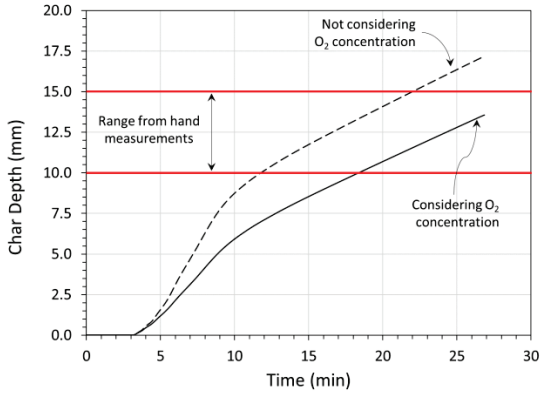

Figure 11: *Char depth of MT1 ceiling as a function of time compared to hand measurements*

Figure 12: *MT1 charred specimens cut for hand measurements*

While the difference between the charring predictions and hand measurements may not be large, it is noted that the fire was left to burn in the open for only 27 min and subjected to a low moveable fuel load (±190 MJ/m²). In an actual compartment scenario where a greater fuel load is present and oxygen may be limited, the difference between considering and neglecting the effect of oxygen concentration will further increase, which would ultimately impact the structural fire-resistance if the char depth is overly estimated.

3.3 STRUCTURAL FIRE RESISTANCE

Structural modelling of timber elements and connections exposed to a standard fire was performed using WoodST. A laminated veneer lumber (LVL) beam and a bolted connection were modelled to assess the time-displacement curve as well as the time to failure and failure mode [17]. The constitutive model was also used to assess the performance of a timber structure in fire, in support of a Technical Report ISO/TR 24679-5 [24] developed by FPInnovations for ISO TC92/SC4/WG12.

https://doi.org/10.52202/069179-0217

3.3.1 Beam

Structural composite lumber (SCL) beams were tested for fire-resistance by the American Wood Council. The beams were exposed to the standard fire on 3 sides. One of them was used to verify and validate WoodST – that is LVL beam #7 of 89 x 241 mm subjected to 50% of its allowable bending strength. It was assumed that SCL has the same thermal properties as timber (i.e., those of EN1995-1-2).

A static stress/displacement analysis was first performed. Under a total load of 16.8 kN, the predicted deformation at mid-span was 15.1 mm, compared to 14.5 mm in the actual test. Then, a transient thermal analysis was carried out to assess the temperature distribution and charring rate. The charring rates for the LVL model were 0.79 mm/min on its side and 0.94 mm/min at the bottom, respectively. The higher charring rate at the bottom is caused due to corner rounding affecting the bottom of the beam. These verifications suggest that the input properties were satisfactory.

Lastly, a coupled thermal-stress analysis was performed. The finite element analysis (FEA) showed that the deformation of LVL beam #7 increased with time and temperature, as shown in Figure 13. Elements of the LVL beam were first charred and then removed once the strain met the criterion. The model predicted a failure time of 28.5 mins, based on the mean properties obtained by converting the allowable stress design values from the LVL evaluation report. The test failure time was recorded as 33.7 min. The prediction would be expected to be closer to the actual test result if the actual material properties of the specimen were known.

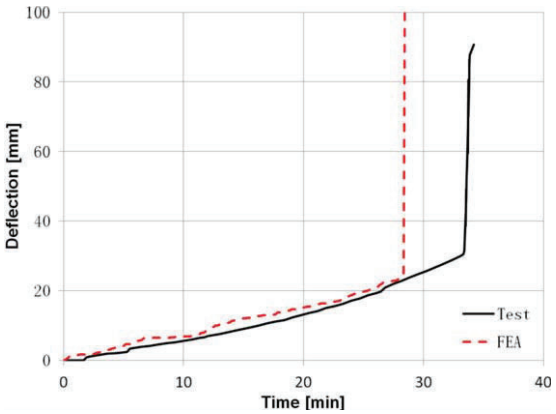

Figure 13: *Deflection as a function of time – LVL beam #7*

3.3.2 Bolted connection

A wood-steel-wood (WSW) bolted assembly was modelled in WoodST. Glue-laminated (glulam) timber elements of 130 x 190 mm were connected axially using 12.7 mm diameter bolts and a 9.5 mm internal steel plate. During the fire-resistance test, a constant axial tension load of 11.5 kN was applied, which represented 10% of the ultimate resistance at ambient conditions [25]. As with the LVL beam modelling, the mechanical properties were soft-converted to their mean values in accordance with CSA O86 standard procedures [26].

The static stress/displacement analysis predicted an ultimate capacity of 111.3 kN, which is within 5% of the test result of 115 kN. The transient heat transfer allowed to assess the temperature profiles of the glulam elements and metallic parts, as well as the charring rate of the glulam with great precision (Figure 14).

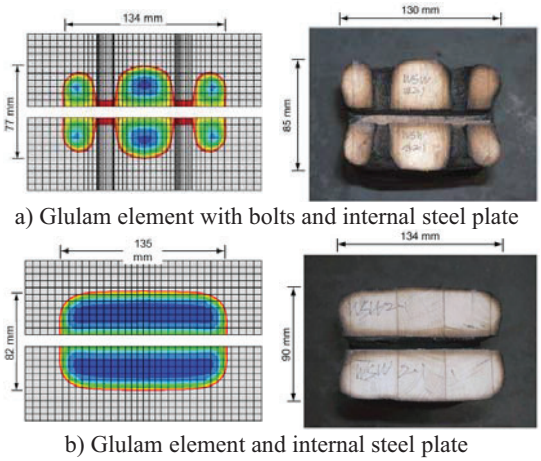

Figure 14: *Residual cross-section*

The coupled thermal-stress analysis showed that the deformation increased in time and temperature (Figure 15). The displacement increased shortly after 10 min, which was caused by the wood crushing in the bolt holes due to the effects of load and fire (Figure 16). The model predicted a failure time of 23.5 min, while it failed at 28.0 min in the test.

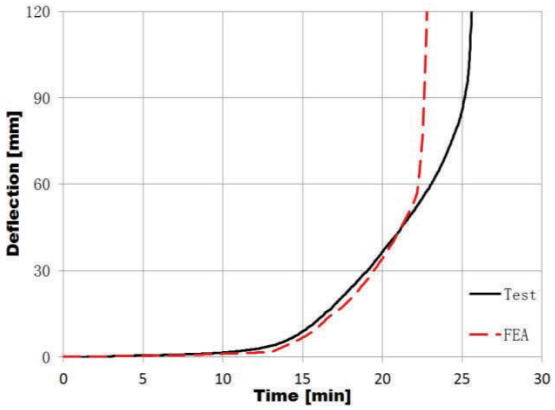

Figure 15: *Deflection as a function of time – Bolted connection*

https://doi.org/10.52202/069179-0217

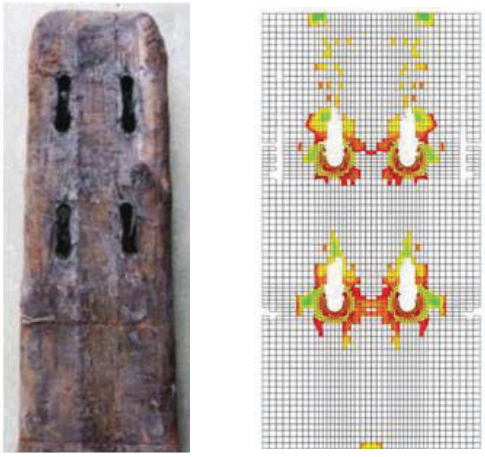

Figure 16: *Bolt elongation in the glulam element*

3.3.3 Performance of structures in fire

The results of design fire scenarios from FDS were used as imposed thermal fields in WoodST, namely the incident heat flux, surface temperature and oxygen concentration at the vicinity of timber elements' surface. This allowed to determine the residual cross-section of elements exposed to a design fire, along with their structural performance. This work was done during the development of a Technical Report (TR) on the performance of structures in fire under the aegis of ISO TC92 SC4 WG12 [24]. ISO/TR 24679-5 should be published during 2023.

The analysis was made for a glulam beam and column, both were partially exposed to fire. The load-displacement curves of both elements were obtained and compared to analytical calculations using CSA O86 [27]. The performance criteria were evaluated accordingly. The incident heat flux and oxygen concentration at the vicinity of the surfaces were explicitly considered for the charring rate. Figure 17 and Figure 18 show the deflection as a function of time (fire exposure) for a beam and column, respectively. Analytical calculations are also presented for comparison between simplified (calculations) and advanced (FEM) methods.

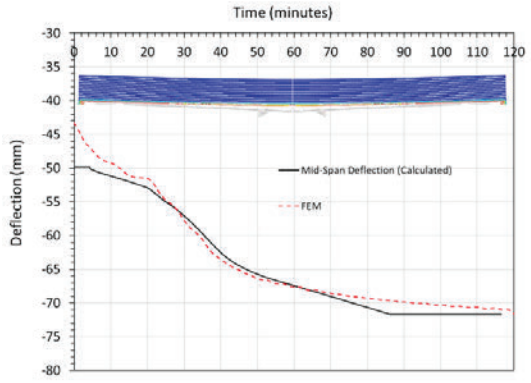

Figure 17: *Assessment of mid-span deflection of beam B1*

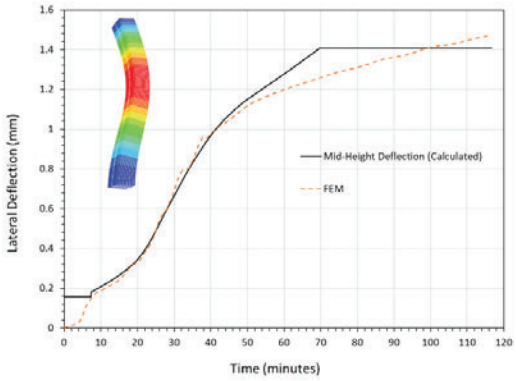

Figure 18: *Assessment of lateral deflection of column C2*

4 DEVELOPMENT OF DATABASE

While all models should be verified and validated appropriately, the quality and accuracy of their results remain at the discretion and knowledge of the users. FDS and models using the FEM require a large number of data entry, including material combustion behaviour and thermo-mechanical properties. Timber is an anisotropic material and therefore its properties vary as a function of the grain orientation between the longitudinal, radial and tangential directions, and should be explicitly considered.

Given the complexity of advanced modelling and the variety of input parameters and properties, the creation of a centralized database becomes relevant. An initiative has been launched at FPInnovations to generate a database of commonly-used products such as those of interior linings and structural elements, with the intent of making it available to the design community. Research organizations members of WoodRise are involved in this initiative, namely FCBA (France) and RISE (Sweden). The material database will be made available through various publications as well as a web platform (host of the platform is yet to be determined).

ACKNOWLEDGEMENT

FPInnovations would like to thank Natural Resources Canada (Canadian Forest Service) for funding this project and supporting our research. The authors would also like to acknowledge and thank Esko Mikkola and Henri Kuronen from KK Consulting (Finland) for their guidance and expertise regarding fire modelling using FDS, as well as guidance by Eric Guillaume from Efectis (France) and Grégoire Pianet from FCBA (France). Technical support provided by FDS developers through the Google forum is also greatly acknowledged. Lastly, we thank Alex Bwalya from National Research Council Canada for sharing test data on wood cribs, as well as Andrew Harmsworth and Claire Yuan from GHL Consultants for the data and observations during the pilot-scale mass timber fire tests.

EFFECT OF THE SACRIFICIAL LAYER THICKNESS AND THE BARRIER LAYER TYPE ON SELF-EXTINGUISHING FOR WOODEN FIREPROOF-STRUCTURAL ELEMENTS

Tomoyo Hokibara[1], Yuji Hasemi[2], Daisuke Kamikawa[3], Tsutomu Nagaoka[4]

ABSTRACT: The effects of the thickness of the sacrificial layer and the type of barrier layer on the self-extinguishing performance of wooden fireproof structural elements made from Japanese cedar were clarified. Three series of small fireproof heating tests were conducted. It was clarified that with a wood-based protection layer, there was an optimum thickness of the sacrificial layer regardless of the heating time. The use of gypsum and fire-retardant wood as the barrier layer was then compared in terms of suppressing the temperature rise through the latent heat of the barrier layer, and the effect of the sacrificial layer thickness on the self-extinguishing performance was clarified.

KEYWORDS: Japanese cedar, glowing combustion, Flame die-out, Fire-resistive construction

1 INTRODUCTION

High-rise wooden structures must be fireproof. The fire-resistant performance in Japan, as an earthquake-prone country that does not assume firefighting activities, requires high-rise wooden structures to self-extinguish and become independent after a fire.

In recent years, there have been frequent international examples of fires rapidly spreading to the upper floors of high-rise buildings and causing enormous damage[1]. Fire-resistant structures that self-extinguish in the event of a fire should thus be considered even for high-rise wooden buildings.

The authors have clarified the specifications of fire-resistive structures that achieve 1 and 2-hour fire resistance adopting the concept of the sacrificial layer as shown in **Figure 1** and clarified the self-extinguishing performance of the sacrificial layer[2][3]. They showed that if the sacrificial layer is designed to be thick according to the required fire resistance time, the performance of the barrier layer can be minimized and an efficient member design achieved[2].

Meanwhile, when a long fire resistance time is required in the case of a high-rise building, the actual fire heating time may be shorter than the required fire resistance time. In this case, the sacrificial layer designed to be thick according to the fire resistance time may maintain glowing combustion after the fire. The fire resistance structure must perform even when it is heated by fire for a time shorter than the required fire resistance time. The present study thus examines the optimum thickness of the sacrificial layer regardless of the required fire resistance time.

The optimum thickness of the sacrificial layer depends on the suppression of the temperature rise through the latent heat of the barrier layer, and the appropriate thickness of the sacrificial layer when the barrier layer is gypsum is thus also examined in the present paper.

Three series of tests were conducted to examine the effects of the thickness of the sacrificial layer and the type of barrier layer on the self-extinguishing performance of the sacrificial layer. In all tests, specimens were heated following the ISO834 fire temperature–time curve and then left in a quiescent environment. All specimens were made from Japanese cedar, the wood most used for construction in Japan.

2 EFFECT OF THE THICKNESS OF THE SACRIFICIAL LAYER ON SELF-EXTINGUISHING WITH A WOOD-BASED PROTECTION LAYER

2.1 THICKNESS AND SELF-EXTINGUISHING OF THE SACRIFICIAL LAYER

2.1.1 Purpose

The first series of tests was conducted to clarify whether fireproof-structural elements with a sacrificial layer thickness designed for the required fire-resistant time will self-extinguish when exposed to heating for a time shorter than the required fire-resistant time.

Specifically, test pieces with sacrificial layers of 50 mm, which were designed to have fire resistance for 120 minutes, were heated for 60 and 120 minutes to verify whether they self-extinguished even after 60 minutes of heating.

2.1.2 Outline of tests

In the first series of tests, using a small furnace at the Forestry and Forest Products Research Institute, test pieces were heated for 1 or 2 hours according to the ISO834 standard heating curve and allowed to cool in the furnace for 6 hours. **Figure 2** is a schematic diagram of the furnace and the layout of the test specimen.

Two specimens were prepared with a sacrificial layer having a thickness of 50 mm and fire-retardant plywood for the barrier having a thickness of 50 mm. The materials of barrier layer, fire-retardant plywood, were rated as quasi-incombustible materials. The fire-retarding agent injected 180 kg/m^3 into the fire-retardant plywood.

The measurement items were the internal temperature of the specimen and the furnace temperature. The temperature measurement points are shown in **Figure 3**.

2.1.3 Test results and discussion

Table 1 shows that the sacrificial layer with the 120-minute heating specification extinguished itself after heating whereas the sacrificial layer with the 60-minute heating specification continued to burn. Previous studies [2] have shown that the self-extinguishing of the sacrificial layer is greatly affected by a rise in the barrier layer temperature to the decomposition temperature of the fire retarding agent (195 °C) during heating. **Figures 4 and 5** show that the temperature within the barrier of self-extinguishing specimen S50-120 exceeded the decomposition temperature 97 minutes after the start of heating, whereas the non-self-extinguishing specimen S50-60 did not even reach 100 °C. This is probably because the sacrificial layer was too thick and the barrier layer did not reach the decomposition temperature of the fire retarding agent during heating and did not self-extinguish.

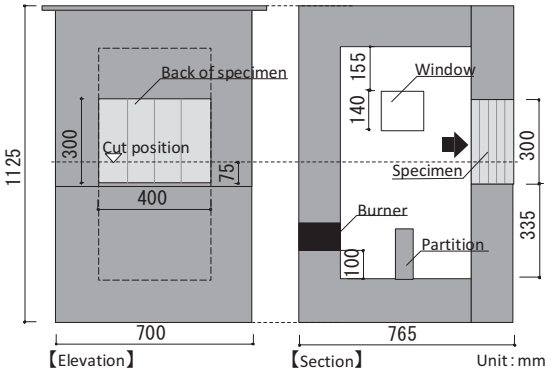

Figure 2: *Specimen layout in the first and second series of tests*

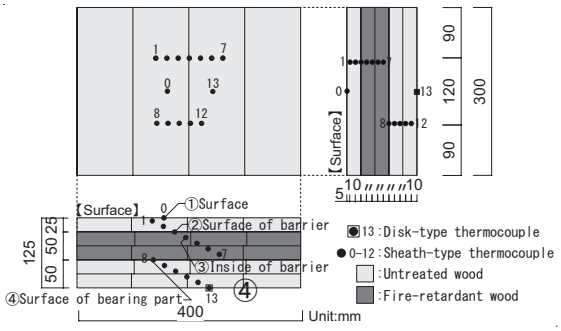

Figure 3: *Specimens in the first series of tests*

Table 1: *Results of the first series of tests*

Specimen	Sacrificial layer thickness [mm]	Heating time [min]	Carbonization [mm]	Results*1
series(1)tests S50-60	50	60		× (Continued to burn)
series(1)tests S50-120		120		○ (Extinguished)

:Untreated wood : Fire-retardant wood : Char layer

*1: ○:Glowing combustion stopped after end of the test, ×:Glowing combustion continued after end of the test

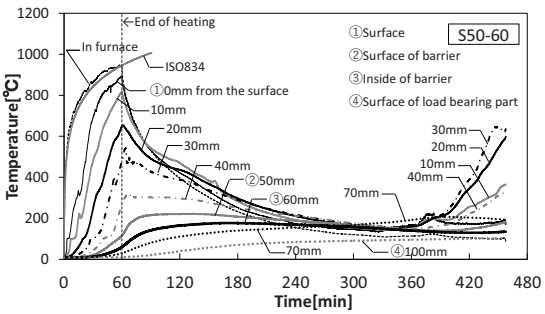

Figure4: *Temperature (S50-60)*

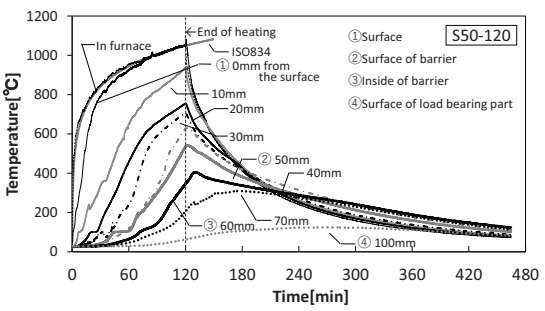

Figure 5: *Temperature (S50-120)*

https://doi.org/10.52202/069179-0218

The results show that for the same thickness of the sacrificial layer, self-extinguishing depends on the heating time. It is considered that there are two reasons for the continuation of combustion in the sacrificial layer.

(1) The barrier layer did not reach the decomposition temperature of the retarding agent during heating and could not contribute to suppressing the temperature rise inside the sacrificial layer.

(2) The carbonized layer on the surface of the specimen suppressed the heat loss to the outside, and the combustion of the uncarbonized part of the sacrificial layer continued.

Therefore, in the next section, the optimum thickness of the self-extinguishing sacrificial layer is examined regardless of the heating time.

2.2 OPTIMUM SACRIFICIAL LAYER THICKNESS REGARDLESS OF THE HEATING TIME

2.2.1 Purpose

The second series of tests was conducted to examine the optimum thickness of the sacrificial layer regardless of the heating time. From the results of past experiments[2], it is thought that if the carbonization depth is under 10–20 mm, a specimen will self-extinguish through heat loss from the surface. The carbonization rate of Japanese cedar is 0.6–0.8 mm/min[4], and it is thus presumed that fire heating for 12.5–33.3 min will result in the specimen self-extinguishing through heat loss from the surface. Additionally, in the case of heating for 30 minutes or longer, the temperature of the barrier layer must reach the decomposition temperature of the retarding agent during heating. **Figure 4** shows that the depth reaching the decomposition temperature of the fire retarding agent (195 °C) after heating for 30 minutes was 20–30 mm, and it is thus estimated that the optimum thickness of the sacrificial layer is 20–30 mm.

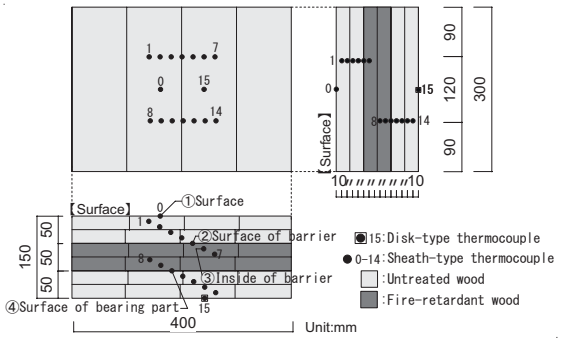

Figure 6: *Specimens in the second series of tests*

Table 2: *Results of the second series of tests*

	Specimen	Sacrificial layer thickness [mm]	Heating time [min]	Carbonization	Char layer depth [mm] Heating end*1	Char layer depth [mm] Test end	Results*2

*2: ○:Glowing combustion stopped after end of the test, ×:Glowing combustion continued after end of the test

2.2.2 Outline of the tests

In the second series of tests, four specimens with a sacrificial layer thickness of 25 mm were prepared for self-extinguishing regardless of the heating time. The fire-retarding agent was injected 180 kg/m^3 into the fire-retardant plywood at as in section 2.1. Following the ISO834 standard heating curve, heating tests were conducted with heating times of 30, 45, 60 and 120 minutes.

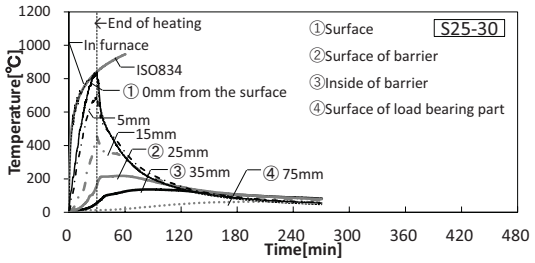

Figure 7: *Temperature (S25-30)*

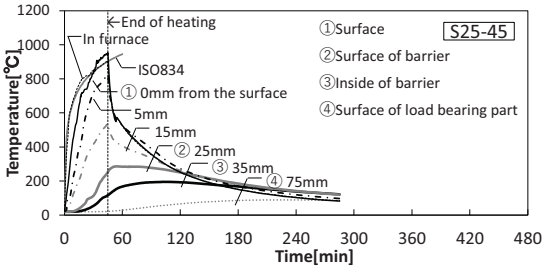

Figure 8: *Temperature (S25-45)*

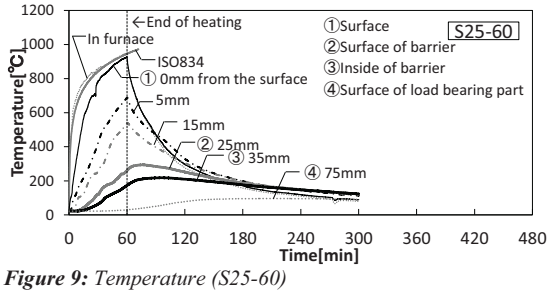

Figure 9: *Temperature (S25-60)*

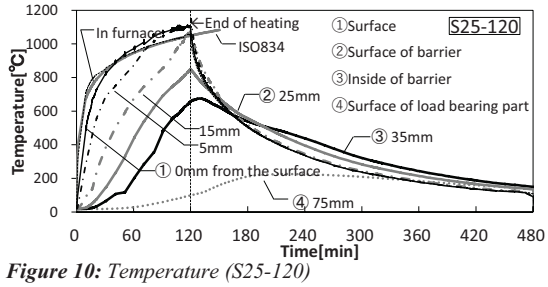

Figure 10: *Temperature (S25-120)*

https://doi.org/10.52202/069179-0218

Specimens were then allowed to cool in the furnace for a time longer than three times the heating time. The layout of the furnace and test specimen and the measurement items were the same as those in section 2.1. The temperature measurement points are shown in **Figure 6**.

2.2.3 Test results and discussion

Table 2 presents the cross section of each specimen, the carbonization depth, and whether glowing combustion continued at the end of the test. There was self-extinguishing for all heating times. **Figures 7** to **10** show the internal temperatures.

Table 2 reveals that carbonization progressed to the load-bearing part after heating for 2 hours. The temperature of the load-bearing part decreased with the temperature inside the furnace, and it is thus considered that the progress of combustion after heating was due not to the glowing combustion of the sacrificial layer but to the insufficient performance of the barrier layer. Additionally, the burning of the ends was due to the poor coating of the ends.

In the specimen heated for 30 minutes, the carbonization depths at the end of heating and at the end of the test were 22 and 27 mm, respectively (**Table 2**). It can be said that the sacrificial layer was generally carbonized entirely during heating and that the barrier layer was hardly carbonized and extinguished by itself after the heating. Meanwhile, because the barrier layer did not reach 100 °C at the end of heating, it is thought that if the sacrificial layer is 25 mm, the sacrificial layer will self-extinguish through heat loss from the surface, regardless of the self-extinguishing effect of the barrier layer.

In the specimen heated for 45 minutes, the sacrificial layer was completely carbonized at the end of heating, and the barrier layer reached the retarding agent decomposition temperature (195 °C) (**Figure 8**). It is thus presumed that an self-extinguishing effect of the barrier layer was exerted.

On the basis of these results, it can be said that the performance of the barrier layer determines whether the specimen can self-extinguish when exposed to fire heating for 45 minutes or longer. Therefore, the thickness of the sacrificial layer that reliably self-extinguishes regardless of the heating time is estimated to be 25 mm from the heat loss from the surface and the effect of the barrier layer.

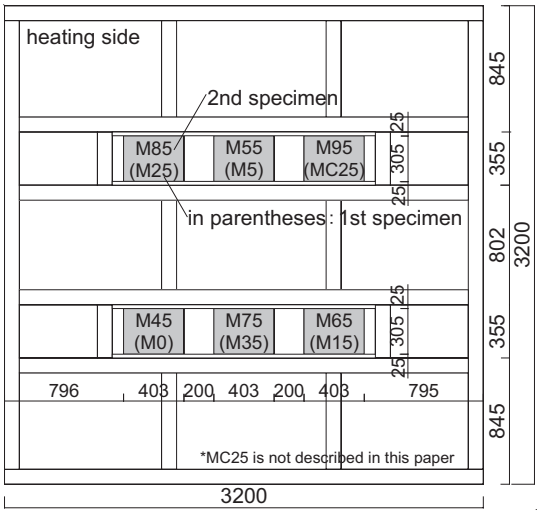

Figure 11: *Specimen layout in the third series of tests*

3 EFFECT OF THE THICKNESS OF THE SACRIFICIAL LAYER ON SELF-EXTINGUISHING IN THE CASE OF A GYPSUM-BASED PROTECTION LAYER

3.1 Purpose

The results obtained in section 2 revealed that the self-extinguishing performance is affected by whether the effect of suppressing the temperature rise due to the latent heat of the barrier layer is exerted during heating.

Gypsum exposed to heat suppresses a temperature rise of the sacrificial layer through the heat of vaporization of the water of crystallization within.

In a third series of tests, with gypsum used as the barrier layer, the thickness of the sacrificial layer was prepared from 0 to 95 mm, to clarify the effect of the thickness of the sacrificial layer on the self-extinguishing performance.

3.2 Outline of tests

In the third series of tests, using a wall furnace (3 m × 3 m) at the Takenaka Co. Research & Development Institute, specimens were heated for 1 hour following the ISO834 standard heating curve and allowed to cool in the furnace for 4 hours. **Figure 11** is a schematic diagram of the furnace and the layout of the test specimen.

Eleven test specimens were prepared with the thickness of the sacrificial layer ranging from 0 to 95 mm in increments of 10 mm. Gypsum-based self-leveling material and Japanese larch were used for the barrier layer. The thickness of the barrier layer was set at 40 mm. The load bearing part and sacrificial layer were integrated, and the gypsum-to-larch length ratio of the barrier layer was set at 2:1 considering the minimum width that could bear the shear force that needs to be borne by a structural member. The measurement items were the internal temperature of the specimen and the furnace temperature. Specimens and the temperature measurement points are shown in **Figure 12**.

https://doi.org/10.52202/069179-0218

3.3 Test results and discussion

Table 3 presents the cross section of the specimen, the carbonization depth, and whether glowing combustion continued at the end of the test. No specimen carbonized up to the load-bearing part. Self-extinguishing was confirmed when the thickness of the sacrificial layer was 55 mm or less, but with a sacrificial layer having a thickness of 65 mm or more, glowing combustion continued and the sacrificial layer did not self-extinguish. **Figure 8** shows the temperature of the barrier layer and **Figure 9** shows the temperature of the sacrificial layer for M35 to M85, which became the boundary of self-extinguishing. **Table 3** shows that the sacrificial layers of self-extinguished of M0 to M45 were uniformly carbonized. After heating, the temperature at the inside of the barrier layer (55 to 85 mm deep surface from) of M45 quickly reached 100℃ and was maintained until the end of the test (**Figure 14**). It is thus considered that the carbonization of the sacrificial layer was completed by heat conduction after the end of heating, and the continuation of combustion was suppressed by the heat of vaporization of the barrier layer.

As shown in **Figure 14**, the temperature of M55, which also extinguished itself, gradually increased to a maximum of 150 °C inside the barrier layer more than 1 hour after the end of heating.

In M55, after heating, the temperature of the inside of the sacrificial layer (15 to 35 mm in **Figure 13**) decreased as the temperature inside the furnace decreased, and then increased again to a maximum of approximately 500 °C. Furthermore, **Table 3** shows there were variations in the carbonization depth within the cross section of a specimen. It is thus considered that the temperature of the barrier layer rises owing to glowing combustion in the sacrificial layer after heating, and the heat of vaporization of the moisture present in the gypsum suppresses the continuation of combustion.

Meanwhile, in M65, which continued burning, the temperature of the barrier layer rose owing to heat conduction after heating, but the temperature of the barrier layer deeper than 95 mm from the heating surface did not reach 100 °C. Additionally, **Table 3** shows that an uncarbonized sacrificial layer with thickness of approximately 10 to 20 mm remained after the test was

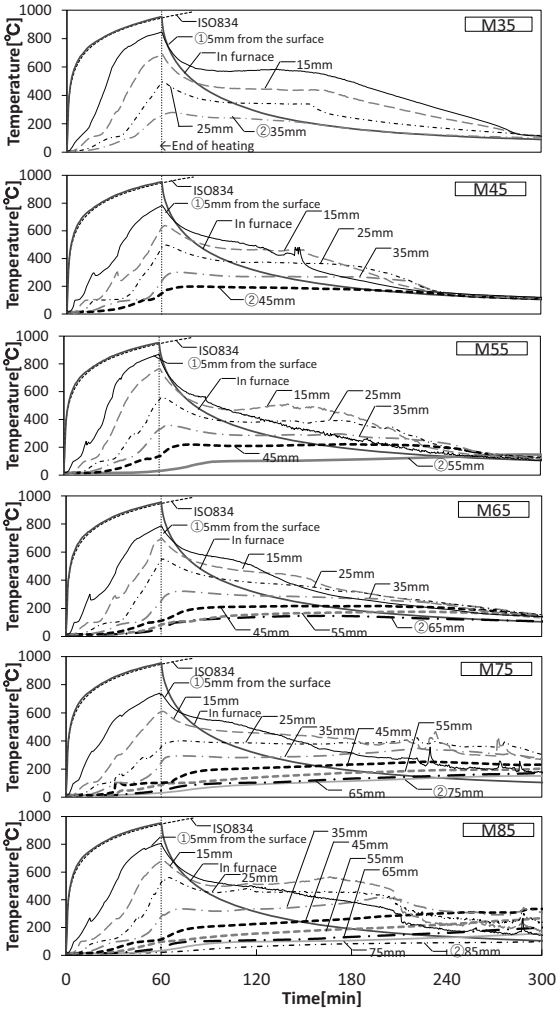

Figure 13: *Temperature of the sacrificial layer (M35, M45, M55, M65, M75, M85)*

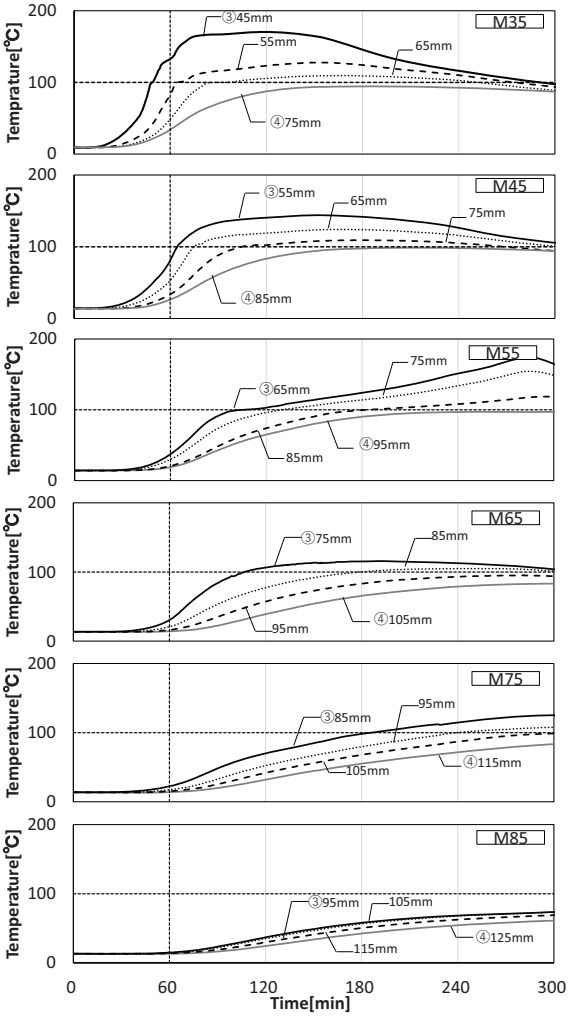

Figure 14: *Temperature of the barrier layer (M35, M45, M55, M65, M75, M85)*

https://doi.org/10.52202/069179-0218

complete. It is thus considered that the sacrificial layer was so thick that the temperature did not rise to the vaporization temperature (100 °C) of the moisture present in the gypsum and did not self-extinguish within the test time.

4 EFFECT OF THE DIFFERENCE IN THE BARRIER LAYER TYPE ON ACHIEVING SELF-EXTINGUISHING

The results presented in sections 2 and 3 reveal that the self-extinguishing performance is determined by whether or not there is latent heat of the barrier layer during heating. In the specimens with a barrier layer made from fire-retardant plywood, the thickness of the sacrificial layer was set at 25 mm or less, and the sacrificial layer extinguished regardless of the heating time.

In the test specimens with a gypsum barrier layer, the sacrificial layer reached the vaporization temperature through refractory heating at a thickness of the sacrificial layer of 45 mm or less and the sacrificial layer extinguished by itself.

With the gypsum barrier layer, the sacrificial layer self-extinguished even if it remained uncarbonized by approximately 20 mm. The water evaporation temperature in gypsum is lower than the decomposition temperature of the fire-retardant wood, and it is thus thought that the temperature control effect appears earlier for gypsum.

Furthermore, from the relationship between the heating time and the carbonization depth in **Tables 2 and 3**, the minimum thickness of the coating layer of the sacrificial layer + the barrier layer can be found with respect to the required fire resistance time. For example, in the case that the fire resistance time is 60 minutes, when the barrier layer is wood (as in the second series of tests), the minimum thickness of the covering layer is 48 mm, whereas when the barrier layer is gypsum (as in the third series of tests), the minimum thickness of the covering layer is approximately 32 to 58 mm, which is not so different.

Therefore, if the required fire resistance time increases, it will be necessary to consider changing the thickness of the sacrificial layer according to the type of barrier layer and improving the performance of the barrier layer.

5 CONCLUSIONS

The following conclusions are drawn from the results of the study.

(1) If the heating time is shorter than the required fire resistance time, it may not be possible to ensure self-extinguishing of the sacrificial layer.

(2) The optimum thickness of the sacrificial layer is 25 mm when using fire-retardant wood as the barrier layer.

(3) The gypsum barrier layer self-extinguished even if the sacrificial layer was about 20 mm thicker compared to the fire retardant wood-based barrier layer in the case of heating for 1 hour. It is thought that the effect of suppressing the temperature rise through the latent heat of water in the gypsum appears earlier.

ACKNOWLEDGEMENT

Part of this study was conducted under a JSPS Grant for "Engineering Approach to the Fire Safety Design of Large Scale Wooden Structural Assemblies". We thank Edanz (https://jp.edanz.com/ac) for editing a draft of this manuscript.

FIRE TESTING EXTERIOR CROSS-LAMINATED TIMBER WALLS TO NFPA 285

David Barber[1], Hans-Erik Blomgren[2]

ABSTRACT

Mass timber buildings are utilizing CLT for floors, walls and if permitted by regulations and codes, as exterior wall elements. In the United States, the IBC allows an exterior (external) wall to be load-bearing and constructed from Cross-Laminated Timber, provided the exterior surface is protected with fire rated gypsum board and if located above 12.2m, passes an NFPA 285 fire test. Supported by a US Forest Service grant, two CLT based exterior wall assemblies have been fire tested to NFPA 285, a global first. This paper presents the design of the exterior walls, summarizes the required code path and provides the results of the fire tests. The fire test assembly includes a 3 ply CLT panel, fire rated gypsum board, a commonly used water resistive barrier and mineral wool. Both of the CLT based exterior wall assemblies successfully passed the NFPA 285 test and will enable greater use of mass timber in future buildings. All data, drawings and test reports will be made public to progress the acceptance of CLT for fire safe use in exterior walls.

KEYWORDS: Mass Timber, Cross-Laminated Timber, Exterior walls, NFPA 285, Tall timber buildings, Fire testing

1 INTRODUCTION

Mass timber construction utilizing glulam and Cross-Laminated Timber (CLT) continues to be popular globally due to the carbon storage it offers, the efficiency in construction and as a differentiator in a competitive leasing market. Within the US, the nationally adopted model code is the International Building Code (IBC) [1] and the 2021 edition includes new provisions that increase the use of mass timber in multi-story office and residential buildings, up to 18 floors in height. As part of this change there are new requirements for exterior (external) walls that allow construction to be based on CLT panels. This change allows building designers to consider differing structural typologies for mass timber high-rise buildings.

1.1 EXTERIOR WALLS UTILIZING CLT – MOTIVATION FOR FIRE TESTING

The 2021 IBC provides a significant step-change for mass timber construction and CLT is permitted to be used as part of an exterior wall assembly for buildings of the new IBC mass timber Construction Types IV-A, B and C. Type IV-A construction allows mass timber up to 18 floors and 82m (270ft) in height. CLT can also continue to be used as an exterior wall in the mid-rise Construction Types IV-HT, V-A and V-B, being limited to a height of 25.9m (85ft) or less. The prescriptive IBC language says CLT can be utilized in a load bearing or non-load bearing exterior wall, provided the CLT is clad on the exterior side with a single layer of fire rated gypsum board of 16mm (5/8in). An exterior wall is made up of a number of different layers and components from the interior to the exterior face, with these components referred to as an assembly. The CLT forms the supporting panel for the exterior wall components (see Figures 1 and 2).

Figure 1: *CLT exterior wall assembly prefabricated off-site being lifted at site. CLT forms the support for the thermal and water barriers to the exterior face (image credit: Blomgren)*

Due to CLT combustibility, the IBC contains multiple conditions for exterior walls that trigger a requirement that the exterior wall assembly pass a fire test to NFPA 285 "*Standard Fire Test Method for Evaluation of Fire Propagation Characteristics of Exterior Wall Assemblies Containing Combustible Components*" [2]. The NPFA 285 testing requirement is most commonly triggered for wall heights greater than 12.2m (40ft).

NFPA 285 is the nationally adopted fire test standard to determine vertical flame spread acceptance for exterior walls. It is the author's understanding that no CLT based exterior wall has ever successfully passed an NFPA 285 fire test. Due to the compliance cost and timing barriers of completing an NFPA 285 test, building designs in the

[1] David Barber, Arup, Melbourne, david.barber@arup.com
[2] Hans-Erik Blomgren, Timberlab, Seattle WA, hanserikblomgren@timberlab.com

https://doi.org/10.52202/069179-0219

US typically avoid using CLT as part of an exterior wall, even though a CLT exterior wall can provide efficiencies in construction, especially for residential buildings. A building project wanting to use CLT as a load bearing, or non-load bearing exterior wall over 12.2m (40 ft) in height will face a technical justification barrier and will need to invest in an NFPA 285 fire test specific to the proposed wall assembly, adding significant project expense and risk.

Figure 2: *Five story building constructed in the US with CLT exterior wall approved without NFPA 285 fire testing (image credit: Blomgren)*

With the lack of substantive fire testing available globally on CLT as part of an exterior wall and given the issues of interpretation and application by building authorities of the IBC requirements, and further, to remove a degree of project risk, a project supported by a 2021 US Forest Service Wood Innovation Grant has been undertaken. The project aims were to determine: 1) The IBC code language requirements for exterior walls; 2) If the IBC approved solution for CLT use in exterior walls above 12.2m (40ft) will pass an NFPA 285 test; and 3) The minimum encapsulation required for the CLT exterior wall to pass an NFPA 285 test. The background to the IBC requirements, exterior wall test set up and results are described in this paper.

1.2 GLOBAL IMPLICATIONS

The use of combustible construction within exterior walls of buildings is of global concern given the number of catastrophic fires that have occurred when highly combustible composite panels have been used. Building Regulations in England have been changed to severely limit the use of timber as part of exterior walls due to fire safety concerns [3]. No fire testing has occurred on mass timber based external / exterior walls to prove or disprove if this change in regulations is appropriate. With few fire tests to any national standards on CLT exterior walls available for designers and regulators to assess, these fire tests to NFPA 285, an internationally recognized standard, will be of significant interest and can assist with decision making regarding the fire-safe implementation of CLT as part of a building's exterior wall.

2 IBC REQUIREMENTS

Where CLT is used as part of an exterior wall above 12.2m (40ft), the exterior wall assembly must be checked for compliance based on a range of code sections. The IBC requirements for exterior walls are included within Chapters 6, 7 and 14 and are open to interpretation, as compliance is based on building construction type, height of the exterior wall, separation to neighbouring buildings, the combustibility of the water resistive barrier (WRB) and the inclusion of CLT or other timber in the assembly.

The IBC requires that where CLT is used for an exterior wall assembly that it be protected from fire by direct fixing a layer of 16mm (5/8in) fire resistant gypsum board to the exterior face, so no timber is exposed and is deemed to protect the timber by 40 minutes. These requirements apply up to 82m (270ft) or 18 floors. The interior face of the CLT may be exposed or covered by non-combustible protection, required by separate IBC requirements not related to exterior walls. The WRB in use has strict flammability limits and when a WRB is combustible, which the majority are for use in modern construction, the IBC then requires an NFPA 285 fire test when used above 12.2m (40ft).

For a non-load bearing CLT based exterior wall assembly within Construction Type IV-A, IV-B, IV-C or IV-HT construction, the code requirements are summarized below and introduce one possible code compliance path. It should be noted that each building situation will differ and may result in outcomes that change the path to code compliance. The type of exterior wall arrangement is also important as to whether the exterior wall is part of a "balloon framing" solution (also referred to as a by-pass or curtain wall); or part of a platform framed solution (also referred to as an in-fill or window wall). The code references below are based on the unmodified 2021 IBC.

Chapter 6

Table 601:	Sets a fire resistance rating requirement for exterior load bearing walls from no requirement for Type V-B to a 3-hour FRR for Type IV-A.
Section 602.4:	Allows mass timber to be used in exterior walls in Type IV construction provided the requirements are met including the following:
Section 602.4.1.1: IV-A **Section 602.4.2.1: IV-B** **Section 602.4.3.1: IV-C**	Requires 40 minutes of non-combustible protection for the exterior face of the CLT determined per section 722.7 and flammability requirements for the WRB. The 40 mins can be provided with one layer of 16mm (5/8in) Type X fire rated gypsum board. Requires all components of the exterior wall covering be non-combustible except WRBs meeting the flammability requirements.

https://doi.org/10.52202/069179-0219

Section 602.4.4.2: IV-HT	Requires exterior protection of CLT in exterior walls in IV-HT of either 11.9mm (15/32in) fire retardant treated sheathing, 12mm (½in) gypsum board, or any non-combustible material.
Chapter 7	
Section 705.5:	Sets a fire resistance rating required of an exterior wall based on fire separation distance if the building is located near a boundary lot line or another building. Also determines if the fire resistance rating is required for fire exposure from the exterior only or both the interior and exterior.
Section 705.6:	Sets the requirements for the supporting construction of the exterior wall with different requirements for interior elements and exterior elements or within the exterior wall. Requires elements that brace the exterior wall but are not located within the plane of the exterior wall, to achieve a fire resistance meeting Table 601. This is relevant where the CLT wall is balloon framed or platform framed.
Section 715.4:	If the CLT is balloon framed (by-pass or curtain wall), the exterior wall intersection to the floor requires an approved fire seal that meets with ASTM E2307, to provide an "F" rating consistent with the floor (for Type IV-B this is 2hrs).
Section 722.7	Where required in Type IV construction, determines the required protection from non-combustible coverings on the exterior of the CLT. Recognizes that 40 mins can be provided with one layer of 16mm (5/8in) Type X fire rated gypsum board.
Chapter 14	
Section 1402.5:	For an exterior wall over 12.2m (40ft) in height in all but Type V construction, if the water-resistive barrier (WRB) is combustible then the exterior wall is required to undergo a fire test to NFPA 285 "*Standard Fire Test Method for Evaluation of Fire Propagation Characteristics of Exterior Wall Assemblies Containing Combustible Components*". There are two exceptions. Both Exceptions are not applicable to CLT framed exterior walls as the exceptions apply when the WRB is the ***only*** combustible component in the exterior wall assembly. Most, if not all, commercially viable WRBs are combustible. The combination of the combustible WRB and with mass timber framing in the exterior wall results in this Section requiring the exterior wall assembly comply with the NFPA 285 acceptance criteria when used above 12.2m (40ft).
Section 1405.1.1:	In all but Type V construction, exterior wall coverings are not permitted to be constructed of fire-retardant-treated wood above 18.3m (60 ft) above the grade plane nor constructed of other combustible materials above 12.2m (40 ft) above grade plane.

2.1 Summary

Where CLT is to be used within an exterior wall assembly, once the wall is above 12.2m (40ft) an NFPA 285 fire test is required, as the WRB will normally always be combustible. This is further clarified within the document "*Mass Timber Buildings and the IBC 2021 Edition*" [4] by the International Code Council and American Wood Council under "Change Significance 602.4.1.1 Exterior Protection" as follows:

> Buildings of Type IV-A, IV-B and IV-C construction will be subject to testing prescribed for exterior walls. Section 1402.5 of the IBC requires these walls to be tested according to NFPA 285. Nothing in this section is intended to preclude that test being applicable to these new types of construction. Even for wall assemblies passing the NFPA 285 test, all construction materials exterior to a mass timber wall, except the water-resistive barrier, must be noncombustible.

The CLT based exterior wall in Type IV-A, B, and C construction differ in required protection to the exterior face compared with Type IV-HT. Type IV-HT has more flexibility in the required non-combustible covering to the exterior face. A higher level of protection by non-combustible materials may also be needed if the exterior wall is load bearing or has a close fire separation distance.

3 DESCRIPTION OF THE NFPA 285 FIRE TEST

NFPA 285 "*Standard Fire Test Method for Evaluation of Fire Propagation Characteristics of Exterior Wall Assemblies Containing Combustible Components"* specifies a fire test for an exterior wall assembly to determine the potential for flame spread vertically up the wall, laterally across the wall and within the wall assembly. The fire test requires a two-story wall, including a window opening, to be constructed. A successful test demonstrates the exterior wall assembly, as a whole, passes the test, not any individual element.

The NFPA fire test uses two separate gas burners, one located within the lower story room that ignites from time zero. This burner provides a simulated fire that replicates the ASTM E119 *Standard Test Methods for Fire Tests of Building Construction and Materials* [5] fire curve which is used to determine fire resistance. After 5 mins of testing, a second gas burner is moved into position in front

https://doi.org/10.52202/069179-0219

of the window to simulate large external flames for a fire, replicating a fire that starts internally, then breaches a window or wall and then grows on the exterior face of the building (See Figure 3). This method of fire testing was developed from testing in the 1980's to assess combustible exterior cladding materials.

There are several different pass or fail criteria for the wall, with temperatures checked at various heights above the window and laterally away from the window. Temperatures are also checked within the wall. Flame spread height above the window is also visually observed and measured (see Figure 3). A wall needs to meet all test criteria to have been deemed to have passed.

Figure 3: *NFPA 285 test showing window burner in position for testing (image credit: Barber)*

4 EXTERIOR WALL ASSEMBLY DESIGN AND FIRE TEST SET-UP

Two CLT based exterior wall assemblies were designed, constructed and tested. The assemblies were selected based on a typical wall that would be constructed for locations with a mild temperature and humidity range in the U.S. The aim of the design was to make the exterior wall applicable and extendible to a broad range of mass timber projects (see Figures 4 to 12).

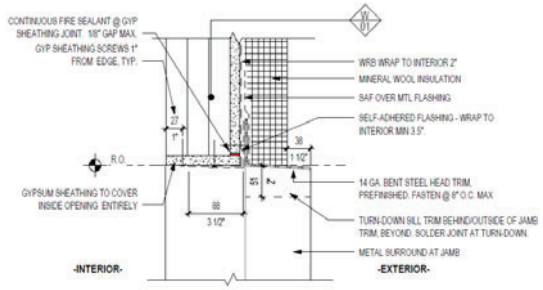

Figure 4: *Details at window head (image credit: Mithun Architects)*

The exterior wall assemblies included:

- A 3 ply 105mm (4.1in) CLT panel manufactured to ANSI/APA PRG 320-2019. Given this is the minimal CLT thickness expected for any exterior wall.
- The WRB was specified to have a reasonable performance for moisture control. The WRB did not meet the flammability classification criteria within IBC Sections 602.4.1.1, 602.4.2.1, 602.4.3.1 or 1402.5 Exception 2, being more flammable. This was based on understanding how limited the supply is for a very low flammability WRB and their high cost. A WRB typically used for mid and high-rise construction was chosen.
- The mineral wool batts were non-combustible and of a high-density given their better insulative performance with a minimal thickness included. A typical building in most USA climate regions will have a thicker depth of mineral wool.
- The window opening jambs, sill, and header were highly detailed given this is an area of likely failure. A window frame product was not included in the tests. For actual projects the expectation is the window will positively fasten to the CLT edges at the opening.
- The interior face of the CLT was left exposed given this may be the architectural solution desired. In having the interior face of the CLT exposed, there was additional combustible fuel added to the test as the CLT interior face combusted and charred.
- The CLT based exterior wall assemblies were tested with no exterior facing rain screen or wall covering. This allows additional non-combustible coverings to be directly fixed on the exterior face of the assembly. By not including a rainscreen, the exterior face of wall was exposed to worst-credible fire conditions, as a rainscreen would beneficially shield the wall.
- For Test 1 the exterior side of the CLT is clad with 16mm (5/8in) fire rated gypsum board, a combustible water resistive barrier and 50mm (2in) of mineral wool insulation.
- For Test 2 the wall assembly is similar to Test 1, but the fire rated gypsum board was removed, with only the WRB and 50mm (2in) of rockwool in place.
- All details are provided within drawings that will be available for download from www.woodworks.org.

https://doi.org/10.52202/069179-0219

5 FIRE TEST RESULTS

A brief description of the two fire tests undertaken to NFPA 285 are provided below.

5.1 Test 1 Summary

Test 1 was designed to be near compliant with the 2021 IBC, with a single layer of 5/8in (16mm) Type X fire rated gypsum board located on the exterior side of the CLT face, meeting section 602.4.2.1. As noted above, the WRB did not meet section 602.4.2.1 or section 1402.5 for limited flammability.

https://doi.org/10.52202/069179-0219

The CLT based exterior wall assembly passed the NFPA 285 test with no temperatures exceeding the failure criteria of the standard and the flame extension was limited in height and lateral spread. During the test and on completion of the test and disassembly of the panel, the following was observed:

- Interior face of the CLT was visibly flaming through the whole test, as expected and was charred.
- The mineral wool above the opening was heavily scorched yet still provided protection to the underlying CLT, preventing flame spread.
- The WRB had significant heat damage directly above the window, but this was limited in height to about 600mm (24in)
- The window surround suffered damage and remained in place throughout the test.

The interior face of the CLT based exterior wall assembly was exposed to the gas burner was significantly charred. The combustion of the CLT and resultant charring negatively impacted the performance of the exterior wall by increasing the extent of flames above that prescribed by the NFPA 285 test. By exposing the CLT on the internal face, the worse-case conditions for the CLT exterior wall assembly were tested (see Figures 13 to 18).

5.2 Test 2 Summary

Given the results of Test 1, the CLT based exterior wall assembly was modified and the single layer of 16mm (5/8in) Type X fire rated gypsum board was not included on the exterior face of the panel. The exterior face of the CLT panel relied on the mineral wool to provide the protection against fire spread. This exterior wall assembly also passed the NFPA 285 test. The following was observed:

- Similar charring to the panel as for Test 1.
- Similar damage to the mineral wool and window surrounds as for Test 1.
- More heat damage to the WRB was observed, with damage extending up the face behind the mineral wool approximately 900mm (36in) and across the width of the window opening (see Figure 18).
- Overall temperatures and flame heights were similar to Test 1.

https://doi.org/10.52202/069179-0219

Figure 19: *Test 2 completed, showing extent of damage, with mineral wool manually removed. Damage can be compared with that of Test 1, shown in Figure 16 (image credit: Blomgren)*

5.3 Discussion

Two successful NFPA 285 fire tests were completed for a CLT based exterior wall. Test 1 was closely compliant with the requirements of the IBC as a CLT based exterior wall, with only the WRB being of a higher flammability classification. Test 2 did not include the non-combustible protection of gypsum board to provide 40 minutes of protection to the exterior face, utilizing mineral wool only to provide the non-combustible protection. The WRB was the same as for Test 1. Hence the CLT based exterior wall assembly for Test 2 had two variances with the requirements of IBC Section 602.4.

The test set-up for both walls was based on a design that replicates a typical project, acknowledging that there are many different types of exterior walls that could be designed and constructed. While the tests demonstrated the assembly as tested will pass the NFPA 285 test, an assembly with any of the following changes is also expected to pass the NFPA 285 criteria:

- CLT as a load bearing wall: Using the CLT as a load bearing wall is determined via ASTM E119 testing or similar approved method.
- Change in CLT depth: A thicker CLT panel can be used and would have no detrimental impact on the outcomes of the fire test.
- Addition of an exterior wall covering: A non-combustible wall covering can be included to the exterior face. This exterior covering would need to be direct fixed to the mineral wool insulation and could not include a vertical void or airspace as this could result in accelerated vertical flame spread between the mineral wool and the exterior wall covering.
- Addition of an interior covering to the CLT: The NFPA 285 tests had the CLT exposed on the interior side (facing into the interior or occupied building area). The results would not be changed if the CLT was covered with a non-combustible covering.

Test 2 was successful without the inclusion of a single layer of 16mm (5/8in) Type X fire rated gypsum board, which IBC Table 722.7.1(2) recognizes to provide the required 40 mins of non-combustible protection. For Test 2 the mineral wool insulation provided the CLT the non-combustible protection. For Test 2 to be used in a Type IV A, B or C building, an application to the authority having jurisdiction would be required, such as applying for a code variance or alternative material, design, or method of construction, given the wall assembly did not include the IBC required single layer of Type X fire rated gypsum board.

5.4 Applicability of NFPA 285 Testing to Mass Timber Buildings

NFPA 285 is a standard for assessing fire spread on exterior walls. Like all international fire tests for exterior / external walls and facades, the test methodology may need to be revisited where a building includes a large area of exposed mass timber structure (internal to the building), given that the exterior flaming is extended in length and temperatures are increased, due to the exposed timber structure [6]. NFPA 285 is a referenced standard for the IBC and would be used where an exterior wall is of a height over 12.2m (40ft), hence applicable for mid and high-rise mass timber buildings.

Fire testing of CLT based exterior walls with similar design set-ups is encouraged to occur in other countries to national standards, especially to test standards such as BS 8414 [7] and the proposed harmonised European test [8].

6 CONCLUSIONS

This project has demonstrated that a CLT based exterior wall assembly can pass the NFPA 285 fire test. In doing so, the results provide guidance to building officials, architects, engineers, and contractors as to how they can design and construct a CLT based exterior wall assembly that satisfy IBC requirements. The wall assemblies were designed so that the exterior face of the CLT was not directly exposed to flames and the detailing was well-thought through to prevent vertical flame spread.

With funding from a USFS Wood Innovation Grant, a current market barrier to mass timber construction has been removed by successfully demonstrating that a CLT based exterior wall assembly can pass NFPA 285. By publishing the details of the exterior wall designs and the fire test results, these CLT based exterior wall assemblies can be replicated for future multi-story mass

https://doi.org/10.52202/069179-0219

timber building projects and can be used by building authorities, architects, engineers and contractors, acknowledging the exterior wall design and limitations of the test method.

ACKNOWLEDGEMENTS

The project was led by Timberlab, supported by Arup, Mithun Architects, SmartLam, Rothoblaas, Rockwool and WoodWorks, with funding from the USDA 2021 Wood Innovation Grant # 21-DG-11062765-735.

FIRE SAFETY OF MID-RISE BUILDINGS WITH LIGHT TIMBER STRUCTURES – STUDIES OF THE FIRE RESISTANCE OF A NOVEL CONSTRUCTION SYSTEM

Kathinka Leikanger Friquin[1], Johan Kr. Møller[2]

ABSTRACT: A novel construction system with light timber structures is being developed for mid-rise timber buildings. Requirements for the fire resistance of the building elements and structures increase with taller buildings because the consequences of a fire are higher than for small buildings. Mid-rise buildings therefore need fire resistance of 60-90 minutes. Floor elements with light timber structures have been studied with regards to the fire performance. Experimental results for the floor construction designed for large spans are presented here. The experimental results show that it is possible to achieve fire resistance REI 90 or more for the floor. The results indicate that large void cavities in the construction delays the charring of the timber structure. The construction provides fire protection of the main beams throughout the full fire scenario.

KEYWORDS: Light timber frame, construction system, fire resistance, temperature development, void cavity

1 INTRODUCTION

1.1 BACKGROUND

Wood is a renewable resource, light, easily and locally available in most areas, and environmentally friendly. The focus on sustainability therefore makes timber structures attractive and its suitability is now evaluated for all types of buildings. Elements with light timber frames can be prefabricated with a high degree of completion, with insulation, cladding/flooring, etc. Prefabrication ensures high quality, and the work environment is better than outdoors. Installation of the elements is fast, which makes the construction time for a building shorter than with traditional methods, reducing the time-related costs and exposure to wind, rain and frost [1]. An important challenge for mid-rise and tall buildings with light timber structures is the fire safety. The performance-based building regulations developed in Europe and many other countries the 1990s allowed for larger timber buildings than previously. However, the research focus has since mainly been on development of heavy timber structures for large buildings [2].

1.2 A NOVEL CONSTRUCTION SYSTEM

A novel floor construction is developed for spans of approximately 8 m, which is longer than what is possible for traditional light timber floors. The structure is therefore designed to achieve a higher stiffness and strength. A novel solution to enable installation of the noise reducing ceiling in the factory is developed to achieve a higher degree of prefabrication. The construction is also designed to give long fire protection of the main load-bearing structure.

1.3 OBJECTIVES

The main objective of the project is to develop a novel construction system with light timber structures and a high degree of prefabrication, for buildings with 5-8 floors with large open spaces. The main objectives of the experiment presented in this paper were to study; the fire resistance performance of the novel floor construction, whether it is possible to prevent involvement of the main structural members in the full duration of the design fire scenario, if the insulation would fall out during the fire and if the large void cavity would delay the thermal exposure on the timber construction. The fire behaviour during exposure to a "complete" fire development, including the cooling phase, is studied as this is a requirement for mid-rise timber buildings in Norway [3].

2 METHOD

2.1 TEST SETUP

The standard test method described in EN 1365-2 [4] was used. The floor specimen is placed on top of a horizontal furnace with dimensions 3080 mm x 4060 mm, see Figure 1. Siporex elements are used to cover the furnace completely, as the specimen is not wide enough, see pt. 2.2. A few deviations from the test method were made; on the cold side of the floor only the thermocouples for measurements of the average temperature change were installed, external load was not applied on the floor during the test because the span across the furnace is too short to

[1] Kathinka Leikanger Friquin, Department of Architecture, Materials and Structures, SINTEF Community, Norway, kathinka.friquin@sintef.no
[2] Johan Kr. Møller, Department of Architecture, Materials and Structures, SINTEF Community, Norway, johan.moller@sintef.no

https://doi.org/10.52202/069179-0220

test the load bearing capacity for a structure as stiff as this floor. Numerous additional thermocouples were installed inside the construction. The planned temperature-time curve was also different than described in the test method, see pt. 2.4.

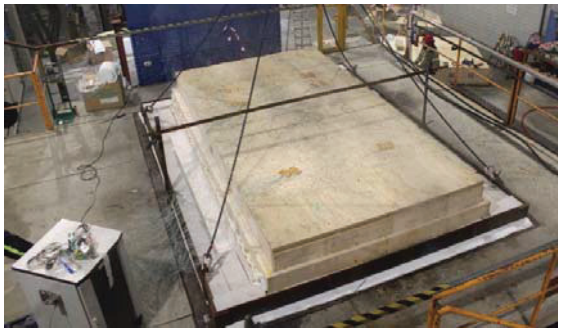

Figure 1: *The floor specimen mounted on the horizontal furnace (Photo: RISE Fire Research AS)*

2.2 TEST SPECIMEN

The novel floor construction is optimized with respect to the strength and stiffness, and to protect the load-bearing structure. The specimen is 2400 mm wide and 4382 mm long, with free span of 4300 mm. Description of the floor, see also Figure 2:
(1) wooden board
(2) structural timber beams
(3) structural timber flange
(4) ceiling system with 2 x 15 mm fire rated gypsum boards, acc. EN 520 [5]
(5) stone wool insulation, acc. EN13162 [6].

The cavity between the gypsum boards and timber structure is larger than 50 mm deep. The three main beams in the specimen are numbered BA1, BA2 and BA3.

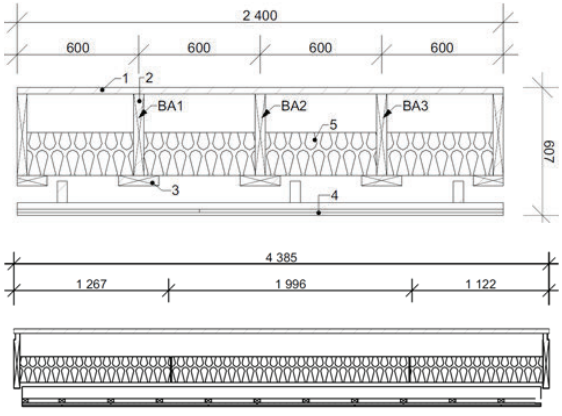

Figure 2: *Floor construction, cross-section (top) and longitudinal section (bottom). Measurements in metre (m) (Ill.: Støren Treindustri AS)*

The gypsum boards in the ceiling, the flanges and the insulation between the beams are, among other factors, designed to maximize the performance during fire. The load-bearing structure is made of structural timber. The specimen was stored inside the lab for 6 days before testing, at approximately 21°C. The moisture content in the components was not measured.

2.3 INSTRUMENTATION

Instrumentation of the floor was partly according to the test standard EN 1365-2 [4], but with additional instrumentation at three locations inside the construction to gain more knowledge and information about the temperature development inside the floor. The three locations are on/near beam BA1 at distance 966 mm from one end of the floor, on/near beam BA2 at distance 2193 mm from one end of the floor, and on/near beam BA3 at distance 1092 mm from the other end of the floor. Thermocouples of the type Quick-Tip were installed on and inside the beams, and at several other positions at the three locations. Figure 3 shows the positions on the surfaces of the flanges and beams, and the positions on/between each layer.

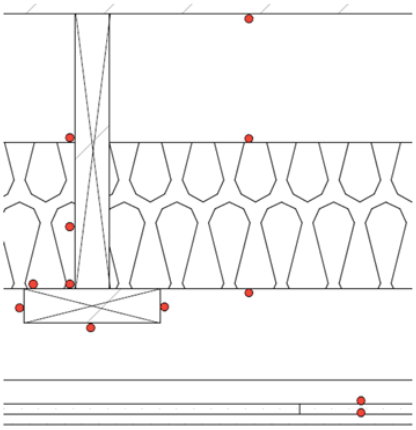

Figure 3: *Instrumentation on the surfaces inside the construction (Ill.: Støren Treindustri AS)*

Thermocouples were also drilled into the flanges from the top, see Figure 4. To measure the temperatures in the vertical direction, thermocouples are positioned at a distance of 10 mm to the side of the beam, see Figure 5. Depths from the underside of the flanges are 8, 18, 28, 38 mm. Horizontal measurements are positioned 10 mm below the top surface of the flange, at depths from the lateral side 10, 20, 30, 40, 50 mm.

https://doi.org/10.52202/069179-0220

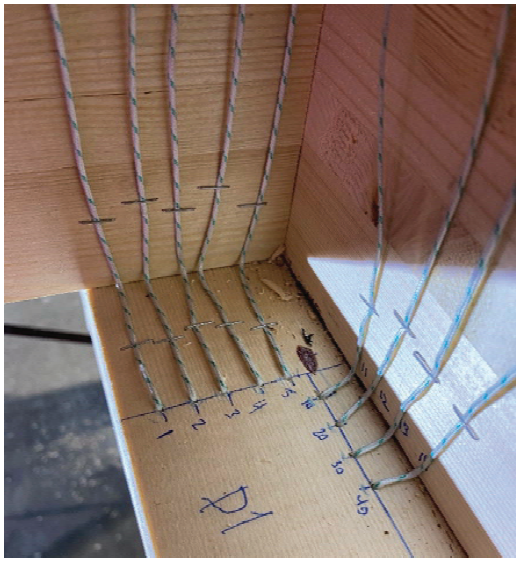

Figure 4: *The TCs inside the flange were drilled into the wood from the top of the flange*

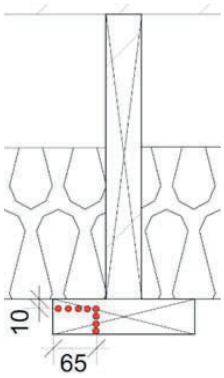

Figure 5: *Instrumentation inside the flange of the main beams (instrumentation group D) (Ill.: Støren Treindustri AS)*

2.4 TEST CONDITIONS

The furnace temperature followed the standard temperature-time curve given in EN 1991-1-2 [7] for 90 minutes. After 90 minutes the temperature was planned to decrease, with a cooling rate of 20°C/minute to represent the cooling phase of a complete fire, see the blue curve in Figure 6. Cooling was planned to be achieved by reducing, and eventually turning off, the gas burners, and removing the Siporex elements on the sides of the specimen.

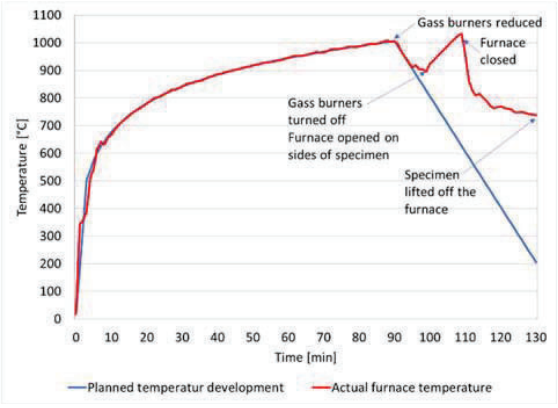

Figure 6: *Planned (blue) and achieved (red) temperature-time development in the furnace*

3 RESULTS AND DISCUSSION

3.1 TEMPERATURE MEASUREMENTS

The temperatures in the furnace and inside the floor were not registered during the time-period 100-109 minutes, because the logging stopped when the gas burners were turned off after 100 minutes. In the figures showing the results, a straight line is drawn between these two points. However, this might not be the actual temperature development. This does not affect the analysis of the results where charring of the wood has started, but can give a few minutes error for the reading of when charring temperatures of 300°C were reached on the top of the flange and inside the flanges. The error is less than 9 minutes.

Before lifting the specimen off the furnace after 130 minutes, the cables for the thermocouples had to be cut because they were too short. The temperatures in the specimen were therefore not measured after this.

The specimen was left outside the furnace until 255 minutes, i.e. 125 minutes after lifting it off the furnace. No flaming combustion was observed during this period, only glowing. It was then cooled with water to stop the combustion.

3.2 FURNACE TEMPERATURE

The planned temperature development in the furnace was difficult to achieve, and the cooling phase became different than planned, see Figure 6. The gas burners were reduced after 90 minutes to decrease the temperature, and turned off after 100 minutes when the cooling no longer followed the planned curve. At the same time, the Siporex elements on the sides of the specimen were removed. However, cooling at the planned rate was still not possible, mainly due to the free surfaces of flanges and other combustible material. After 130 minutes, the floor was therefore lifted off the furnace for continued cooling, but without external extinguishment, see Figure 7. The presence of combustible materials such as the flanges

https://doi.org/10.52202/069179-0220

made it difficult to decrease the temperature in the furnace after the gypsum board fall-off, and removing the Siporex increased the supply of Oxygen. These are the main reasons the planned cooling was not achieved.

Figure 7: *Lifting the floor off the furnace to achieve cooling*

The temperature development inside the cross-section and flanges might be affected by the elevated temperatures during the cooling phase, with a quicker temperature increase than if the cooling had evolved as planned. It is not possible to determine the scale of this.

3.3 TEMPERATURE DEVELOPMENT INSIDE THE FLOOR

Temperatures between all layers and on the surfaces were measured with thermocouples, as described in pt. 2.3. Figure 8 shows the average of the temperature development at each position, based on three measuring points. Observed fall-off of the gypsum boards and measurements of start of charring of the flanges are given in Table 1. The charring temperature of wood is defined to be 300°C in EN 1995-1-2 [8]. Time to start of charring is therefore determined by the time at which the temperature on the surface of the wood reaches 300°C.

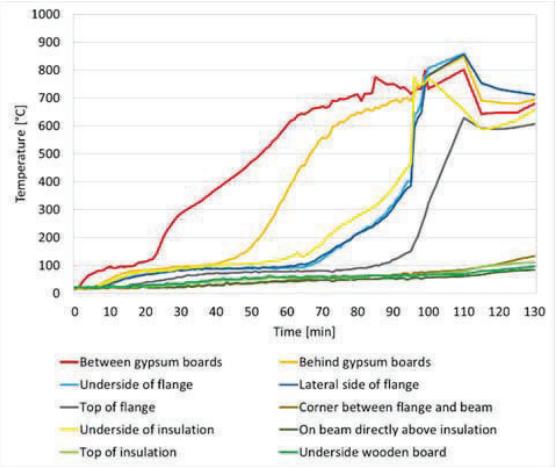

Figure 8: *Temperature development through the floor at different positions, average of the three measuring locations in the floor*

Table 1: *Time until fall-off of gypsum boards and start of charring of wooden battens and flanges*

Measuring point	Results
Temperature behind gypsum boards >300°C	57 min
Temperature on underside of insulation >300°C	83 min
Temperature on underside of flanges >300°C	88 min
Temperature on lateral sides of flanges > 300°C	89 min
Fall-off second gypsum board layer	95 min

Figure 8 shows a considerable difference between the temperature behind the gypsum boards and on the undersides and lateral sides of the flanges. The temperature on the unexposed surface of the gypsum boards increased fast after evaporation of the moisture in the boards, while on the other surfaces the heating rate was considerable slower. At its maximum the difference is approximately 370°C. This is probably caused by the large void cavity, which delays the temperature development considerably.

Charring temperatures behind the gypsum boards were reached after 57 minutes, but on the flanges, charring only started after 88-89 minutes. Charring of the flanges was, in other words, delayed by approximately 31 minutes. As mentioned above, this is probably mainly due to the large void cavity between the gypsum boards and flanges. The positive influence of a void cavity of a certain depth has been reported by Schleifer [9], and is included in design models for determination of the fire resistance of light timber frame assemblies [10]–[12].

3.4 FIRE PROTECTION PROVIDED BY THE GYPSUM BOARDS

Charring temperature 300°C was reached behind the gypsum boards in the ceiling after 57 minutes. Both gypsum board layers had fallen down after 95 minutes. The combination of fire protection provided by the boards and the large void cavity contributed greatly to prevent charring of the wooden structure before 88 minutes into the fire exposure.

The gypsum boards provided fire protection longer than expected based on guidance given in [10], [11], where 2 x 15 mm fire rated gypsum prevents charring for 46 minutes and falls down after 57 minutes. The design methods, developed to calculate the fire resistance of load-bearing timber structures and fire separating building elements, are meant to be conservative to cover most products on the market. Based on the results, the gypsum boards used in this experiment had better fire properties.

https://doi.org/10.52202/069179-0220

3.5 CHARRING

Charring of the timber structure in the floor element started at approximately 88 minutes, when the undersides and lateral sides of the flanges reached 300°C, see Table 1. This is 31 minutes after the temperature behind the gypsum boards in the ceiling reached 300°C. As described in pt. 3.1, this indicates that the large void cavity in the floor element significantly delayed the start of charring behind the gypsum boards in the ceiling. Calculations based on the design methods given in [10], [11] do not account for an effect of this magnitude from void cavities.

The temperature development in the flanges measured by the thermocouples drilled into the wood is shown in Figure 9 for vertical direction, and in Figure 10 for horizontal direction. See Figure 5 for the positions of the thermocouples.

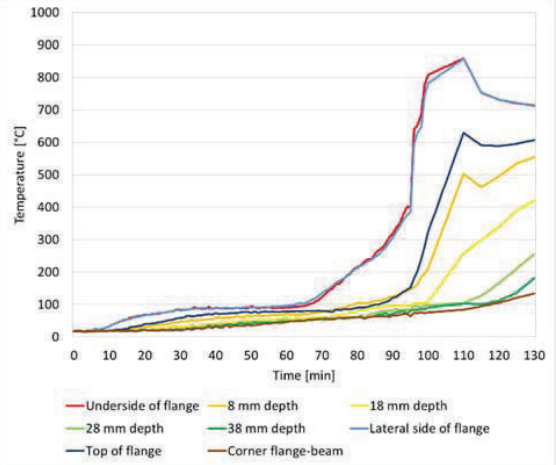

Figure 9: *Temperature development inside the flanges at depths 8, 18, 28, 38 mm from the underside, average of the three measuring locations in the floor*

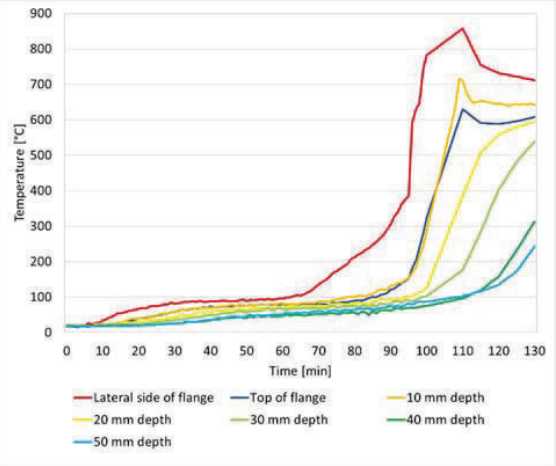

Figure 10: *Temperature development inside the flanges at depths 10, 20, 30, 40, 50 mm from the lateral side, average of the three measuring locations in the floor*

The average char depths of the flanges after 90 and 130 minutes, based on the temperature measurements inside the flanges, are given in Table 2.

On top of the flange the temperature approximately 20 mm in from the corner, see Figure 3, follows the temperature at depth 10 mm in the flange from lateral side. This indicates that there is some air leakage between the flange and the insulation. This leakage is negligible in the corner between the flanges and beams, at distance 75 mm from the lateral side of the flanges.

The residual cross-sections of the flanges were also measured physically after the fire experiment at three positions, see Figure 11 and Table 2. These are not at the same positions as the thermocouples. Residual height and width, plus width of the "shelf" of the flange for insulation to rest on, are similar to the last readings before the thermocouples were disconnected after 130 minutes, see Table 2. The cooling phase continued after this for approximately 125 minutes, but the charring of the timber stopped early in the cooling phase or the charring rate decreased considerably.

Figure 11: *The residual cross-sections of the flanges after the fire experiment. The main load-bearing beam is discoloured but not charred*

Table 2: *Average char depth at 90 minutes, when the specimen was lifted off the furnace at 130 min, and after the experiment*

Measuring point	Char depth at 90 min	Char depth at 130 min	Char depth after experiment
Flange height	5 mm	31 mm	27 mm
Flange width	7 mm	48 mm	49 mm

The char depth varied considerably between the measuring locations, between 2-25 mm, with largest variation for the height of the flange.

https://doi.org/10.52202/069179-0220

Charring after the specimen was lifted off the furnace and the surrounding temperature dropped to around 20°C, during the 2 hours before extinguishment, was negligible.

The charring rates during the different phases of the charring of the flanges are given in Table 3. The phases are:
Phase 2 – before fall-off of gypsum boards
Phase 3 – after fall-off of the gypsum boards
Phase 4 – after the char layer has reached a thickness of 28-30 mm.

Table 3: *Charring rates during different phases*

Charring phase	Vertical direction	Horizontal direction
Phase 2, before fall-off	0.60 mm/min	0.89 mm/min
Phase 3, after fall-off	0.74 mm/min	1.38 mm/min
Phase 4, char layer min. 28-30 mm	0 mm/min	0.70 mm/min

Charring on the lateral sides of the flange is faster than on the underside, with 10 mm larger char depth at 130 minutes. This is due to the simultaneous heating from the underside.

3.6 FIRE PROTECTION OF THE MAIN LOAD-BEARING STRUCTURE

The novel design of the floor, with 2 x 15 mm fire rated gypsum boards, large void cavity and flanges under the beams, protected the main load-bearing beams and prevented charring of them for the duration of the fire experiment. In addition to the fire protection given by the gypsum boards and the cavity reported above, the flanges prevented charring of the beams from below. The flanges also held the insulation in place and prevented charring from of the lateral sides of the beams.

3.7 FIRE RESISTANCE

Fire resistance of the floor is at least 90 minutes for both the load-bearing and fire separating properties. No external loading was applied on the floor in the experiment. This is because the structure has high strength and stiffness, and it would therefore not be possible to apply a sufficiently large load to cause noticeable deflections. The floor will have little deflection also with a span of 8 m. It can therefore be assumed that the fire protection with gypsum boards will remain intact also in a real building.

4 CONCLUSIONS

An experiment has been performed to study the fire behaviour of a novel floor construction with light timber structure during a "complete" fire development, including cooling phase. The main findings are:

- it is possible to achieve fire resistance of 90 minutes or more for the floors load-bearing and fire separating properties,
- the large void cavity between the gypsum boards and wooden surfaces of the structure delays the charring of the timber structure,
- the construction provides fire protection of the main load-bearing beams throughout the fire,
- the experimental results were significantly better than results from design methods, mainly due to longer fire protection provided by the gypsum board and the effect of the large void cavity,
- the insulation is held in place by the flanges throughout the fire experiment,
- the charring stopped when the specimen was lifted off the furnace.

Achieving a cooling phase in the furnace was difficult due to the large surfaces of the combustible elements in the specimen.

The effect of the void cavity should be studied further, and design methods improved to account for this effect.

EXPLORING THE INFLUENCE OF HEATING CONDITIONS IN THE CHARRING PROFILE OF BARE TIMBER AND TIMBER PROTECTED WITH A THIN INTUMESCENT COATING

Stavros Spyridakis[1], Jeronimo Carrascal[2], Felix Wiesner[3], David Barber[4], Cristian Maluk[5]

ABSTRACT: This research examines the influence of a thin intumescent coating applied on mass timber, focusing on how changes in the in-depth charring rate may occur during a fire event. An experimental fire methodology was used whereby the transient in-depth heating conditions were carefully measured during testing. The heating conditions at the exposed surface of each sample were controlled by keeping a constant incident radiant heat flux at the exposed surface of the sample, considering the transient swelling of the intumescent coating – employing the H-TRIS method. Test samples of (200×200) mm^2 were prepared from Cross Laminated Timber (CLT) with a depth of 110 mm. The mean measured DFT amongst the coated samples was 1.19 ± 0.10 mm. Fire experiments were conducted for bare and coated timber samples, with the heated surface exposed at three different heat fluxes of: 25, 50, 75 kW/m^2. The outcomes of this experimental study demonstrated that timber protected with a thin intumescent coating shows a delayed onset of charring and reduced in-depth charring rate for all heating conditions examined. However, the coating underwent considerable thermal degradation and regression at higher heat fluxes. Additionally, the mean measured charring rate was directly proportional to the incident radiant heat flux.

KEYWORDS: Mass timber, Thin intumescent coatings, Timber charring, Fire experiment, H-TRIS

1 INTRODUCTION

1.1 BACKGROUND

Mass timber structures are becoming prominent across the globe as an avenue to a greener and more sustainable building industry, among other benefits such as speed of construction. Advances in the manufacturing of mass timber have led to the mainstream use of Engineered Wood Products (EWPs) – e.g., Cross Laminated Timber (CLT) and Glue Laminated Timber (Glulam) for varied applications (Figure 1) – with more reliable mechanical properties over sawn timber.

The increased aspiration for EWPs to be used in the built environment, especially in applications where fire safety considerations are vitally important (e.g., mid-, and high-rise buildings), has highlighted the need for understanding the fire behaviour of mass timber structures. One key challenge is the flaming combustion (i.e., burning) of exposed mass timber surfaces during a fire, including circumstances where flaming or smouldering (i.e., flameless combustion) of timber continues even after the moveable fuel load in the compartment has burnt out.

Figure 1: *Interior views of exposed mass timber framing (Ascent building, Milwaukee, Wisconsin – USA). Photo © David Barber.*

Consequently, burning of exposed mass timber elements can increase the severity and duration of a fire event [1-4], with potentially detrimental fire safety and structural implications. To date, a common fire engineering solution to mitigate the challenges with mass timber structures burning in a fire event has been the partial or complete

encapsulation of timber using fire rated plasterboards. In its most basic definition, the purpose of encapsulating mass timber elements is to prevent timber from becoming part of the fuel load during a fire [5], and for load-bearing purposes to prevent or delay timber charring. Charring is usually assumed to occur when timber has reached a temperature of approximately 300 °C [6], with the charred section assumed to have negligible mechanical properties. However, the use of plasterboard does not allow for the expression of mass timber elements and can result in additional construction costs, as plasterboards need to be fitted after EWPs have been erected and installed on-site.

1.2 THIN INTUMESCENT COATINGS

Thin intumescent coatings are extensively used for steel construction in lieu of traditional passive fire protection, due to their proven architectural aesthetics, versatility (on-site or off-site application), and speed of application [7]. They are thermally reactive materials, applied to a coating thickness of a few millimetres – referred to as Dry Film Thickness (DFT). Intumescent coatings can swell multiple times their original thickness when heated [8], forming a thermal barrier that insulates the substrate material during fire, keeping its temperature below critical values, thus preserving its mechanical properties.

Despite the proven fire performance of thin intumescent coatings on steel structures, there is sparse published research available on their effectiveness for mass timber structures [9, 10]. However, exploratory testing to date on their application for mass timber has shown that they do swell during fire exposure, resulting in a delayed onset of charring and a reduced in-depth charring rate [11].

Additionally, recent developments in the production of intumescent paint products have led to the emergence of transparent intumescent coatings – which would make their commercial exploitation for mass timber buildings more likely. In the near future, the mainstream use of thin intumescent coatings on mass timber structures could result in (1) ease of application on-site or even off-site and (2) building aesthetic benefits.

1.3 RESEARCH MOTIVATION

This experimental study aims to demonstrate and provide confidence that thin intumescent coatings can be used for reducing the in-depth charring of mass timber during a fire, and to quantify how sensitive this may be to varied fire scenarios. Additionally, the work presented herein is the first stage of a larger experimental campaign of fire tests, to illuminate the effects of different intumescent paint types and thicknesses on the fire performance of mass timber.

2 EXPERIMENTAL METHODOLOGY

2.1 TESTING APPARATUS

A bench-scale version (Figure 2) of the Heat-Transfer Rate Inducing System (H-TRIS) test method [12] was used to impose fire exposure conditions for this study.

This bench-scale version of H-TRIS is comprised of four radiant panels with a radiative surface of (300x400) mm^2, capable of controlling the incident radiant heat flux at the heated surface of test samples – in the range of 5 and 100 kW/m^2. For this study, H-TRIS was coupled with a sample holder with an integrated spark ignition system providing piloted ignition during testing.

The objective of this testing setup is to control the heating conditions at the target surface of the test sample protected with a intumescent coating or the bare timber sample. The position of the radiant panels is corrected to account for the swelling of the coating. The integrated spark ignition system was kept in a fixed position to the test sample.

2.2 TEST METHOD

The samples were tested at constant incident radiant heat fluxes of either 25, 50, or 75 kW/m^2 for 60 min. This time duration has no relation with the Fire Resistance Rating or Level used in Standard fire testing. Instead, it was selected for the purpose of obtaining sufficient data during testing based on the dimensions of the selected samples.

For the bare timber samples, the spark ignition was turned off when sustained flaming at the heated surface of the sample was observed – defined as continuous flaming greater than 30 sec. This is longer than the time required by standard reaction-to-fire tests [13].

For timber samples with intumescent coating, the spark ignition was kept on for the first 5 min of the experiments to capture the expansion of the coating under piloted conditions, also ensuring a consistent testing approach with the bare timber samples. This time was verified by

https://doi.org/10.52202/069179-0221

preliminary testing. Further, the presence of the pilot is considered a more realistic testing approach, as in a real-life fire scenario pilot sources (e.g., flame, spark, embers) will usually be present.

The lowest heating condition (25 kW/m^2) was chosen to assess the burning behaviour of the samples above the critical heat flux for ignition of timber (13-14 kW/m^2) [14], but also near the threshold whereby most cellulosic materials are expected to auto ignite in a real fire (≥ 20 kW/m^2) [15]. The middle heating condition (50 kW/m^2) was selected such that to prevent self-extinction of bare timber [16], thus allowing for the timber's charring to continue. The purpose of the highest heating condition (75 kW/m^2) was to further examine the ability of the thin intumescent coating to reduce timber charring and char depth under more onerous heating conditions.

2.3 INSTRUMENTATION

The swelling of the tested thin intumescent coating was measured using a high-resolution video camera placed perpendicular to the direction of the expanding paint (i.e., on the side of the coated sample).

The internal temperature of timber was measured using thermocouples along the sample's depth and placed near the middle of the exposed surface. The 300 °C isotherm was tracked during post-processing of the experimental data, associated with the timber's char depth. The location of the 300 °C isotherm was calculated from a smoothing spline fit [17, 18] for every time instant.

Prior to testing, the thermocouples were inserted from the side of the sample (i.e., perpendicular to the principal direction of heat inside the sample) – minimising error of temperature readings as described by past researchers [19, 20]. Thermocouples were placed at the following depths from the heated surface: 5, 10, 20, 33, 50, 78, 110 mm.

The interior temperature evolution for both bare timber and timber protected with intumescent coating was recorded along the depth of each sample for the whole duration of heating (60 min) and cooling after the radiant panels were turned off (30 min).

2.4 TEST SAMPLE PREPARATION

Test samples of (200×200) mm^2 were prepared from CLT with a depth of 110 mm. The tested CLT comprised of three lamellas (32.5 mm, 45 mm, 32.5 mm) of Australian radiata pine softwood.

A commercially available solvent-based thin intumescent coating was used. Samples with intumescent coating were sprayed using an airless paint gun by a registered professional contractor, as per the product guidelines. The coating used has an opaque white finish and was originally formulated for structural steel applications, for either on-site or off-site use.

The bulk density of each sample was measured before each test by measuring its mass on a laboratory scale. The mean DFT of the coated timber samples was measured using an electronic gauge with an ultrasonic probe for timber substrates. The mean measured DFT for the six coated samples was 1.19 ± 0.10 mm – see Table 1.

The bulk moisture content of the tested timber was estimated using the oven dry method [21] from four sacrificial samples, which were stored in the same conditions as the test samples – at ambient temperature in a laboratory environment; the moisture content varied between 9.1 % and 9.8 %. Lastly, when placed inside the sample holder, each sample was wrapped on its sides using a ceramic wool and aluminium foil tape before being tested (Figure 3). This was done to minimise heat exchange between the sides of the sample and the metallic sample holder during testing, in order to enforce one dimensional heat transfer conditions akin to those in large, panelised mass timber.

3 TEST RESULTS

3.1 INTERIOR TIMBER TEMPERATURE

The temperature inside the timber was measured during heating (60 min) and cooling (30 min) of each test sample.

Figure 4 shows the in-depth temperature vs. time data carried for each repeat test – comparing plots without and with intumescent, side-by-side. Figure 5 shows the profile of temperature for each repeat test during heating – i.e., in-depth temperature vs. depth from the heated surface.

3.2 CHARRING OF TIMBER

Figure 6 shows char depth from the heated surface against time. As noted before, the char front is assumed to be aligned with the 300 °C isotherm. In addition, the mean charring rate is calculated from the char depth data during heating; a summary of this data is provided in Table 2.

4 ANALYSIS OF RESULTS

4.1 INFLUENCE OF INTUMESCENT COATING

The thin intumescent coating influence in the charring rate of the tested timber samples is summarised as follows:

Onset of charring – As shown from plots in Figure 6, there is at least a 5-min-delay on the onset of charring for timber samples with intumescent coating when compared to bare timber samples, irrespective of the heating condition.

In-depth charring rate – For the lowest heating condition (25 kW/m^2), a ~60 % reduction in the mean measured charring rate was observed for coated timber samples when compared to bare timber, while for the higher incident radiant heat fluxes of 50 and 75 kW/m^2, the mean measured charring rate was reduced by ~40 %.

Further, where periods of plateaus are noticed for the measured char depths presented in Figure 6 (i.e., in-depth temperature at the given location < 300 °C, thus zero charring rate), this reflects periods during testing where the timber samples either didn't start charring (e.g., at the beginning of the experiment), or due to char fall off in bare timber samples exposing the thermocouples to gas phase. The latter results in a delay of the subsequent in-depth solid phase measurements, given the gas phase measurements were removed from the temperature data (see Figure 4 and Figure 5) at the point of thermocouple exposure, as these readings do not represent this study.

4.2 INFLUENCE OF HEATING CONDITION

As seen in Table 2 below, the charring rate is directly proportional to the incident radiant heat flux at the heated surface of timber (without or with intumescent coating). In addition, the coating application significantly delayed the timber's time-to-ignition for samples tested at the higher incident radiant heat fluxes (50 and 75 kW/m^2), and it prevented ignition altogether at 25 kW/m^2.

Table 2: *Mean measured charring rate and time-to-ignition.*

Sample ID	Time-to-ignition [sec]	Charring rate [mm/min]
BT-25	67 ± 5	0.65 ± 0.02
BT-50	14 ± 1	0.95 ± 0.02
BT-75	13 ± 1	1.11 ± 0.04
IC-25	no ignition	0.25 ± 0.04
IC-50	257 ± 62	0.56 ± 0.10
IC-75	229 ± 14	0.66 ± 0.09

Note: *Time-to-ignition and mean measured charring rate values in each row are from two tested samples (bare or with coating) at the specified heat flux condition. The charring rate is taken as the mean of the char depth's first derivative – based on the 300 °C isotherm derived from a smoothing spline fit [17, 18] for every time instant.*

4.3 OBSERVATIONS DURING TESTING

In addition to the above, the following relevant events were observed during testing:

- The intumescent coating generally began to crack first along the edges of the timber boards (85 mm wide). For samples tested at 50 and 75 kW/m^2, the swelled coating underwent considerable thermal degradation (i.e., oxidation) and regression during the fire tests.
- Although at the end (> 60 min) of the 25 kW/m^2 fire tests the coating remained in place and no flaming was observed at the heated surface, edge crack formation propagated causing the swelled coating to regress.
- Flaming combustion (during the 50, 75 kW/m^2 tests) of the coated timber samples was generally observed near the sides of the heated surface due to shrinkage and thermal degradation of the timber and coating, exposing the bare timber edges to direct radiant heat. There were also small pockets of poor paint formation near the centre of the samples – creating small gaps exposing timber to direct radiant heat, resulting to intermittent flaming of the timber underneath.
- Swelled intumescent coating fall off was observed during late stages of the fire tests (during heating or cooling) for samples tested at 50 and 75 kW/m^2 – e.g., IC-50-S2 (> 70 min) and IC-75-S1 (> 50 min). This resulted from adhesion failure of the oxidated coating or delamination of charred timber.

5 CONCLUSIONS

Based on the experimental outcomes described herein, the following can be concluded:

- The onset of timber charring was delayed for at least 5 min for the intumescent-coated samples, regardless of the heating condition.
- The mean measured in-depth charring rate of timber was greatly reduced when using intumescent coating – in the range of ~40 to 60 % depending on the severity of the heating condition.
- Timber ignition was either prevented at the lowest incident radiant heat flux (25 kW/m^2), or significantly delayed at more onerous heating conditions (50 and 75 kW/m^2) when using a thin intumescent coating – for the duration of the 60 min heating period.
- The integrity of the thin intumescent coating was challenged at high heating conditions, experiencing large crack formations, or fall off when tested at an incident radiant heat flux of 50 or 75 kW/m^2.

Future work, being part of this fire research, will include testing and analysis of the following campaigns – under the previously nominated heating conditions:

- Timber test samples with intumescent coating applied at a higher DFT of the same commercially available intumescent product presented herein; and
- Timber test samples with a transparent intumescent paint product, also at different coating thicknesses. This paint product is a water-based thin intumescent coating for timber substrates, generally applied at low DFTs (< 1 mm).

MEASUREMENT OF DIRECTIONAL CHARACTERISTICS OF MOISTURE TRANSPORTATION IN WOOD UNDER HEATING

Hirokatsu Kimura[1], Tomoyo Hokibara[2],Yuji Hasemi[3], Soma Suzuki[4], Tatsuro Suzuki[5], Ryo Takase[6]

ABSTRACT: Time variations in moisture content and temperature inside Japanese Cedar *(Cryptomeria Japonica)* specimens exposed to steady heating from three different directions were measured with small resistive sensors, as developed by Suzuki et al [1]. Radial, tangential, and longitudinal heating at 4.5 kW/m^2 with Cone Calorie Meter were conducted to investigate the anisotropy of water transfer and its effect on the rise in temperature under fire heating; specimens were controlled in air-dry or bone-dry conditions. As a result, longitudinal water transfer was large and observed most frequently in the three heating directions, because of which tracheid worked as a path of transporting vapor away from the heating surface. Moreover, the rise in the temperature of Air-Dried specimens was suppressed compared to that of Bone-Dried specimens, especially in longitudinally heated specimens, and the temperature difference was up to 4.6 times larger than that of radially and tangentially heated specimens. It was because the heating caused by re-condensation was the smallest in longitudinally heated specimens, according to the largest water transfer.

KEY WORDS: Moisture Content, Heat and Water Transfer, Sorption, Anisotropy, Cone Calorie Meter, Japanese Cedar

1 INTRODUCTION

With the increasing number of high-rise wooden buildings, the importance of accurate prediction of the mechanical properties of wooden member has increased. Water content in wooden members is a key factor that affects the decrease in the mechanical property of wooden members under fire. Kaku et al. [2] reported that the moisture content and rising temperature reduced the mechanical properties at high temperature; the Young's modulus of Japanese Cedar specimen at high moisture content near 100 ℃ is was found to be as low as that of the dry specimen at 200 ℃. It was confirmed that the water in the wooden members exposed to fire transferred as vapor from high temperature part to low temperature part for recondensation [1]. Considering the rise in moisture content, the Young's modulus of inner part of wooden fireproof beam after heating for 2 h near 100 ℃ was estimated to decrease as low as that of 230 ℃ in dry wood [3].

As for anisotropy of properties of wood, that of thermal conductivity is discussed by Maku [4] that longitudinal thermal conductivity is approximately 2.5 times larger than that of the radial or tangential ones; Kawabe et al. [5] measured longitudinal permeability and found it to be significantly larger than the transverse ones.

Moreover, structural members are heated three dimensionally under fire heating as shown in Figure 1, and there is temperature incline in longitudinal direction, because the wooden thermal conductivity is significantly small. Therefore, it is assumed that the water transfer has anisotropy as thermal and vapor pressure incline as a driving force of water transfer has anisotropy. Furthermore, it can affect the moisture content distribution in wooden structure members. Although, water transfer in wooden members is measured in previous studies, the anisotropy of wood is not considered. In this study, to measure the time variation of local moisture content caused by anisotropy of wood, three directional steady heating tests were conducted on two conditions of Japanese Cedar (*Cryptomeria Japonica*) specimens.

2 EXPERIMENTAL METHOD

2.1 METHOD

Each Specimen were heated with Cone Calorie Meter, with heat flux of 4.5 kW/m^2 for 60 min. The incidence of heating flux supposes the heating situation of load-bearing part of fireproof timber which temperature lower 180 ℃. The temperature and moisture content distribution of four points in specimens were measured. Temperature was measured with thermocouples in each 2 s. Moisture content was measured with resistance moisture meter proposed in previous paper [1]. The resistance between the two electrodes installed in the specimens was measured and converted into moisture content by a reported calibration curve. The two electrodes were lined up parallel to the tangent of growth ring with a 10 mm gap between them. A couple of electrodes separated by 2 V were applied to measure resistance in interval of 16 s, because it takes 4 s to measure the resistance of each point.

2.2 SPECIMENS

Specimens are made of heartwood of Japanese Cedar (*Cryptomeria Japonica*). As shown in Figure 2, size of 100×100×45 mm, and the largest surface were heated. Four sets of thermocouples and moisture sensors were inserted from non-heating surface in each specimen, two sets were placed at 20 mm from heating surface, and other two sets were placed at 30 mm from the heating source. Each measuring point was named as below.

Moisture Content or Temperature – Depth – No.
[MC or T] – [20 or 30] – [a or b]

The side surface of specimens was sealed with aluminum foil tape with an aim to stop the water transformation orthogonal to a heating direction.

2.3 EXPERIMENTAL CONDITIONS

Table 1 shows the specimen list. The heating directions and initial moisture content were the parameters. As shown in Figure 2, the heating directions were radial, tangential, and longitudinal, which are referred to as R, T, L, as shown below.

The initial moisture contents were air-dry and bone-dry. Air-dry specimens were stored in a plastic jar. The relative humidity in the plastic jar was controlled by saturated NaCl solutions until the weight became stable. The average moisture content of the R, T, L specimens are in the range of 12.0–13.6%. The initial moisture content of each specimen was obtained by drying a sample, which was cut from as same wood as each specimen and stored in the same condition as the specimen. First, the bone-dry specimens were dried in the drying furnace at 90 ℃ until the weight of specimens became stable, after that the specimens were stored in a tightly sealed plastic bag with silica gel desiccant in room temperature. In Bone-dry condition tests, only the thermal couples were inserted to clarify the anisotropy of heat transfer without the effect of water.

***Table 1**: Condition of specimens*

Condition of Moisture Content	Heating Direction	ID		Bone-Dry Density* [g/cm^3]		Width of Annual Rings [mm]		Initial Moisture Content* [%]

https://doi.org/10.52202/069179-0222

3 RESULTS

3.1 BONE-DRY SPECIMENS

Figure 3 shows the temperature variation of Bone-Dry specimens in each condition and the difference of the rise in temperature among the longitudinally heated specimens (DR), radially (DR), and tangentially (DT) heated specimens, Figure 4 shows temperature increase rate of Bone-Dry specimens in each condition and the differences as same as those shown in Figure 3. We obtained the rate of temperature rise as a moving average of the two minutes of temperature rise for each specimen and averaging them.

The difference of the rise in temperature of DR and DT were small, that is, 0.2 to 3.6 ℃. The temperature rise of DL was found to be 34.7 ℃ higher than that of DR, and DT after 20 min. The difference was increased 25.5 ℃ on 20 min to 34.7 ℃ on 60 min at 30 mm depth. After 20 min, the difference in the rise in temperature differed in the cases of 20 mm depth 30 mm depth; that is, the temperature rise was 8.4 to 14.7% smaller in the case of 20 mm depth compared to that in the case of 30 mm depth. However, until 20 min, there was a difference between the temperature difference in the case of 20 mm depth and that of 30 mm depth.

Moreover, Figure 4 shows that the rate in temperature increasing of DL was larger and had sharper peak than that of DR and DT. The difference of the rate increased quickly in the maximum rate of 4.0[℃/min] until 8.0min at 20mm depth, and maximum rate of 2.7[℃/min] until 19.8min at 30mm depth, then those differences kept increasing similarly at an average rate of 0.25 [℃/min] for 60 min.

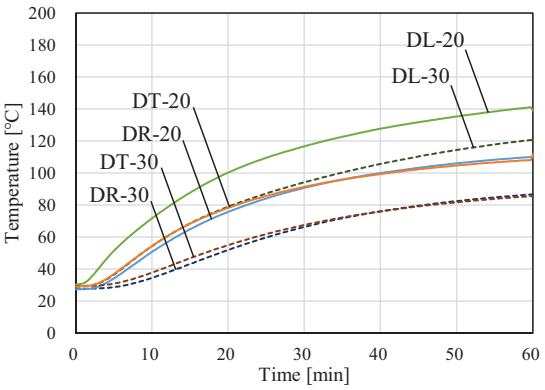
The temperature difference between DL to DR and DT was due to the anisotropy of thermal conductivity; thermal conductivity of longitudinal direction is 1.5 to 2.8 times larger than that of the radial or tangential direction [6]. Moreover, the difference of thermal conductivity caused the difference of temperature increasing rate of 0.25 [℃/min]; therefore, for the cases of 20 mm and 30 mm depths, heating was considered to be steady after 8.0 and 16.8 min, respectively, according to the slope of temperature difference became nearly constant and thermal conductivity is thought to be the critical factor of temperature increasing in materials with equal heat specific heat and density.

3.2 AIR-DRY SPECIMENS

3.2.1 INITIAL MOISTURE CONTENT

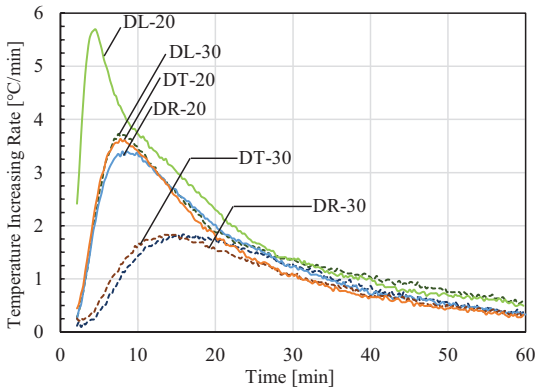
Figure 5 shows the relationships of the initial moisture content obtained by sample drying and initial moisture content obtained by moisture sensor.

Initial moisture content obtained by sample drying was distributed in the range of 11.5–13.9%, while the initial moisture content measured by the moisture sensor was in the range 10.9 ─ 19.8%. Although several values obtained by moisture sensor were higher than those obtained by sample drying, a few of them were lower. The difference between the values obtained by sample drying and



*: Each line shows mean value. “-20”, “-30” indicate values at 20, and 30mm depths, respectably

***Figure 3**: Time Histories of Temperature of Bone-Dry Specimens*



*: Each line shows mean value. “-20”, “-30” indicate values at 20, and 30mm depths, respectably

***Figure 4** Time history of the Rate of Temperature Rise of Bone-Dry Specimens*

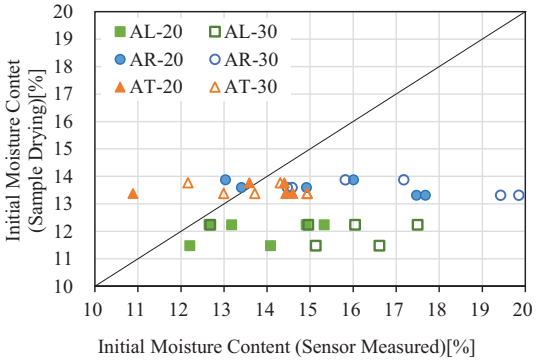


***Figure 5**: Relationships of initial moisture content obtained by sample drying and by moisture sensor*

moisture sensor was in the range 2.5–6.5% in all the specimens and average value of the difference was 1.8%. The factors affecting the initial moisture content remains unclear, and these factors can be categorized into two groups: (1) The factors affect the resistance of moisture sensors, and (2) the factors affect the moisture content in

https://doi.org/10.52202/069179-0222

wood. For instance, the first group includes the amount of adhesive used to fix electrodes in wood and width between the electrodes; lower amount of adhesive or larger width of electrodes causes higher resistance which results in lower moisture content value. The other group includes distribution of moisture content in a wood specimen. In this experiment, we cannot clarify the factors affecting the difference, and identifying the causes is a future issue.

3.2.2 TIME HISTORY OF MOISTURE CONTENT AND TEMPERATURE

Figure 6 shows the time history of temperature and moisture content of typical one specimen of each condition. Figure 7 shows the range of increase of moisture content and range of decrease of moisture content of each condition. We obtained increase and decrease range of moisture content as below Equation (1) and (2). Increase range of moisture content indicates maximum moisture concentration in each specimen. Furthermore, if both the ranges of increase and decrease were large, we considered that both the moisture concentration and transfer to have occurred in the specimen.

$$(Increase\ range) = (Maximum\ value) - (Initial\ value) \quad (1)$$

$$(Decrease\ range) = (Initial\ value) - (Minimum\ value) \quad (2)$$

In AR-1, the moisture content increased or decreased at MC-20-a, b and slowly increased at MC-30-a, b. Some types of moisture content variations were measured at six points of MC-20 in three specimens. In two specimens (AR-1, 3), the moisture content of MC-20-a increased up to 18.4 and 22.3 %, which then decreased. The moisture content of MC-20-b kept decreasing. When the moisture content decreased, the average temperature was 71.5 ℃. In one specimen (AR-2), both of MC-20-a, b kept increasing until 60 min up to 27.8 and 28.2%. Additionally, the rise in the moisture content at MC-30 in AR-2 was significant. The moisture content increased continuously till it reached 39.9 and 87.0% over the valid range (10–30%) of moisture sensor. The moisture content at the other MC-30 measuring points kept increasing slowly for 60 min. The increase in temperature was similar in six measuring points. The average temperatures and coefficient of variation at 60 min were 85.6 ℃, 3.0% at T-20, and 73.5 ℃, 1.9% at T-30.

In AT-1, the moisture content kept decreasing until the heating stopped at almost all the measuring points. As shown in Figure 7, the mean value of the increase range of AT was 0.4% at MC-30, 0.6% at MC-20, and these were smallest in three conditions. Similar to AR, the increase in temperature was similar in six measuring points. The average temperatures and coefficient of variation at 60 min were 91.0 ℃, 3.0% at T-20, 75.7 ℃, 3.5% at T-30.

In AL-1, the moisture content first increased up to 15.7 to 19.4%, and then decreased. Although, MC-20-b in AL-1, MC-20-a, and MC-30-b in AL-2 showed little increase,

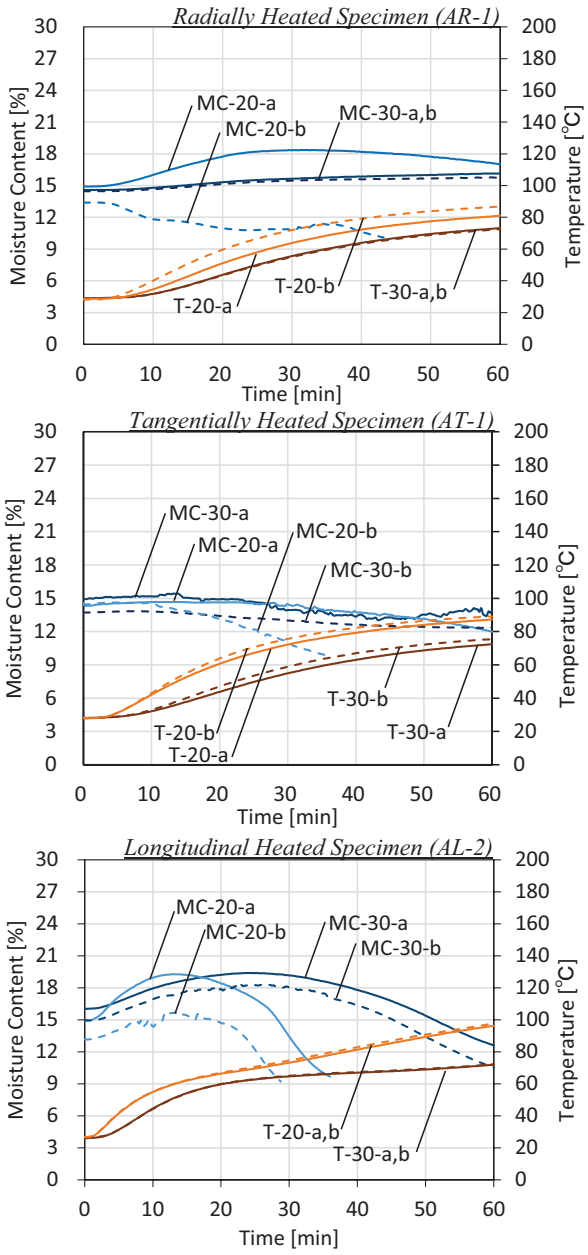

***Figure 6**: Time Histories of Temperature and Moisture Content*

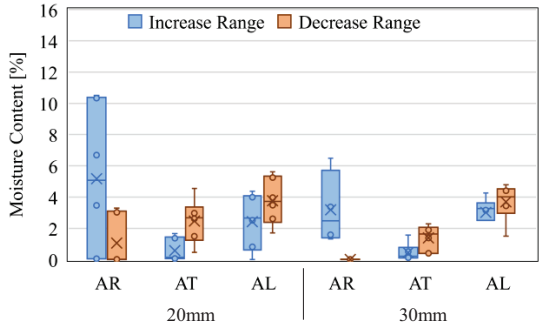

R: Radial heating, T: Tangential heating, L: Longitudinal Heating
20 mm, 30 mm: depth from heating surface
*Values of MC-30-a, b in AR-2 were excepted because maximum value exceeded range of moisture sensor.

***Figure 7**: Increase and Decrease Range of Moisture Content*

https://doi.org/10.52202/069179-0222

other nine measuring points showed the increase and decrease in the moisture content. When the moisture content decreased, the average temperatures of the measuring points were 67.7 ℃ and 65.0 ℃ at T-20 and T-30, respectively. Additionally, the temperature variation was similar in all the specimens. The average temperatures and coefficient of variation at 60 min were 97.6 ℃, 4.3% at T-20, 75.5 ℃, 5.5% at T-30. However, in AL, the increase in temperature was faster than that in the AR or AT for 20 min; furthermore, the increase in the temperature was almost linear until the end of experiment.
As shown in Figure 7, according to the result of each condition, moisture increase range of the longitudinally heated specimens were as large as the radially heated specimens and 4.2–6.8 times larger than that of the tangential heated specimens and decrease range of longitudinal direction was 1.4–3.6 times larger than that of other direction; however, the result of MC-30 in AR was excepted, as moisture content of the condition kept increasing for 60 min and the decrease range of MC-30 in AR was 0.0%.
Increase of moisture content in radial heated specimens indicated that less diffusion or desorption from measuring points occur in radial direction and possibility of significant moisture concentration. As mentioned above, variation of moisture content in AR specimens was apparently different in each specimen. The water concentration in radial direction can be significantly affected by individual difference of each specimen.
Water transfer, especially the decrease in moisture content was fastest in longitudinal direction. Figure 6 showed large variation of moisture content in longitudinal heated specimens. Furthermore, as shown in Figure 7, both the increase and decrease of moisture content were largest in the three conditions. Moreover, Figure 8 showed that the rate of moisture content range was largest in the three conditions.
Considering that the increase of moisture content indicates concentration of water at measuring points and decrease of moisture content indicates vaporing or diffusion or desorption at measuring points, significant increases and decreases of moisture content indicate the occurrences of both water concentration and diffusion or desorption in the longitudinal heated specimens.

3.2.3 CORRELATION BETWEEN MOISTURE CONTENT VARIATION AND TEMPERATURE

Figure 8 shows the relationship between the changing rates of temperature and moisture content. We obtained the ongoing change in the rate of change in moisture content by calculating moving average of the two minutes moisture content change for each specimen and averaging those changes of three specimens. In all the conditions, the rate of change of moisture content generally remained in the range of -0.20–0.20 [%/min] and there was small difference between values of 20 mm depth to 30 mm depth. The rate of change of moisture content in AT generally took negative values; whereas for AL and AR, the rate increased from room temperature to 49.1–53.3 ℃ and then decreased, with negative rates at approximately 65 ℃ in AL and 76 ℃ in AR. AL exhibited a significant decrease in the negative range and took a minimum rate of moisture content change of -0.49 [%/min] in the high temperature range above 70 ℃. The minimum rate of change of moisture content in AL was 2.6 times larger in absolute value.
Figure 8 showed that the rate of moisture content range of longitudinally heated specimens was largest in three conditions and the increase and decrease of moisture content was largest in longitudinally heated specimens as mentioned above. These results clarify higher mobility of water in longitudinally direction.
For several wooden properties, such as permeability, diffusivity of water and diffusivity of vapor higher water mobility in the longitudinal direction (along the grain) was reported compared to that of radial or tangential direction (across the grain). Kawabe [5] reported that the permeability along the grain was 5.6–9.3×10^3 times larger than that across the grain. Yokota [7] reported that diffusivity of water and vapor along the grain were 5–20 and approximately one hundred times larger than those across the grain respectably. According to these reports, the anisotropy on diffusivity of water was near to the anisotropy of increase or decrease of moisture content and

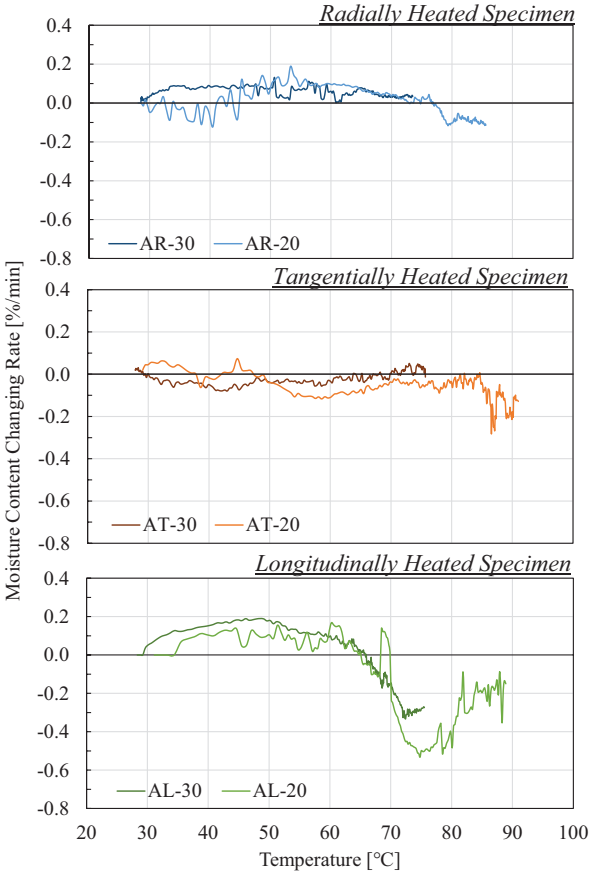

***Figure 8**: Relationship of Temperature and the Rate of Change in Moisture Content*

https://doi.org/10.52202/069179-0222

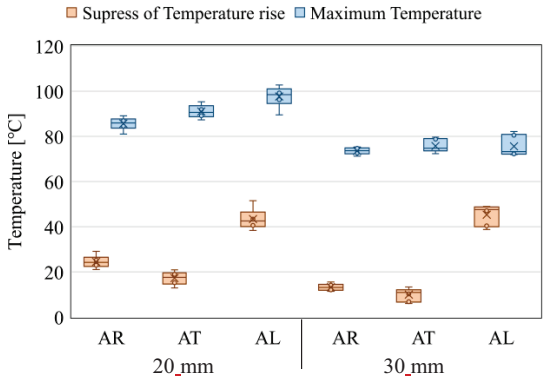
the rate of change in the moisture content, whereas the anisotropy of the permeability and diffusivity of vapor were ten to hundred times larger than that of the isotropy we measured in this experiment. Considering that the rate of change in the moisture content decreased in the range of 20–30 °C, which is lower than the vaporing temperature, vaporing was considered to be occurring inactively when the rate decrease.

Therefore, we consider that properties affect transfer of vapor do not significantly affect the water transfer and mobility of bound water is dominant or other properties such as desorption rate of water on wood tissues limited the water transfer in wood under fire heating.

3.3 COMPARISON OF AIR-DRY AND BONE-DRY CONDITIONS

Figure 9 shows the maximum temperature of Air-Dry condition and suppression of the rise in temperature between the bone-dry to air-dry conditions. Maximum temperature of each condition was AL>AT>AR at both of 20 mm and 30 mm depths; however, the difference was larger at 30 mm depth. The average maximum temperatures were 82.1 ℃ in AL, 79.6 ℃ in AT, 74.0 in AR at 30 mm depth, and 102.7 ℃ in AL, 95.3 ℃ in AT, 86.1 ℃ in AR at 20 mm depth. The rise in the temperature of air-dry specimens were reduced to be lower than that of bone-dry specimens in all the heating directions. The temperature differences between the air-dry specimens to bone-dry ones on 60 min at 20 mm and 30 mm depth were 9.9, 17.2 ℃ in AR, 12.8, 24.1 ℃ in AT, 45.3, 43.4 ℃ in AL on average, respectively.

The difference at 30 mm depth from the heating surface in AL was 1.8–2.5 times at 20 mm depth and 3.6–4.6 times larger than for the other conditions; suppression of the rise in temperature was the largest in longitudinal direction. Furthermore, the suppression of the rise in temperature in AL at 20 mm depth was as same that of the suppression of 30 mm depth; however, that in AR or AT at 20 mm depth was twice larger than that of the suppression at 30 mm depth.



R: Radial heating, T: Tangential heating,
L: Longitudinal Heating
20 mm, 30 mm: depth from heating surface

***Figure 9**: Suppression of Temperature rise and Maximum Temperature at 60 min*

From the result, it is evident that the moisture content can suppress the temperature rise, and the effect is apparently largest in longitudinally heating.

We considered that the suppression of temperature rise was caused by large heat capacity of water. The heat capacity of water is approximately 4.18 [kJ/(kgK)], which is approximately 3.5 times larger than that of heating capacity of Bone-Dry woods [6]. This is the reason for Air-Dry specimens having 1.3 times larger heat capacity that that of Bone-Dry specimens and the difference caused the difference of temperature rise.

Furthermore, anisotropy of suppression of temperature rise is caused by anisotropy of transfer of water. At first, temperature suppression in wood under fire heating was caused by difference of heat capacity as mentioned above, indicating that the moisture is heated instead of wood. Then, the heated moisture is thought to transfer along heating direction as vapor or bound water because of the gradient of vapor pressure or moisture content in wood tissue; furthermore, water can heat wood tissues away from heating surface with lower temperature after the transfer. In this scenario, if moisture transfers quickly and it is released out of wood, temperature rise is further suppressed as moisture does not heat wood tissues. Therefore, the rise in temperature was largely suppressed in the longitudinally heated specimens of which moisture transfer is fastest in three directions.

4 CONCLUSIONS

Following information was obtained measuring time variations of temperature and moisture content in air-dry and Bone-Dry Japanese Cedar specimens under 4.5 [kW/m^2] steady heating for 60 min with Cone Calorie Meter.

(1) Temperature rise of Bone-Dry specimens was larger in longitudinally heated specimens compared to that of the other conditions, and that of the other two conditions were similar. The difference between longitudinally to radially or tangentially heated specimens increased up to 34.7 ℃ at 30 mm depth from heating surface. The difference between longitudinally heated specimens to radially or tangentially heated specimens at 20 mm depth was as same as that of the 30 mm depth.

(2) Increase in the moisture content was 4.2–6.8 times larger in the longitudinally and radially heated specimens compared to that in the tangentially heated specimens and decrease of moisture content in longitudinally heated specimens was 1.4–3.6 times larger than the other two conditions.

(3) The rate of moisture content changing rate of the longitudinally and radially heated specimens increased up to 49.1–53.3 ℃ and then decreased. These rates took zero around 65–76 °C. Moreover, the minimum of the rate of moisture content changing of longitudinally heated specimens was 2.6 times larger in absolute value compared to the other conditions.

https://doi.org/10.52202/069179-0222

(4) In all the conditions, the rise in temperature in air-dry specimens was lower than that of bone-dry specimens. In the longitudinally heated specimens, the temperature rise was 1.8–4.6 times largely reduced compared to radially or tangentially heated specimens, and difference of the suppression between 20 mm depth to 30 mm depth was little in longitudinally heated specimens but twice in the radially or tangentially heated specimens.

In this experiment, we noted some future issues. One is discrepancies of the moisture content between the values obtained by sample drying and by moisture sensor, another is the difference of moisture content variation between each specimen in radially heated specimens. Moreover, experiment under conditions of higher heating intensity is required, which can clarify water transfer around heating surface in wooden structural members.

FIRE SAFETY ENGINEERING OF BUILDINGS WITH VISIBLE TIMBER CONSTRUCTIONS

Leif Tore Isaksen[1], Martin Hagen[2]

ABSTRACT:

Is it possible to build high rise timber buildings without sacrificing fire safety?

On a global basis, the use of timber as building material is rapidly increasing. Fire safety engineers meet new challenges compared to prevalent design with incombustible building materials. There are several questions and problems which must be addressed for the engineer to design a firesafe building from wooden construction materials.

The ambition of the project Mjøstårnet was to build the tallest wooden building in the world, at the same time being a distinct wooden building allowing visible wooden constructions. These ambitions may come into conflict with Norwegian fire regulations that requires the building to withstand a complete burnout without structural failure of the primary load bearing system. Standard fire safety calculations will not verify neither burnout nor required fire resistance to withstand burnout with combustible construction materials. A common belief, also reflected in the building regulations, is that surviving burnout requires incombustible materials, or incapsulating combustible construction materials, hence disfavoring the choice of timber as a building material. To address these challenges, an innovative approach was established for the design and verification of legal requirements for the tallest wooden building in the world, Mjøstårnet.

1 INTRODUCTION

1.1 SUSTAINABLE QUALITIES

Wood is one of the most sustainable and environmentally favorable construction materials available. This is due to its absorption of carbon dioxide while growing. Wood is a renewable material, it lasts a long time, can be recycled and reused, it's great at retaining heat, its waste is 100 percent biodegradable, and it has a positive effect on your physical and mental health[1,2,3].

Pressing environmental concerns and urgent housing needs, urban densification, and the use of existing resources together with otherwise sustainable materials are of key importance for the increasing use of timber.

Besides its many other benefits, timber as a construction material is especially suitable due to its low weight and ample prefabrication possibilities.

1.2 FIRE SAFETY

Working with fire safety in wooden buildings, the fire safety engineers meet new challenges compared to traditional design with incombustible building materials. There are several questions and problems which must be addressed for the engineer to design a firesafe building from wooden construction materials.

- Firstly, can the loadbearing system resist fire when the construction materials themselves burn?
- Secondly, can existing calculation methods and test criteria, often based on incombustible materials, be utilized in the design?

There is an ever-growing base of experimental evidence and related guidance documents that shed light on these questions. Just in the last few years there are a number of review papers that summarizes the experimental work done on fire in timber compartments [4,5,6,7]. These highlight some of the gained knowledge and future challenges. A recent paper [6] reviews 63 compartment fire experiments involving timber constructions, the majority of which use cross laminated timber (CLT). The recent experiments show that timber constructions can survive a full duration [8,9] of a fire deemed "burnout", however the papers also address some challenges. Some of these include significant uncertainty and variability in for instance charring rates. They also highlight the need for more research on a range of compartment configurations, including larger compartment sizes.

[1] Leif Tore Isaksen, Discipline Coordinator – Fire & Safety, Sweco Norway AS, leif.isaksen@sweco.no
[2] Martin Hagen, Senior Engineer - Fire & Safety, Sweco Norway AS, martin.hagen@sweco.no

https://doi.org/10.52202/069179-0223

Although the major focus on recent research effort is CLT elements, it highlights an important difference between CLT and common constructions elements like glue-laminated members (Glulam). CLT elements can be susceptible to delamination of lamellas during fire, giving access to uncharred wood and consequently an increase in fire severity.
Some of these challenges are addressed in guidance documents for fire safety design of timber buildings [10]. However, the constant progression of research dictates a continuous development of guidance documents and legislation that deals with these new challenges including design of tall timber buildings. In the US The International building code [11] is one such example and a guidance document for building compliance of mass timber structures [13] is produced in the UK.

2 FIRE SAFETY DESIGN IN MASSIVE TIMBER BUILDINGS

Sweco has worked with fire safety design in several timber buildings, where the most famous one is Mjøstårnet. Mjøstårnet with a height of 85,4 meters was officially ratified by Council on Tall Buildings and Urban Habitat and Guinness World Records as the tallest timber building in the world (May 2019). The building, located in Brumunddal Norway, is an 18-story mixed-use building, containing offices, apartments and a hotel.
The building is constructed as follows:

- High strength glulam columns, beams and diagonals
- CLT shafts for elevators and stairs
- Wooden decks in the first ten floors (made by Moelven Træ8 floor elements), protected with plasterboards in the ceilings and concrete on the floors
- Concrete slabs in the upper floors for apartments. This improves the dynamic behavior (horizontal accelerations), and the sound insulation between the apartments in the building
- Wooden prefabricated façade elements make up the building's envelope

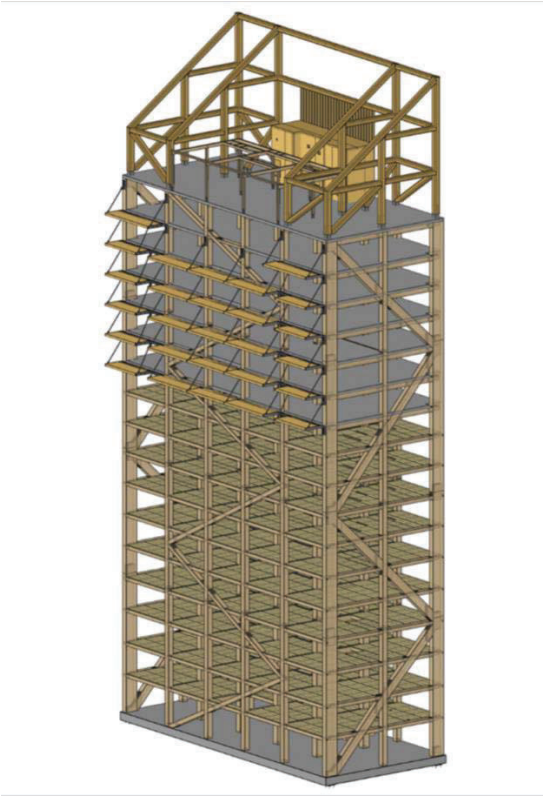

Figure 1: *The structures in Mjøstårnet*

2.1 FIRE SAFETY REQUIREMENT AND APPROACH

The ambition of Mjøstårnet was to build the tallest timber building in the world, with distinct visible timber constructions.
One major hurdle for the project was the fire safety design and its compliance with Norwegian fire regulations.
The regulations require verification that the building will survive a complete burnout without structural failure of the primary load bearing system.
Standard fire safety calculations will not verify neither burnout nor required fire resistance to withstand burnout with combustible construction materials. To address these challenges, an innovative approach was established for the design and verification of legal requirements for Mjøstårnet.

This approach consisted of:

- Prolonged fire testing, including the decay phase, of glulam columns to document the charring rate and the protection of the connections.
- Extending calculation methods for charring rates based on Eurocodes and parametric fire exposure.
- Introducing additional safety measures in the building

https://doi.org/10.52202/069179-0223

2.2 FIRE TESTING OF GLULAM COLUMNS

To support the analytical design of Mjøstårnet, experiments were set up to study the charring and burning behavior of glulam columns throughout the duration of the fire. Emphasis was made on the decay phase of the fire (Figure 2, and whether charring eventually ceases.

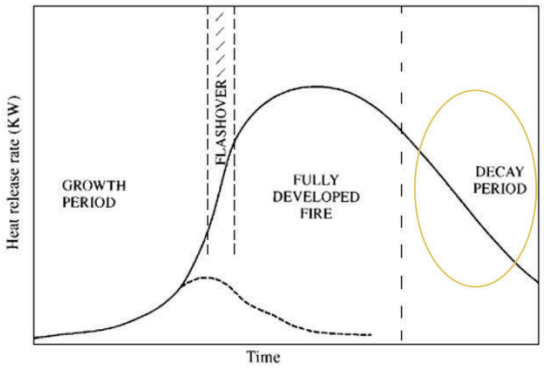

Figure 2: *Heat release including the decay period*

Additionally, the project needed proof that steel connectors were well protected inside the timber. To help answer these questions, full scale testing of three glulam columns was conducted to record the charring behavior of wooden structures with emphasis on the decay period of the fire. The fire tests were conducted by Rise Fire and research AS, together with Moelven and Limtreforeningen.

2.2.1 Findings from the fire tests

3 glulam columns with the measurements of 0,5meter width and depth and a height of 3 meter were used in the fire test:

- 2 identical glulam columns to study the charring and burning behavior throughout the duration of the fire
- 1 glulam column mounted together with steel connectors inside, to study whether steel connectors can be protected inside the timber
- All the samples were mounted with thermocouples inside, measuring the temperature inside the timer construction during the fire test

Figure 3 shows a horizontal cross section of the columns with the thermocouples mounted inside the samples.

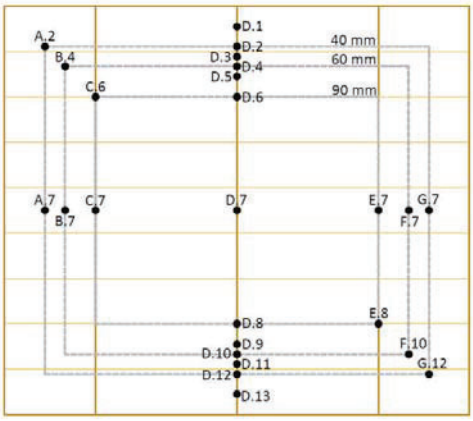

Figure 3: *Thermocouples mounted inside the samples*

The tests were carried out using the ISO 834 temperature curve for 90 minutes. After 90 minutes the burners were turned off. One of the two identical samples (column A) was left inside the furnace to slowly cool for 330 minutes as shown in Figure 4. The other sample (column B) was lifted out of the furnace to cool for 330 minutes in a large laboratory area with natural ventilation from an open door to the outside

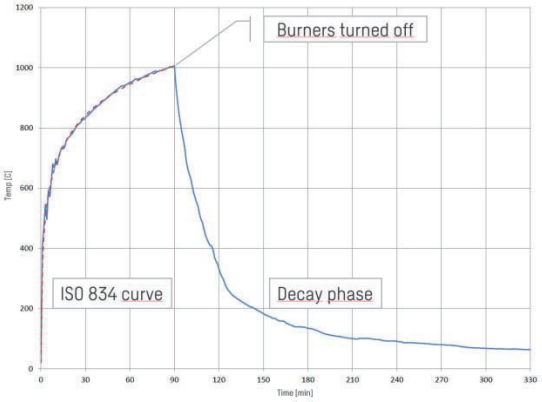

Figure 4: *time/temp curves form the test recorded in the furnace*

These tests showed that the charring rate decreased in the decay period of the fire and eventually stopped. According to Figure 5 the charring reached 40 mm into the columns after 60-70 minutes, 60 mm into the columns after 100-110 minutes, but never reached 90 mm into the columns. In Figure 5 the temperatures 40 and 60 mm into the samples are only shown until the results indicated that the thermocouples begin to loosen (uncertain results when the charring reach the thermocouples). Another interesting result learned from this test is that the temperature in the center of the columns never reached

https://doi.org/10.52202/069179-0223

more than 40 degrees Celsius during the 330 minutes the temperatures were recorded.

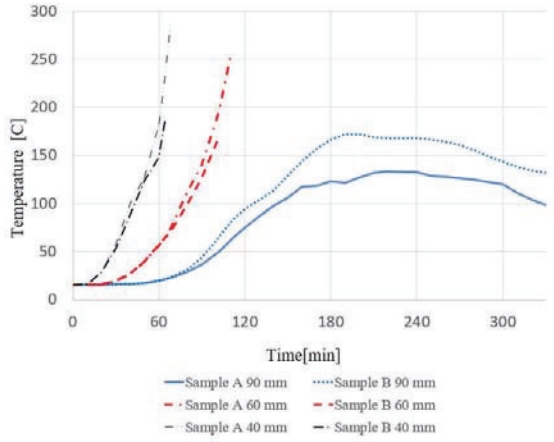

Figure 5: *temperatures inside the columns during the fire test*

At the end of the test (330 minutes with burning and charring) the actual charring depths was measured:

- Column A: 74 mm
- Column B: 71 mm

It was also noted that the actual charring rates in the heating phase were less than notional design charring rates in the Eurocodes. Even though the results might support a less conservative approach the design was made on the safe side according to the Eurocodes.

The steel connectors inside the columns were mounted together with bolts, and the openings were covered using wooden plugs to protect them from high temperatures. In the fire test some of the bolts were left unprotected to study the sensitivity of the solution as well. Figure 6 depicts a vertical arrangement of the bolts and steel plates and the corresponding thermocouples.

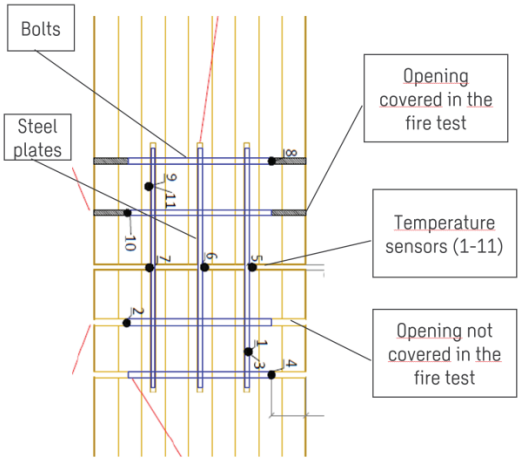

Figure 6: *Steel connectors inside the columns*

The results shown in Figure 7 showed that the steel connectors were well protected inside the timber. The temperatures of the steel connectors never reached more than 270 degrees (C) throughout the duration of the test.

The dotted lines in Figure 7 shows the temperatures of the unprotected bolts (not covered with wooden plugs). It is noted that solid lines, belonging to the temperatures of the protected bolts, did not differ much from the temperatures in the unprotected bolts. In the design of Mjøstårnet, all the bolts were protected. The results from the tests were only used to verify the robustness of detailing, and this indicates that the connectors are well protected, even considering failure in the protection of the steel connectors.

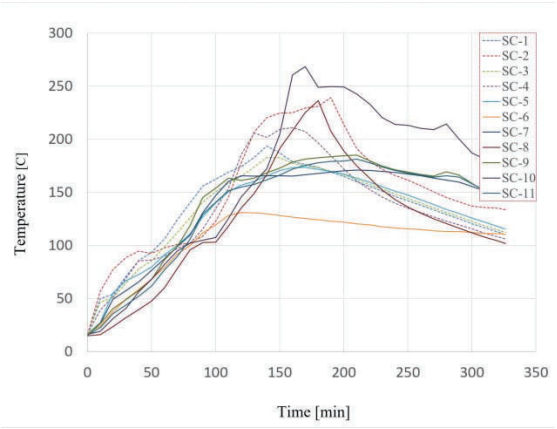

Figure 7: *Temperatures in the steel connectors.*

2.2.2 The heat wave that progresses through the timber

The fire test showed that the charring rate decreased and eventually stopped over the duration of the test. But there is still a heat wave that progresses through the timber after burnout and weakens the uncharred timber to such an extent that failure after burnout is possible. This is an important consideration when designing timber constructions. As structural response of the timber constructions is beyond the scope of this study, only the outlines and conclusion of these considerations are presented here.

Disproportionate collapse due to accident or fire was considered in the structural design of Mjøstårnet. The results from the fire test, measuring temperatures inside timber constructions during a complete fire, was used together with calculation methods from Eurocodes [12] and relevant handbooks[3].

The conclusion is that the timber constructions in Mjøstårnet can withstand a burnout, even considering the heat wave that progresses through the timber after a burnout fire.

https://doi.org/10.52202/069179-0223

2.3 ANALYTICAL DESIGN WITH WOODEN STRUCTURES BASED ON NATURAL FIRES

Parallel to the full-scale tests, calculations for modeling the full duration of a fire in timber structures needed further development and verification.

Standard design charring rates in the Eurocodes are constant values and do not reflect a fire scenario with a decay phase. The charring rate based on the parametric fire exposure, given in annex a of Eurocode 5 [13], on the other hand considers varying fire severity including the decay phase, using actual compartment geometry. However, the model is based on a constant fire load and gives no consideration of the extra fire load form the wooden structures themselves. The altered method used in the design of Mjøstårnet includes the following steps:

- Based on the parametric fire exposure of Annex A of Eurocode 5, the final charring depth can be calculated together with the corresponding mass of wood contributing to the fire.
- This corresponding mass of charred wood produces additional fire load
- The calculation of the parametric fire exposure is repeated, this time, adding the extra fire load.
- This again will make the charring depth increase and add even more energy to the fire.
- These iterations are repeated, and if they converge, they indicate burnout.

Figure 8 shows schematically the iteration of the parametric time-temperature curve and Figure 9 the corresponding charring depth, according to the methodology described above.

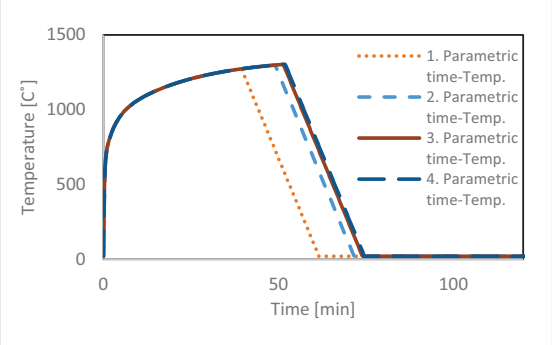

Figure 8: *Parametric time temperature with 4 iterations.*

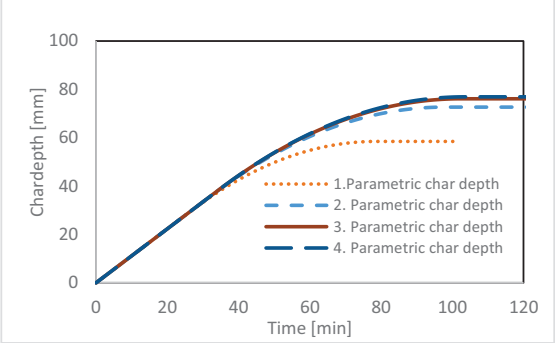

Figure 9: *Parametric charring depths with 4 iterations.*

If the calculations do not converge within reasonable charring depths, they can be repeated reducing the exposed area of wooden surfaces. This makes it possible verifying the acceptable extent of exposed wooden surfaces and at the same time indicating burnout before structural failure.

After the design of Mjøstårnet, similar and improved analytical methodologies are presented by Brandon [14] together with more advanced methodologies that seeks to capture more details of the fire dynamics and material response [8].

2.3.1 Validating the methodology

To validate the analytical methodology used in the design of Mjøstårnet a comparison of experimentally observed charring depths were used. A set of recent experiments where the burning and charring stops after prolonged exposure were selected [9,15-20]. These experiments and their governing parameters are summarized in several recent publications[6,7].

As wood itself is an inhomogeneous material a large scatter of results would be expected. These experiments also contain a broad spectrum of geometries and wooden constructions which would contribute to the uncertainties. Inputs in the calculations are based on values given in the Eurocodes. This means that all wooden constructions area assumed to have a heat of combustion of 17.5 MJ/Kg and a combustion factor of 0,8 with a charring rate of 0,65 mm/min for standard fire exposure. The fire load and geometry are taken from the experiments and the thermal absortivity for the total enclosure is assumed to be 500 $J/s^{1/2}m^2K$. The methodology assumes a one-dimensional charring rate based on the parametric fire exposure over the entire surface of wooden constructions and is iterated as previously explained. Figure 10 shows a plot of measured char depths against calculated char depths. Experiments that significantly exceeds the validation range of relevant parts of the Eurocodes are excluded from the plot. All safety factors in the Eurocode for determining fire load are taken as 1 in these calculations. The calculated results will therefore deviate from the design values.

https://doi.org/10.52202/069179-0223

The grey line constitutes a perfect match between experiments and calculations and points on the right-hand side will be on the safe-side meaning an overprediction of charring depths.

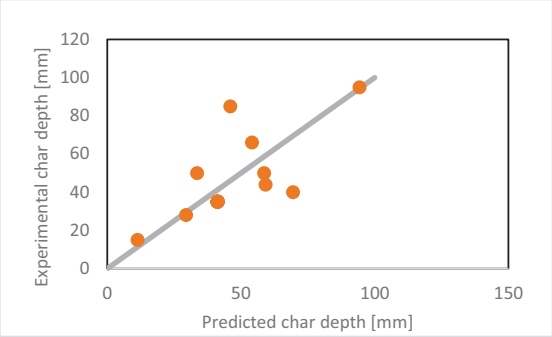

Figure 10 *Predicted vs experimental char depth*

The experiments on the left-hand side which underpredicts the char depths, either experienced delamination of the CLT element or increased charring due to local effects of abutting wooden surfaces. It is also noted that several experiments, all with a large overprediction, are excluded as the time limitations of the parametric charring rate are exceeded.
Considered the validity range of the Eurocodes, the methodology gives a good match between predicted and experimental charring depths.

2.4 ADDITIONAL SAFETY MEASURES IN MJØSTÅRNET

Using an innovative approach for the design and verification of relevant requirements, introduces uncertainties in the results.
To ensure robustness and increase the level of safety for Mjøstårnet, several additional design solutions/fire safety technologies were implemented in the building. Some of them are:

- Loadbearing structures with fire resistance R120 (Designed to resist a burnout with safety margins included)
- Shafts are fire stopped at each floor with fire resistance EI 60
- Sprinklersystem with increased reliability according to EN 12845 Annex F. Hazard class OH3, double water supply, and quick response sprinkler heads
- The water supply to the sprinkler systems is specially designed for Mjøstårnet. In addition to normal water supply, the swimming pool facilities in the building can deliver water to the sprinkler systems. This will secure functionality of the sprinkler, even if the water supply system in the area fail.
- Fire protection of ventilation ducts with incombustible insulation
- No combustible surfaces in voids and technical rooms
- Two pressurized escape stairs
- Automatic fire alarm, which automatically alarms the Fire brigade
- Facilitation for the Fire brigade
  - Firefighting lift
  - Dry risers
  - Control room
- Façade
  - Materials that comply with the requirement B-s1,d0. (Materials that has limited combustibility, low smoke production, no burning droplets)
  - No combustible insulation materials in the building
  - Certain areas of the façade are sprinkler protected (The balconies and façade covered with combustible materials in the two first levels of the building).
  - Firestop in the cavities at each floor. Vertical gaps are thus closed for each floor. In addition, there are fire stops over the windows to further reduce the chance for fire spread in the façade.
  - The risk of fire-spread between different floors in the building is also reduced, introducing balconies and/or vertically distance between windows in different floors

2.4.1 Level of safety in Mjøstårnet

Some of the requirements implemented in this project follows from the Norwegian regulations for buildings of more than 8 floors. These requirements are further combined with additional design solutions/fire safety technologies to ensure robustness and increase the level of safety. Combined with the analytical design methodology used in this project, it's verified that the level of safety in Mjøstårnet meets the requirements following from the Norwegians codes, even when using timber as construction materials.

3 Conclusion

A tall timber building can be designed to resist a complete burnout without failure of the primary loadbearing system at the same time allowing visible timber constructions. Careful considerations of fire behavior, verification methods and additional fire safety measures must build the foundation of such design.

OBSERVATIONS OF SMOULDERING FIRE IN A LARGE TIMBER COMPARTMENT

Harry Mitchell[1], Rikesh Amin[1], Panagiotis Kotsovinos[2], Mohammad Heidari[3], Daniel Thomson[2], David Barber[4], and Guillermo Rein[1]

ABSTRACT: Understanding the end of the decay phase in a compartment fire is important for safety design, as it can indicate when structural hazards in a compartment have ceased. However, smouldering, a slow, persistent, and flameless form of combustion, can continue for days and hours following flames. Smouldering of mass timber has rarely been reported in timber experiments due to many experiments being stopped shortly after flames. This work presents for the first-time observations following the end of flames in three large compartment experiments with cross-laminated mass timber ceiling and glulam columns, known as CodeRed. The analysis focuses on initiation and growth of smouldering over 48 hours. 0.012–0.58 hotspots per m of timber edge developed in 19 locations, and nine spread through the CLT, forming holes in the ceiling, compartment integrity failure, and collapse of an unloaded column. Visual and infrared imaging was used to track smouldering, extinction, suppression, transition to flaming, and formation of holes. This paper shows that smouldering poses a hazard to mass timber buildings because it is hard to detect and can weaken the structure over days following flames, and transition to flaming, starting new flaming fires. These findings are important for building post-fire recovery.

KEYWORDS: Mass timber, Wood, Fire safety, Smouldering, Tall building

INTRODUCTION

Fire safety is a hazard that continues to be a hot topic in safe mass timber design. As well-acknowledged in previous research [1] and current design standards such as Eurocode 5, timber elements including ceiling slabs and columns will char and degrade during a building fire, reducing their overall structural capacity and posing hazards that need to be addressed in design. However, comparatively less research and recommendations have been made to address the hazards posed to a timber building after flames have become extinct. One key hazard present after a building fire is smouldering.

Smouldering is a phenomenon involving the slow, persistent, flameless combustion of porous media such as timber [8,9]. Timber smouldering has been studied in the context of wildfires, however little research is available on the smouldering in real mass timber compartments. Thick timber elements such as logs and roots can continue to smoulder in the hours and days after a wildfire has passed through a region, known as residual burning [13].

There has been very few observations of smouldering in timber compartment fire experiments (currently <5 cases of smouldering in the 65< experiments in the literature). This can firstly be attributed to firstly to previous experiments not including a large volume of mass timber compared to current building demands – the largest compartment timber experiments prior to 2021 were 84 m^2, resulting in less usage of mass timber, and less complex design requirements (e.g. minimal slab-to-slab timber connections). Secondly, many experiments conclude observations either during or shortly after the end of flames by means of suppression or cessation of data collection, meaning observation bias may impact the perception of the likelihood of smouldering following a timber building fire.

A previous mass timber compartment fire experiment [11] observed structural failure of a mass timber ceiling 29 hours following the onset of heating, which was attributed to unseen smouldering. As only the collapse of the ceiling was observed, smouldering was only highlighted as a possible driving factor. Smouldering of mass timber has been investigated at the small scale [3], which determined that, for CLT in the arrangement specified, smouldering did not self-sustain unless subjected to a threshold heat flux and airflow.

However, very little work has been done to analyse the formation and spread of smouldering in structural mass timber elements following a compartment fire. Despite this concern, smouldering has been highlighted as a hazard in timber design by insurance bodies [10], researchers [1] and fire-safety design [14].

As a result, this paper outlines for the first time experimental observations and analysis of smouldering following the end of flames in three large open-plan mass timber compartment fire experiments. This paper will overview the Infrared (IR), visual and thermocouple analysis carried out on a smouldering hotspot observed in the CLT over 38 hours following the end of flames in the compartment.

1 METHODOLOGY

The CodeRed experiment series comprised of a 352m^2 compartment with a CLT ceiling and two glulam columns [12], as shown in figure 1. In the three experiments discussed (CodeRed #01 [5], #02 [6], and #04 [7]), the ventilation (50% reduction in CodeRed #02) and level of encapsulation (50% CLT encapsulated in CodeRed #04) were varied to investigate their impact on fire dynamics and charring during and after the end of flames.

Figure 1: *Photo of CodeRed compartment before ignition.*

Following the end of flames, both IR and visual cameras were used to track localised regions of smouldering, known as hotspots, in both the CLT ceiling and Glulam columns. Hotspots were identifiable visually by glowing and the emission of smoke, although not in all cases, particularly for concealed or in-depth smouldering. IR imaging was significantly more effective at identifying hotspots, as they were indicated by regions of high IR intensity, indicating regions of elevated temperature, as depicted in figure 1.

All mass timber elements were studied for the development, progression, and extinction of hotspots over the 48 hours following the end of flames for each experiment. Sixteen smouldering hotspots in total were observed across the three experiments, with nine resulting in holes through the thickness of the CLT ceiling, and one resulting in the collapse of a glulam column. The lateral spread rate of several hotspots were also tracked to further understand the behaviour of smouldering timber hotspots. Using IR, the lateral spread of smouldering hotspots was tracked as shown in figure 2.

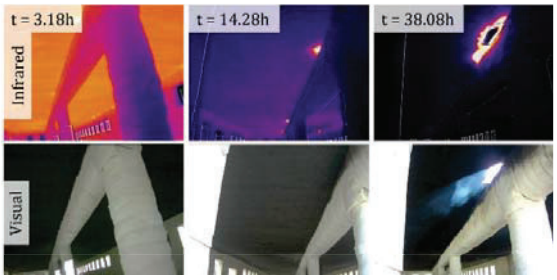

Figure 2: *Initiation and spread of an observed hotspot in CodeRed #01, underneath the concrete beam above the crib ignition line. At 3.18h after flames, the hotspot is only visible in infrared, and not visual observation. The hotspot spreads in-depth until a hole is formed through the ceiling, at which point the smouldering is visible due to the hole and smoke emitted.*

2 RESULTS AND DISCUSSION

2.1 FORMATION OF HOTSPOTS AND HOLES

Table 1: *Summary of observed smouldering behaviour*

CodeRed #	01 [5]	02 [6]	04 [7]
Hotspots	3	7	9
Holes	2	6	2

Immediately after the flames along the timber ceiling and wood crib reached extinction, the entire charred ceiling surface continued to glow, until internal compartment temperatures steadily decayed to ambient conditions within 4 hours, as shown in figure 3. However, over this period of decay and cooling several localised regions in all three experiments continued to glow, both in the ceiling and glulam columns; these regions are known as smouldering hotspots, an example of which is shown in figure 2. A summary of the number of smouldering hotspots in each experiment is given in table 1, which shows that over three experiments 19 hotspots were observed, nine of which resulted in holes through the thickness of the mass timber ceiling, and one resulting in the collapse of a glulam column.

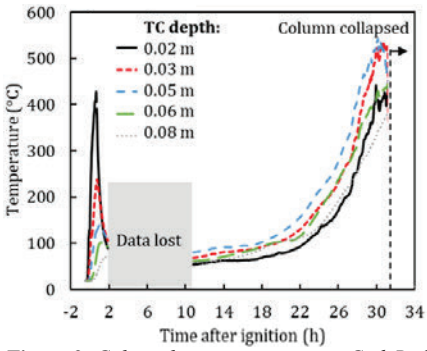

Figure 3: *Column base temperature in CodeRed #02 after ignition. Flames lasted for 27 min before temperatures decayed to ambient levels. In the 32 hours following this, the base column temperatures increased steadily, indicating smouldering.*

Smouldering hotspots in the ceiling initiated exclusively along the edges of each slab, including connection lines between two CLT slabs, connections between the wall and CLT slabs, and the interface between CLT slabs and the insulated concrete column along the compartment length. A summary of the smouldering observed over the three experiments is outlined in table 1.

In CodeRed #01, over the 38 h after flames, a hotspot developed and spread at the ignition end of the compartment (figures 2 and 5), at the midpoint of the CLT

https://doi.org/10.52202/069179-0224

surface near the mineral wool insulated concrete mid-span beam. Infrared imaging was applied to identify the location of the hotspot which immediately after the end of flames were not otherwise identifiable from direct observation. Figures 2 and 5 show that smouldering occurred in the CLT in a small, localised region, which grew in area over the span of 38 h after the end of flames. At 38 h after flames, a 23 min period of rainfall occurred, causing the smouldering to extinguish. Although suppression is an important tool in fire response, without thermal tools such as thermocouples or IR cameras these hotspots can be hard to identify before they begin to alter the structural capacity of the mass timber element.

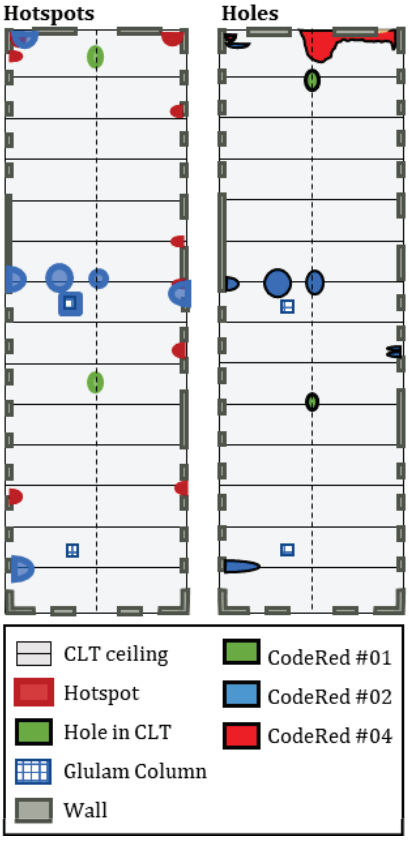

Figure 4: *Sketch of smouldering hotspots in the ceiling and columns from the end of flaming to the end of smouldering (> 48 h) in each experiment. Straight black lines represent edges of timber slabs.*

2.2 SMOULDERING IN COLUMNS AND ENCAPSULATION

Columns are typically structurally loaded elements and can therefore be of increased risk of structural failure during, or after, a fire [4]. However, each glulam column was unloaded and had no in-built connection to the ceiling or floor, partially contributing to one column in CodeRed #02 falling to the ground. This column was observed to smoulder at its base from 0 h after the end of flames. The column reached temperatures of ≤ 400°C during the fire, before steadily cooling below 100°C. However, as can be seen in Fig. 7, temperatures at thermocouple locations

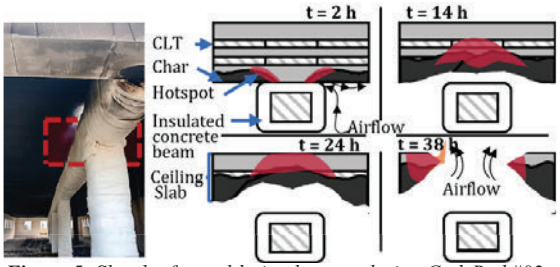

Figure 5: *Sketch of smouldering hotspot during CodeRed #02 progressing through the ceiling thickness, and forming a hole in the ceiling.*

embedded both inside the timber element and along the glue line began to increase above ambient conditions from around 12 h following the end of flames, indicating the spread of smouldering from the base of the column in-depth and upwards along the column length. Smouldering at the base of the column was also observed with IR imaging. The column base smouldered for 31.82 h through the cross-section of the column base until the top of the column was observed to shift from the ceiling connection point. At 32.02 h, as shown in Fig. 6, the column collapsed fully onto the floor. This was attributed to degradation of the column base cross-section due to continued smouldering.

Embedded thermocouples at the base of the column are depicted in Fig. 7, showing the column base reaching up to 500°C at 28 h after the end of flames, above the temperature at which flaming could reoccur. After the column collapse, the side of the column facing the floor continued smouldering, resulting in near-full decay of the column cross-section across the column length, as shown in figure 6.

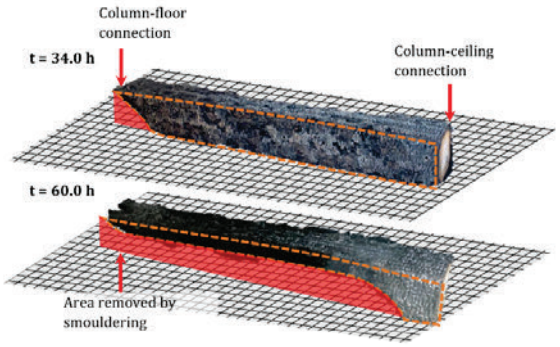

Figure 6: *Smouldering under collapsed Glulam column from CodeRed #02 after collapsing to the concrete floor.*

Encapsulation is used in mass timber design to protect timber elements from fire, therefore limiting their contribution to the fire load, and limiting the impact of the fire on the element's structural integrity. Smouldering not only can still occur in encapsulated timber elements, but this can often make smouldering more challenging to locate even while using IR [2]. The encapsulation used in CodeRed #04 was a commercial encapsulation that covered 48% of the exposed surface of the CLT ceiling, with the goal of reducing the overall contribution of the CLT to the fire load. During the fire, the majority of protected CLT remained uncharred by the flames. Over

https://doi.org/10.52202/069179-0224

48 h of observation, no smouldering was observed underneath the encapsulation.
Two hotspots at the interface between the CLT and the crib ignition-end wall formed holes through the CLT thickness. Further to this, both hotspots continued to spread along the width of the compartment, until the smouldering progressed underneath the encapsulation as shown in Fig. 9. 22 days (528h) following the end of flames, an approximately 1.7 m^2 region of encapsulation collapsed (Fig., directly below a region of smouldering similar in size that had spread through the thickness of the CLT ceiling. This undetected smouldering indicates that although encapsulation can be effective at mitigating the impact of fire on mass timber elements, it is not completely effective at preventing smouldering, particularly when it spreads from the edges of the encapsulation.

2.3 TRANSITION TO FLAMING AND EXTINCTION

Given suitable conditions, smouldering can transition from flameless combustion to flaming combustion. Smouldering to flaming transition is primarily driven by a change in heat flux incident on the smouldering surface, and oxygen supply to the smouldering reaction [20]. Transition to flaming can present a hazard to timber structures following the end of flaming by producing new fires hours after the original fire had ended. This can be particularly hazardous in the case of smouldering that forms penetrations to adjacent compartments or other floors, such as in Fig. 7, as this can lead to unburnt compartments being exposed to a new ignition source.
Smouldering spread and transition to flaming can be more likely to occur with the provision of insulation close to the smouldering surface, while still providing a small gap for air flow. In several smouldering hotspots, transition to flaming was observed following the formation of holes in the ceiling. This is due to an increase in air flow local to the hotspot, providing greater oxygen to the smouldering process, allowing a greater rate of char, leading to flaming.

***Figure** 7: CLT ceiling smouldering hotspot 40 hours after flames, forming a hole in the CLT. Transition to flaming is also observed.*

In a design scenario where a compartment of similar design to CodeRed may represent a single floor in a tall timber structure, transition to flaming in a breach of compartmentation between a unburnt compartment and a burnt-out compartment may lead to a new compartment fire being initiated, presenting all new structural hazards. As a result, this paper recommends that future work continues to understand the conditions under which transition to flaming may occur in smouldering mass timber elements following a compartment fire, and methods of avoiding these conditions to prevent multiple fires in the same structure.
Suppression and subsequent extinction of smouldering hotspots was also observed, both by short 20–40-minute periods of rainfall and direct intervention by firefighters using a firehose. Rainfall was only observed to be partially effective at extinguishing hotspots, whereas after significant intervention a firehose was successfully used to extinguish a smouldering hotspot.

3 DISCUSSION

The end decay phase of a building fire is typically defined as the time at which the entire compartment has cooled to ambient temperatures [12]. Flaming will cease long before much of the compartment has reached ambient conditions, however smouldering, as evidenced by CodeRed, can continue hours and days after the decay phase is assumed to conclude. Following the end of flames of each CodeRed experiment, the entire of the CLT surface smouldered during the decay phase before extinguishing without suppression, known as self-extinction. The definition of "extinction" is typically used by fire safety experts to define when the hazard posed to a building during a fire has ceased. This is typically defined by either when the flames have ended, or shortly afterwards when most of the compartment has cooled to ambient temperatures. However, as evidenced by this paper, smouldering can not only cause localized regions of high temperature within a compartment, but also extend the period over which structural hazards continue to develop over hours and days after flames have ended.
The 9 holes observed in the CLT ceiling posed not only a structural hazard to the building, but also a failure of compartmentation. Further to this, several hotspots were observed to transition to flaming hours after the end of flames, providing pathways to further larger fires forming and further damaging the structure.
The smouldering hotspots that progressed under the encapsulation in CodeRed #04 indicate that encapsulation may not be effective at preventing smouldering of CLT in some situations, particularly when smouldering has initiated in a non-encapsulated area and spreads horizontally to encapsulated parts.
The conditions for self-extinction are important to identify when a mass timber element will cease smouldering, therefore reducing further hazards to the structure. The complex design of timber buildings means that heat losses in certain locations can be low, smouldering surfaces can re-radiate onto each other, and sufficient air flows can occur naturally within a

compartment. Suppression of hotspots occurred either independently or by the addition of water local to the smouldering region, either from a period of rainfall (occurred in both CodeRed #01 and #02), or with a fire hose.

Due to the complex geometries of timber elements observed in the CodeRed experiments, self-sustaining smouldering hotspots were observed over the 48-h following the end of flames. Smouldering timber favours regions which reduce head losses of smouldering, including voids, underneath encapsulation, and near insulating materials such as mineral wool. Smouldering will also spread at a greater rate when subjected to a higher airflow, providing a greater supply of oxygen to the oxidation reaction. In the context of tall timber buildings, the spread of smouldering may be enhanced by regions where airflow exists, such as small gaps between timber connections. Compared to future and current occupied mass timber buildings the design of the CodeRed compartments is low in complexity, meaning that in practice the presence of smouldering in a modern timber building may be more challenging to predict, detect, and suppress than what is discussed in this paper.

Identifying design components and locations where smouldering is likely to occur is key to not only reducing the likelihood of smouldering, but aiding firefighting services in detecting its presence. To that end, self-sustaining smouldering was only observed along the edge of timber elements. Considering the overall edge length of each experiment (154 – 257 m where edges comprise of ceiling slab to wall connections, ceiling slab to ceiling slab connections, and ceiling slab to insulated concrete beam connections), a hotspot occurrence frequency of 0.012 – 0.58 hotspots per meter of edge was found. Scaling this to modern design demands such as office spaces of 5000 m2, 30 – 150 hotspots may occur, each presenting a hazard to the structure.

The prevention of smouldering in timber buildings can be addressed by avoiding designs which promote its initiation. However, in application timber structures have other design components. Therefore, this paper recommends smouldering is studied further in complex timber design elements to determine the hazard that smouldering may pose. These include voids between compartments with combustible elements (e.g. ceiling and wall slabs, voids behind combustible facades), structural connections (e.g. ceiling slab connections, ceiling to column connections, beam and column connections), penetrations in slabs for electrical/plumbing servicing, and any regions where mass timber is insulated by another design component or an air gap (encapsulation, insulation, and other low-conductivity construction materials).

Detection is vital to help firefighting operations identify if smouldering is present in a timber structure, and therefore if structural hazards are present. This paper has shown that in many cases smouldering may not be visible by direct observation, due to it being flameless and occurring in-depth and in hidden areas of in timber elements. Therefore, it is recommended that when investigating a timber building after a compartment fire, infrared imaging is used [2]. However, it should be noted that concealed timber surfaces such as voids, encapsulation, and cavities can cause smouldering to not be immediately observable with infrared either. This paper and previous work [2] show that water mist hoses can extinguish smouldering hotspots when identified. However, it is recommended that work is conducted to understand the most effective methods to apply water to extinguish smouldering hotspots, and how to extinguish smouldering in regions that may be more challenging for firefighters to access.

4 CONCLUSIONS

This paper outlines experimental observations that show that smouldering fire is a structural threat to modern timber buildings. The remaining 19 hotspots observed highlight that structural hazards in a compartment fire continue not only during the decay phase, but in the hours and days afterwards. Smouldering presents a hazard for two reasons: one, the smouldering hotspots after a flaming fire are difficult to detect and suppress, so smouldering can burn through timber elements overnight and lead to partial collapse. Secondly, smouldering can lead to transition to flaming, which creates pathways to further fires hours after both the fire, and decay periods. Also, encapsulation was found to be not completely effective at mitigating smouldering. This is the first study focused on smouldering fires in mass timber, showing that smouldering is proven to be a structural hazard that must be considered and addressed by designers, stakeholders, and firefighters.

EXPERIMENTAL INVESTIGATION OF THE RELATIONSHIP BETWEEN TIMBER SPECIES AND SMOULDERING

Wenxuan Wu[1], Luis Yermán[2] Juan P Hidalgo[3], Jeffrey Morrell[4], Felix Wiesner[5]

ABSTRACT: Smouldering, the exothermic solid-phase oxidation process of porous char, can damage or destroy timber structures long after a fire has burnt out or its flame front has passed. Reaction kinetic parameters (i.e. activation energy E_a and frequency factor A) of timber oxidation can be determined from thermogravimetric analysis (TGA). These parameters along with timber density could potentially be used to predict the self-sustaining smouldering of timber species. To verify this hypothesis, the relationship between the occurrence of self-sustained smouldering and the properties of different timber species, namely density and activation energies of pyrolysis and oxidation, was determined through bench-scale smouldering tests using Cone Calorimeter and TGA for nine Australian timber species. Less dense timbers with lower activation energies were more prone to initiate and sustain smouldering under extreme laboratory conditions.

KEYWORDS: Timber, Timber Species, Smouldering, Oxidation, Thermogravimetric Analysis, Fire Safety, Combustion, Bushfires

1 INTRODUCTION

As an organic material, timber is combustible and therefore its use in construction poses multiple fire safety challenges. Flaming ignition is usually considered an indicator of the start of a fire, while the extinction of the flame marks the end of the event. Because of the large amounts of energy released by visible flames, and their associated spread and damage, the focus of research and standardised guidance documents often focuses on the flaming combustion process.

Subsequent smouldering combustion is sometimes overlooked for structural fires due to its occurrence at relatively low temperatures, lack of visible indicators (i.e. flames) and slow spread rate [1, 2]. Consequently, smouldering in timber infrastructure often appears only as a footnote to recent primary research outcomes concerned with flaming. Nevertheless, the consequences of timber infrastructure under smouldering combustion can also be catastrophic. For example, a mass timber slab collapsed 29 hours after flame self-extinction, due to the subsequent smouldering combustion in a structure fire [3]. Smouldering spread along bridges via the deck planks and across the bridge via the crossbeams has been reported after bushfires [4].

Smouldering combustion can be observed in timber after it has been pyrolysed [5, 6] and is a leading combustion phenomenon in wildland fires [7, 8], constituting a hazard to assets and a health issue from the smoke (Figure 1). Moreover, the transition from smouldering to flaming can occur under the appropriate conditions [4] and introduces hazards to fire intervention in timber buildings and post-bushfire areas.

Figure 1: *Examples of wood smouldering after a bushfire exposure (photos from cn.depositphotos.com)*

Smouldering combustion of timber involves multiple chemical reactions that can be approximated by a lumped 3-step chemical pathway as described in [2, 9]:

Pyrolysis: **Wood (s)** $\rightarrow$ Pyrolyzate (g) $+$ **Char (s)** $+$ Ash (s) , $\Delta H > 0$ (endothermic) (1)

Gas-phase oxidation: Pyrolyzate $(g) + O_2 \rightarrow CO_2 + H_2O + other\ gases$, $\Delta H < 0$ (exothermic) (2)

Heterogeneous oxidation: **Char (s)** $+ O_2 \rightarrow CO_2 + H_2O + other\ gases +$ **Ash (s)** , $\Delta H < 0$ (exothermic) (3)

When solid timber is exposed to fire, its surface heats up and decomposes (pyrolysis), creating a char layer. This process occurs at around 300 °C [10]. The char comprises a porous reactive matrix with a high surface-to-volume ratio that allows oxygen diffusion [2]. The external heat supply initiates pyrolysis and other endothermic processes, such as evaporation, before oxidation occurs. Self-sustained smouldering will occur after the external heat is removed and progress if the exothermic oxidation reaction (Equations 2 and 3) generates sufficient heat to propagate pyrolysis (Equation 1) and compensate other endothermic processes such as water evaporation, sensible enthalpy increase and heat losses. Smouldering is not sustainable without these attributes and will quench [11, 12].

According to the Arrhenius model (Equation 4), the kinetic parameters that govern a chemical reaction are the activation energy (E_a) and the frequency factor (or pre-exponential factor A).

$$\dot{\omega}''' = Ae^{-E_a/RT} \quad (4)$$

Ea is the energy threshold and must be surpassed to transform reactant molecules into products. A represents the proportion of molecules participating in the reaction if all molecules are beyond the activation energy.

These parameters can be used to predict the reaction rate of the process and can be determined from thermogravimetric analysis (TGA) results, considering the peak temperature at the maximum decomposition rate. Wu et al. [13] found that lower activation energy in preservative-treated pine was more likely to initiate self-sustained smouldering in bench-scale (Cone Calorimeter) tests and caused faster mass loss rates during smouldering combustion. Similarly, lower-density timber also led to faster smouldering combustion. These processes may be linked to porosity of wood, which generally decreases with increased density [14-16]. In addition, high thermal diffusivity caused by low density leads to deeper heat penetration at a given time.

This study explored the influence of the timber species on self-sustained smouldering, evaluated in terms of occurrence and rate. Micro-scale TGA and bench-scale smouldering tests were performed on nine native Australian timbers with a wide range of bulk densities. Determining smouldering occurrence and rate can help assist in the selection of timber species for specific end-use applications, especially in bushfire-prone areas. Ultimately, a better understanding of the smouldering phenomenon can help to develop risk mitigation strategies and optimise trade-offs between availability, durability, design life, and fire resilience.

2 MATERIAL AND METHODS

2.1 MATERIAL PREPARATION

Nine Australian hardwood timber species were used in this study: *Acacia mearnsii* (Black Wattle – BSL), *Erythrophleum chlorostachys* (Cooktown Ironwood – CTI), *Eucalyptus tetrodonta* (Darwin Stingybark – DSB), *Eucalyptus paniculata* (Grey Ironbark – GIB), *Intsia bijuga* (Merbau – MRB), *Cardwellia sublimis* (Northern Silky Oak – NSO), *Flindersia brayleyana* (Queensland Maple – QMP), *Alstonia scholaris* (Queensland Whitewood – QWW), *Elaeocarpus grandis* (Silver Quandong – SLQ).

Australian bushfire standard AS 3959 [17] defines the term bushfire attack level (BAL) as the hazard for bushfire-prone areas. The severity of BAL is measured by potential exposure to ember attack, radiant heat and direct flame contact, using radiant heat flux expressed in kW/m^2 [18, 19]. Among the species used in this work, based on their density, GIB, DSB and CTI are considered suitable timber species for BAL – 19, representing a moderate risk from ember attack and ignition of debris with a heat flux of up to 19 kW/m^2. Merbau is considered a bushfire-resistant timber species according to AS 3959 [17], enabling its use in BAL – 29 areas.

Specimens for TGA were ground to pass through a 0.25mm-mesh screen using a RETSCH Cutting Mill SM 300. The initial moisture content and dry density of all samples (measuring 100 mm by 100 mm by 19 mm) for the bench-scale smouldering tests were determined using the oven-drying method, according to ASTM D4442 [20], in duplicate. The mean density and initial moisture content of the timber species are summarised in Table 1. The oven-dry samples were used in bench-scale testing immediately after removal from the oven, to minimise the effect of different moisture contents across the timber species. This is a conservative boundary condition to assess the smouldering occurrence, where a minimum amount of additional energy is required to evaporate the free water. Ceramic paper was used as insulation around the sample edges to reduce heat losses and allow for oxygen mass transfer.

Table 1: *Dry density and initial moisture content of the nine timber species.*

Sample	Texture	Dry Density (kg/m^3)	Initial Moisture Content (%)

BSL		586	11.6
DSB		1047	8.5
QMP		572	11.5
MRB		769	10.5
QWW		467	10.4
CTI		1213	9.8

2.2 THERMOGRAVIMETRIC ANALYSIS

Thermogravimetric analysis of the nine timber species was conducted in an oxidative (air) environment using a NETZSCH STA449-F3 Thermogravimetric Analyzer using 10 ± 0.5 mg of undried powdered sample in an alumina crucible at 5, 10 and 20 °C/min heating rates, from 50 to 800 °C and using an airflow rate of 100 mL/min. Thermal decomposition reaction rates were assessed by applying the first derivative to the mass-temperature data (DTG).

From Kissinger's model (Equation 5) [21], the activation energy (Ea) and pre-exponential factor (A) can be obtained by identifying the oxidation peak temperature (T_p) from the DTG curves of different heat rates (β).

$$\ln\left(\frac{\beta}{T_p^2}\right) = -\frac{Ea}{RT_p} + \ln\left(\frac{AR}{E}\right) \quad (5)$$

2.3 BENCH-SCALE SMOULDERING TEST

The Bench-scale smouldering method used herein was designed to simulate passing bushfire scenarios. For these experiments, the nine timber species were ignited in a Cone Calorimeter with pilot ignition to establish an initial flaming combustion period where the heat release rate was measured according to AS/NZS 3837 [22]. A heat flux of 20 kW/m^2 was chosen as the fire intensity for this study, which was considered a moderate fire risk.

Heat flux exposures were maintained at 20 kW/m^2 until flaming combustion produced a timber mass loss of 40 %. This mass loss criterion was used as an indication of the degree of physical damage associated with flaming duration. A quasi-steady flaming state before external heat removal was confirmed from stable heat release rate readings and CO_2 yield to substantiate thermal equilibrium within the sample. Once the target mass loss was reached, the external heat supply was removed, the time to ignition and flaming duration were recorded, and the samples were transferred to an Ohaus V-7000 load cell under ambient temperature conditions. From that point onwards, the mass loss over time was measured to determine the smouldering rate. Each species was tested twice to ensure repeatability.

Both optical and infrared cameras were used to record the propagation pattern of the self-sustained smouldering along the sample surface. The airflow from the exhaust hood was measured via a Hot-Wire Anemometer to vary between 0.02 to 0.1 m/s; this was the lowest achievable airflow under our laboratory conditions. Figure 2 shows a schematic representation of the equipment and procedure with the different stages of a self-sustained smouldering test.

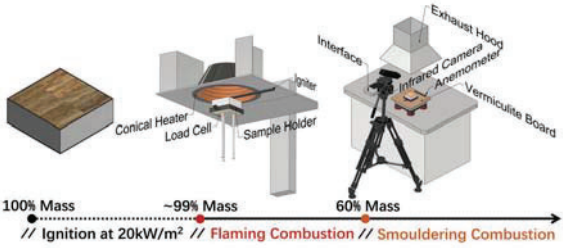

Figure 2: *Schematic representation of the equipment and procedure showing the stages of the bench-scale self-sustained smouldering tests.*

3 RESULTS AND DISCUSSION

3.1 THERMOGRAVIMETRIC ANALYSIS

Figure 3 shows representative DTG results for BSL under 5, 10 and 20 °C/min heating rates. All timber species showed the same pattern. The first small peak from the left, around 80 °C was due to water evaporation. The second peak, around 320 °C, was attributed to endothermic wood pyrolysis (Equation 1). The third peak, between approximately 450 and 485 °C, corresponded to exothermic char oxidation (Equation 3). Both the drying and pyrolysis stages were relatively consistent among species, while more marked differences among species were observed in the onset and maximum temperature of the third peak, at all heating rates. The peak temperatures for the pyrolysis and oxidation stages of nine species are summarised in Tables 2 and 3, respectively.

Linear correlations were established by plotting $\ln(\beta/T_p^2)$ against $1/T_{(\beta,p)}$ **(**Equation 4**)**; the correlation fittings are shown in figures 4 and 5. The E_a for pyrolysis and oxidation stages were calculated based on the slopes from figures 4 and 5, respectively, and are summarised in Table 4.

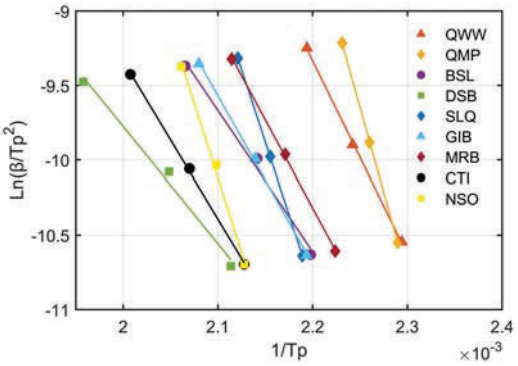

Figure 5: *Plot of $ln(\beta/Tpp^2)$ versus inverse peak oxidation temperature $1/T_{(\beta,p)}$ for all species.*

The Ea of the pyrolysis stage for all nine timber species was approximately 40 to 50 kJ/mole, while the Ea for the oxidation stage varied markedly across species. This indicates that wood species affected the characteristics of the char that was produced during the pyrolysis, which influenced the subsequent oxidation kinetics.

3.2 BENCH-SCALE SMOULDERING TEST

3.2.1 Duration of heat exposure

Table 5 shows the mean ignition time and flaming duration from the bench-scale tests. Timber species with a higher density require a longer time to ignite and for the flame to consume the same mass percentage. Longer flaming increases heat production and penetration depth and generates more char as an insulator, which can affect subsequent smouldering behaviour.

Timber density was strongly positively correlated with the flaming duration with a Pearson Correlation Coefficient of 0.87 suggesting that these parameters cannot be considered independent towards smouldering performance due to their collinearity (Figure 6).

Table 5: *Density, time to ignition, and flaming duration to reach 40% mass loss for the nine timber species.*

Sample	Density (kg/m^3)	Ignition (minutes)	Flaming to 40 % Mass Loss (minutes)

CTI	1213	22.3	20

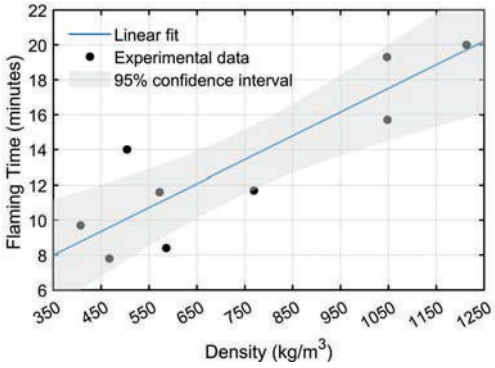

Figure 6: *Linear regression between timber density and the flaming time to reach 40 % mass loss with a Pearson Correlation Coefficient 0.87.*

3.2.2 Propagation pattern

A series of representative infrared and optical images of timber undergoing self-sustained smouldering at different times were used to analyse the smouldering front (Figure 7). A rapid cooling stage occurred on the surface after the external heat supply ceased (Figure 7a to 7b). The smouldering front then propagated from the edges to the centre, generating visible smoke. A transition to flaming only occurred for QWW (Figure 7b) from the insulated edge for around 10 minutes. The smouldering front then progressed deeper into the wood, coinciding with surface regression from char oxidation. At this stage, glowing could be observed (Figure 7c). Eventually, the temperature decreased until less than 1 % mass residual was left after 75 minutes (Figure 7d).

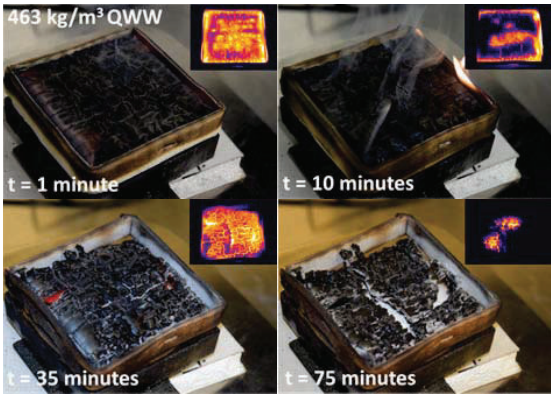

Figure 7: *Photographs of QWW at different times during the smouldering combustion stage. Note the transition to flaming from one side at 10 minutes and the glowing at 35 minutes. Thermal images showing the exposed surface are inserted in the top-right corners of the figures.*

3.2.3 Smouldering Performance

Figure 8 shows the mass percentage evolution during the smouldering stage for all the timber species that exhibited self-sustained smouldering (QWW, MRB, GIB, and BSL). Those samples ultimately lost more than 99 % of their initial mass. In contrast, the smouldering for other species (i.e., NSO, SLQ, DSB, QMP, CTI) either quenched during the smouldering process or never initiated smouldering. An example of QMP smouldering and quenching is shown in Figure 8, with a flat tail at around 30 % mass remaining, indicating the end of the reaction.

Table 6 summarises the density, smouldering occurrence and the time to reach a remaining mass of 1 %. This time can be considered to approximately correspond to the time required to fully complete smouldering, since the asymptotic behaviour in Figure 8 indicates that 0 % mass may never have been reached.

The porosity (which can be deduced from density) of timber and char is crucial as it determines the oxygen availability in the smouldering front through oxygen diffusion.

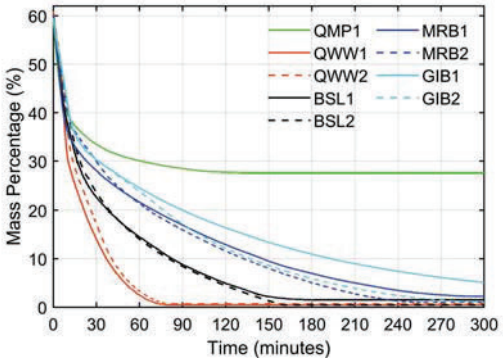

Figure 8: *Mass evolution during the smouldering stage of QWW, QMP, BSL, MRB and GIB*

Table 6: *Density, smouldering occurrence and time to reach less than 1 % mass during smouldering in nine timber species.*

Sample	Density (kg/m^3)	Self-sustained Smouldering? (Y/N)*	Time to <1% of initial mass (minutes)
GIB	1048	Y	299
NSO	504	N	-
SLQ	407	N	-
BSL	586	Y	159
DSB	1047	N	-
QMP	572	N	-
MRB	769	Y	252
QWW	467	Y	77
CTI	1213	N	-

* Y = yes, N = no smouldering initially propagated or quenched.

Table 7 combines the micro-scale measured Ea for oxidation, with the wood density and smouldering occurrence of the nine timber species tested at bench scale. These results show that:

- NSO, SLQ and QMP had the highest Ea_o, which meant they required higher residual heat from flaming combustion to initiate oxidation. This resulted in insufficient energy to initiate the reaction or caused quenching after some time, despite the relatively low densities of these species.
- CTI had the highest density (usually related to lower porosity) among nine species, which may have limited oxygen mass transfer. This would have negatively affected the reaction rate (Equation 5). Thus, despite CTI's relatively low Ea_o , smouldering did not initiate.
- In contrast, GIB with a similar density as CTI has a higher exponential factor A. However, it had the lowest smouldering rate compared to QWW, MRB or BSL, which had low Ea_o and low densities.
- DSB had the lowest Ea_o and similar density to GIB; however, the smouldering did not self-sustain. It suggests the presence of yet unknown underlying factors affecting smouldering. Further tests are required to reduce uncertainties arising in the kinetic parameters in the model.

Figure 9 graphs wood density against activation energy and demarcates the occurrence of self-sustained smouldering. High Ea_o, above a threshold between 120 and 160 kJ/mole, appeared to prevent self-sustained smouldering for species with a relatively low density. Oxidation in this range for those timber species required higher energy to initiate, which was seemingly not compensated by the increased oxygen supply that occurs in lower density (and thus higher porosity) species.

DSB and GIB have a similar density around 1050 kg/m^3; the former did not smoulder while the latter smouldered. At the same time CTI did not self-sustained smoulder, which could be attributed to its high density. Similarly, an activation energy threshold may exist around 110 kJ/mole – where two low density species (i.e., NSO and QWW) exhibited different smouldering performances. A distinction in Ea_o between these species cannot be confirmed with confidence according to the errors arising from the imperfect linear fit. These results suggest that the boundary defining the occurrence of self-sustained smouldering is sensitive to experimental variability at the bench and micro-scale (e.g., limited repetitions, measurement error, imperfect fitting, and apparatus heating non-uniformity). Furthermore, underlying parameters could affect the smouldering behaviour and merit further study. For example, the pre-exponential factor A of oxidation was the lowest for DSB (2.8E+06 s^{-1}, Table 4), which could help to explain why the smouldering quenched midway, as effective collisions for those molecules beyond the Ea_o failed to generate sufficient heat to overcome the heat losses and energy required for further pyrolysis.

Table 7: *Ea_o and A of oxidation, densities and smouldering occurrence for nine timber species.*

Sample	Ea_o (kJ/mole)	A (s^{-1})	Density (kg/m^3)	Smouldering (Y/N)
GIB	93.6	1.5E+10	1048	Y

3.3 Limitations

Some experimental conditions in this study were deliberately conservative in detecting distinct behaviour between species in smouldering. This allowed comparisons between smouldering and activation energy or density, providing fundamental knowledge about the link between self-sustained smouldering and micro-scale parameters or material properties. However, it should be acknowledged that completely dry timber is unlikely to exist in the field, even in wildfire conditions, where mean moisture contents have been reported as ranging between 3 to 6 % [23]. Thus, the results of smouldering for individual species tested herein should not be interpreted to completely account for the smouldering propensity of these species under field conditions.

While the moisture contents were chosen conservatively to be as low as possible to limit variability between species, the ventilation conditions were also chosen as low as possible to reduce their influence on the results and focus on the timber's intrinsic kinetic and physical properties instead of external conditions. The ventilation conditions were non-conservative, and increased airflow may increase the occurrence and rate of smouldering.

Further studies on external effects may help improve our understanding of smouldering factors and develop better selection criteria for bushfire performance that consider performance beyond the flaming period.

4 CONCLUSION

This paper investigated multiple factors that may affect the rate and occurrence of smouldering. Some qualitative conclusions are:

- Grey Ironbark (GIB) is considered a suitable timber species for BAL-19, and MRB is on the list of bushfire-resistant timbers. However, both show propensities to self-sustained smoulder under extreme conditions, indicating the need for more appropriate methods for assessing bushfire performance.
- Activation energy and density combined to affect the rate and occurrence of smouldering. Overall, low density and Ea_o should facilitate self-sustained smouldering.

Future work should be done to reinforce the conclusion:

- More timber species, covering a wider range of densities (i.e. complementary data points).
- More heating rates to increase confidence in linear fitting of the activation energy for each species.
- Other parameters to assess the influence of further factors (e.g., primary elemental composition difference).

PREDICTING THE EFFECTIVE CHAR DEPTH IN TIMBER ELEMENTS EXPOSED TO NATURAL FIRES, INCLUDING THE COOLING PHASE

Andrea Lucherini[1,2], Daniela Šejnová Pitelková[3,4], Vladimír Mózer[5]

ABSTRACT: This paper presents a numerical study on the effect of the heating and cooling phases on the reduction of the effective cross-section of timber elements, in particular on the evolution of the char depth (300°C isotherm) and zero-strength layer. An advanced calculation method based a finite-difference heat transfer model is compared to the simplified approach suggested by Eurocode 5. For the heating phase, defined as the standard fire curve (ISO 834), the simplified Eurocode 5 method generally provides more conservative char depths, while the zero-strength layer is under-predicted. Nevertheless, the values of effective char depth are comparable. Including the cooling phase evidences that, during this phase, the heat wave penetration leads to a significant increase in the char depth and zero-strength layer. Particularly, this increase directly depends on the fire cooling rate: a slower cooling phase further reduces the effective cross-section of timber members. As a result, this research highlights how the heat wave penetration during the fire cooling phase can significantly reduce the load-bearing capacity of timber elements.

KEYWORDS: timber structures, fire safety, heat transfer, charring, zero-strength layer, cooling.

1 INTRODUCTION

Urban densification, sustainability drivers and technological advances are fostering the development of high-rise structures using bio-based materials like engineered wood products. Tall mass timber buildings now represent the fastest growing sector in the construction industry [1]. However, challenges related to their fire safety represent a main barrier for the robustness and the success of these structures. The primary difference from traditional construction materials, like steel, concrete, and masonry, is that timber buildings are mainly composed of wood, which is combustible and can contribute to building fires [2]. From a structural engineering perspective, the wood pyrolysis and combustion reduce the effective cross-section and therefore load-bearing capacity of structural elements. Consequently, they can compromise the structural integrity and stability of individual timber components, as well as the whole structural system [3].

The structural performance of timber elements is typically associated with the concept of charring. Charring, considered as the formation of a residual high-carbon char upon pyrolysis, is generally assumed to undergo for temperatures above 300 ºC. Charred wood is typically characterised by low mechanical properties (strength and stiffness), which are normally assumed null [3]. Accordingly, in structural applications, the penetration speed of the char layer, known as charring rate, plays a key role in the evaluation of the load-bearing capacity of timber elements exposed to fire.

The fire performance of structures, as well as the charring rate, is normally defined in a prescriptive manner relying on the standard fire curve, an unrealistic ever-increasing thermal exposure with time, conceived as the worst-case design scenario [4]. Crucially, although a compartment fire within a building enclosure is typically composed of a growth phase, a fully-developed phase, a decay phase and a cooling phase, the standardised fire tests completely ignore what happens after the fully-developed fire phase, deemed less onerous due to its lower temperatures [5,6].

However, during the fire decay and cooling phases, heat continues to penetrate within structural materials through conduction. Consequently, the structural capacity of load-bearing elements gradually continues to reduce [7]. This phenomenon can be more or less significant for various construction materials and systems. This problem is more critical for timber structures because wood loses its mechanical properties in an irreversible manner at relatively low temperatures, compared to traditional construction materials like steel and concrete. For instance, at 100 ºC typical softwood has a compressive strength reduction of about 75%, compared to the value at ambient temperature [4]. Consequently, after the end of the fully-developed fire phase, the load-bearing capacity of timber element can reduce up to an additional 30%

https://doi.org/10.52202/069179-0226

(compared to the ambient one), and structural failure could occur after fuel burnout, even after a fire seems extinguished [8-12]. The main challenge is related to the fact that, after fire extinction, this hazard cannot be easily detected, and structural collapse may occur with little or no warning. This situation represents a critical scenario for fire brigade interventions.

As a result, this framework leads to an inadequate assessment of timber structures exposed to fire. The precise interaction between fire and structural materials needs to be understood and carefully considered because the temperature propagation through the load-bearing timber can unexpectedly lead to structural collapse [10]. Current regulations simplify the problem by adding a zero-strength layer (ZSL), which is introduced to take into account the reduced mechanical properties of the heated uncharred wood [4,13]. However, the methodology is highly simplified (constant value for ZSL) and typically only carried out for the heating phase of a post-flashover compartment fires. The available literature on the matter is quite limited, but this hazardous issue has been underlined by many researchers [8-12]. Fundamental technical issues still need to be resolved to fundamentally comprehend the heat wave penetration in timber elements during all the fire phases to truly enable the performance-based design of fire-safe tall timber buildings.

This research study investigates the effect of the heating and cooling phases on the reduction of the effective cross-section of timber elements. The study focuses on the evolution of the char layer and zero-strength layer, thus the effective char depth. Simplified (Eurocode 5) and advanced calculation methods (conductive heat transfer model) are employed to estimate their thicknesses and penetration speeds during both the heating and cooling phases. For the cooling phase, the effect of various cooling rates is also investigated.

2 METHODOLOGY

A pure conduction heat transfer model is formulated to investigate the heat penetration within structural timber elements exposed to fire conditions. The finite differences model is based on the numerical method developed by Emmons and Dusinberre, and it explicitly solves a one-dimensional heat conduction problem by resolving energy-balance equations in the main direction of the heat flow [14-16]. The model is discretised into a number of finite elements, associated to nodes.

The heat transfer model is defined in accordance with the Eurocode advanced calculation methods (ACM) [4]. Solid softwood is modelled using the Eurocode 5 effective temperature-dependent material properties, namely mass density ratios, specific heat capacity and thermal conductivity [4]. Common timber density and moisture content are assumed: mass (wet) density equal to 420 kg/m^3 and a moisture content of 12%. The thickness of the timber element is set 200 mm to ensure its thermal thickness (semi-infinite solid), taking into consideration the defined material properties and thermal conditions.

The thermal boundary conditions at the fire-exposed timber surface are also defined according to Eurocode, starting from a defined temperature-time curve: a convective heat transfer coefficient equal to 25 W/m^{2}K and a timber surface emissivity equal to 0.8 [4,17].

The solid space is discretised in finite elements with a thickness of 1 mm, and the time step is set to 0.025 s, following model stability criteria [14-16].

3 RESULTS FOR STANDARD FIRE (ONLY HEATING PHASE)

The heat transfer in structural timber elements is first investigated considering the fire exposure as the standard fire temperature-time curve for a duration of 2 hours.

3.1 THERMAL CHARACTERISATION AND CHAR DEPTH

The modelling results are first analysed in terms of temperature. Figure 1 shows the temporal evolution of the temperatures at various depths within the timber substrate, while Figure 2 reports the various in-depth temperature profiles at various instants.

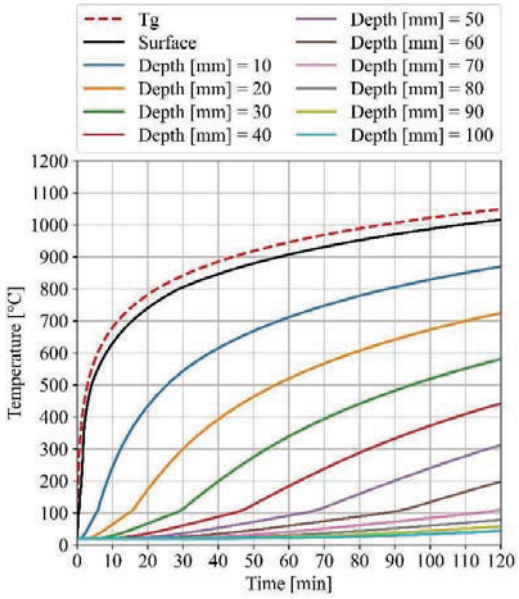

***Figure 1**: Temperature evolution at various depths within the timber substrate.*

The plots highlight how the timber surface closely follows the gas fire temperature and typical thermal gradients within timber elements exposed to fire are shown. These thermal evolutions are directly related to the defined thermo-physical properties of timber at ambient and elevated temperatures (in particular, thermal inertia and thermal diffusivity). It is also important to emphasise that, within the 2 hours of standard fire exposure, the heat wave only slightly penetrates beyond 100 mm in the timber substrate.

https://doi.org/10.52202/069179-0226

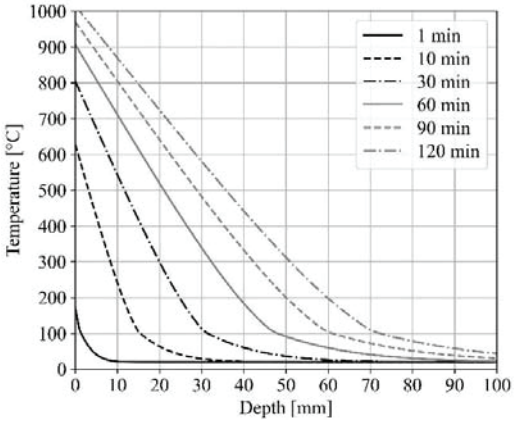

***Figure 2**: Evolution of thermal profiles within the timber substrate at different instants.*

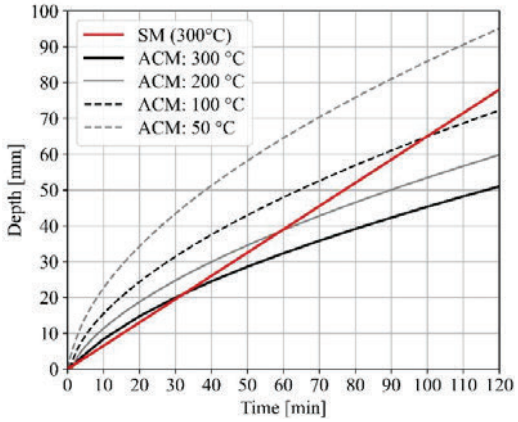

***Figure 3**: Evolution of the isotherms depths (300 ºC, 200 ºC, 100 ºC and 50 ºC) and comparison with EN 1995-1-2 simplified method (SM).*

The temperature fields shown in Figure 1 and Figure 2 are further analysed to study the thermal penetration of various isotherms within the timber substrate. Figure 3 and Figure 4 report the depths and penetration speeds of the 300 ºC, 200 ºC, 100 ºC and 50 ºC isotherms during the fire exposure. These isotherm curves correspond to various levels of reduced timber mechanical properties, and they are fundamental to quantify the structural capacity of load-bearing timber elements. In particular, the 300 ºC isotherm usually represents the location of the char front and, from its evolution, it is possible to estimate the charring rate within the load-bearing timber cross-section. Beyond this temperature, timber pyrolysis process is typically assumed completed and the resulting charred wood has null strength and stiffness [3].

Figure 3 shows how, for the defined case, the various isotherm curves penetrate the timber substrate, while Figure 4 displays their penetration speeds. It is evident how isotherms of lower temperatures typically have a higher speed compared to isotherms of higher temperatures. At identical instants, 50°C has always the highest penetration speed, while 300°C the lowest. Nevertheless, Figure 4 underlines how the penetration speeds gradually decrease during the fire exposure, all tending to values included between 0.2 and 0.5 mm/min. Accordingly, the distance between the various isotherms increases during the fire exposure, hence the thermal gradient becomes less steep (see Figure 2).

Special attention is paid to the 300°C isotherm depths (i.e. char depth) and penetration speed (i.e. charring rate). In particular, this curve evaluated using the described heat transfer model (advanced calculation method – ACM) is compared to the simplified method (SM) which assumes a constant charring rate [4]. For the case of softwood, this value is set equal to 0.65 mm/min (β_0). Figure 3 and Figure 4 show how this value over-estimates the timber charring rate for standard fire exposures above 15 minutes, while the timber char depth is under-estimated only below 15 minutes.

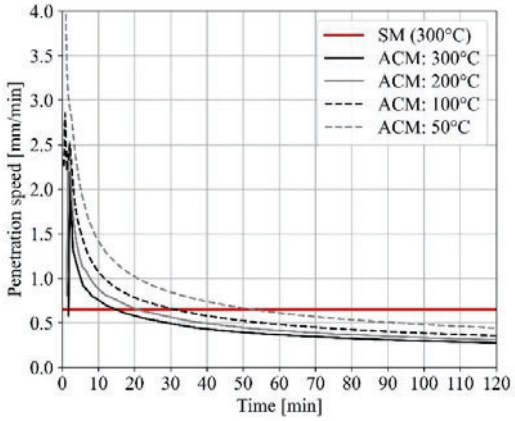

***Figure 4**: Evolution of the isotherms penetration speeds (300 ºC, 200 ºC, 100 ºC and 50 ºC) and comparison with EN 1995-1-2 simplified method (SM).*

3.2 ZERO STRENGHT LAYER

Once estimated the char depth, the effect of the heat penetration within the timber cross-section must be considered to assess the load-bearing capacity of timber structural members exposed to fire. Indeed, timber undergoes significant decomposition processes also for temperatures below charring (300°C) and, consequently, important reductions in the mechanical properties.

The Eurocode reduced-cross section method traditionally introduces a "zero-strength layer" (ZSL) to take into account the reduced mechanical properties in the timber heated below charring temperature [4]. This layer is assumed to have null strength and stiffness as charred wood, and it is summed to the char depth to estimate the residual effective cross-section. Eurocode 5 typically prescribes a zero-strength layer of constant thickness: in the current version, this is equal to 7 mm, for fire exposures beyond 20 minutes [4]. In contrast, the new version suggests various constant thicknesses depending on the member types and stress state.

Since the zero-strength layer is linked to the structural capacity of timber members, it is rarely associated with a temperature interval, given the fact that it should theoretically depend on both the mechanical state of the

https://doi.org/10.52202/069179-0226

cross-section (i.e. stresses) and the thermal gradient within the heated timber. However, using the presented numerical heat transfer model and assuming various constant thicknesses suggested by the Eurocode, it is possible to study the thermal gradient within the zero-strength layer. One edge of the thermal gradient is defined by the charring temperature (300°C), while the other depends on the defined thickness.

Figure 5 shows the evolution of the thermal gradient within zero-strength layers of various thicknesses: 7 mm, 9 mm, 14 mm, and 16 mm. Thicker zero-strength layers have larger thermal gradients and the thermal gradient gradually decreases for longer fire exposures: this is in line with the decreasing thermal gradients observed in Figure 2 and Figure 3. In general, the zero-strength layer extends up to temperatures as low as 70-80°C. This result is in line with what found by Huc *et al.*, who estimated 80-120°C as the edges of the zero-strength layer for timber beams exposed to parametric fire curves [18].

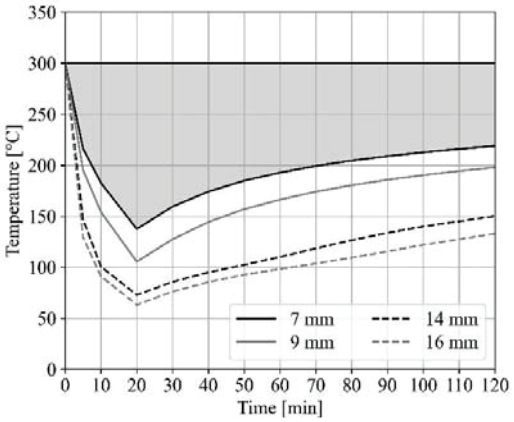

***Figure 5**: Evolution of the thermal gradients within the zero-strength layer for different thicknesses (7mm, 9mm, 14mm, and 16 mm).*

Following these considerations, the zero-strength layer is also estimated for the presented case study using two different approaches. The first approach assesses the zero-strength layer based on the in-depth temperatures. Following the previous analysis, the temperature gradient within the zero-strength layer is set to 80-300°C, 100-300°C, and 120-300°C. The second approach calculates the zero-strength layer considering the reduced mechanical properties of the timber section, as shown in Figure 6. Using the reduction factors prescribed by Eurocode 5 (tension and compression) [4], the in-depth thermal gradient shown in Figure 2 can be associated to a distribution of reduced mechanical properties within the timber section (see Figure 7). Assuming the timber cross-section under a homogenous stress state (tension or compression), once estimated the char depth (d_{char}), the zero-strength layer (d_{ZSL}) can be simply calculated based on an effective area equivalence, as shown in Figure 6.

Figure 8 reports the results related to the estimation of the zero-strength layer according to the two methodologies and compared to the current Eurocode 5 simplified method (7 mm). Since temperature continues to penetrate the timber substrate, the zero-strength layer continuously increases during the whole fire exposure. The highest values are calculated for the reduced mechanical properties approach for compression, which induces the highest reductions in the material strength, while the 120-300°C temperature approach represents the least critical conditions. In general, the estimated values are far beyond the 7 mm prescribed by Eurocode 5, ranging between 17 and 34 mm after 2 hour of standard fire exposure. This result again agrees with the research study carried out by Huc *et al.*, who found out thicknesses of zero-strength layer up to 30.5 mm [18].

https://doi.org/10.52202/069179-0226

3.3 EFFECTIVE CHAR DEPTH

To finally assess the structural capacity of timber members, the effective load-bearing cross-section is obtained considering both the contribution of the charred wood and the wood heated below charring temperature. Indeed, the effective char depth that is assumed to have null strength and stiffness can be calculated as the sum of the char depth and the zero-strength layer. This process can be carried out according to the above-mentioned methodologies. If the results for the char depth (Figure 3) and the zero-strength layer (Figure 8) are merged together, the effective char depth can be evaluated.

Figure 9 shows the effective char depths obtained following the temperature and reduced mechanical properties approaches, compared to the current Eurocode 5 simplified method. The previous sections have highlighted how the Eurocode 5 simplified method generally over-estimates the timber charring rate (beyond 15 min) and under-estimates the zero-strength layer, compared to the results obtained with the presented advanced calculation method based on heat transfer modelling. However, the values of effective char depths appear comparable, as shown in Figure 9. Nevertheless, for the presented case, these results evidence how the Eurocode 5 simplified method is usually less conservative, at least for standard fire durations below 60 minutes.

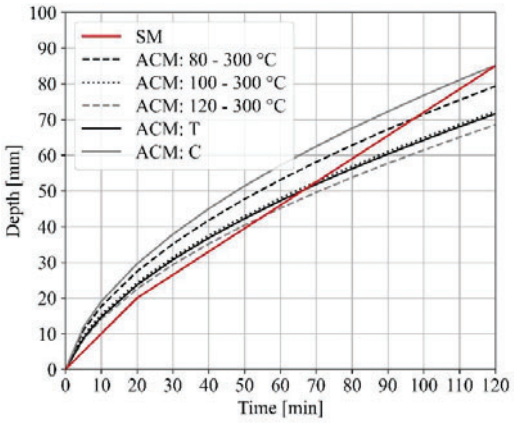

***Figure 9**: Evolution of the effective char depth according to temperature and reduced mechanical properties approaches, compared to EN 1995-1-2 simplified method (SM).*

4 RESULTS FOR NATURAL FIRE (HEATING AND COOLING PHASES)

The previous section has presented the modelling results considering the fire exposure as the standard fire temperature-time curve (ISO 834), hence only analysing the fire heating phase. In this section, a cooling phase is introduced, and the fire exposure is modelled according to the Eurocode parametric fire curves (EPFC) methodology [17]. The case of a squared compartment of 7.5 m × 7.5 m in plan, 3 m in height, with an opening factor of 0.04 $m^{0.5}$, a fuel load density of 720 MJ/m^2 and compartment linings with a thermal inertia of 1160 $J/m^2s^{0.5}K$ is considered. The resulting fire curve is shown in Figure 10. This scenario is chosen to provide a heating phase of 1 hour similar to the standard fire curve (Γ factor equal to 1), followed by a cooling phase from maximum temperature (944°C) to ambient temperature (20°C) of about 2 hours, causing a cooling rate of about 8.3°C/min (linear cooling according to the Eurocode parametric fire curves methodology).

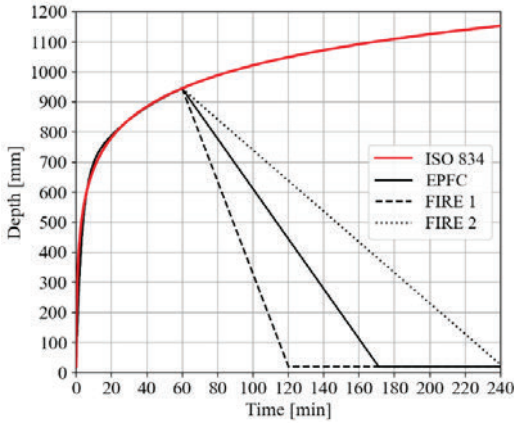

***Figure 10**: Standard fire curve (ISO 834) compared to Eurocode parametric fire curve (EPFC) and other fire curves with different cooling rates (FIRE 1 and FIRE 2, see Section 5).*

The thermal conditions within the timber element are identically calculated using the same heat transfer model in Section 3. Nevertheless, for the cooling phase, various assumptions and simplifications are necessary. The temperature evolution in each investigated node is strongly dependent on material properties, which are temperature-dependent. Once again, the thermo-physical properties of timber at elevated temperature are set according to Eurocode 5 [4]. However, these relationships are relevant and have been validated only for the heating phase, hence it is not known if these material properties can be assumed identical for the cooling phase. This is because certain underlying phenomena are not reversible, for instance water evaporation and thermal decomposition processes. To address this limitation, the timber material properties for the cooling phase are fixed and remain the same depending on the highest temperature reached in each node. This simplification avoids reverse thermal decomposition processes and moisture re-condensation.

4.1 THERMAL CHARACTERISATION AND CHAR DEPTH

The temperature evaluation in the studied material under the exposure of the described Eurocode parametric fire curve (EPFC) is presented in Figure 11. Based on the defined conditions, the heating phase (60 min) is identical to the previous analysis. In contrast, in the cooling phase, the effect of surface cooling on the in-depth temperature and the penetration of the heat wave within the timber element can be observed. The temperature decrease is evident mainly at depths closer to the exposed surface, while this effect decreases with increasing depth. In particular, from 70 mm the temperature evolution almost plateaus within the investigated time period.

The thermal profiles presented in Figure 12 confirm the penetration of the heat wave within the timber cross-section. More specifically, it can be noted the progress of

https://doi.org/10.52202/069179-0226

the char depth (300°C) for 30 minutes into the cooling phase (note 60 min and 90 min thermal gradients). Similarly, the amount of heated wood slowly increases, causing a further reduction of the in-depth timber mechanical properties and therefore an increase of the zero-strength layer.

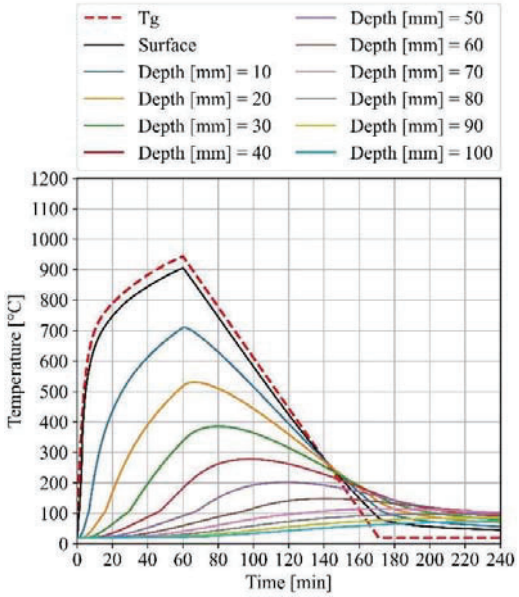

***Figure 11**: Temperature evolution at various depths within the timber substrate.*

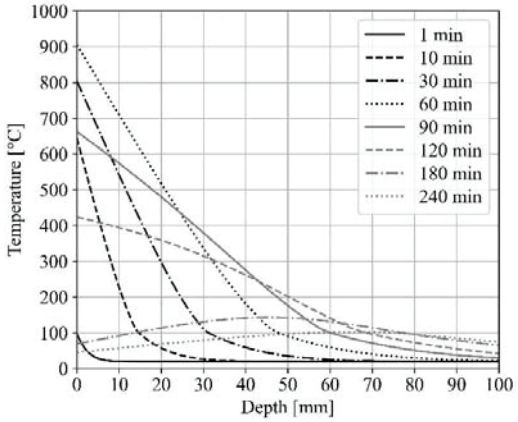

***Figure 12**: Evolution of thermal profiles within the timber substrate at different instants.*

A clearer illustration of this trend is evident through the penetration of the various isotherms (300 ºC, 200 ºC, and 100 ºC) during the fire exposure, presented in Figure 13. The isotherm curves highlight the continuous progression of char front and heat wave into the timber element even during the cooling phase. In particular, the 300°C isotherm evidences how the char front further increase for about 20 minutes during the cooling phase, increasing from 32 mm at the end of the heating phase to the maximum value of 37 mm. Similar conclusions can be drawn for the other isotherm curves, underlying how lower temperatures have a further and longer penetration into the timber cross-section during the cooling phase.

These results are also evident in Figure 14, which displays the penetration speeds of the discussed isotherm curves. Once again, the isotherms of lower temperatures have a higher speed compared to isotherms of higher temperatures, thus the thermal gradients tend to become less steep. In addition, the penetration speeds gradually decrease during the fire exposure. Given the defined thermal boundary conditions, there is a sharp change in the penetration speed of the various isotherm curves a few minutes after the end of the heating phase (note the 300°C isotherm). After this point, the penetration speeds quasi-linearly decrease to zero following specific rates. Consequently, the maximum penetration depths are reached long after the end of the heating phase, causing a further reduction of the timber mechanical properties. For instance, the 100°C isotherm reaches its maximum value about 140 minutes after the end of the heating phase (30 min after the end of cooling phase).

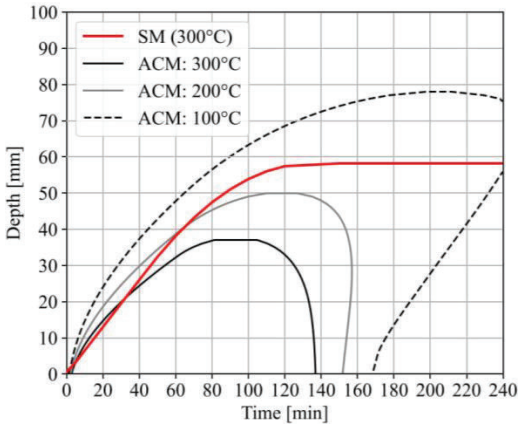

***Figure 13**: Evolution of the isotherms depths (300 ºC, 200 ºC, and 100 ºC) and comparison with EN 1995-1-2 simplified method for parametric fire curves (SM).*

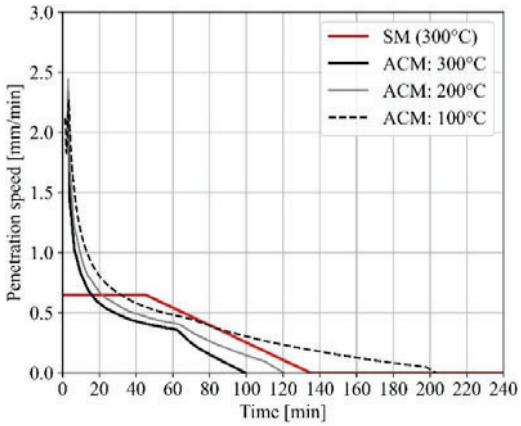

***Figure 14**: Evolution of the isotherms penetration speeds (300 ºC, 200 ºC, and 100 ºC) and comparison with EN 1995-1-2 simplified method for parametric fire curves (SM).*

Special focus is again placed on the 300°C isotherm depths (i.e. char depth) and penetration speed (i.e. charring rate). In particular, in Figure 13, the char depth (300°C isotherm) is compared to the Eurocode 5 simplified method for the parametric fire curve (Annex A) [4]. As in the previous case, the estimation of the char

depth and charring rate according to Eurocode 5 (SM) is a more conservative approach compared to the presented advanced calculation method (ACM).

4.2 ZERO STRENGHT LAYER

Similarly to Section 3.2, once estimated the char depth, it is necessary to analyse the effect of heat penetration within the timber cross-section and the consequent reductions in the mechanical properties. This is done again through the concept of the zero-strength layer (ZSL), which is calculated according to the two previously-described approaches.

As regards to the mechanical properties approach, the reduction factors of the timber mechanical properties are estimated assuming their irreversibility. The reduced mechanical properties are based on the maximum temperature reached in each node, hence the reduction factor remains at the lowest attained value even if the node temperature decreases during the cooling phase. Starting from the thermal gradients shown in Figure 12, the distribution of reduced mechanical properties within the timber section can be obtained for tension and compression. As displayed in Figure 15, the effect of the heat penetration on the timber mechanical is evidenced by the lower reduction factors at higher depths.

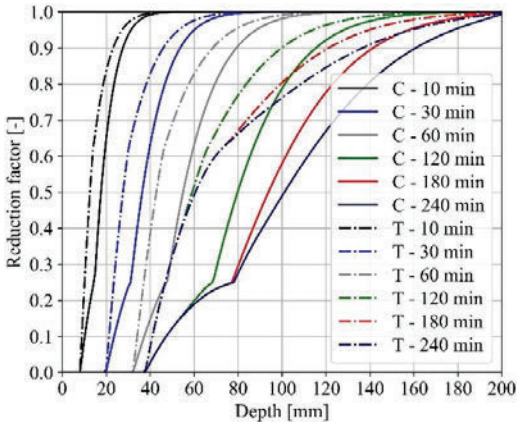

***Figure 15**: Evolution of the reduction factor of timber mechanical properties for compression (C) and tension (T) at different instants*

Figure 16 shows the calculated thicknesses of the zero-strength layer according to the temperature and reduced mechanical properties approaches. As a comparison, the constant value suggested by the Eurocode 5 simplified method (7 mm) is also reported. It is evident how all approaches and assumptions offer different results, with the highest values obtained for the reduced mechanical properties approach for compression and the lowest values for the 120-300°C temperature approach. In general, Figure 16 underlines how the zero-strength layer keeps increasing for a long time after the end of the heating phase and, possibly, the cooling phase. Constant values are achieved for the temperature approaches. In contrast, due to the continuous penetration of the heat wave (and corresponding reduction in the mechanical properties), the zero-strength layer according to the mechanical properties approach does not reach its maximum value even after 1 hour after the end of the cooling phase. Nevertheless, these results evidence how the values of the zero-strength layer at the end of the heating phase are about 2-3 times smaller than the values calculated by including the penetration of the heat wave during and after the cooling phase. When compared to the simplified Eurocode simplified method (SM), it is evident how this approach largely under-estimates the thickness of the zero-strength layer. The presented methodologies predict thickness between 30 and 65 mm, which is up to 10-times greater than the value suggested by the simplified method.

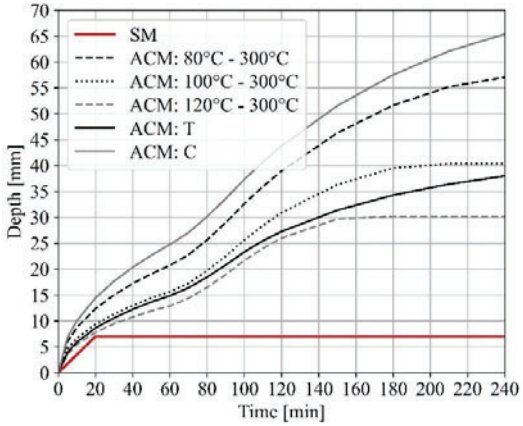

***Figure 16**: Evolution of the zero-strength layer according to temperature and reduced mechanical properties approaches, compared to EN 1995-1-2 simplified method (SM).*

4.3 EFFECTIVE CHAR DEPTH

The results related to the char depth and the zero-strength layer are finally combined to evaluate the structural capacity of timber members. Figure 17 reports the effective char depths obtained following the temperature and reduced mechanical properties approaches, compared to the Eurocode 5 simplified method for parametric fire curves (SM).

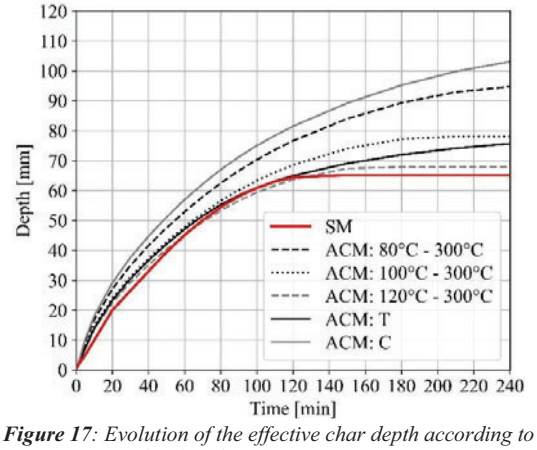

***Figure 17**: Evolution of the effective char depth according to temperature and reduced mechanical properties approaches, compared to EN 1995-1-2 simplified method for parametric fire curves (SM).*

https://doi.org/10.52202/069179-0226

The Eurocode 5 over-estimation of the char depth and important under-estimation of the zero-strength layer lead to a general under-estimation of the effective char depth. The results are only comparable for the 120-300°C temperature approach, which are the lowest values according to the advanced calculation method. Otherwise, the simplified method generally offers less conservative values. For the highest values obtained for the reduced mechanical properties approach (compression), the final effective char depths differ by more than 34 mm (103 mm vs. 68 mm).

5 PARAMETRIC STUDY: COOLING RATE

The previous section has highlighted how the cooling phase of natural fire exposure have a key role in assessment of the heat penetration and the consequent reduction of the mechanical properties of timber structural elements. For this reason, this section investigates the influence of the cooling phase on this problem. Considering the same heating phase defined in Section 3 and Section 4 (standard fire curve for 1 hour), the two additional curves (FIRE 1 and FIRE 2) are introduced, starting from the previous-adopted Eurocode parametric fire curve (EPFC) as the median case. As the EPFC case, the fire curves are characterised by a constant cooling rate. The considered EPFC has a cooling phase from maximum temperature to ambient temperature of about 2 hours, resulting in a cooling rate of about 8.3°C/min. In constant, FIRE 1 has faster cooling (1 hour) and a cooling rate of about 15.4°C/min, while FIRE 2 slower cooling (3 hours) and a cooling rate of about 5.1°C/min. The defined fire curves are shown in Figure 10.

5.1 THERMAL CHARACTERISATION AND CHAR DEPTH

As in the previous cases, the penetration of the heat wave within the timber cross-section can be investigated by analysing the penetration depths and speeds of the various isotherms. In this case, Figure 18 and Figure 19 displays the results for the 300 ºC and 200 ºC isotherms. Similar conclusions to the cases of the standard fire curve and parametric fire curve can be drawn. However, the fire curves characterised by different cooling rates underline the influence of the cooling phase on the penetration of the heat wave. Indeed, even if the thermal boundary conditions defined for the fire exposure are applied at the element surface, these have an evident effect on the distribution of the in-depth temperatures. Both Figure 18 and Figure 19 highlight how lower cooling rates enable higher penetration depths and speeds, and lower temperatures have a further and longer penetration into the timber cross-section during the cooling phase. The penetration speeds quasi-linearly decrease to zero during the cooling phase, after a clear trend change a few minutes after the end of the heating phase.

Focusing on the 300°C isotherm, it can be observed that the final (maximum) char depth is reached much later than the end of the heating phase. In particular, the difference between the char depth at the end of the heating phase and the maximum char depth is directly related to the cooling rate. A slower cooling phase allows a deeper penetration of the char front: 32 mm at the end of the heating phase and a maximum value of 35 mm, 37 mm, and 41 mm for lower cooling rates, respectively. Similar conclusions can be drawn for the other isotherm curves, emphasising the fact that this effect becomes more important for lower temperatures (higher penetration depths and speeds). As a consequence, it can be expected that the cooling phase has an important impact on the reduction of the mechanical properties in heated timber, therefore the zero-strength layer.

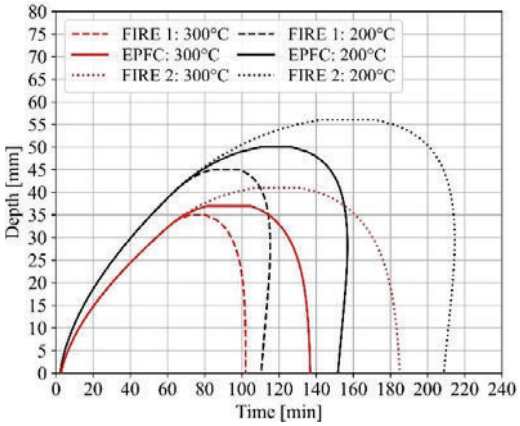

***Figure 18**: Evolution of the isotherms depths (300 ºC and 200 ºC) for different fire exposures.*

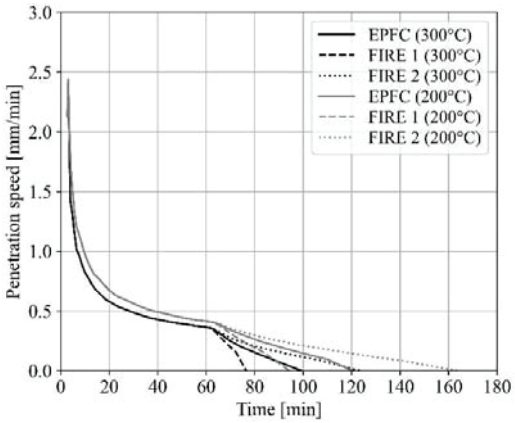

***Figure 19**: Evolution of the 300°C and 200 ºC isotherms penetration speeds for different fire exposures.*

5.2 ZERO STRENGHT LAYER

Starting from the temperature evolutions and in-depth gradients and once estimated the char depth, the zero-strength layer (ZSL) can then be calculated according to the two previous-discussed approaches. Figure 20 displays the calculated thicknesses of the zero-strength layer for the various fire exposures according to the temperature approach, while Figure 21 the ones according to the reduced mechanical properties approach. The results again estimate a large range of thicknesses, from 25 mm to 77 mm), up to more than 10-times the value suggested by the Eurocode 5 simplified method. The numerical results also underline how the zero-strength layer continues to grow for a long duration after the end

https://doi.org/10.52202/069179-0226

of the heating phase and the final value directly depends on the cooling phase. A slower cooling leads to a deeper heat penetration, therefore a higher reduction of the timber mechanical properties and higher zero-strength layer (± 5-10 mm). It was also confirmed that the 120-300°C temperature approach is the least conservative approach and the reduced mechanical properties approach for compression the most conservative. This is again related to the continuous penetration of the heat wave, which proceeds differently according to the investigated temperature: lower temperatures have deeper penetration depths and therefore the zero-strength layer reaches its maximum value at a later instant.

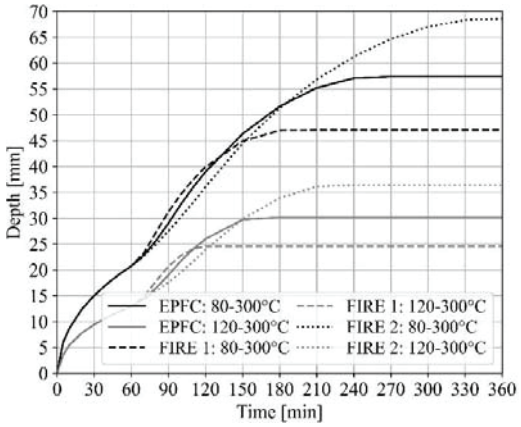

***Figure 20**: Evolution of the zero-strength layer according to the temperature approach (80-300°C and 120-300°C) for different fire exposures.*

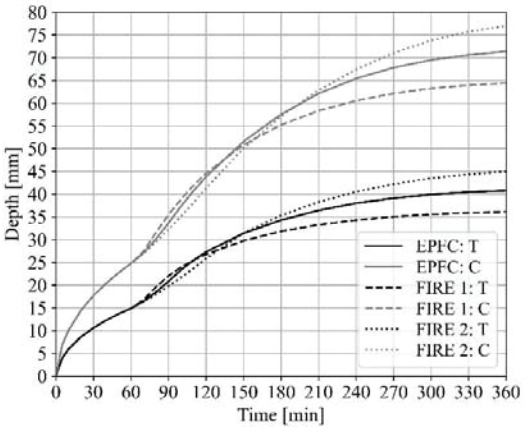

***Figure 21**. Evolution of the zero-strength layer according to the reduced mechanical properties approaches (tension and compression) for different fire exposures.*

5.3 EFFECTIVE CHAR DEPTH

The final effective char depths for the different fire exposures, shown in Figure 22 and Figure 23 and obtained by summing the char depths and the zero-strength layers, offer a similar understanding on the influence of the cooling phase on the structural capacity of timber members. The maximum effective char depths, hence the most critical design conditions, are typically achieved after the end of the fire cooling phase and sit within a wide range of values, from 60 mm to 118 mm.

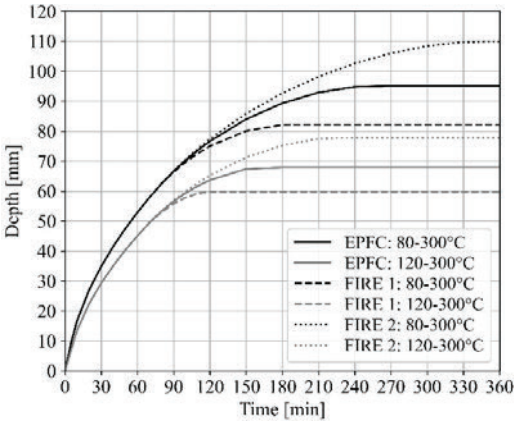

***Figure 22**: Evolution of the effective char depth according to the temperature approach (80-300°C and 120-300°C) for different fire exposures.*

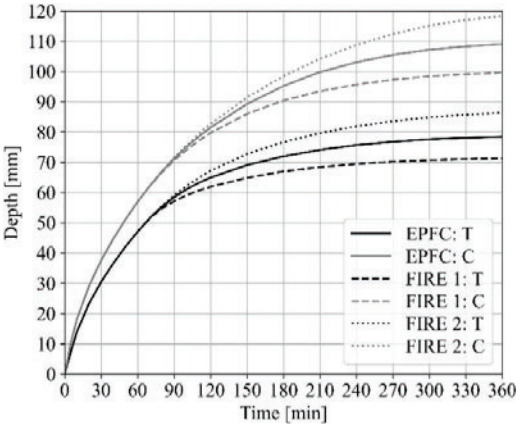

***Figure 23**: Evolution of the effective char depth according to the reduced mechanical properties approaches (tension and compression) for different fire exposures.*

6 CONCLUSIONS

The presented research study focuses on the comparison of the char depth and zero-strength layer determined using the simplified approach suggested by Eurocode 5 and those estimated through an advanced calculation method. The advanced calculation method was based on a finite-difference heat transfer model using effective temperature-dependent material properties. The char depth was calculated as the 300°C isotherm, while the zero-strength layer was determined following two approaches: one based on the timber in-depth temperatures, and one based on the timber reduced mechanical properties (tension and compression).

The first comparison investigated the fire heating phase only, defined according to the standard fire temperature-time curve (120 minutes). For the defined case, it was found that the simplified Eurocode 5 method provides more conservative of char depths from 30 minutes onwards, while the zero-strength layer is generally under-predicted (up to 34 mm, instead of 7 mm). However, the overall comparison revealed that the two methods offer comparable results, with Eurocode 5 being usually less conservative, at least for standard fire durations below 60 minutes.

https://doi.org/10.52202/069179-0226

The influence of the cooling phase on the evolution of the char depth and zero-strength layer was then investigated defining a series of fire exposures: a heating phase of 60 minutes standard fire curve followed by a cooling phase defined according to the Eurocode parametric fire curves, compared to a slower and faster cooling. For all the cooling phases, the heat wave penetration within the timber cross-section led to an increase in the char depth, up to 1 hour after the end of the heating phase. In particular, the difference between the char depth at the end of the heating phase and the maximum char depth is directly related to the cooling rate: a slower cooling phase allowed deeper penetration of the char front. Similar but more pronounced behaviour was also observed for the zero-strength layer. Even for the fastest cooling rate, the zero-strength layer kept increasing for at least 1 hour after the onset of the cooling phase. Accordingly, the maximum effective char depth was typically achieved after the end of the cooling phase.

The research outcomes highlight the importance of including the cooling phase in modern performance-based methodologies for the fire-safe timber structures. It was shown how, during the cooling phase, the load-bearing capacity of timber elements can significantly reduce due to the heat wave penetration and disregarding this phenomenon can lead to important under-estimation, on the unsafe side.

This research study was based on a finite-difference heat transfer model using the effective temperature-dependent material properties suggested by Eurocode 5. Future studies should focus on the effect of various wood species (e.g. density) and wood thermo-physical properties, with various complexities: from various effective material properties for pure conduction heat transfer to the inclusion of models of higher levels of complexity, for instance including the moisture transport and pyrolysis reactions. Also, in this research study, only a few specific heating and cooling phases were investigated, and future studies should cover a broader range of fire exposures to generalise the observed trends. Finally, future research should certainly aim at validating the presented numerical results with experimental data and quantifying the accuracy of the estimated char depth and zero-strength layer approximations, which significantly contribute to the overall effective char depth.

EXPERIMENTAL AND FINITE ELEMENT ANALYSIS OF IRISH SITKA SPRUCE CLT WALL PANELS UNDER EXPOSURE TO STANDARD FIRE CONDITIONS

Muhammad Yasir[1], Conan O'Ceallaigh[2], Kieran Ruane[3], Andrew Macilwraith[4]

ABSTRACT: Cross-laminated timber (CLT) is a sustainable engineered timber product. The fire behaviour of cross-laminated timber (CLT) is a significant concern due to its combustible nature. Currently, there is limited data available on the performance of charring of CLT panels made from C16 grade timber under fire. In this research, an experimental and numerical investigation of CLT floor panels exposed to a standard fire i.e., ISO 834 was performed. The CLT floor panels were manufactured from C16 grade Sitka spruce grown in Ireland. Overall, four CLT floor specimens were tested using standard heating conditions. The charring rate and temperature distribution at different depths from the fire-exposed face of the CLT panel were studied. The test panels were also protected with different protective claddings and the delay in charring of the CLT panel provided by these claddings is presented. Furthermore, a 2D finite element (FE) model was developed and the results from the FE model were compared with experimental results that show a good correlation in terms of the charring rates and temperature distributions.

KEYWORDS: Charring rate, Cross-laminated timber, Finite element analysis, Fire testing, Sitka spruce.

1 INTRODUCTION

Cross-laminated Timber (CLT) consists of at least three layers of timber boards that are glue bonded orthogonally. CLT is gaining popularity due to its enhanced structural capabilities compared to traditional timber construction methods and its simple erection process. The fire behaviour of CLT is an important research aspect and therefore the investigation of fire analysis of timber products has increased in the past few years. For the fire design of timber structures exposed to ISO 834 [1], two simplified methods i.e., the reduced cross-section method and the reduced properties method are presented in Eurocode 5 [2]. The former method measures the charred depth of timber by considering that the char will occur at a uniform charring rate of 0.65 mm/min for solid timber with a density greater than 290 kg/m^3. Furthermore, a section of 7 mm, called the zero-strength layer adjacent to the charred area that is considered to have zero load-bearing capacity, will be added to the char depth.

Timber undergoes thermal degradation upon heating which passes through different stages to reach the decay phase [3]. During the thermal degradation of timber, combustible gases evolve in addition to a mass loss which results in the formation of a char layer. The lower thermal conductivity of the char layer protects the inner section of the timber from heating up rapidly until cracks appear in the char layer causing heat penetration to the unburnt timber [4]. The degradation of timber on heating and fire behaviour can be analysed in terms of charring rate. Various factors that affect the charring rate include the type of wood, density, heat flux and ventilation conditions [4]. Eurocode 5 (EC-5) [2] uses the simplified one-dimensional charring rate β_0 for solid and glue-laminated timber panels with a density of more than 290 kg/m^3 when exposed to standard fire conditions i.e., ISO 834 [1]. A notional charring rate β_n is used to consider the effect of corner rounding in beams and columns which leads to an increase in the charring at the corner of the cross-section. The one-dimensional and notational charring rates for different wood products from EN 1995-1-2 are shown in Table 1.

Both experimental [3, 4] and numerical investigations [5]–[8] have been performed on the fire behaviour of CLT panels. The studies performed by Friquin et al. [3] show that the fire behaviour and charring rates of CLT panels largely depend on the fire curves. High temperatures and fast temperature growth of a fire curve led to a higher charring rate compared to fire curves with slower temperature growth and low peak temperatures. The magnitude and duration of the charring peak of CLT depend on the rate of heating, the test setup, as well as the size of the test sample and its orientation [5]. A series of 5-layer CLT floor panels were tested when exposed to Standard temperature conditions by Fragiacomo et al. [11]. The authors found that the CLT panels which were directly exposed to fire exhibited similar charring rates as given in the Eurocode 5. Furthermore, the finite element

(FE) model showed a good correlation in predicting the charring rates with that of the experimental results [11].

Table 1: *Charring rate as per the EN 1995-1-2 [2]*

Material	β_0 (mm/min)	β_n (mm/min)
Softwood and beech Glued laminated timber with a characteristic density of 290 kg/m^3	0.65	0.70
Solid timber with a characteristic density of 290 kg/m^3	0.65	0.8
Hardwood Solid or glued laminated hardwood with a characteristic density of 450 kg/m^3	0.50	0.55
Panels*		
Wood paneling	0.9	
Plywood	1.0	
* The one-dimensional charring for the panels is applied to a panel thickness of 20 mm or more with a characteristic density of 450 kg/m^3.		

The behaviour of CLT can be different from solid timber in a fire. Experimental tests have been performed to study different factors that affect the fire performance of CLT including the behaviour of the adhesive [12], layer thickness and the number of layers [12]–[14], the effect of protective cladding [11, 15], and calculation of a zero-strength layer [7].

Numerical models are often developed to extend the experimental results and to avoid expensive fire tests [10], [15]–[18]. Validated numerical models can be useful tools to examine the behaviour of CLT in a multitude of different fire-loading situations, ensuring compliance with design standards and can significantly increase the safety associated with CLT in construction. Wong, B.V.Y [10] developed a 2D FE modelling to simulate the thermal behaviour of CLT when exposed to a standard fire and found good agreement with the experimental results.

Similarly, Wang et al. [19] developed a FE model which was validated with experimental fire test results and it was shown to accurately simulate the thermomechanical behaviour of the CLT panel under elevated temperatures. While CLT has been used as an exposed surface in many structures, there are also alternative finishes that are commonly used to protect the CLT from direct exposure to fire which include gypsum plasterboard. Gypsum plasterboard is a protective cladding that is widely used as a fire protection system due to its easy installation, ready availability, and high specific heat capacity [20]. Gypsum plasterboards are non-combustible and are commonly available in two thicknesses i.e., 12.5mm and 15mm. At a temperature of up to 100°C during a fire, the gypsum plasterboard absorbs a significant amount of heat to remove water causing delays in the development of high temperatures until the whole board is dehydrated. Furthermore, the low thermal conductivity of the gypsum plasterboard keeps the unexposed surface of the plasterboard at lower temperatures [21].

For the CLT panels which are initially protected, the following will need to be considered:

- The charring behind the protective cladding is delayed until time t_{ch}, where t_{ch} is the time at which the charring behind the protective layer starts.
- The charring behind the cladding can start before the failure of the protective layer with a lower charring rate until the failure time t_f of the fire protection as shown in Figure 1. After the failure of protective cladding (t_f), the charring rate increases in line with the values shown in Table 1, from the EN 1995-1-2, until time t_a, where t_a is the time at which a char depth of 25 mm has been made.
- The charring rate returns to the value given in Table 1 of EN 1995-1-2 at a time t_a when the charring depth is either 25 mm or equal to the charring depth of the same member without fire protection.

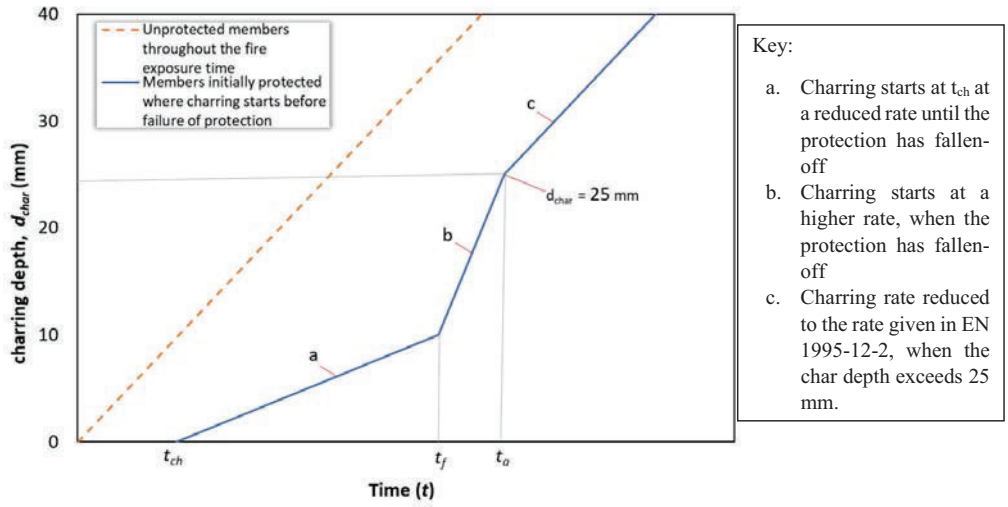

Figure 1*: Variation of the charring depth when for* $t_{ch} < t_f$ [2]

https://doi.org/10.52202/069179-0227

In recent years, considerable efforts have been made to focus on the fire analysis of CLT panels. However, the fire behaviour of CLT can vary for different timber species. Limited research studies have been conducted on the fire analysis of CLT floor panels made of Irish spruce which is characterised as a low-density timber due to the rapid growth conditions in Ireland and typically achieves a C16 structural grade. In this study, Irish spruce CLT floor panels were tested under exposure to standard temperature conditions. Furthermore, an FE analysis was carried out and validated against the experimental results creating an FE tool for CLT elements manufactured from Irish-grown Sitka spruce to be modelled in more significant and severe conditions.

2 EXPERIMENTAL TESTING

2.1 Materials

Boards of C16 grade Irish Sitka spruce were used to produce CLT floor panels that were 970 mm long and 500 mm wide. Boards used in the production of CLT floor panels were conditioned at a relative humidity of 65% ± 5% and a temperature of 20 °C ± 2°C. For the preparation of CLT panels, one-component polyurethane (PUR) adhesive was applied on the surface of the lamellae at a spread rate of 0.0160 microns/cm^2. The pressing of the panels was performed using steel plates to apply a pressure of 60 N/cm^2 for 120 mins. The panels were placed again in the conditioning chamber before the experimental tests to ensure and limit the moisture content of the specimens.

2.2 Test Specimens

The experimental work was carried out at the Structural Engineering laboratory of the Munster Technological University (MTU). A total of four CLT floor panels were tested in the fire-testing kiln under ISO standard heating conditions [1]. Three and five lamellae CLT lay-up configurations were studied having an overall thickness of 110 mm and 140 mm, respectively. All the CLT panels were simply supported and a constant concentrated load of 0.8 kN was applied at the mid-span throughout the fire testing. A deflection gauge was installed to measure and record the deflection at the mid-span during the testing. Specimen details and test setup for both the 3-layer and the 5-layer CLT panels are shown in Figure 2. The tested CLT panels were manufactured from Irish Spruce timber having a measured average density of 381 kg/m^3 at a 12% moisture content (MC). The measured average moisture content was 11.5-12.5% prior to the testing. The details of specimens and test configurations are provided in Table 2. Specimens A-1 and B-1, which comprised 3 layers and 5 layers, respectively received no protective cladding. The exposed surfaces of the remaining 3-layer and 5-layer CLT panels were protected with different protective claddings. The 3-layer CLT panel was protected with two different protective cladding configurations i.e., a combination of 12.5 mm Fireline gypsum plasterboard (FP) and 12.5 mm plywood (PW). The exposed face of the 5-layer CLT panel was protected with a 12.5 mm Fireline gypsum plasterboard.

2.3 Placement of thermocouples

The temperature of the kiln was monitored throughout the test and each CLT panel was instrumented with thermocouples (TC). A plate thermometer was used to record the temperature in the kiln during the test. Type K TCs were inserted in a drilled hole from the side of the CLT panels at different depths, to record the internal temperature distribution and the progression of the char line during fire testing. The thermocouples were strategically placed at the interfaces between different layers of the CLT panels as well as between the fire-protective cladding and the CLT panel. The details of the thermocouple tip location and its depth from the exposed surface are shown in Table 3.

3 RESULTS

Different researchers defined the charred front at different temperatures in timber due to the high-temperature gradient. In this study, the charred front which is a transition between charred wood and pyrolysis layer is considered to be at the 300˚C isotherm as defined in EN

1991-1-2. The charring rate of CLT panels and their individual layers were measured by considering the temperature measured at various TCs from the exposed surface. For CLT panels which were protected with different protective claddings, the charring rate of the outermost layer is taken when the temperature at the interface between the protective claddings and the CLT panel reaches 300˚C.

3.1 Temperature distribution

The temperatures recorded at different depths of the CLT panels using K-type TCs for all fire tests are shown in Figure 3. Moreover, the kiln temperature was recorded using a plate thermometer, ensuring the experimental fire curve is comparable with the ISO-834 curve heating conditions.

It can be seen from Figure 3 (a-d), the temperature of the kiln closely followed the standard fire curve in all tests. It can also be observed from the temperature-time curves, that the temperature at different depths of the CLT panels plateaus at around 100°C which was then followed by a rapid rise in temperature. This can be attributed to the loss of water at around 100 ˚C to 120˚C which also results in a decrease in the density as well as a decrease in specific heat capacity. In panels which were initially protected with different claddings, the temperature distribution at the interface between the CLT panel and cladding demonstrates the same trend. In all protected panels, the temperature behind the cladding reached the kiln temperature when the interface temperature between the CLT panels and the cladding was around 700°C and 800°C. This quick rise in temperature behind the claddings indicates that the fall-off of the protective cladding occurs when the temperature of the inner face of the cladding reached approximately 700°C and above.

3.2 Charring rate

The charring rate of the CLT panels and their individual layers were measured by considering the temperature measured at various TCs and their respective depths from the exposed surface. The char line which is a transition between charred wood and the pyrolysis layer is taken at the 300°C isotherm as given in the EC-5 (EN 1995-1-2). The temperature recorded by TCs installed at various depths of the CLT panels was used for measurement of the charred depth with time which in turn gives the charring rate. The charring rate calculated from TCs data at different depths of the CLT panels is illustrated for each specimen in the right column of Figure 3. It can be observed that in an unprotected CLT floor panel (Figure 3a (A-1), and Figure 3c (B-1)), the charring rate calculated throughout the cross-section of the CLT panels was close to the one-dimensional charring rate of 0.65 mm/min as defined in the EC-5. The CLT panels which were initially protected with different claddings showed a delay in the charring of the CLT panels as expected. The charring of the CLT panels was then started with a lower rate as shown in the right column of Figure 3 (c) and (d). The lower charring rate was followed by a sudden higher charring rate which is due to the fall-off of the protective cladding on the exposed face of the CLT. The fall-off of the cladding exposes the CLT panel directly to fire and thus the char rate increases. The fall-off of the claddings happens in all tests at around 70 min to 80 min from the start of the fire which can be observed from the sudden increase in temperature between the CLT panel and the exterior cladding. The temperature recorded by the thermocouple placed between the CLT panel and protective cladding is shown by TC0 in Figure 3. (b), and (d).

Table 3: *Location of thermocouples from the exposed face of the CLT panel to fire*

Specimen	Between two claddings	Between cladding & CLT panel	Thermocouples depth from the exposed surface of CLT panels (mm)

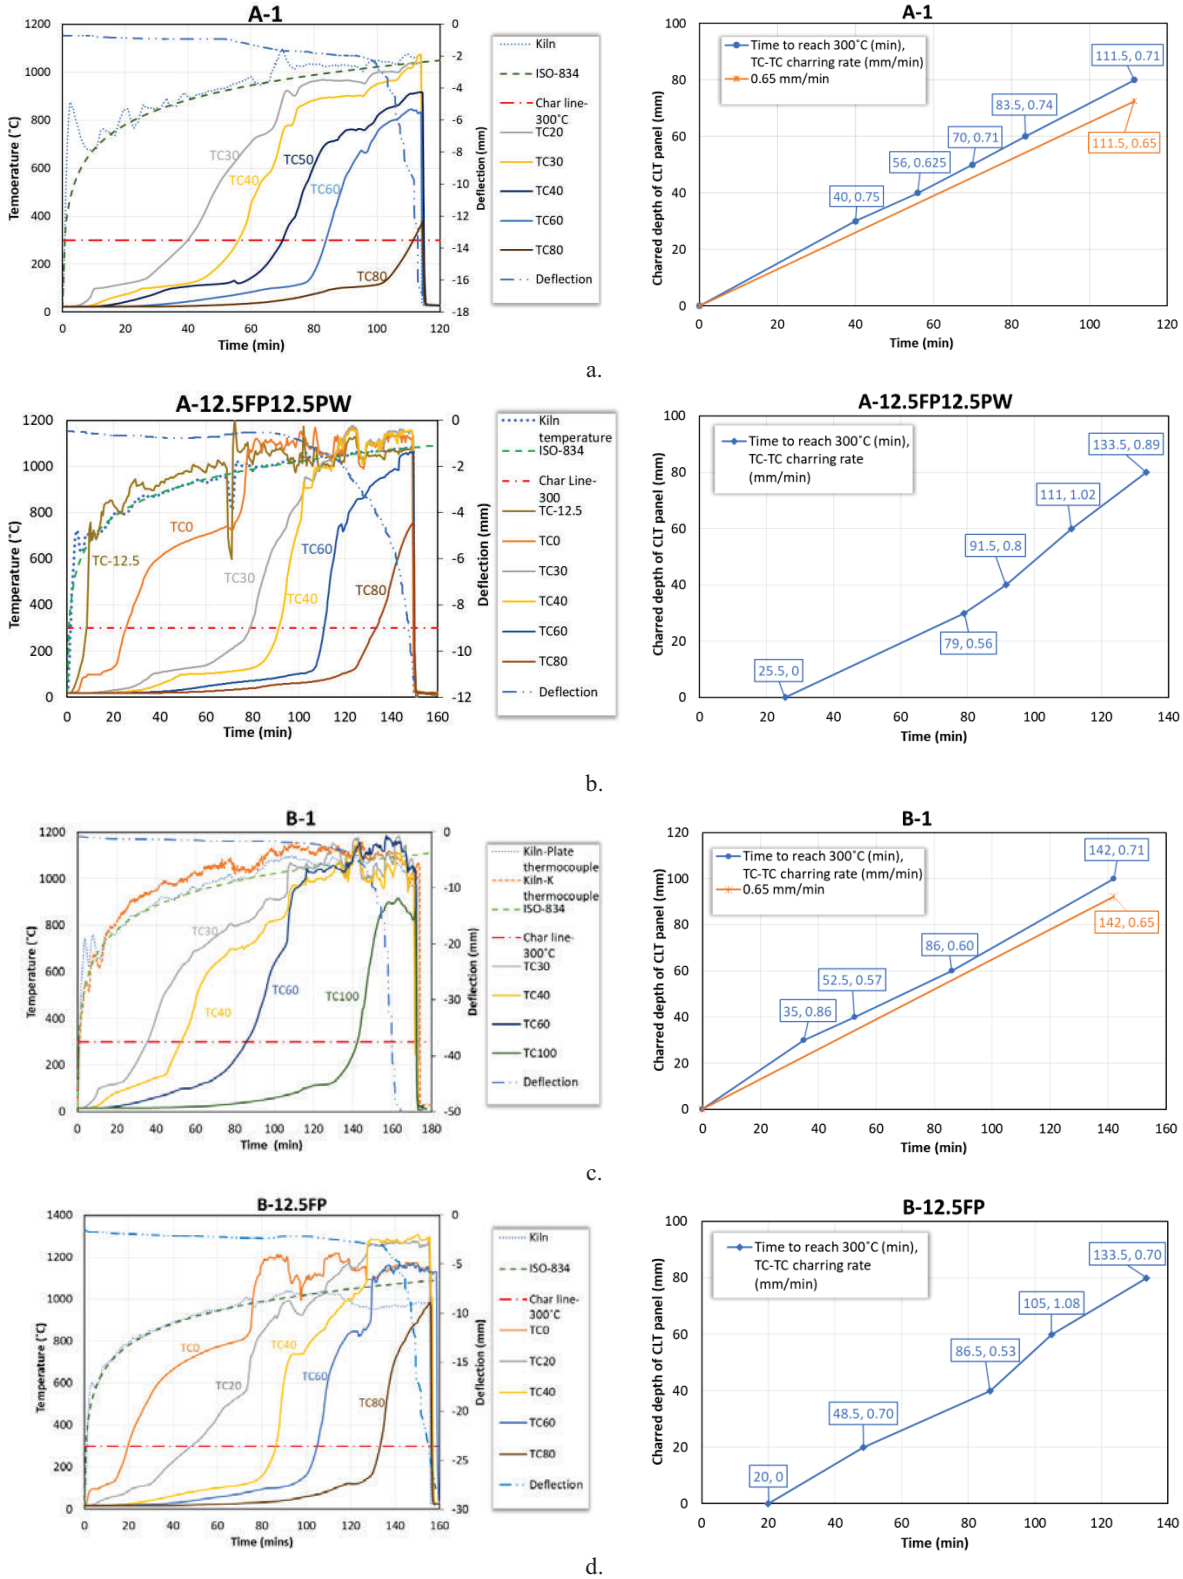

Figure 3: *Left column: Temperature-time curves of test panels, Right column: Charring rate from TC-TC, (a) A-1, (b) A-12.5FP12.5PW, (c) B-1, (d) B-12.5FP*

https://doi.org/10.52202/069179-0227

The charring rate of plywood from EN 1995-1-2 with a thickness of less than 20 mm is given in Equation (1).

$$B_{0,\rho,t} = \beta_0 * k_\rho * k_h \quad (1)$$

Where, $k\rho = \left(\frac{450}{\rho k}\right)^{0.5}$, $kh = \left(\frac{20}{hp}\right)^{0.5}$

h_p is the thickness of the panel in millimetres and ρ_k is the characteristic density in kg/m^3.

The charring rate from Equation (1) for a 12.5 mm plywood layer is 1.10 mm/min while the experimental testing gave a higher charring rate of 1.47 mm/min.

It can be observed from the charred depth-time curves of protected panels as shown in the right column of Figure 3 (b), and (d), that the charring behind the protective cladding is delayed until time t_{ch}. It can also be observed that the charring behind the cladding started at a reduced rate, while the protective layer is still up against the CLT panel. However, an increase in the charring rate was observed after the failure of the protective claddings in all protected test panels. The overall charring rate at the end of the fire tests for all panels is shown in Figure 4 (a). The overall charring rate of both unprotected 3-layer and 5-layer CLT panels were 0.71 mm/min and 0.70 mm/min, respectively, which is slightly higher than the one-dimensional charring rate of 0.65 mm/min as defined in EC-5 for glue laminated or solid timber with densities greater than 290 kg/m^3. The charring rate calculated for initially protected panels after the charring begins was at a similar rate to unprotected panels. This shows that the protective cladding initially delays the charring of the CLT panel. However, after the CLT panel starts charring, the char rate remains similar to the unprotected panel, if it's exposed to fire for a longer duration. This shows that the protective cladding only delays the charring of the CLT panels, and it still chars at a similar rate if it's exposed to fire for a longer duration.

3.3 Effect of protective cladding on the delay of charring

Protective claddings provided at the exposed face of the CLT panel delayed the charring of the test specimens. The delay in charring of the CLT panels provided by different claddings on the exposed face of the CLT panel to fire in terms of time (mins) is given in Figure 4 (b). The 12.5 mm FP gives a protection time of 20 mins when used on the exposed face of a 5-layer CLT floor panel. A combination of 12.5 mm FP and 12.5 mm PW delayed the charring of the CLT panel by 25.5 mins. It was observed that the temperature at the interface between the exterior 12.5 mm PW layer and the inner 12.5 mm FP reached 300˚C in 8.5 mins. EN 1995-1-2 [2] provides the relation as given in Equation 2 to measure the start of charring of the CLT panel behind the gypsum type A or F plasterboards at internal locations or the perimeter adjacent to filled joints. The delay in charring of the CLT panels calculated using Equation 2. for type A and type F plasterboards are 21 mins, which is very close to the experimental values of 20 mins as calculated in this research for 12.5 mm FP.

$$t_{ch} = 2.8h_p - 14 \quad (2)$$

Where h_p is the thickness of the protective cladding.

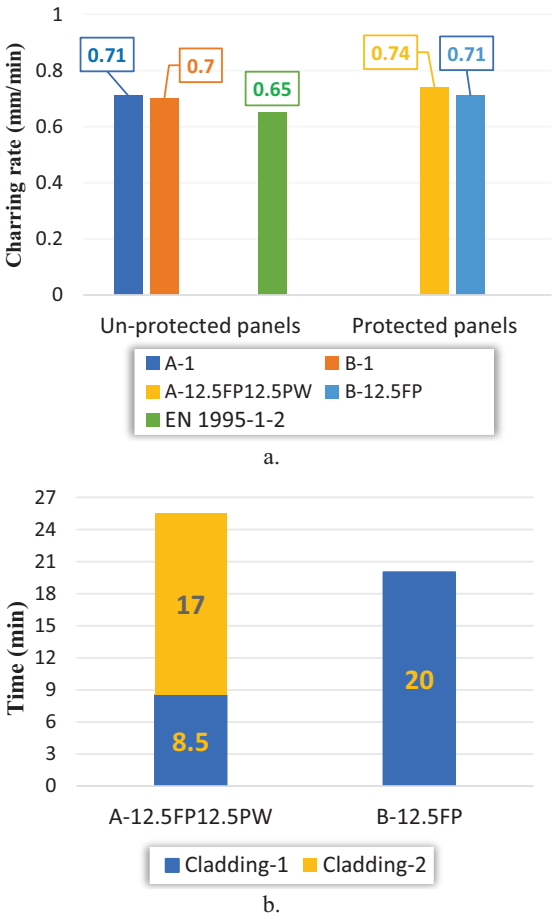

Figure 4: *a) Charring rate for tested CLT panels, b) Fire protection provided by different cladding configurations.*

4 NUMERICAL ANALYSIS

The numerical FE analysis was carried out in Abaqus FE software. The 2D model of the CLT panel was developed in full length with the load and supporting conditions, material properties, and exposure to fire applied. The element type considered for this analysis was CPE4T which is a 4-node plane strain thermally coupled quadrilateral, bilinear displacement and temperature. Thermomechanical analysis which is a sequential thermal stress analysis was performed for all CLT panels. The analysis was performed in 2 steps. In step one, the load was applied to the CLT panel followed by the fire exposure of the CLT panel in the second step.

4.1 Material properties

The mechanical properties of the C16 timber both in parallel and orthogonal orientation were applied to the model. In this research, the EC-5 temperature-dependent modulus of elasticity model was used. The material properties were taken from the research performed on similar wood by O'Ceallaigh et al. [22]. The temperature-dependent thermal properties of the timber including the conductivity, specific heat and density relationships were used as defined in the EN 1995-1-2 [2]. As recommended

by EN 1991 and EN 1995-1-2, the convection coefficient and emissivity were taken as 25 W/(m^2.K) and 0.8, respectively. In addition to the thermal properties provided by EC-5, the FE analysis was also performed using modified values of conductivity at higher temperatures as shown in Table 4. In order to make the analysis simpler, the conductivity values of timber given by EC 5 were adopted to consider the effect of faster charring and quick temperature raise after the layer's fall off.

A mesh sensitivity study was carried out and an element size of 10 mm was used in all CLT panels to ensure adequate accuracy in the results as well as to obtain temperature data for the nodes in a similar location to the location of thermocouples in the experimental testing. For the CLT panel which was initially fire-protected with plywood and plasterboard, the plywood has not been modelled due to the unavailability of its thermal properties at higher temperatures as well as its negligible mechanical resistance.

Table 4: *Temperature-dependent thermal conductivity used in FE analysis*

New Proposal	EC-5	Temperature
W. m^{-1}. K^{-1}		(°C)
0.12	0.12	20
0.15	0.15	200
0.07	0.07	350
0.09	0.09	500
0.35	0.35	800
0.5	-	850
1	-	900
2	-	950
10	1.5	1200

4.2 FE results and comparisons with experimental tests

In all of the experimental tests, the temperature of the kiln closely followed the Standard fire curve [1]. Therefore, the standard heating conditions were applied on the exposed face to fire in the FE analysis of initially unprotected panels. The comparison of experimental and FE results in terms of the overall charring rate from the fire-exposed side of the CLT panels was made and is shown in Table 5. It can be observed from Table 5 that the charring rate predicated using the model proposed in this research gives a closely matching charring rate to that of experimental fire testing. The charring rate predicated using EC-5 thermal properties gives a lower charring rate than the experimental results. This is partially due to the fact that thermal properties in EC-5 are presented for solid or glue-laminated timber which doesn't consider the effect of delamination, which usually happens in horizontal CLT panels. Furthermore, the char layer provides extra protection to timber from direct exposure to fire and thus reduces its overall charring rate. Thus the effect of an increase in the charring rate due to the fall off of sections of charred timber is needed to be considered in the thermal analysis. A simplified procedure to consider a higher charring rate after the layers charred has been included in the FE model which is validated with the experimental results. This is performed by using higher thermal conductivity values for a temperature of more than 800°C to avoid considering the complexity of modelling the char fall-off in the numerical simulation. In Figure 5, the charred depth at 60 mins from the start of the fire test from the FE analysis is shown for B-1 and B-12.5FP panels using the EC-5 thermal properties with the conductivity values taken from the new proposal as shown in Table 4. The charred depth of the CLT panels in Figure 5 is represented by a grey colour while the pyrolysis layer is shown in red.

Furthermore, the temperature distribution at different depths from the exposure of a panel to fire from experimental tests is compared with the FE analysis and is shown in Figure 6. It can be observed that the temperature-time curves for both experimental tests and FE results using the new proposal follow a similar trend to reach the char line temperature (i.e., 300˚C). Overall the temperature distribution from the numerical analysis, which is predicated using thermal properties given in EC-5 gives lower temperature distribution than the experimental results. The temperature-time curves from the FE analysis using EC-5 thermal properties follow a similar trend to that of the experimental results for the first hour of the FE analysis. The difference in the time to reach the char line temperature from FE analysis using EC-5 was higher than the experimental results for a longer duration of tests. On the other hand, the proposed model not only gives a good approximation of the char depth but also closely predicts the time to reach the char line temperature and the charring rate well.

Table 5: *Comparison of experimental and FE results*

Specimen	Overall charring rate (mm/min)		
	Exp	FEM	
		New Proposal	EC-5
A-1	0.72	0.71	0.58

5 CONCLUSIONS

The experimental testing of CLT floor panels made from C16 Grade Irish Sitka spruce was performed to measure the charring rate under ISO-834 standard heating conditions. Different protective claddings were used on the fire-exposed side of the CLT panels to determine their effectiveness in delaying the charring of the CLT panels. The main conclusions drawn from the experimental testing and FE analysis are as follows:

- The charring rate of both 3-layer and 5-layer unprotected CLT panels is 0.71 and 0.70 mm/min respectively, which is slightly higher than the one-dimensional charring rate given by the Eurocode 5 (EN 1995-1-2). No significant difference in the effect of the thickness of CLT layers was observed on the charring rate.
- The 12.5 mm Fireline gypsum plasterboard delayed the charring of the CLT panels by 20 minutes. A combination of a 12.5 mm Fireline gypsum

plasterboard with a 12.5 mm plywood protects the CLT panel from charring by 25.5 minutes.

- All CLT panels which were initially protected using different protective claddings give an overall charring rate of 0.70 mm/min to 0.71 mm/min. A higher charring rate was observed after failure and fall off of the fire protective cladding.
- In all of the panels with a protective layer, the charring of the CLT panels started while the protective cladding was still intact with the panels. In all of the panels, the protective claddings fall off around 70 mins to 80 mins from the start of the test.
- It was observed that the protective layer on the fire-exposed face of the CLT panels delayed the start of charring of the CLT panels. However, there is no significant difference in the overall charring rate of both unprotected and initially protected CLT panels at the end of the fire test.
- A 2D FE model was developed in Abaqus with a new proposal to consider higher values of conductivity than that defined in EC-5 for temperatures more than 800°C. The results from the FE analysis using the new proposal were shown to be in good agreement with the temperature distribution and charring rate of the experimental testing of the CLT panels. The FE analysis using the new proposal demonstrated good agreement with the experimental results in terms of charring rate and time to reach the charring temperature compared to the FE analysis performed using EC-5 thermal properties.
- The validated FE model may now be used to analyse a series of different fire loading conditions, panel lay-ups and protective measures for C16 Grade material and will serve as a useful tool to improve the safety and reliability of timber structures subject to fire loading.

ACKNOWLEDGEMENTS

The MODCONS Project is a joint project between the Timber Engineering Research Group at the University of Galway and Munster Technological University focused on increasing the knowledge and use of timber in modular construction. The MODCONS Project is funded by the Irish Department of Agriculture, Food and the Marine Competitive Research Funding Programmes (Project Ref: 2019R471).

A DESIGN APPROACH TO EXTERNAL FIRE SPREAD FROM BUILDINGS WITH EXPOSED MASS TIMBER

Adam Glew[1*], Rory Turnbull[2], Frederik Møller Poulsen[3], Eirik Christensen[3], Panagiotis Kotsovinos[4], Eoin O'Loughlin[3], David Barber[5], Judith Schulz[3]

ABSTRACT: Engineered wood products (EWPs) are relatively new, innovative construction materials which, if used correctly, can serve as sustainable alternatives to more common construction types. They provide an opportunity for designers to reduce the embodied carbon of proposals. Given the climate crisis, it is vital that the sector decarbonises.
However, lessons must be learnt from previous sustainability-driven design decisions that did not sufficiently consider safety implications. Often there is a desire from building owners, occupiers and/or designers to expose mass timber. Doing so can provide aesthetic, wellbeing, cost and carbon benefits over encapsulation. However, exposing large areas of mass timber introduces an additional fuel load to the compartment – the structural fuel load, and compartment fire experiments to date have shown that this can lead to larger external flaming.
This paper aims to investigate potential implications of this phenomenon on: (i) large-scale 'standard' façade tests, and (ii) radiation assessments to neighbouring buildings.
First, temperature data recorded outside the opening(s) of seven mass timber compartment fire experiments is compared to temperatures in front of the façade recorded during three 'standard' industry façade fire tests. It is found that BS 8414 and the proposed harmonised European test generally expose the façade to more/as severe temperatures than observed during mass timber compartment fire experiments. Therefore, these tests are considered applicable to exposed mass timber buildings. The NFPA 285 test, which was designed for traditional buildings, is less severe than the mass timber experiments reviewed.
Heat fluxes recorded opposite openings in three mass timber compartment fire experimental series are then compared to heat flux predictions made following first principles-based radiation calculations following the enclosing rectangles and configuration factor method (as in BR 187). Using the "low" and "high" fire load assumptions in BR 187 leads to underpredictions of heat flux received. Modelling the external flame as an emitter (of the same temperature as the opening) has little impact on results. Therefore, a higher emitter temperature is recommended when carrying out radiation calculations from exposed mass timber compartments.

KEYWORDS: timber, external flaming, external fire spread, standard façade tests, radiation, compartment experiments

1 INTRODUCTION

1.1 THE CLIMATE CRISIS AND TIMBER

Buildings are responsible for approximately 40% of global CO_2 emissions, with embodied carbon accounting for around a quarter of that. Unlike operational carbon emissions, which can be reduced over time, embodied carbon is 'locked in' once an asset is constructed. As the global building stock is expected to double in terms of floor area by 2060, there is an urgent need for architects and engineers to use sustainable construction materials, such as engineered wood products (EWPs) [1], [2].
Innovations in EWPs (or 'mass timber') have presented opportunities for designers to use timber for larger structures. Timber sequesters carbon during its growth, and when it is sustainably sourced, used efficiently, and designed with the end-of-life scenario considered from the outset, can result in buildings with lower embodied carbon than those predominantly using steel and/or concrete [3], [4]. In addition, EWPs are aesthetically desirable, can have wellbeing benefits for building users [5], and may command higher rental rates [6].

1.2 EXPOSED MASS TIMBER AND EXTERNAL FLAMING

Exposing large areas of mass timber introduces additional fuel load to a compartment. The majority of small- and medium-scale compartment fire experiments conducted to date have shown that this can result in larger external flames [7], [8] and increased heat flux to both the building of fire origin and opposite [9] than from an otherwise identical compartment constructed from non-combustible materials. One experimental series, with a very high movable fuel load (of 1085 MJ/m^2), did not observe a significant increase in flame height when mass timber was

https://doi.org/10.52202/069179-0228

introduced, but did report higher temperatures [10]. Significant external flaming was also observed during the large-scale *CodeRed* experimental series [11]–[13].
These observations highlight the need for existing fire safety design methods to be revisited, scrutinised and, if necessary, adjusted before they are applied to buildings with large areas of exposed mass timber. Larger external flaming may have an impact on:
(i) applicability of 'standard' large-scale façade tests,
(ii) radiation assessments to neighbouring buildings,
(iii) heat transfer analyses to external loadbearing structure.
The latter has been studied in separate work [14] so is not covered in this paper.

1.3 FIRE SAFETY OBJECTIVES

Broadly speaking, buildings are legally required to limit the risk of external fire spread:
- over the façade of the building of fire origin, and
- from one building to another,

to an 'acceptable level'. An 'acceptable level' may be determined based on a number of parameters, such as the type and scale of the building, occupancy characteristics, proximity to other buildings, etc.
Building regulations typically consider life safety. Clients and insurers may have additional objectives to limit damage to property, contents and/or business operations.
Different guidance documents exist as reference to enable designers to demonstrate compliance with fire safety objectives. In England, statutory guidance in the form of the approved documents "provide guidance for common building situations". "Compliance with the guidance set out in the approved documents does not provide a guarantee of compliance with the requirements of the regulations because the approved documents cannot cater for all circumstances, variations and innovations" [15].
Mass timber is a recent innovation within the construction industry that has not yet been widely adopted in the UK, so its use does not yet represent a "common building situation" [16].
Whilst there will always be some knowledge gaps, and "satisfactory engineering solutions may be achieved with partial information" [17], research is needed so that built environment professionals can understand mass timber further, and design, construct and maintain safe, sustainable buildings.

1.3.1 Limiting fire spread over external walls

Designers typically have two options for limiting fire spread over the façade of the building of fire origin:
(i) selecting materials which meet prescriptive reaction-to-fire performance requirements, or
(ii) conducting a large-scale 'standard' façade fire test and passing specified performance criteria.
This paper focuses on the latter. Large-scale façade tests submit a multi-storey test sample of the façade to a large fire, represented by wooden cribs or a gas burner. The 350kg wood crib specified in BS 8414 as part of the large-scale test, for example, gives a total energy output of ~4500 MJ over a 30 minute period, with a peak heat release rate of 3 ± 0.5 MW [18]. The intent of these tests is to simulate a realistic worst-case fire scenario, such as the flame projecting from a compartment fire post-flashover, or from a burning skip positioned close to the façade [19]. NFPA85 uses gas burners.
Data has been sourced by the authors from the proposed harmonised European test, the NFPA 285 test and the BS 8414 test for comparison with data from seven large-scale timber compartment experiments.

1.3.2 Limiting fire spread from one building to another

It is generally acknowledged that the risk of fire spread between buildings should be limited, however there is no internationally agreed method for doing so. Most national building codes (e.g., National Construction Code (NCC) [Australia], NFPA 5000 [USA], International Building Code (IBC) [USA], The Model Building Code [Germany], etc.) set out prescriptive separation distances based on building type. However, there is little scientific reasoning provided in support of these methods, which are often based on historical observations [20], [21]. The national building codes of some countries permit a calculation-based methodology to be used by designers to quantitatively assess the emitted radiation from a severe post-flashover fire onto an adjacent building/boundary such that they can ensure a maximum heat flux is not exceeded. BR 187 – *External fire spread – Building separation and boundary distances* [22] is one such method, which is the focus of this paper. The BR 187 method is based on research carried out by Margaret Law in the 1960s [23], [24]. The fire compartment is assumed to be a radiating emitter with a uniform temperature of either 830 °C (low fire load) or 1040 °C (high fire load). The typical acceptance criteria for incident radiation on an exposed building is 12.6 kW/m^2, the threshold for piloted ignition of wood.
The 2014 revision of BR 187 notes that some compartments, such as those that are well insulated, can result in higher temperatures. A document released as part of The Grenfell Tower Public Inquiry highlighted the need for further guidance on higher compartment temperatures and external flaming from well insulated compartments [25]. However, no guidance is currently provided on this topic, and it is therefore often not considered by designers. Similarly, no guidance currently exists on whether the assumptions within BR 187 are suitable for compartments with large areas of exposed mass timber.

1.4 STRUCTURE AND CONTENT OF THIS PAPER

This paper presents novel data from *CodeRed*, supplemented by data from the RISE [26] and Épernon experiments [27]. Temperatures recorded above and heat fluxes recorded opposite the openings in the experiments are used to understand the impact of exposed mass timber on externally venting flames and radiation from the compartments. First, temperature data is compared to temperatures from a selection of 'standard' façade fire tests (the proposed harmonised European test, NFPA 285 and BS 8414), to evaluate whether the tests are sufficiently severe. Then, the heat fluxes recorded opposite the openings are compared to heat fluxes

https://doi.org/10.52202/069179-0228

calculated following a common radiation calculation method (BR 187).

2 THE *CODERED* EXPERIMENTS

Arup designed and commissioned a purpose-built facility for the *CodeRed* experimental series which took place at CERIB's Centre d'Essais au Feu (Fire Testing Centre).

The experiments aimed to study the fire dynamics in large, open-plan compartments with an exposed timber surface. The test geometry is shown in Figure 1.

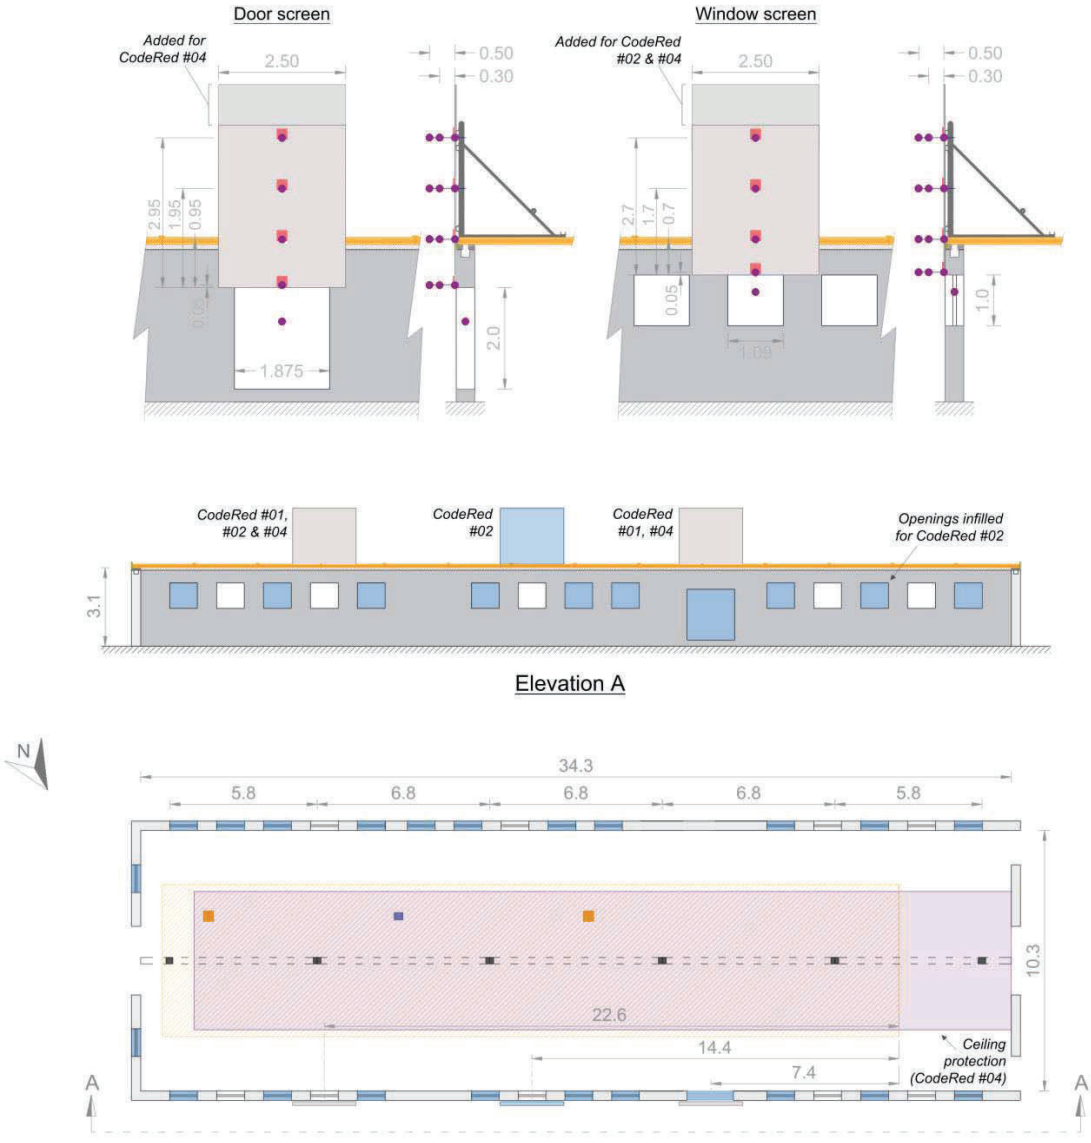

Figure 1: *Plan of CodeRed compartment, with elevations showing instrumented doors and windows. Openings coloured blue were infilled during CodeRed #02. Purple shading on plan indicates the area of encapsulation on the CLT ceiling in CodeRed #04.*

The compartment had an internal floor area of 352 m^2. The fuel bed was identical in all experiments and consisted of continuous wood cribs with a fuel load density of ~380 MJ/m^2 over a floor area of 174 m^2. The fuel load was chosen to enable comparison with earlier experiments studying travelling fire dynamics in equivalent non-combustible compartments *x-ONE* [28], *x-TWO* [29]. Table 1 summarises the key parameters of the *CodeRed* experiments without suppression.

2.1 INSTRUMENTATION

The fire development in the *CodeRed* experiments, both inside and outside the compartment, was captured via an extensive arrangement of instrumentation. A brief overview of the instrumentation used to capture the data presented within this paper is presented in this section. A more detailed description of the instrumentation used for each experiment can be found in the literature [11]–[13].

https://doi.org/10.52202/069179-0228

Table 1: *Summary of the key parameters of the three CodeRed experiments without suppression.*

Experiment		*CodeRed #01*	*CodeRed #02*	*CodeRed #04*
Date		09 Mar 2021	01 Jun 2021	14 Dec 2021
Internal floor area, A_F	[m^2]	352	352	352
Total area of openings, A_w	[m^2]	56.6	**28.3**	56.6
Exposed CLT area, A_{CLT}	[m^2]	352	352	**176.7**
Total internal surface area of compartment (floor, ceiling and walls), **inc. opening area**, A_t	[m^2]	980	980	980
Total internal surface area **exc. opening area**, A_T	[m^2]	923	952	923
Area-weighted average window height, h_{eq}	[m]	1.488	1.818	1.488
Opening factor as per Eurocode [30] $A_t/(A_w h_{eq}^{1/2})$	[m$^{-1/2}$]	14.2	25.6	14.2
Opening factor as per L&O'B [31] $A_T/(A_w h_{eq}^{1/2})$	[m$^{-1/2}$]	13.4	24.9	13.4
Modified opening factor as per [32] $(A_T-A_{CLT})/(A_w h_{eq}^{1/2})$	[m$^{-1/2}$]	8.3	15.7	10.8
Instrumented openings		W1, D1	W1, **W2**	W1, D1
TC in openings?		No	**Yes**	**Yes**
HFG opposite openings?		No	**6m, 8m**	**6m, 8m**

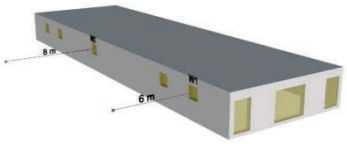
2.1.1 Internal instrumentation

To measure the gas temperature distribution within the compartment, 57 thermocouples (TCs) were distributed across the compartment, organised into 17 thermocouple trees. To account for the radiative heat flux from the fire, the recorded temperatures were corrected using a methodology referred to as the *β-method*, which was consistent across *x-ONE* [28], *x-TWO* [29] and *CodeRed*.

2.1.2 External instrumentation

Outside the compartment, non-combustible screens were installed above two openings as shown in Figure 1. The screens were annotated to allow approximation of flame geometry. Thermocouples and plate thermometers were installed on each façade screen. In *CodeRed #02* and *#04*, thermocouples were also positioned within the openings.
The thermocouples recorded data every 10 seconds (i.e., a frequency of 0.1 Hz) for *CodeRed #01* and every 5 seconds for *CodeRed #02* and *#04* (i.e., a frequency of 0.2 Hz). To reduce noise, all data from the thermocouples was smoothed using the Savitzky-Golay filter [33] available within SciPy, with a time frame of 60 s.

CodeRed #02



CodeRed #04

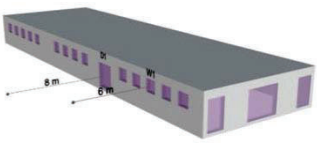


Figure 2: *Isometric models of CodeRed #02 and #04 showing instrumented openings.*

Unlike the internal thermocouple data, the temperatures recorded by the external thermocouples were not corrected to account for radiation received from the compartment fire, because the radiation received is expected to be small.
Heat flux gauges (HFGs) were installed opposite the centroid of the instrumented openings in both *CodeRed #02* and *#04*, as shown in Figure 2.
Two cameras were positioned opposite each instrumented opening to observe the external flame extension above the openings. Various other stationary cameras were placed around the compartment. Drones and handheld cameras were also used to give a dynamic view of the fire.

3 EXPERIMENTAL DATA

Papers covering the *CodeRed* experiments have been published which include detailed plots of internal and external temperature and heat flux data [11]–[13]. The following section presents additional data which has not yet been published.

3.1 HEAT FLUX OPPOSITE THE OPENINGS

Heat fluxes measured opposite the instrumented openings for *CodeRed #02* and *#04* are plotted in Figure 3. As expected, the heat flux measured by the HFG positioned 6 m opposite opening W1 recorded slightly higher heat fluxes in both experiments than the HFGs placed 8 m away from openings W2 / D1.
The peak heat flux recorded opposite W1 in *CodeRed #04* was 11.6 kW/m^2, compared with 7.9 kW/m^2 in *CodeRed #02* – an increase of 47 %. Despite the ceiling in *CodeRed #04* being partially encapsulated ceiling, it caused a higher heat flux opposite the same W1 opening. This is thought to be due to the greater number of openings in *CodeRed #04* radiating to the HFG.
The heat flux reading opposite the larger D1 opening was lower than the measurement opposite the window, contrary to expectations when considering the openings as uniform temperature emitters (i.e., ignoring external flames). The D1 opening had smaller external flames than the window openings which suggests the external flames were responsible for the higher measurement opposite the window opening W1 [13].

https://doi.org/10.52202/069179-0228

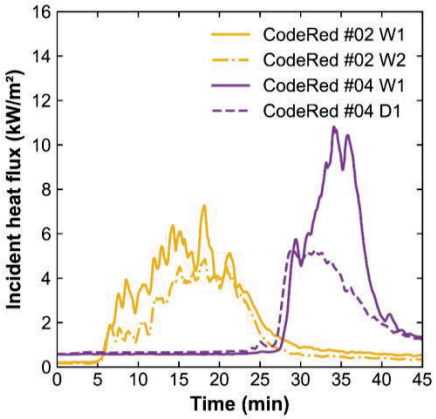

Figure 3: *Heat fluxes recorded at 6 m opposite opening W1 and 8 m opposite openings W2/D2 in CodeRed #02 and #04.*

Figure 3 also shows that peak heat fluxes occur later in *CodeRed #04* compared to *CodeRed #02*, due to the encapsulation slowing the growth phase and delaying the involvement of the CLT ceiling in the fire.

The fire duration in *CodeRed #02* was longer due to the reduced ventilation [12]. This is reflected in Figure 3, where an incident heat flux was registered opposite the openings for a period of around 20 minutes, compared to 10-15 minutes for *CodeRed #04*.

3.2 GAS TEMPERATURE IN THE OPENINGS

The temperatures recorded in the openings (shown in Figure 4) largely mirror the heat fluxes recorded opposite. Peak temperatures in the openings during both *CodeRed #02* and *#04* are very close to the 1040 °C that BR 187 assumes for "high fire load" compartments.

The temperatures in the window openings were broadly similar in each experiment. The door opening in *CodeRed #04* had a lower peak temperature, nearer 830 °C. This may be because the thermocouple for this opening was positioned lower in the opening (see Figure 1).

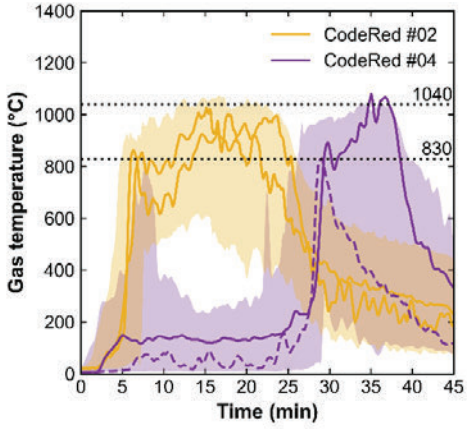

Figure 4: *Gas temperatures recorded during CodeRed #02 and #04. Lines show temperatures recorded within the windows (solid lines) and door (dashed line). Clouds show the range of corrected gas temperatures recorded inside the compartment.*

4 ANALYSIS

4.1 COMPARISON WITH 'STANDARD' LARGE-SCALE FAÇADE FIRE TESTS

As discussed in Section 1.3.1, large-scale testing of façade systems containing combustible materials (such as insulation or cladding) is a route to compliance for limiting external fire spread on the building of fire origin.

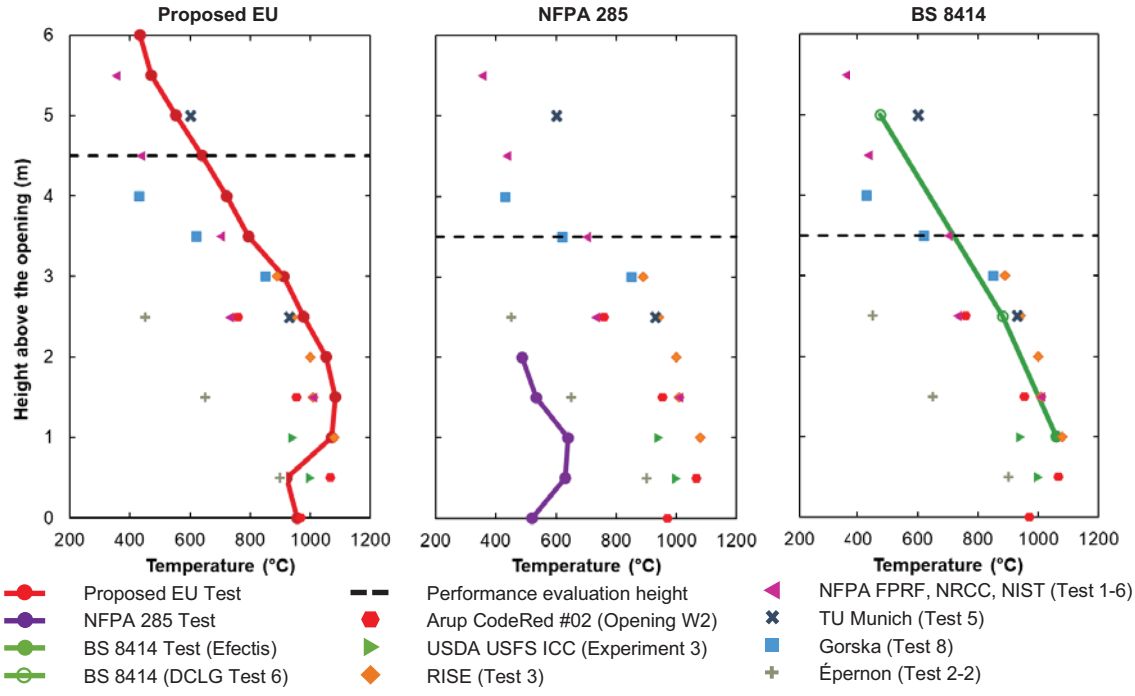

Figure 5: *Temperatures recorded outside timber experiments compared with those experienced during 'standard' large-scale tests.*

https://doi.org/10.52202/069179-0228

To understand whether the existing 'standard' test fires are severe enough to represent the external flaming observed in large scale experiments with exposed timber, the external temperature data from *CodeRed* and other notable mass timber experiments with external instrumentation has been compared to available data from large-scale industry 'standard' façade fire tests. Namely:

- the BS 8414 test.
- the NFPA 285 test, and,
- the proposed large-scale harmonised European (EU) test, which is broadly based on the BS 8414 test [34].

These tests were chosen as they are widely applicable, and data was available from tests which had either no façade system installed [34]–[36] or a limited combustibility façade installation only [37], such that the façade system itself did not contribute to the temperature data.

Figure 5 plots the 'standard' façade fire test data on top of maximum temperatures recorded at different heights outside the openings of a range of small- to large-scale mass timber compartment fire experiments.

The proposed EU test represents a relatively accurate upper bound of the external temperature data recorded during the mass timber compartment fire experiments. The only minor inaccuracy is at around 0.5 m above the top of the opening, which may be due to the thermocouple being placed outside the flaming region (e.g., if the flame did not adhere to the façade).

The BS 8414 test performs similarly, however has slightly lower temperatures than the proposed EU test. Some timber compartment fire external flame temperatures slightly exceed the BS 8414 test temperatures, by approximately 50-100 °C.

The NFPA 285 test, on the other hand, exposes the façade to much lower temperatures than those seen during timber compartment fire experiments. This is not surprising given the room gas burner follows the ASTM E119 *Standard Test Methods for Fire Tests of Building Construction and Materials* time-temperature curve. The temperatures recorded during calibration of the NFPA 285 test are lower than all external temperatures recorded during the mass timber compartment experiments chosen for this analysis. These findings are similar to those reported by [38].

4.2 COMPARISON WITH THE BR 187 RADIATION ASSESSMENT METHOD

As discussed in Section 1.3.2, one route for demonstrating compliance in terms of limiting fire spread from one building to another is completing a quantitative assessment of the expected incident radiation on a neighbouring building or boundary in case of a post-flashover fire. BR 187 describes one such method.

4.2.1 Temperature of emitter

BR 187 recommends adopting 830 °C for "low fire load" spaces (office, residential) and 1040 °C for "high fire load" spaces (industrial, retail) when selecting the emitter temperature. It also notes that "further work is required to investigate whether a higher temperature should be used for … buildings with higher levels of insulation" [22].

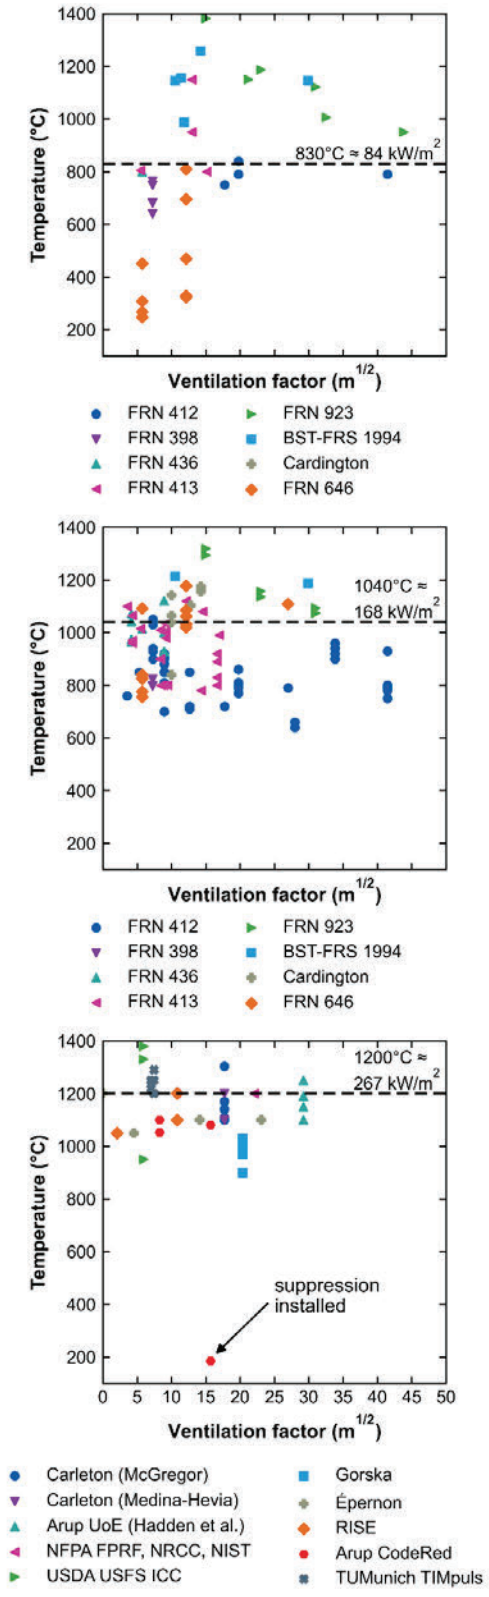

***Figure 6**: Maximum internal temperature versus ventilation factor for compartment experiments with (i) low fire load, (ii) high fire load, and (iii) exposed mass timber structure.*

https://doi.org/10.52202/069179-0228

Figure 6 presents the original data that the 830 °C and 1040 °C values within BR 187 are based on. A wide scatter of the underlying data from various small- and medium-scale compartment fire experiments is notable.
To determine a more suitable emitter temperature for mass timber compartments, a similar plot has been made for ten mass timber compartment fire experimental programmes. A general shift towards higher temperatures is evident through the three subplots. This suggests that a higher emitter temperature may be appropriate when conducting BR 187 assessments for buildings with exposed mass timber which do not benefit from e.g., sprinkler protection. 1200 °C has been chosen as a representative temperature for the analysis in this paper.

4.2.2 Geometry and emissivity of emitter(s)

BR 187 presents three methods to evaluate fire spread risk between buildings, namely, in BR 187 Section:
2.2.1. Enclosing rectangles,
2.2.2. Aggregate notional areas (or protractor method),
2.2.3. An alternative approach using look-up tables.
The enclosing rectangles method is typically used for modern buildings with a majority glazed façade whereby the entire glazed façade is modelled as an emitter.
Appendix A of BR 187 outlines the radiation calculation which is then made following configuration factor theory. Appendix B of BR 187 summarises Law and O'Brien's seminal work on external flaming [31], though in the experience of the authors, this is rarely applied in practice. BR 187 states that, when Appendix B is followed, the results are very similar to the 'conventional' analysis [22].

4.2.3 Parametric study of radiation to other buildings

A parametric study has been completed to evaluate various emitter temperatures, geometries and emissivities.

4.2.3.1 Scenarios modelled

Scenario 1 (BR 187 Appendix A)
In this scenario, all openings are modelled as radiating emitters, following BR 187 Section 2.2.1 and Appendix A. All other construction is assumed to be 'protected' i.e., constructed from fire resisting construction and not emitting radiation to the nearby building. The temperature of the emitters was taken as 830 / 1040 / 1200 °C.

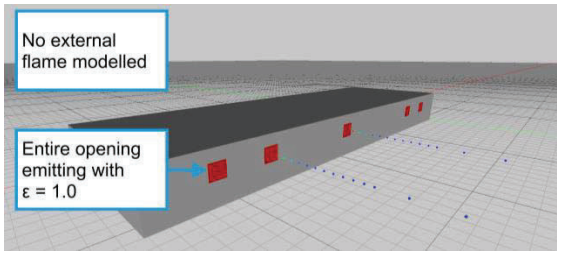

Figure 7: *Scenario 1 modelling parameters for CodeRed #02.*

Scenario 2 (BR 187 Appendix B)
Following BR 187 Appendix B, whereby the upper ⅔ of the opening(s) and an external flame are modelled as radiating emitters, both with the same emitting temperature. The emissivity of the opening, $\varepsilon_o = 1.0$. The emissivity of the flame, ε_f, calculated as per BR 187 / Law and O'Brien using $\varepsilon_f = 1.0 - exp(-0.3X_{ef})$, where X_{ef} is the thickness (depth) of the flame. Flame height was calculated based on the crib fuel load only (i.e., no CLT contribution was considered), as no generally agreed analysis method currently exists that determines the impact of the structural (CLT) fuel load on external flame height. Temperature of emitters is also varied as per (1).

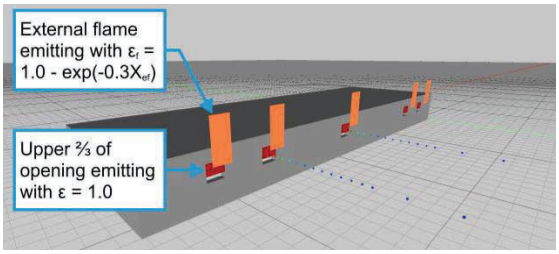

Figure 8: *Scenario 2 modelling parameters for CodeRed #02.*

Scenario 3 (BR 187 App. B, with $\varepsilon_f = 1.0$)
The same as (2), but with an assumed worst-case emissivity of the external flame, $\varepsilon_f = 1.0$, used.

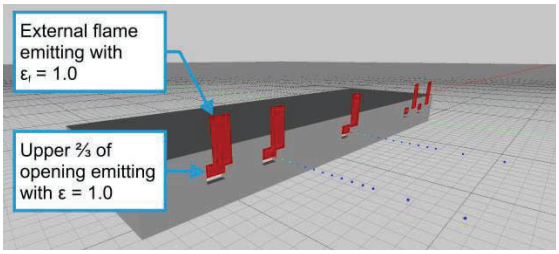

Figure 9: *Scenario 3 modelling parameters for CodeRed #02.*

Only Scenarios 1 and 3 are presented in this paper, due to the quantity of data and because the predictions in Scenario 2 were very similar to Scenario 1. This aligns with BR 187 Figure B4, which also shows very similar predictions between the two methods.

4.2.3.2 A note on flame emissivity, ε_f

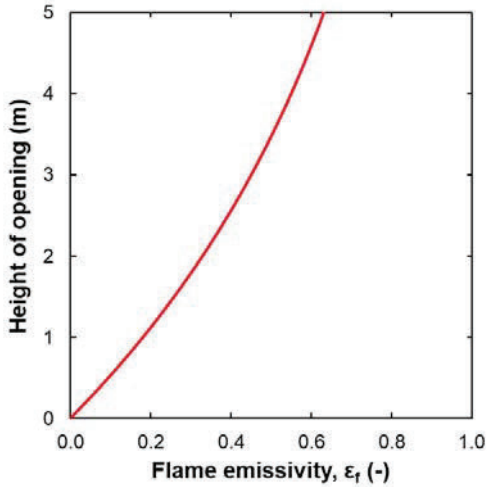

Figure 10: *Relationship between opening height and ε_f.*

Figure 10 shows the BR 187 correlation between the emissivity of the flame and the height of the opening (which determines the flame thickness (depth), X_{ef}).

https://doi.org/10.52202/069179-0228

In *CodeRed*, the window openings were 1.0 m tall, which results in a calculated flame emissivity of 0.18, meaning the contribution of the external flames to the incident heat flux calculated opposite is minimal when following BR 187 Appendix B. This is also the case for most real-world design scenarios. For example, a fire in a single-storey compartment with 3.0 m tall floor-to-ceiling glazing (assuming full glass breakage) would result in flames with an emissivity of 0.45. This would reduce the heat flux calculated from the flame emitter by over half.

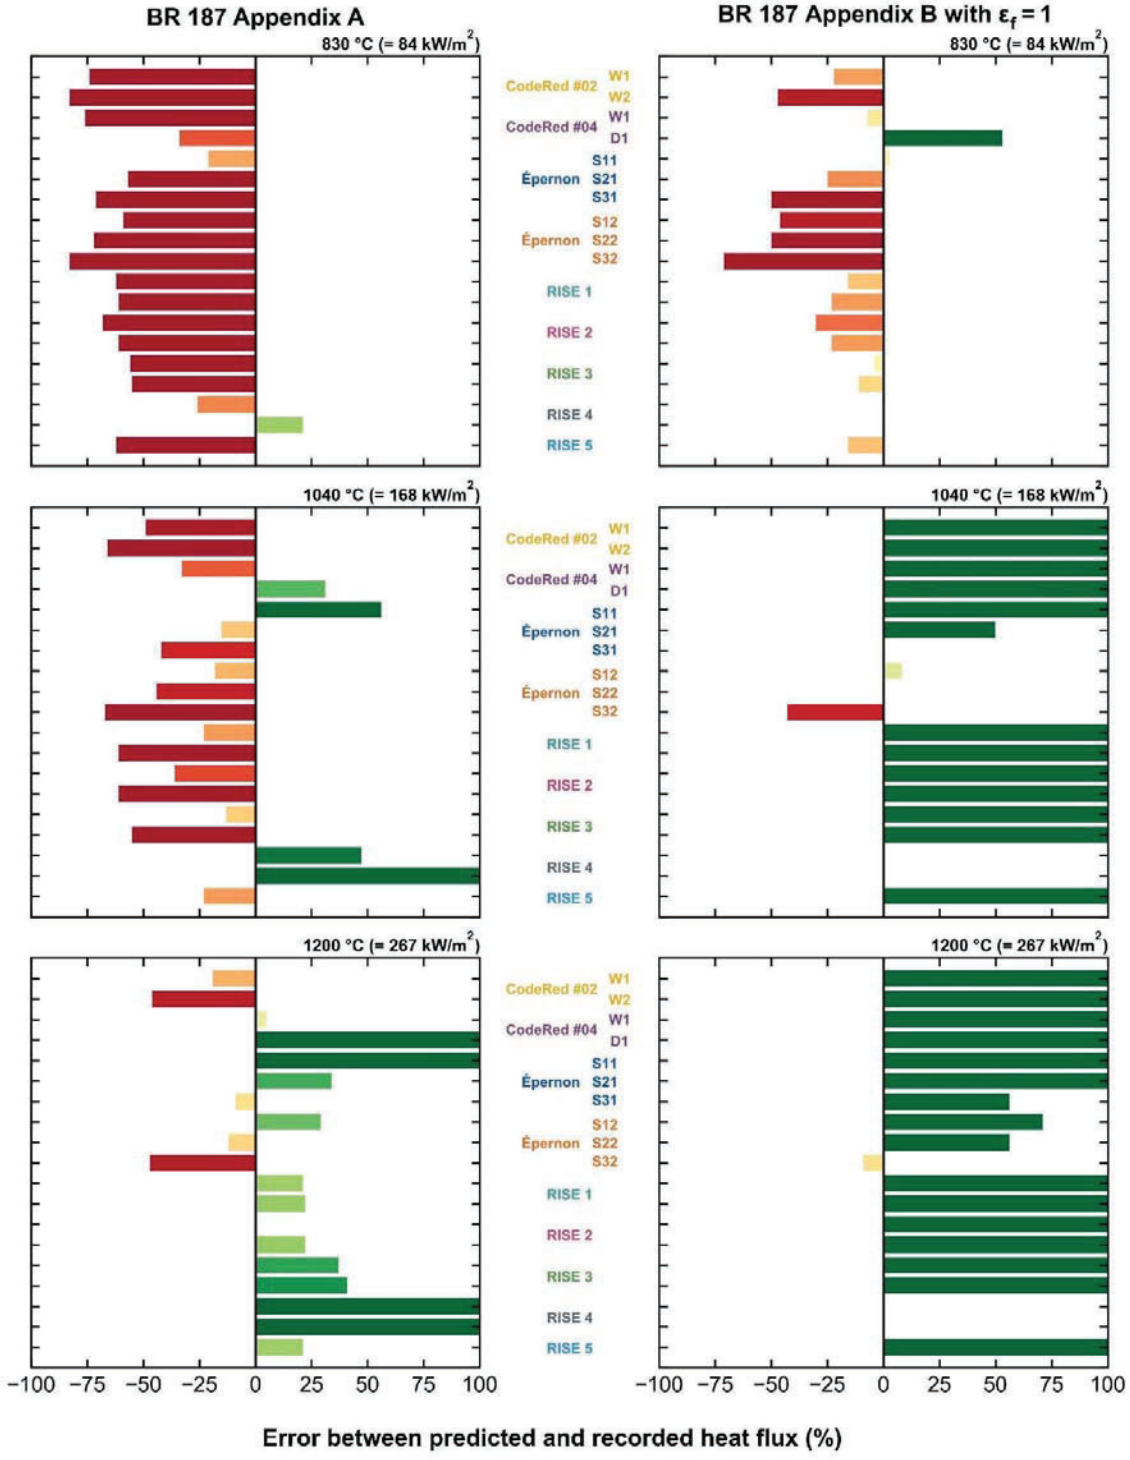

Figure 11: *Bar charts showing percentage error between predicted heat fluxes and the peak heat fluxes recorded during a range of timber compartment fire experiments. An error of +100% represents a heat flux prediction which is twice the recorded heat flux.*

https://doi.org/10.52202/069179-0228

4.2.3.3 *Compartment experiments analysed*

The parametric study was applied and compared to:

- Large-scale experiments *CodeRed #02* and *#04*, which had external HFGs as per Section 2.1.2.
- Medium-scale timber compartment fire experimental programmes by RISE and Épernon, which also had external HFGs as per [26], [27].

RISE Test 4 was not modelled following BR 187 Appendix B because the flame height calculated was so low as to be negligible. Sprinklers are not considered in this work as none of the compartment experiments analysed had them installed.

4.2.3.4 *Comments on results*

Figure 11 presents the results from the parametric analyses using bar charts. The plots visualise the performance of the predictions made following BR 187 compared to the actual heat fluxes recorded during the experiments, as percentage error between predicted heat fluxes and the peak heat fluxes recorded during a range of timber compartment fire.

Figure 11 shows:

- Using an emitter temperature of 830 °C resulted in significant underpredictions of heat flux across the experiments analysed. 18 out of 19 predictions were low when modelling the opening only as an emitter. 15 out of 17 predications were low when following BR 187 Appendix B (i.e., modelling the external flame) and conservatively assuming the flame emissivity is 1.
- Using an emitter temperature of 1040 °C made only a small improvement to the predictions. When modelling only the opening, three predictions were satisfactory (i.e., overpredicted with a reasonable factor of safety). However, one prediction largely overpredicted, and the other 15 predictions were low.
- When the modelled geometry was adjusted following Appendix B (i.e., with a flame at the same temperature as the opening (1040 °C) and with an emissivity of 1), the predictions swung the other way. 12 predictions overpredicted significantly. The same observation (albeit slightly worse) is made for the 1200 °C emitters following Appendix B.

The best predictions for heat flux received opposite the mass timber compartments analysed were from the models which assumed emitters representing the opening geometry only (i.e., without external flames) at a temperature of 1200 °C. 10 out of 19 of these predictions (i.e., more than 50%) were satisfactory (made overpredictions by a reasonable factor of safety). In four cases, significant overpredictions were made while underpredictions were made in only five cases.

5 DISCUSSION

5.1 APPLICABILITY OF EXISTING LARGE-SCALE 'STANDARD' FAÇADE TESTS

External temperature data recorded during seven mass timber compartment fire experiments has been gathered and presented. This data has been compared to temperatures recorded in front of the façade during three 'standard' industry façade fire tests – namely BS 8414, NFPA 285 and the proposed harmonised European test – to evaluate if the existing tests subject façade system to an appropriate fire severity where a building contains exposed mass timber.

The comparison showed that the proposed harmonised European test has the most severe external flame, which envelopes the data from mass timber compartment experiment well: 89% of the data points from mass timber compartment experiments were exceeded by the test.

The BS 8414 test also showed relatively good enveloping of the data: 65% of the data points from mass timber compartment experiments were exceeded by the test.

However, it should be noted that the BS 8414 data was more limited than the proposed European test data. Only three data points were available, from two different sources. Therefore, the observations are less robust than those made when comparing to the proposed European test. The proposed European test is based on BS 8414, and broadly represents that test, so similar observations should be expected (as was evident in this work).

The NFPA 285 test was shown to have a lower external flame severity than all the mass timber compartment experiments reviewed (i.e., it didn't envelope any of the data points). NFPA 285 is referenced in the IBC and NFPA 5000, for use with buildings that include combustibles as part of the exterior wall, located over 18m in height. The applicability of the NFPA 285 test for analysing the performance of façades of buildings that include large areas of exposed mass timber structure (interior to the building) is therefore questionable and future editions of this standard will need to address the available experimental data.

5.2 APPLICABILITY OF EXISTING RADIATION CALCULATION METHODS

The underlying data behind the "low fire load" and "high fire load" assumptions within BR 187 for compartment temperature has been presented. This has been compared to a new dataset, of the peak internal compartment temperatures recorded during a selection of ten mass timber compartment fire experimental programmes. The general upward shift indicates a hotter emitter temperature may be appropriate for buildings with large areas of exposed mass timber and no beneficial fire protection measures such as sprinkler protection. 1200 °C was chosen as a "very high fire load" compartment temperature. This enveloped most of the timber compartment experiments reviewed, with a scatter no greater than seen in the underlying data for non-combustible compartment experiments.

Based on this, a parametric analysis has been undertaken to evaluate the accuracy of existing BR 187 calculation methods when applied to mass timber compartment fire experiments. The analysis evaluated three different emitter temperatures (830 °C, 1040 °C and 1200 °C), two geometry combinations (openings only, openings and flame) and three emissivity combinations ($\varepsilon_o = 1.0$, $\varepsilon_o = 1.0$ and $\varepsilon_f = 1.0 - exp(-0.3X_{ef})$, and $\varepsilon_o = 1.0$ and $\varepsilon_f = 1.0$). A total of 53 calculations were made across three different mass timber compartment fire experimental series.

https://doi.org/10.52202/069179-0228

The analysis showed that, if the existing assumptions within BR 187 for temperatures of "low fire load" and "high fire load" compartments were applied to spaces with large areas of exposed mass timber, underpredictions can be expected, even when modelling the external flaming following Appendix B. Adjusting the Appendix B external flaming method to include a flame emissivity of 1.0 was found to be overly conservative.

The best predictions for heat flux were made following the existing BR 187 enclosing rectangles method using a "very high fire load" compartment emitter temperature of 1200 °C. Whilst the authors recognise the 'crudeness' of the BR 187 method, it has been the focus of this paper because it is a popular method for assessing the risk of external fire spread between buildings in the UK. The findings are based on first principles radiation analyses, so could be adopted elsewhere where similar quantitative design methods are permitted [21].

Other more sophisticated approaches, such as the probabilistic method outlined in BR 187 IP 3-16 [39], will require further investigation to determine if these methods are appropriate on timber buildings, or if further amendments are needed.

It is noteworthy that the current draft of EN 1995-1-2 [40] proposes a modified version of the existing external flame correlation in EN 1991-1-2 [30] and BR 187 Appendix B to account for the structural fuel load present in timber buildings. This method has not been assessed as part of this study though further review against the available datasets are recommended.

6 CONCLUSIONS

Many timber compartment fire experiments, including *CodeRed*, have shown that large external flames and higher compartment temperatures can be expected from compartments with exposed mass timber where there is no automatic fire suppression installed. This paper investigates the impact of this phenomenon on: (i) the applicability of large-scale 'standard' façade tests, and (ii) radiation assessments to neighbouring buildings.

Firstly, novel external temperature and heat flux data from the *CodeRed* experiments is presented. Then, this data is supplemented with temperature data from a collection of ten medium- and large-scale compartment fire experiments with varying areas of exposed mass timber, and compared to temperatures recorded outside three industry 'standard' large-scale façade fire tests. Two of the large-scale tests, the proposed large scale harmonised European test and the BS 8414 test, generally enveloped the timber data points well. These large-scale tests therefore are reasonable tests to use for façade systems on buildings with large areas of exposed mass timber. NFPA 285 did not envelope any of the timber compartment fire data points.

The second focus of the paper is existing radiation calculation methods for assessing the heat flux that may be expected on neighbouring buildings/boundaries. When carrying out such a calculation, the temperature of the emitter is a key parameter. Temperature data which underlies existing assumptions within BR 187 is presented and compared with temperature data from a selection of 10 mass timber compartment fire experiments. An obvious trend towards higher peak internal temperatures is observed, which indicates that a higher emitter temperature may be appropriate for buildings with large areas of exposed mass timber.

Based on this, a parametric analysis has been completed to assess the performance of the BR 187 calculation method (the current design method in the UK for evaluating the external fire spread risk between buildings). Heat flux data recorded opposite three mass timber compartment fire experimental programmes is compared to predictions made following BR 187. It was found that simply increasing the emitter temperature to 1200 °C yielded the best results based on the test data available to the authors. Should further data come to light that contradicts the findings of this analysis, then this temperature may need to be revaluated.

Whilst this paper has focused on the BR 187 method, the findings are based on first principles, therefore will apply to other countries which have similar quantitative analysis methods.

ACKNOWLEDGEMENT

This research has been fully funded by Arup and was undertaken in partnership with Imperial College London. The experiments were carried out at CERIB's Centre d'Essais au Feu (Fire Testing Centre) in France throughout 2021. All CERIB staff and PhD students from Imperial College London that were fundamental in the successful completion of the experiments are gratefully acknowledged. Clara Bermejo Bordons (Engineer at Arup) was fundamental in the production of Figures 1 and 2 in this paper. The authors would also like to acknowledge Gary Walker (now retired fire safety engineer at Arup) for the preliminary analysis into BR 187 and the collation of the underlying data sources. We would also like to extend our heartfelt thanks to the steering group guiding the project, which includes Dr Susan Lamont, Andrew Lawrence, and Dr Clare Perkins. The contribution of Dr Eglė Račkauskaitė in the design of the experiment is also acknowledged.

NUMERICAL ANALYSIS ON THE FLEXURAL PERFORMANCE OF COMPOSITE STEEL-TIMBER BEAMS UNDER FIRE CONDITIONS

Zhiyuan Liu[1,2], Binsheng Zhang[1,*], Huijuan Jia[2] and Tony Kilpatrick[1]

ABSTRACT: Recently, a novel type of composite structure, composite steel-timber (CST) structure, has attracted much attention by connecting steel and timber in an effective way to form composite structural components. However, the relevant research is lacking, especially in structural fire design and analysis. In this study, based on the sequentially coupled method, commercial finite element software ABAQUS was used to numerically simulate the dynamic performances in the temperature field and the flexural behaviours in the displacement field of a novel CST beam with steel element embedded within the Glulam and connected by adhesives and bolts under standard fire for two hours. During the numerical simulations, the temperature distributions within the CST beam were explored, and the flexural performances of the beam in the displacement field were examined. Through the comparative analysis, the temperature distributions of the embedded steel beam and the surrounding Glulam beam under one-hour standard fire verified the advantages of this type of CST beam in structural fire design. Parametric studies on the fire resistance of the CST beam were also conducted by adjusting the bolt spacing and the protection thickness of Glulam. The obtained results indicated that reducing the bolt spacing and thickness of the Glulam protection layer would have an adverse effect on the temperature distributions in the embedded steel element to a large extent.

KEYWORDS: composite steel-timber (CST) structure; structural fire design and analysis; numerical simulation and analysis; bearing capacity; refractory limit

1 INTRODUCTION

Since enhanced structural effectiveness and combined material properties, composite structures, especially composite concrete-steel structures have been thoroughly researched and form relatively complete structural systems. Recently, composite steel-timber (CST) structures have attracted more attention from researchers and gained initial engineering applications in Japan [1,2]. This innovative composition mainly combines advantages of high strength and excellent ductility of steel and decent sustainability and fire resistance of timber while potentially helping overcome the instability and fire susceptibility of steel members and brittle behaviour of timber components [3-6].

Based on the literature review, it is found that current researches are focusing on the structural performance, bearing capacity, initial stiffness and failure modes of various CST structural components, i.e. beams [7-9], columns [10-13], shear walls [14], flooring systems [15] and their connections [16,17] under static or cyclic loading conditions by experiments and/or numerical simulations and parametric studies to investigate the potential impacts brought by the adjustment of steel/ timber members' geometry and shear connectors' spacing on their ultimate load-bearing capacity. However, there are few investigations and analyses related to structural fire design and analysis of the CST structure.

Considering potential structural and economic losses brought by fire accidents in buildings, therefore, during structural design, fire safety has been regarded as a basic requirement and should be equally treated as the load carrying capacities [18]. Two methods are recommended for structural fire design and analysis based on Eurocodes. In practice, prescriptive approach is one of the commonly approaches recommended by Eurocodes and can be further divided into two categories, i.e. standard fire test method and simplified calculation method. Both methods for timber and steel materials are described in Parts 1-2 of Eurocodes 3 and 5 in details [19,20].

In this study, comprehensive numerical simulations were conducted by using ABAQUS to investigate the flexural performances and fire resistances of a novel CST beam under fire conditions with different bolt connection spacings and timber protection thicknesses by following general approaches indicated in Eurocodes 3 and 5.

2 PROFILES OF THE CST, GLULAM AND STEEL BEAMS

CST beams for simulations in this study were assumed to be used in Canada, where the annual average temperature

https://doi.org/10.52202/069179-0229

is relatively low. Thus, the ambient temperature could reach 0℃. In addition, the composite beam could be integrated with timber or concrete floor slabs to form composite flooring systems and hence the CST beam could be seen as three sides directly exposed to fire in the structural fire analysis [21]. For simplification, each type of beam specimens was modelled and analysed for a unit length.

2.1 STANDARD CST BEAM

In Figure 1, the proposed standard CST beam was mainly composed of three parts: Glulam beam, steel beam and bolts. The Glulam beam was assumed to be formed by bonding ten Glulam blocks made of Canadian beech [22] with epoxy ethane adhesives. The steel beam was the steel I-beam section, with the dimensions of length × height × width × flange thickness × web thickness = 1000 mm × 150 mm × 100 mm × 8 mm × 6 mm, embedded in the middle of the Glulam beam with adhesives, and the outer edges of the steel beam flanges had a 50 mm distance to the outer edges of the Glulam beam. Common M20 bolts were selected to strengthen the composition, and the bolts had a 200 mm spacing in the longitudinal direction and penetrated into the composite beam.

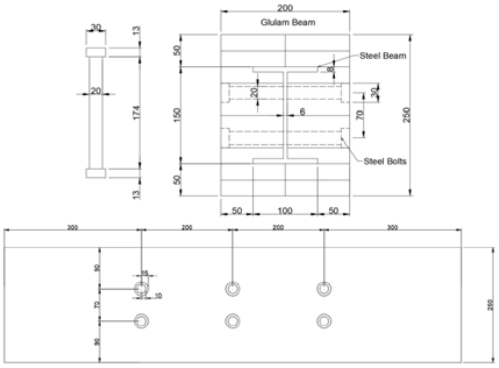

Figure 1: *Profiles of the CST beam model and M20 steel bolts for the standard CST beam*

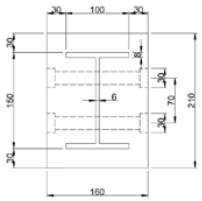
2.2 COMPARED GLULAM AND STEEL BEAMS

As indicated in Figure 1, the Glulam and steel beams for comparison had the same sizes as the standard CST beam.

2.3 CST BEAMS FOR PARAMETRIC STUDY

As to the CST beams for the parametric study, illustrated in Figure 2, the bolt spacing was reduced from 200 mm to 150 mm or the protection thicknesses of the outer Glulam layer for the steel beam along the height and width were reduced from the original 50 mm to 30 mm.



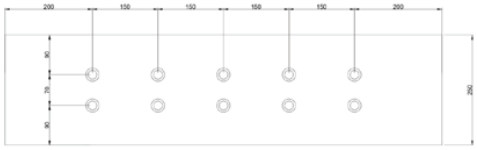


Figure 2: *The profiles of the parametric CST beam models*

3 FINITE ELEMENT ANALYSIS (FEA)

From the experimental test results, Tsai [13] and Zhang [26] indicated that the CST specimens did not have large structural deformations and damages that affected the heat transfer and temperature field distributions in the process of fire. Considering the accuracy in the thermal-solid coupling simulations and analyses on this kind of CST beam model and computational costs, the commercial finite element software ABAQUS and the sequentially coupled analysis method recommended by some previous researchers [26,27] was adopted.

Therefore, the temperature field would be first operated and analysed based on the ISO standard fire curve [28], and then the calculated temperature results were imported into the displacement field as the predefined field to calculate the final bending performances of the CST beams after being exposed to fire for 2 hours.

3.1 THE ESTIMATION METHOD

The material properties, including thermal and mechanical properties of steel and timber, show variations in response to elevated temperatures and their specific relationships would be input into ABAQUS in the tabular form based on the relevant specifications and the existing research data.

For steel, indicated by BS EN 1993-1-2 [19], its density ρ could be seen as a constant value when the surrounding temperature rises, i.e. ρ = 7850 kg/m^3, and the specific heat and thermal conductivity are shown as functions of temperature, respectively. Similarly, BS EN 1995-1-2 [20] also gives the suggested thermal parameter values for timber materials after fully considering water evaporation, wood carbonisation decomposition and material composition changes during combustion.

As for the mechanical properties, steel was regarded as an isotropic material and an elastic-linear – perfectly plastic model was adopted [27]. Generally, timber materials for Glulam have different properties in normal, radial and tangential directions and can be regarded as an ideal anisotropic elastoplastic body with suggested engineering data [22] for simulations.

3.2 SETUP OF THE NUMERICAL MODELS

During the modelling, the influence of adhesives on the temperature field was not considered. It was assumed that there was no air layer between the components. Because the thickness of the adhesives layer was small, and the heat from the external fire site would be quickly transferred to the interior components. The 3 mm fine mesh around the bolt holes and the 15 mm loose mesh for other areas were applied according to the configuration

https://doi.org/10.52202/069179-0229

characteristics of the parts. The final assembled model is shown in Figure 3.

Transient heat transfer and general static steps are defined for the thermal and mechanical models, respectively. Besides, the external fire site should be applied in the temperature field by defining an amplitude based on the standard fire curve, and in the displacement, the uniformly distributed load should also be directly applied on the top surface of the composite beam in the pressure form of 100 kN/m^2. As to the boundary conditions, the absolute zero temperature, the Steve-Boltzmann constant (5.678×10^{-8} W/m^{2}K^4) and the ambient temperature, the emissivity values (0.7 and 0.8 for steel and timber) and convection coefficient (25 W/m^2°C) [27] should be defined in advance to facilitate the calculations and analyses of heat conduction, radiation and convection in the temperature field. As to the contact definitions, in the normal direction, hard contact was defined to apply no restrictions to the pressures transferred between timber and steel and the Coulomb's friction model [26] with the friction coefficients of 0.3 and 0.001 for steel-timber and steel-steel contacts. During the flexural performance analysis, both ends of the composite beam in two directions shall be restricted, for the simulation requirement of a simply supported beam. More modelling details can be found from the ABAQUS User Manual [24].

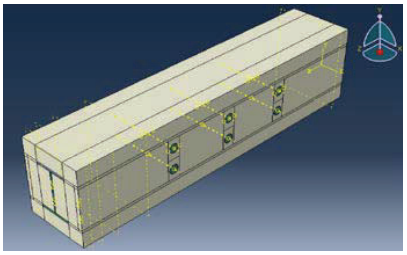

Figure 3: *The final assembled CST beam model in ABAQUS*

4 NUMERICAL SIMULATION RESULTS AND ANALYSES

4.1 TEMPERATURE FIELD ANALYSES

4.1.1 Temperature distributions

As shown in Figure 4, the temperature distributions for the Glulam, steel beam and steel bolts are presented and analysed.

The Glulam serving as the protection layer, firstly carried out heat transfer between itself and the surrounding fire environment. Therefore, the calculated node temperatures of the outermost layer of the Glulam quickly reached a high value, up to 1000°C, while the top surface of the Glulam beam was not directly affected because it directly contacted with the floor slab. The overall temperature distribution presented a trend that node temperatures would decline from the outside towards the centre, where they had the lowest values, which is consistent with the test results in the literature [26].

The web and lower flange of the steel beam were the parts with the highest temperatures in the whole beam, namely 350°C ~ 420°C. The bolt holes in the middle of the web, where steel bolts were through the beam and carried out the heat transferred from the external fire field, induced the rises in the node temperatures near the bolt holes of the steel webs, especially around the bolt holes near the bottom of the CST beam, which bear the double heat penetration from all three heat transfer directions of the fire field and from the external bolts. The upper flange at both ends of the steel beam was far away from the thermal penetration of the bolt holes and was insulated by the outer Glulam beam. Therefore, the node temperature did not increase significantly and remained at around 150°C.

All six bolts show the characteristics of high temperatures at both ends and lower temperatures in the middle. The reason for this is that both heads and nuts of the bolts were exposed first to fire conditions, and were surrounded by the Glulam beam, so the heat would mainly extend along the bolt direction, which was in line with the engineering practice. Furthermore, the temperature distributions of the lower bolts were slightly different from the upper ones and more unfavourable, which were consistent with the differences in the temperature distributions of the bolt hole areas adjacent to the lower and upper flanges of the steel beam, due to the uneven heat transfer from the fire field onto three sides of the CST beam. However, the temperatures of the central bolts at the mid-span were higher than those of the bolts near the supports, which may be due to the superposition effect of the temperature penetrations from the bolts on the left and right sides.

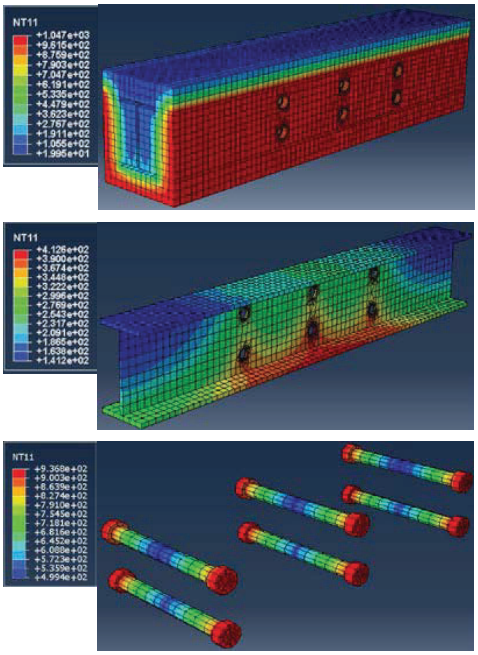

Figure 4: *Node temperature contours of the Glulam beam, steel beam and steel bolts at t = 120 min*

4.1.2 Assessment of the protection ability of Glulam

In Figures 5 and 6, the temperature distribution results at t = 15 and 60 min are presented and further analysed, combined with results illustrated in Figure 4, in terms of the protection effects brought by the external Glulam beam.

When *t* is equal to 15 min, according to the standard fire curve, the ambient temperature had completed nearly 70% of the final temperature loading, and the heads and nuts of the steel bolts had reached around 260°C. However, the overall temperature of the steel beam was no higher than 30°C because the outer Glulam beam provided good insulation, which was highly consistent with the Tsai's test results [13], and the protection effect of the outer Glulam was reliable and effective within the first 15 minutes under the fire conditions. In addition, due to the heat conduction of the bolts through the CST beam, the temperature growth of the steel beam started from the bolt holes in the steel web and gradually extended to the flanges and both ends of the steel beam.

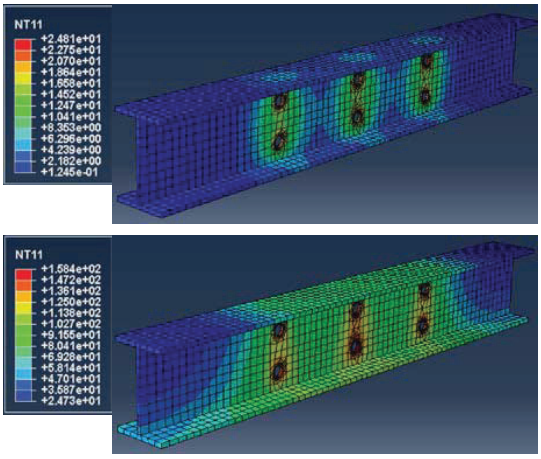

Figure 5: *Node temperature contours of the steel beam at t = 15 min and 60 min.*

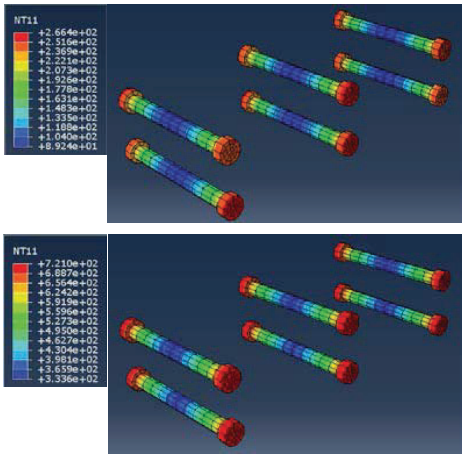

Figure 6: *Node temperature contours of the steel bolts at t = 15 min and 60 min.*

When the standard fire was applied for 60 minutes, the ambient temperature gradually increased to 945.3°C. At this point, the temperature field near the areas of the bolt holes in the middle of the steel beam became significantly superposed, and the temperatures in the areas at the mid-span were the highest, which was presented by the software with the large red block. In addition, the mid-span temperature "diffusion" increased further and extended to the lower flanges at both ends of the beam, but the temperatures in the upper flanges at both ends remained below 50°C. Combined with the temperature field distributions of the bolts at this time, the node temperatures in the middle of the bolts had reached the temperature range of 330°C ~ 400°C, while the maximum temperature in the middle of the steel beam was only about 160°C, presenting a "gap" of heat transfer. This may be because when the bolts temperature rose rapidly, part of the heat was absorbed by the surrounding Glulam beam, while the rest was absorbed by the steel beam. In other words, the internal Glulam played a vital role in absorbing and blocking the fire heat transferred from the bolts.

After the 2-hour burning, the temperature increment of the external fire site levelled off, reaching 1049°C, and the heat transfer lasted for quite a long time. However, from Figure 5, the highest temperature zone of the steel beam occurred in the web and lower flange of the mid-span, reaching about 410°C, while the temperatures in most areas were in the range of 200°C ~ 300°C. This distribution characteristic was similar to that in the 60-minute stage where the temperatures at both ends were low and those at the mid-span were high. According to the typical stress-strain curves [29] of the steel (see Figure 7) at elevated temperatures, the mid-span of the inner steel beam could retain most of its yield strength, and more strains could be spared for deformations, showing stronger plasticity even in the 120-minute fire stage.

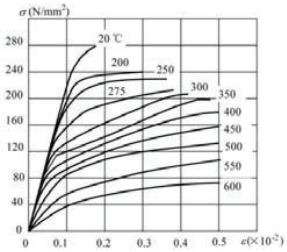

Figure 7: *Typical stress-strain curves of steel at elevated temperatures [29].*

4.1.3 Analysis of the charring results of the Glulam

For the ABAQUS simulations, the timber elements with temperatures exceeding 300°C should be regarded as the carbonised layers. Charring rate, referring to the ratio of the depth of the charring layer to the fire exposure time, is an important index to verify the accuracy of the numerical model. However, the charring rate is not constant [26], and the formation of the charring layer hinders the heat transfer to the interior. Therefore, with the increase of the heating time, the charring rate decreases.

The charring depths and charring rates were roughly calculated (based on the bottom surface) by analysing the temperature distributions in the CST beam section in four time points (see Table 1). According to the calculated data in the table, it can be found that the charring depth increased with the increase of the acting duration of the standard fire curve, while the charring rate decreased as the process continued, which would basically conform to

https://doi.org/10.52202/069179-0229

the law mentioned above. Besides, with the increase of the charring depth, the outer Glulam gradually lost its ability to protect the steel, and Figure 8 shows that a 50 mm outer Glulam protection layer for the steel beam was basically burned out completely. If the fire temperature kept rising, the temperatures in the steel beam would quickly increase, eventually causing the complete strength loss of the steel.

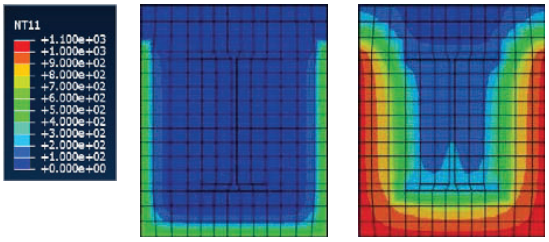

Figure 8: *Temperature field distributions of the CST beam section at t = 15 min and 120 min.*

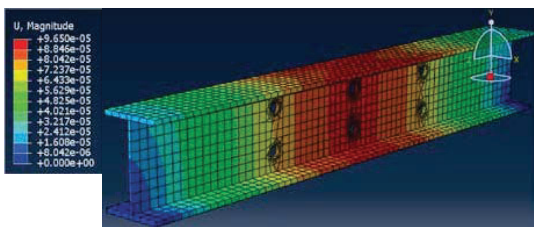
Table 1: *Summary of the charring depth and rate results at the selected four time points*

Time duration (min)	Charring depth (mm)	Charring rate (mm/min)
15	13.3	0.89
30	20.2	0.67
60	30.1	0.50
120	49.8	0.42

4.2 DISPLACEMENT FIELD ANALYSES

4.2.1 Analysis of the simulation results

Figure 9 illustrates the 3D displacement and von Mises stress contours of the embedded steel beam. For the simulated displacement results, the maximum displacement appeared in the mid-span region and decreased from that region toward both ends. This was consistent with the displacement distribution of a simply supported steel beam under bending actions at room temperature. Under the uniformly distributed load of 100 kN/m^2, i.e. 10 kN/m line load, the maximum displacement was 9.65 × 10^{-5} m. According to the linear relationship between the maximum mid-span displacement and bending loads applied onto the steel beam, combined with the generally recognised deflection limit of L/360 under service loading, the maximum load capacity could be estimated to be close to 300 kN/m, which also matches the engineering practice. Therefore, this served as an initial validation for the established model and based on this, reflected a good deformation capacity for the embedded steel beam subjected to the 2-hour fire conditions.



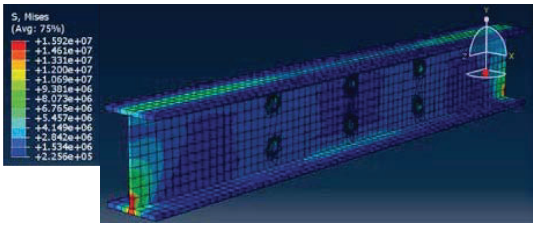


Figure 9: *Simulated 3D displacement and von Mises stress of the embedded steel beam in the displacement field.*

The 3D von Mises stress contour shows that lower flange at the two ends and the upper flange in the middle span region of the steel beam sustained unfavourable stress distributions. This may be because the steel beam at this moment had a tendency of buckling on both sides of the upper flange under the applied uniformly distributed load, and the lower flange in the middle span, subjected to the highest bending moment and tensile stress, was weakened by the bolt holes in the web, resulting in strong stress concentrations. The general trends matched the original expectations and were similar to the generally recognised stress distributions of the steel beam under the bending action. However, due to the restrictions of the outer residual timber beam, the stress distributions of the embedded steel beam were not obvious.

4.2.2 Manual estimation calculations

Figure 10 illustrates the simplified calculation diagram of the steel beam and the geometrical parameters of its cross-section by ignoring the imperfection effect caused by the bolt holes in the steel web. Therefore, the second moment of area and the sectional modulus of the steel beam could be calculated as 9277185 mm^4 and 123696 mm^3. It was also assumed that the UDL acting on the steel beam was w in kN/m, including the self-weight of the steel beam and the variable loads on the upper flange.

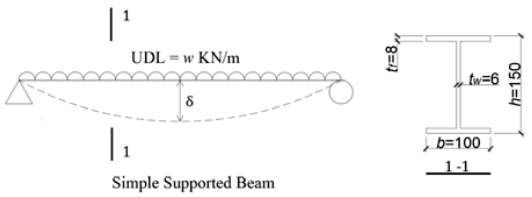

Figure 10: *Illustration of the simply supported embedded steel beam under the UDL.*

Under fire conditions, the maximum temperature of the embedded steel appeared in the lower flange at the mid-span, which coincided with the maximum bending moment and deflection point of the steel beam under the static loading at room temperature. In this case, the load bearing capacity calculation would mainly be focused on the mid-span location. The temperature at the mid-span of the steel beam reached 416°C after a two-hour standard fire. According to BS EN 1993-1-2 [19], both the elastic modulus and yield strength of steel would drop at this temperature and the reduction coefficients could be applied as 0.685 and 0.97, respectively, i.e. E = 0.685 ×

210000 = 143850 N/mm^2 and f_y = 0.97 × 400 = 388 N/mm^2.
According to BS EN 1993-1-1 [30], the bending moment capacity could be related to the UDL as

$$M_{c,Rd} = \frac{W_{pl} f_y}{\gamma_{M0}} = \frac{123695.80 \times 388 \times 10^{-6}}{1.0} = M_{Ed} = \frac{w L^2}{8}$$

i.e. $M_{c,Rd}$ = 47.99 kNm and w = 383.95 kN/m.
Under the UDL w = 383.95 kN/m, the mid-span deflection δ_{max} would be:

$$\delta_{max} = \frac{5 w L^4}{384 E I} = 3.75 \text{ mm} > \delta_{limit} = \frac{L}{360} = 2.78 \text{ mm}$$

The steel beam failed due to the exceeded deflection under the UDL w = 383.95 kN/m. Thus, letting the maximum deflection at the mid-span be equal to its limit would yield the maximum UDL the steel beam could support, that is, w = 284.70 N/mm = 284.70 kN/m.
At this time, although the bearing capacity could reach up to 383.95 kN/m, the deflection would exceed its design limit. Therefore, if the deflection requirements were met, the final bearing capacity would still need to be further reduced. However, in practice, since the outer Glulam beam had not completely burned out, it serves as a T-shape coating outside the steel beam to limit its excessive deflection and the buckling failure of its upper flange and web. Thus, the ultimate bearing capacity would still be governed by the bending moment capacity.

4.3 COMPARATIVE ANALYSES

4.3.1 Steel Beam

A steel beam model with the same size as the embedded steel section in the standard CST beam was created in ABAQUS (without bolt holes), with the similar step, amplitudes and interactions assigned as well. The calculation results for t = 15 min were selected and are shown in Figure 11 below.
It can be seen from the figure that, without the protection of the outer Glulam, the temperature of the steel beam rapidly reached above 600°C within only 15 min, and the highest temperature in the web was nearly 700°C. The steel beam exhibited "thermo-plastic" phenomenon, and most of the strength was lost. At this moment, even a small load was applied on the steel beam, its web would quickly buckle due to insufficient strength and stiffness, leading to the failure of the steel beam.

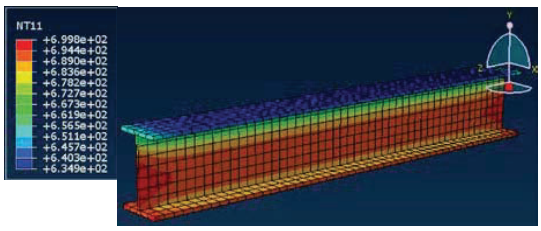

Figure 11: *Node temperature contour of the pure steel beam at t = 15 min.*

4.3.2 Glulam beam

The Glulam beam model without embedded steel and through bolts was created in ABAQUS with the same size as the external Glulam beam of the standard CST at t = 15 min and 60 min.
It is apparent that the overall temperature distributions and charring depth of the Glulam beam, which was about 16.7 mm, were similar to those of the CST beam. This means that the steel bolts, which brought the heat from the outside fire environment, did not have a critical effect on the overall temperature distributions of the Glulam beam during the first heating hour. As for its bending capacity, it could be estimated by using the reduced cross-section method, as described in BS EN 1995-1-2 [20]. In this case, the effective cross-sectional dimensions of the Glulam beam were smaller than 160 mm × 230 mm under the external loads. However, with the introduction of the steel beam, the overall bearing capacity can be a sum of the individual capacities of both Glulam and steel beams [13], which was greatly improved. Moreover, with the increase of the fire exposure time to one hour, the external Glulam gradually lost most of its strength, with the charring depth to 45.2 mm, while the steel beam material strength reduction was relatively small. Thus, the overall combined value would still show a good bearing capacity or resistance to the external loads.

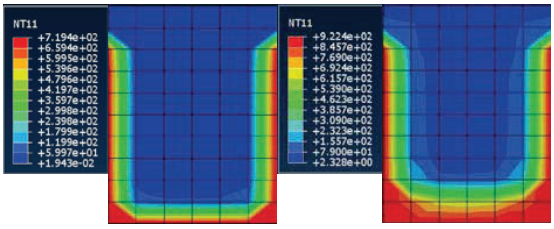

Figure 12: *Temperature distribution contours of the pure Glulam beam section at t =15 min and 60 min.*

5 PARAMETRIC STUDY

To improve the simulation efficiency in ABAQUS, parametric models were symmetrically established as the quarter of an entire beam by creating appropriate symmetry boundary conditions in ABAQUS.

5.1 EFFECT OF REDUCING BOLT SPACING

5.1.1 Charring characteristics

The charring depth was basically the same as that of the standard beam without significant difference for up to one-hour fire exposure (see Figure 13). However, when the fire action extended to 2 hours, the node temperatures of the bottom of the Glulam beam reached 400°C, and thus it was considered that all the protection layers of Glulam failed by then.

5.1.2 Temperature field of the embedded steel beam

By comparing Figures 4 and 14, it can be found that in terms of the overall temperature distributions, due to the decrease in the bolt spacing, more heat from the external fire field penetrated into the internal steel beam through the bolts, specifically through the bolt hole areas in the

https://doi.org/10.52202/069179-0229

web, which resulted in the heat conduction to the surrounding area and eventually the overall temperature distributions in the steel. For instance, for t = 60 min, the average temperature in the steel web exceeded 130°C, while the average temperature in the standard beam was only 110°C. In addition, the smaller bolt spacing made it easier to connect and superimpose the temperature fields around adjacent bolt holes. This could be verified by the fact that the temperature field near the areas of the bolt holes of the standard beam for t = 15 min only had a tendency, while the current beam model completed most of the temperature field connections. Consequently, due to this strengthened superimposition impact, after burning in the fire field for 120 min, the lower flange of the embedded steel beam had reached 462°C. Compared with that of the standard CST beam, namely 416°C, the temperature rose significantly.

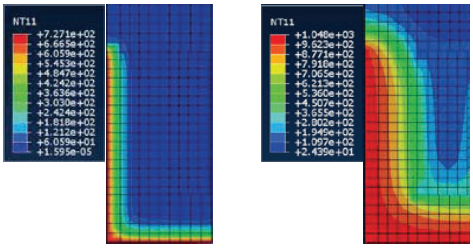

Figure 13: *Node temperature contours of the Glulam section of an adjusted CST beam with the reduced bolt spacing at t = 15 min and 120 min.*

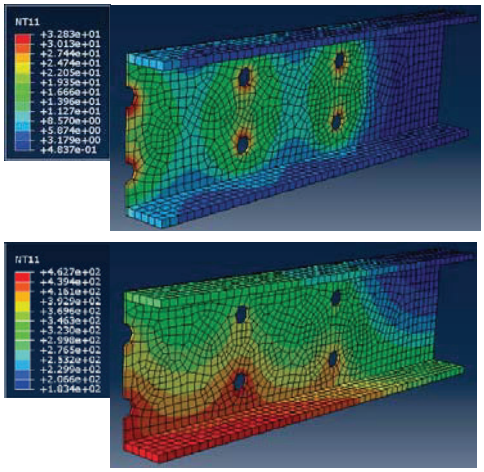

Figure 14: *Temperature contours of the quarter steel beam with the reduced bolt spacing at t = 15 min and 120 min.*

5.1.3 Estimated consequent displacement field

The reduction in the bolt spacing and the increase in the number of bolts per unit length could improve the composition robustness of the Glulam and steel beams, and additionally better the bending performances under room temperature. For structural fire design and analysis, this adjustment would pump more external heat into the internal steel beam, making the temperatures in its web rise faster. Especially after the structure was exposed to the fire for 2 hours, the Glulam at this moment was completely burnt out, and the lower flange of the embedded steel beam would be fully exposed to the fire. If a continuous fire field was applied, the steel beam would be heated up quickly and largely lose its strength. In other words, this would finally weaken the protection ability of Glulam, and the steel beam would lose its bearing capacity faster than the standard CST beam.

5.2 EFFECT OF REDUCING GLULAM PROTECTION THICKNESS

5.2.1 Charring characteristics

By comparing Figures 8 and 15, it can be found that there was a big difference in the charring depth of the adjusted model at t = 2 hour, but there was not much difference between the corresponding charring depths at t = 15 min. This could be because when the protection layer thickness of the Glulam decreased with the increase of the fire duration, the protection layer was burned off and heat gradually came into contact with the bottom flange of the steel beam. Thus, the steel beam could well transfer the heat evenly to other areas of the beam for a better thermal conductivity. This would help absorb some heat from the Glulam. When the action time was small, the protection effect of Glulam still played a governing role, and thus the charring depth difference was not so big.

5.2.2 Temperature field of the embedded steel beam

By comparing Figures 5 and 16, it can be found that because of the reduced protection layer thickness of the Glulam, heat from the fire environment would be able to penetrate the bottom flange of the embedded steel beam more quickly, and this led to the quicker rises in the overall temperatures in the steel beam. Especially, at t = 60 min, the average temperature of the lower flange had exceeded 230°C, while the average temperature of the standard beam was only 120°C. This huge difference became more obvious in the 120-min temperature field. At this moment, the maximum node temperature occurred at the mid-span of the lower flange and reached almost 670°C, which was much higher than that of the standard CST beam model, namely 416°C, and would cause excessive reductions in the material properties. Hence, reducing the thickness of the Glulam protection layer would greatly increase the heating rate of the embedded steel beam.

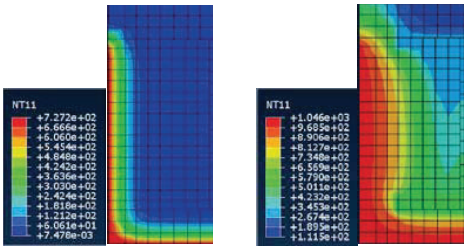

Figure 15: *Node temperature contours of the Glulam section of an adjusted CST beam with the reduced Glulam protection layer at t = 15 min and 120 min.*

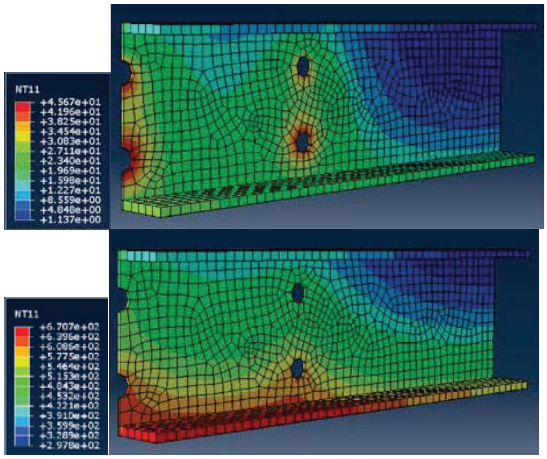

Figure 16: *Node temperature contours of the quarter steel beam with the reduced Glulam protection thickness at t = 15 min and 120 min.*

5.2.3 Estimated consequent displacement field

Although the thickness of the protection layer of the Glulam is reduced, the self-weight of the composite beam decreases as well, and thus the structural efficiency under room temperature will be improved to a certain extent which eventually reduces the costs. However, in terms of structural fire design and analysis, such adjustment will make the heating rate of the embedded steel accelerate because its lower flange prematurely participates in the heat transfer of the temperature field of the whole structure, and the refractory limit will be greatly reduced. If the requirements of structural efficiency and fire resistance are considered at the same time, the optimal protection layer thickness can be determined through subsequent experiments and analysis for achieving the double benefits of economy and structural safety.

6 Conclusions

In this research, based on the commercial finite element analysis software ABAQUS, numerical simulations and analyses of the temperature field and displacement field of the standard CST beam were conducted in a sequential coupling way. Through the analyses on the temperature field results, the validity of the calculation model was verified, and the heat transfer process and distribution characteristics of this type of CST beam under fire conditions were summarised. By analysing the results of the displacement field, the flexural performances of the embedded steel beam after the fire were determined. Additionally, the corresponding steel beam and Glulam beam models were simulated for comparison, and the advantages of this type of CST beam in the structural fire design were verified. Finally, by adjusting the parameters of the standard CST beam model, the effects of reducing the bolt spacing and the Glulam protection layer thickness on the temperature fields of the CST beam were analysed, respectively.

Based on the obtained numerical results, the following conclusions on the research results can be drawn.

- After the 120-min standard fire, the 50 mm external Glulam protection layer was almost burned out and charred completely. However, this could effectively protect the embedded steel beam, except the areas of the bolt holes at the mid-span, from experiencing excessive temperature rises and help maintain most of its mechanical properties and structural performances.
- Under the uniformly distributed load, the embedded steel beam showed fairly good flexural resistance, and the stress and displacement distributions were not largely different from those at normal temperature.
- Pure steel beams and Glulam beams compared with the CST beams, presents the inferior loading bearing capacity due to the strength loss induced by “thermos-plasticity” or the excessively reduced effective cross-section area.
- Although reducing the bolt spacing, i.e. increasing the number of bolts per unit length, could improve the composition integrity of the two materials, but under fire conditions, it reversely promoted the temperature field superposition of the bolt hole areas in the steel beam web and accelerated the heating rate in the embedded steel beam, and thus the ultimate load bearing capacity and refractory limit could be reduced.
- Although reducing the thickness of the Glulam protection layer, i.e. reducing the self-weight of the CST beam, and improving the structural and economic efficiencies, the distributions of the composite structure in the temperature field were largely affected. After the 60-minute standard fire, the Glulam protection layer was completely burned out, and the continuous heating would lead to a rapid rise in the temperature in the embedded steel, and finally the overall failure of the composite steel-timber beam structure would happen.

In general, the structural fire analysis of the new type of CST beam, carried out through the numerical simulations in this study, was relatively abundant, after verifying its potential advantages in fire engineering, evaluating its flexural performance under the two-hour standard fire, and assessing the impacts of the variations in the bolt spacing and Glulam protection thickness on the structural performances of the CST beam under fire conditions. In the future, the comparative explorations between laboratory combustion data and numerical simulation results as well as the parameter optimisation analyses based on the secondary development of finite element software will be the focus of subsequent research.

FIRE-PROTECTED TIMBER ELEMENTS OF CONSTRUCTION – RESPONSE DURING FIRE DECAY AND COOLING PHASE

Paul England[1], Boris Iskra[2]

ABSTRACT: The Building Code of Australia now permits the use of Fire-protected Timber in all classes of buildings up to an effective height of 25 metres (typically 8-storeys). Fire-protected Timber elements of construction consist of lightweight structural timber-frame or massive timber elements protected by fire-protective grade linings to reduce the risk of ignition of timber members and achieve the required fire-resistance level in addition to other criteria such as the acoustic and thermal performance appropriate to the class of building.

In support of this Code change, research was undertaken to investigate the post-fire decay and cooling phase behaviour of lightweight structural timber-frame or massive Fire-protected Timber elements for which there is currently limited research and publicly available data. As with all structural building materials, this post-fire behaviour can lead to failure of structural building elements if not adequately addressed. The research demonstrated that on-going combustion of Fire-protected Timber elements could be prevented using encapsulation provided by an appropriate layer of fire-protective grade coverings.

KEYWORDS: Lightweight timber-frame, CLT, fire, decay phase, cooling phase

1 INTRODUCTION

Changes to the Building Code of Australia Volume One (BCA) in 2016[1] and 2019[2] introduced Deemed-to-Satisfy (DTS) provisions as a means of demonstrating compliance for mid-rise timber buildings based on the concept of Fire-protected Timber.

These changes now permit lightweight structural timber-frame or massive timber elements protected by fire-protective grade linings, installed in conjunction with automatic sprinkler systems, to be used in all classes of building up to 25 metres in effective height (vertical distance from the ground floor storey to the floor of the topmost storey - typically up to 8-storeys); where previously non-combustible building elements were required.

In support of this Code change, a risk-based approach was adopted, incorporating multi-scenario analyses requiring evaluation of scenarios where the ignition criteria of protected timber were exceeded. Conservative assumptions were made including the assumption that if fire brigade intervention was unsuccessful, and the protected timber element was ignited, the element would fail (i.e., self-extinguishment would not occur).

Subsequently, additional research has been undertaken to investigate the potential for exposed and Fire-protected Timber to self-extinguish or, if sustained combustion continues, to evaluate the rate of deterioration of the timber elements during the post-fire decay and cooling phase to further extend applications for timber construction. The post-fire behaviour of both lightweight structural timber-frame and massive Fire-protected Timber construction elements are being investigated.

Detailed analyses undertaken in support of the Australian Code change were made with several conservative assumptions; including that if the surface temperature of timber exceeded 250°C for lightweight timber framing, or 300°C for massive timber elements, combustion would continue until failure occurred; unless fire brigade intervention occurred prior to the temperatures being exceeded.

This paper describes subsequent research undertaken investigating the post-fire behaviour of these timber building elements when exposed to the standard heating regime in accordance AS 1530.4[3] and more severe fire scenarios. This post fire behaviour can lead to failure of structural building elements if not adequately addressed which is not unique to timber.

Further details of the research and analysis is provided in the WoodSolutions Technical Design Guides #18[4] and #38[5].

2 DECAY AND COOLING PHASE RESPONSE

Building enclosure fires are typically categorised into four stages – (1) incipient/initiation, (2) growth, (3) fully developed and (4) decay. In some applications, it may be necessary to extend the analysis and consider a cooling phase if the behaviour of elements of construction after extinction of the contents (i.e., the moveable fire load) and combustible elements is to be considered – refer Figure 1. Typically, this may be necessary where degradation of elements of construction occurs after extinction of the contents due to thermal inertia, degradation on cooling (Dimia *et al*[6]) and/or localised smouldering combustion of elements of construction (McGregor[7]).

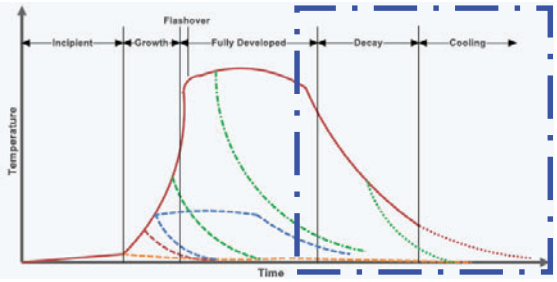

Figure 1: *Building enclosure fire stages*

The response of elements of construction during the decay and cooling phase can be an important consideration; particularly in applications such as high-rise buildings where fire brigade intervention and evacuation of occupants may be difficult during some fire scenarios.

Once the majority of the fire load is consumed, the burning rate will reduce significantly leading to reduced enclosure temperatures. However, there may still be potential for a thermal wave to spread through an element due to its thermal inertia and/or for smouldering combustion of timber structural elements to continue.

Under some circumstances, a thermal wave can subsequently lead to structural collapse of common building structural materials used such as timber, concrete and steel. The risks of smouldering combustion or of incipient fire spread is specific to combustible materials and can also eventually lead to structural collapse or reignition of flaming combustion.

In most instances, both natural and furnace fire-resistance tests are terminated at the end of a nominated exposure time so there is relatively limited data on their behaviour during the decay and cooling phases; which can last for extended periods varying from several hours to 24 or more hours in extreme cases. Recent studies, such as the Epernon Series[8] and Fire Safe Implementation of Visible Mass Timber[9], have monitored conditions at the end of tests to evaluate performance during the decay phase.

2.1 PREMATURE STRUCTURAL FAILURE

Premature structural failure of building elements may occur as a result of failure of automatic sprinkler systems, fire-protective coverings, and detection and alarm systems as well as a relatively slow fire brigade response. However, structural failures can also occur sometime after fire exposure due to several causes, including:

- temperatures of structural elements continue to increase during the decay period of a fire due to the thermal inertia of the enclosure fabric and fire protection systems
- stresses may be induced on cooling
- material properties may change on cooling, and
- smouldering combustion and incipient spread of fire may continue.

Some fire-resistance tests performed for FWPA have included monitoring of simulated decay phases in conditions with normal atmospheric concentrations of oxygen by removing specimens from the furnace and continuing exposure of the specimen to heat as described below.

3 TESTED SYSTEMS

3.1 ENCAPSULATED LIGHTWEIGHT ENGINEERED FLOOR-CEILING SYSTEM

A full-scale, loadbearing fire-resistance test was undertaken on a lightweight engineered timber floor-ceiling system to determine the fire resistance of various types of lightweight engineered beams (e.g., timber and metal webbed parallel chord floor trusses, timber and metal webbed I-joists) protected by a plasterboard ceiling system. The specimen was subjected to the AS 1530.4 standard heating regime for 122 minutes.

The ceiling system comprised three layers of fire-protective grade plasterboard, each 16 mm thick, fixed to metal furring channels that were supported from the floor joists by direct fixing metal brackets using typical industry installation practices. The test was terminated after two hours without failure under the criteria of structural adequacy, integrity and insulation and achieved a 2-hour fire-resistance (FRL 120/120/120).

In addition, a 120-minute Resistance to the Incipient Spread of Fire (RISF) level was also achieved. RISF is a criterion within AS 1530.4 which was originally introduced for ceiling membranes to ensure that the space between a ceiling and roof, or ceiling and floor above, is insulated so as to limit the temperature rise of materials in this cavity space to a level that will not permit the rapid and general spread of fire throughout the space to adjoining compartments. Failure under the criterion of RISF is deemed to have occurred when the maximum temperatures at the nominated positions on the ceiling system exceed 250°C. Application of the RISF criteria was extended to other light-weight Fire-protected Timber elements such as partition wall systems by the BCA in 2016.

https://doi.org/10.52202/069179-0230

After 120 minutes, the heating was terminated and the specimen was raised 600 mm above the furnace allowing free access to the laboratory atmosphere while being exposed to heat from the furnace floor and walls to simulate the decay and cooling phases under natural convection. The floor-ceiling specimen was then monitored for a further 17 hours without intervention – refer Figure 2.

Figure 2: *Exposed face of specimen at the end of the monitoring period.*

The temperatures measured below the ceiling during the fire test exposure and for the first two hours of the cooling phase are shown in Figure 3. The specimen then continued to support the full test load while cooling to ambient temperatures over the remaining 15 hours of the monitoring period.

There was no evidence of combustion of the timber elements during the test and throughout the monitoring period. The temperatures on the upper surface of the plasterboard sheeting peaked after approximately 150 minutes (30 minutes after termination of heating) but temperatures did not exceed 250°C as shown in Figure 4.

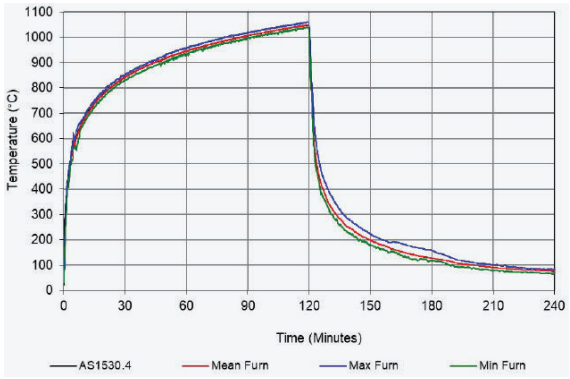

Figure 3: *Complete heating and first two hours of cooling exposure measured by exposed thermocouples*

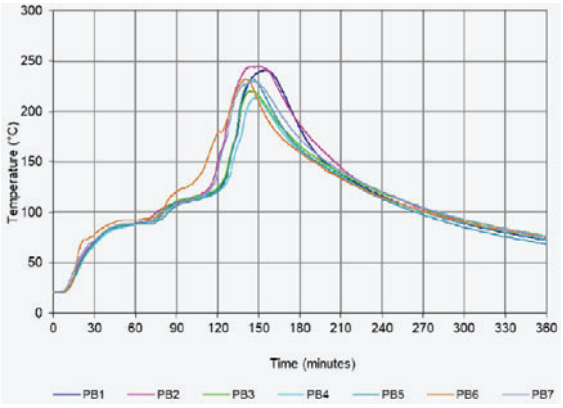

Figure 4: *Temperatures of upper surface of the plasterboard*

3.2 PROTECTED CROSS-LAMINATED TIMBER PANEL

3.2.1 Section within encapsulated lightweight engineered floor system test

A section of cross-laminated timber (CLT) was included within the encapsulated lightweight engineered floor system cavity (described in Section 3.1) and temperatures were measured at various positions within and adjacent to the CLT element. These temperatures are summarised in Table 1 which illustrates that a thermal wave passed through the CLT with temperatures at depths of 20 mm and 55 mm peaking at 94°C and 84°C respectively more than 120 minutes after the end of the heating period.

Table 1: *Peak CLT specimen temperatures and temperatures after 120 minutes*

Ref	Description	Temp. °C @ 120 minutes	Max. Temp. °C
CL-1	Plasterboard-CLT interface temperature	120	226
CL-2	19 mm below CLT soffit (air temp)	109	161
CL-3	CLT soffit	96	151
CL-4	10 mm depth	77	105
CL-5	20 mm depth *(lower glue line)*	52	94
CL-6	55 mm depth *(upper glue line)*	58	84

3.2.2 One layer of 16 mm fire-protective grade plasterboard – Shorter test duration

Two standard fire-resistance tests, in accordance with AS 1530.4, were performed on 105 mm thick CLT panels protected by one layer of 16 mm fire-protective grade plasterboard. The first test was of 45 min duration and the second of 60 min duration. Prior to the tests, the time for the CLT plasterboard interface to reach 300°C was estimated to be approx. 30 minutes and this was confirmed in both tests. Also in both tests, volatiles from the CLT panels ignited at joint positions in the plasterboard but self-extinguished during the monitoring period.

https://doi.org/10.52202/069179-0230

The following is a more detailed review of the 60-minute test.

The specified and measured furnace temperatures for the 60-minute test are shown in Figure 5 for the heating period. At the end of the 60-minute heating period, the area under the mean furnace temperature/time plot exceeded the prescribed standard heating regime by approximately 1.5%.

At the end of the heating period the interface temperatures between the plasterboard and CLT were approximately 500°C and as the specimen was raised above the furnace to allow natural airflow across the surface of the specimen, flaming at the joint between the plasterboard sheets was observed as shown in Figure 6.

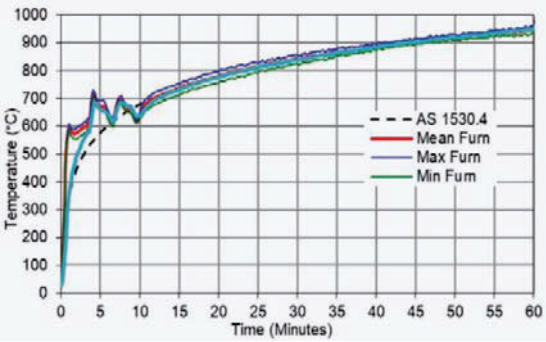

Figure 5: *Furnace temperatures during the 60-minute heating period*

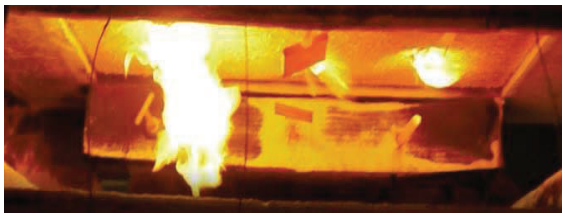

Figure 6: *Flaming from joint between plasterboard 30 seconds after the end of the heating period.*

The flaming gradually reduced and ceased after approximately 11 minutes.

Data monitoring continued for 23 hours and during this period, the CLT panel temperatures had effectively reduced to ambient temperatures with no evidence of continuing flaming or smouldering combustion – refer Figure 7 for interface temperatures between the plasterboard and CLT, and Figure 8 for the temperatures of the CLT panel at varying depths.

This data indicates that the charring was restricted to a depth of approximately 6 mm and that self-extinguishment of smouldering combustion had occurred as well as any flaming combustion.

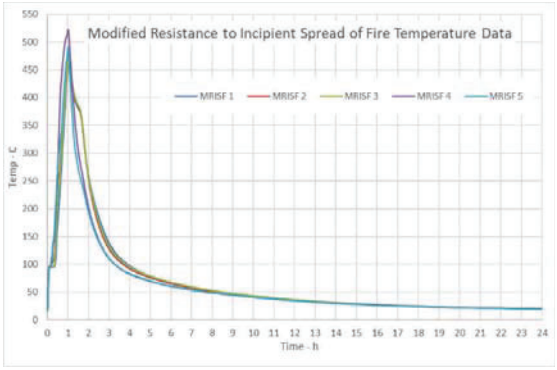

Figure 7: *Thermocouple temperatures at the interface between plasterboard and CLT*

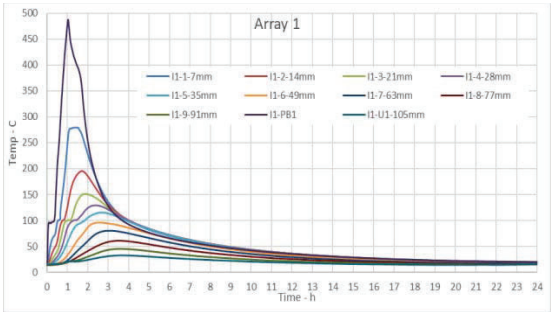

Figure 8: *Thermocouple temperatures across the CLT section*

The incident heat flux to which the underside of the specimen was exposed is shown for the 180 minutes of the monitoring period in Figure 9. Approximately 11 min after completion of heating, the measured heat flux had reduced to approximately 10 kW/m^2; at 42 min after completion of heating, it had reduced to approximately 4 kW/m^2 and 108 min after completion of heating, it had reduced to approximately 2 kW/m^2.

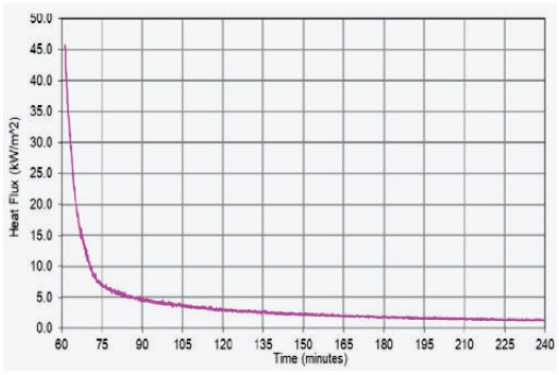

Figure 9: *Heat flux from furnace and specimen for 180 min after heating*

Figure 10 shows the CLT panel with the plasterboard removed clearly highlighting the surface charring to the lower lamella layer. No significant delamination had occurred, but the individual lamella had shrunk in dimension opening the edge joints between the lamella which were not bonded, i.e., no adhesive applied, during the CLT manufacturing process.

https://doi.org/10.52202/069179-0230

Figure 10: *Underside of CLT panel with plasterboard removed after 23-hour monitoring period.*

3.2.3 One layer of 16 mm fire-protective grade plasterboard – Longer test duration

A 225 mm thick CLT panel protected by a single layer of 16 mm plasterboard was subjected to the standard heating regime as a comparative test to the shorter test durations described in 3.2.2.

The CLT panel width was constructed with a central half-lap joint with two joint treatments – half the length of joint sealed with two beads of sealant between the bearing surfaces, and the other half with a plasterboard cover on the non-fire-exposed side.

The test was terminated after approximately 171 min when failure at the joints position was imminent. The conditions were subsequently monitored for a relatively short period of 59 min since the element showed evidence of continuing char oxidation; albeit at a reduced rate. A comparison of the shorter and longer duration CLT tests with one layer of 16mm plasterboard is provided in Table 2.

Table 2: *CLT comparison tests – Single layer of 16 mm fire-grade plasterboard protection*

Test	CLT depth (mm)	Furnace Heating (h:min)	Monitoring period (h:min)	Time CLT-PB interface > 300ºC (min)	PB Fall-off (min)
6	105	0:45	15:00	34	No
8	105	1:00	23:00	32	No
2	225	2:51	0.59	32	115

Heat flux measurements from Test 2 during the decay period are presented in Figure 11. It is noteworthy that, despite evidence of some ongoing combustion, the decay of measured heat flux from the specimen (thin line) reduced to approximately 11 kW/m^2 after 60 min and the measured heat flux received by the specimen from the furnace walls and floor (thicker line) is comparable.

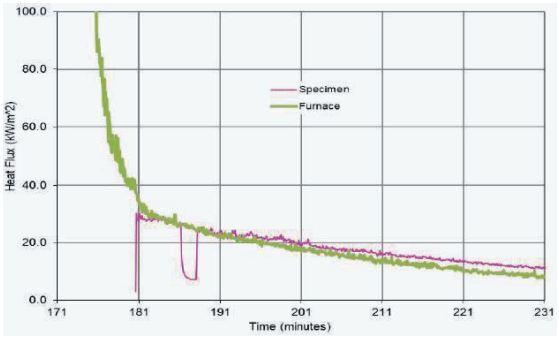

Figure 11: *Heat flux from the furnace and specimen for 60 minutes after heating*

Combustion of the specimen was ongoing at the joint positions and the exposed perimeter of the specimen at the end of the 60-minute monitoring period. Significant delamination occurred such that 90 mm or more of the specimen face had been lost over the heated area, creating a detail at the perimeter where a horizontal face meets a vertical face of timber, facilitating radiative feedback as shown in Figure 12.

Figure 12: *Fire side after the 59-minute monitoring period showing continued edge combustion.*

These observations indicate that as heat penetration into timber elements increases, intersections and joint details will become more critical if self-extinguishment is an objective. It may also be important to maintain fire-protective coverings in place to reduce radiant heat interchanges at intersections of elements.

3.3 TIMBER-FRAME STUD WALL SYSTEM

3.3.1 System construction

A fire-resistance test was undertaken on a loadbearing timber-frame wall system comprising three layers of 16 mm thick fire-protective grade plasterboard applied to each face of 140 mm x 45 mm studs with cavities filled with non-combustible stone wool.

The stone wool insulation was installed, in lamella form, to provide a practical way to reliably install the insulation to be in intimate contact with the timber studs with a controlled level of compression. The high-temperature performance specification and compression was intended to maintain one-directional heating of the timber studs by

https://doi.org/10.52202/069179-0230

avoiding heat transfer through the cavity. The temperature data from the test indicated this was effectively achieved. Figure 13 shows the internal structure of the timber-frame wall system comprising vertical timber studs, horizontal timber noggings and fitted stone wool insulation.

Figure 13: *Internal structure and non-fire side of the high-performance timber-frame wall system*

Laminating screws were used to secure the outer third layer of plasterboard which facilitated the positioning of screw fixings 38 mm from board edges and a reduction of fixing centres over the board area which was expected to significantly improve the retention time for the outer board layer.

3.3.2 Fire performance

The specimen was subjected to the AS 1530.4 standard heating regime for 227 min, after which the specimen was removed from the furnace and conditions were monitored for a further 30 min. The specimen achieved an FRL in excess of 180/180/180 and the Resistance to the Incipient Spread of Fire (RISF) criteria were satisfied for in excess of 120 min.

A total load of 12.3 kN/stud was applied to the specimen; equivalent to a load ratio of 0.5 (i.e., ultimate fire limit state design load to ultimate (ambient) limit states design load). The full test load was applied until 198 min and then progressively reduced until heating was terminated after 227 minutes due to the potential risk of damage to the loading equipment; with no failures under the criteria for insulation and integrity.

Measurements taken during the test included interface temperatures of each plasterboard layer using thermocouples soldered to copper discs at the centre and centre of each quarter section of the wall. Thermocouples were also fitted at approximately these locations on the inner surface of the base plasterboard layer on the fire-exposed side of the specimen to determine the RISF performance.

The RISF results are plotted in Figure 14 and the temperature of the RISF thermocouples after 120 min of the test was approximately 130°C before exceeding the 250°C limit after 136 min.

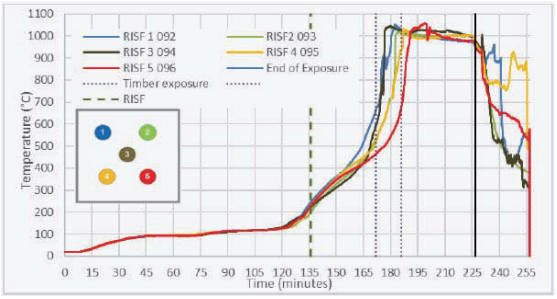

Figure 14: *Resistance to the Incipient Spread of Fire (RISF) temperature data and estimated time of direct exposure of the timber frame to furnace heating*

At the end of the heating period the specimen was removed from the furnace. To enable observation and the fitting of a heat flux meter to measure radiant heat released from the specimen, the specimen was rotated at an angle to the furnace as shown in Figure 15.

(i) Approx. 4 mins post-test *(ii) Approx. 26 mins post-test*

Figure 15: *Exposed face of partition during monitoring period*

Visual observations confirmed continuing combustion and char oxidation with a slight reduction in intensity further away from the furnace, which can be explained by the lower incident radiant heat from the adjacent furnace. Temperatures measured within the char were generally in the range of 500°C to 600°C throughout this period, indicating continued combustion within the char.

Due to the test being of a loadbearing timber-frame, temperature data was obtained from three internal horizontal noggings containing thermocouples and is plotted against time in Figure 16.

Figure 16: *Char depth versus time along nogging centreline*

https://doi.org/10.52202/069179-0230

Char rates obtained during the test were substantially higher than those recommended in EN 1995-1-2:2004 Eurocode 5[10] and AS/NZS 1720.4:2019[11]. For example, the notional char rate in accordance with AS/NZS 1720.4, assuming a nominal density of 550 kg/m^3, would be 0.66 mm/min and for protected systems is increased by a factor of 1.1 yielding an increased char rate of approximately 0.73 mm/min. Whereas the average calculated char rate from commencement of charring (at approx. 158 minutes) to a char depth of 90 mm (at approx. 221 minutes) was 1.43 mm/min.

This may be explained by the longer pre-heating period and higher heat fluxes due to the longer fire-resistance test period and would highlight the need for an upper bound fire resistance time to be specified for the notional char rates currently specified in design codes or additional char rates specified for long durations and different heating regimes.

4 CONCLUSIONS

The overview of the results of extended fire resistance tests performed on Fire-protected Timber elements has been presented. The specimens were monitored at the end of the heating period to determine if the elements self-extinguish, or sustained combustion continued.

The tests demonstrate that on-going combustion can be prevented using encapsulation provided by appropriate fire-protective grade covering systems that maintain the temperature of the protected timber elements below critical values.

The results so far demonstrate that for timber-framed construction, a temperature limit of 250°C is appropriate but above this limit, ignition and sustained combustion is likely to occur.

The results from tests on fire-protected massive timber construction, such as CLT, indicate that at interface temperatures above 300°C, the CLT member may ignite particularly at the position of joints in plasterboard coverings but self-extinguishment is still possible provided (1) the protective coverings remain in place, (2) the exposure is one-dimensional, (3) solid massive timber elements are used and, (4) detailing of joints between panels and at the perimeter of elements prevents increased heating of the timber.

Further work is being undertaken to evaluate the behaviour of Fire-protected Timber and unprotected timber under different heating conditions.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the support provided by FWPA in undertaking this research and the knowledge and dedication of the fire resistance testing team at Warringtonfire Australia's Melbourne testing facility.

NUMERICAL SIMULATION OF FIRES WITH EXPOSED TIMBER

Sabrina Spörri [1], Chamith Karannagodage [2], Joachim Schmid [3], Andrea Frangi [4]

ABSTRACT:

The burning of timber is a complex process because of its inhomogeneous structure and the interlinked processes of material decomposition and gas-phase combustion. One approach to predict the burning behaviour of timber in fire is through simulations. This work studies the charring properties of the timber with the complex pyrolysis model in the Fire Dynamic Simulator (FDS). A timber specimen of 260 mm × 225 mm × 120 mm exposed to an external heat flux in a non-standard experimental environment has been simulated with the FDS using the appropriate input parameters for the pyrolysis and gas phase combustion. The simulations also investigated the influence of the moisture and temperature-dependent specific heat on the simulation results. When the simulation results were compared to the experimental results, there was a good agreement for the charring rates, with a maximum deviation of 0.06 mm/min. The results showed the importance of moisture in the pyrolysis model to obtain accurate results. The findings suggest that the FDS can be used to study and predict the char depth of timber to calculate the residual cross-section for building designs.

1 INTRODUCTION

Fires are a dynamic process with their intensities being dependent on the prevalent boundary conditions. An important factor influencing the behaviour of fires is whether the fire is burning openly or enclosed in a compartment. In open fires, there is an unlimited supply of oxygen for the combustion reaction and the resultant smoke plume can rise unimpeded depending on the stability of the atmosphere. In contrast, when a fire occurs in a compartment, the oxygen supply to the combustion reaction is limited by the size of the opening(s) and the smoke plume is trapped within the enclosure. In these types of fires, all the enclosing components are heated up in a fire, especially in the upper part of the compartment, where the hot combustion products are trapped beneath the ceiling and form a hot layer.

The flames above the fire, the heated surfaces of enclosing components, and the layer of hot combustion products accumulated under the ceiling can all be considered sources of radiant heat flux. These radiating sources potentially contribute to further heating the burning and non-burning fuel. To summarise, the main aspects influencing the compartment fire dynamics are the distribution and the type of fuel load, the compartment geometry, the ventilation configuration and the material of the compartment boundaries [1].

Nowadays, the traditional construction material timber is experiencing a renaissance as it is an environmentally-friendly material which contributes to a sustainable construction, but also satisfies the architectural need for new designs and aesthetics [2–4]. When the boundary surfaces consist of combustible material like timber, this will significantly impact the compartment fire dynamics by adding an additional fuel load to the fire. Studies have shown that the additional fuel will increase the severity of the external flaming and the thermal load that must be resisted by the structure to ensure that safety criteria are satisfied [5,6].

Recent trends have increased the market demand for the larger floor spaces (fire compartments), increased quantities of visible (unprotected) timber and taller buildings. These trends will not only influence the duration and the intensity of the compartment fires but also the techniques used to fight them [7]. Very recent changes in regulations in UK and Scandinavia require the determination of “physically based design fires”. These design fires must consider the compartment geometry, architectural linings and the potential influence of any combustible structures (timber).

Although proposals for modifying the parametric fire design are available [7], it appears to be challenging to

describe the complex aspects of the fire dynamics in timber structures with the available design frameworks. Consequently, it is expected that a performance-based design allows a greater design flexibility, promoting innovation and a better use of resources allowing for a better fire risk management [8]. When applying a performance-based approach to timber structures, a key input that is missing is the development and the combustion of the char layer in the compartment environment.

Moreover, reliable numerical models could decrease the necessity of full-scale tests, which are costly and require a large amount of resources. That way, fire-design approaches could rely on numerical models to assess the use of innovative and more sustainable building materials and allow maximum freedom in building design while upholding the required level of building safety.

This paper simulates the burning behaviour of a timber specimen using a field model. This simulator couples the gas and solid phase processes that occur in a fire. The gas phase processes are the combustion of flammable gases and the local air flow whilst the solid phase processes include the thermal degradation of fuel (pyrolysis). A summary of the simulating steps and an overview of the most important parameters for the simulations are presented with the comparison of results from the fire experiment.

2 STATE OF THE ART

2.1 BURNING PROCESS OF TIMBER

Timber is a substance with an anisotropic structure [8] and mainly constitute with the cellulose, hemicellulose and lignin [10]. Depending on the wood species, the percentage of these three molecules vary, but a rough approximation for dry wood is 50% of cellulose, 25% of hemicellulose and 25% of lignin [10]. Timber naturally contains moisture. This can exist either as bound water in the cell walls (hygroscopic water) or as free water in the voids of the wood (capillary water) [13].

The burning process of timber can be divided into two main processes. First, when the timber is exposed to heat, at high temperatures it begins to change its cellular structure initiating the pyrolysis process. Pyrolysis is the thermal decomposition of fuel material [14]. At elevated temperatures, timber degrade the constituent natural polymers producing volatile gases, tar and char. Secondly, when the pyrolysis volatile gases mix with ambient air it makes a combustible mixture which can lead to a flaming combustion (fuel oxidation) [15].

2.1.1 Pyrolysis of timber

Timber shows different stages in the pyrolysis process due to its material properties as shown in Figure 1. When heated to 100°C, the moisture within the timber starts to evaporate. Upon further heating, the pyrolysis process begins when the fuel reaches around 200°C producing volatiles. This is initially a relatively slow process until the fuel reaches 300°C after which the production rate of the volatile gases increases. [15].

On a general level, the pyrolysis is an endothermic reaction, and the energy is needed to break the polymers into smaller parts to present in the gaseous phase [12,15]. This process produces inert and combustible gases, liquid tar, solid carbon-rich non-volatile char and inorganic non-burning ashes as shown in Equation (1) [15].

$$wood \rightarrow gases + tar + char + ash \quad (1)$$

The produced gases are mainly CO, CO_2 and H_2O. The combustible gases will further undergo the combustion as explained in the Section 2.1.2. The char contains heavier and larger molecules which stay on the timber surface forming a layer which affects the heat transfer to the virgin timber. The char can further undergo the solid phase oxidation which is visible as smouldering or glowing combustion. This decomposition also creates a surface regression of the timber and makes the cross-section smaller [4]. The char yield of the reaction is influenced by the presence of organic impurities in the wood and for most of the situations, the char formation starts around 300°C [15]. It should be noted that, this is a simplified description of the processes. In reality, several interdependent chemical reactions occur at the same time and the process is further complicated by the inhomogeneity of wood and the influence of the produced char layer [9].

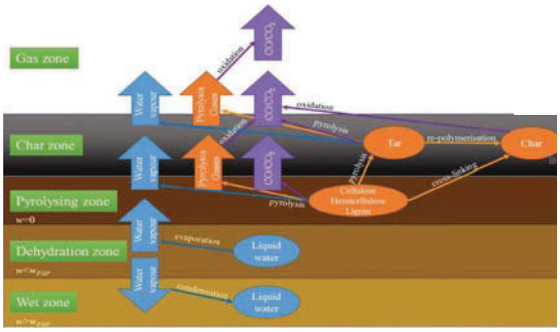

Figure 1: *Chemical and physical processes of a burning timber specimen. Modified from [15].*

2.1.2 Gas phase combustion

The mixing of combustible pyrolysis products with air in the right proportion (flammability limit) and in the right environmental conditions leads to their oxidation. This process is called the gas phase combustion [12,15]. This is an exothermic process producing the energy which could further enhance the production of the pyrolysis gases by transferring heat to the surface of the fuel [15]. If this heat feedback mechanism produces enough heat to release further volatiles within the flammability limit, then the mixture can sustain flaming combustion. The flammability limit or the flammable limit is the amount of combustible gas in an air mixture when the mixture is flammable.

https://doi.org/10.52202/069179-0231

2.2 PYROLYSIS MODELS

As the overall process of pyrolysis is very complex to work with, a lot of models have been proposed to describe the pyrolysis process in a simplified way adapting to desired real-life applications. Moghtaderi [13] gives an overview of the different pyrolysis models and classifies them based on their decomposition reaction as how the conversion from the virgin fuel into the gaseous products and char residues is described.

Distinctions are to be made between simple thermal models and comprehensive models. These two groups differ in the way they define the conversion of the fuel into the products, by the pyrolysis rate. The simplified models derive the rate only from the energy balance and the comprehensive models by a combination of kinetic schemes, mass and energy balances [13].

2.2.1 Simple thermal models

Simple thermal models use the criteria of a critical pyrolysis temperature while ignoring the physical and chemical processes to derive the pyrolysis rate (i.e., mass loss rate) from the energy balance. Depending on the solution method used to solve the equation, the simple thermal models are divided into the Algebraic, Analytical and Integral models. Equation (2) shows an example of an analytical simple thermal modal where the mass loss rate is proportional to the net absorbed heat flux for a thermally thin slab exposed to constant heat flux [13],

$$\dot{m} = \frac{\dot{q}_e^{''} A_s}{\dot{Q}_p} \tag{2}$$

where $\dot{m}$ = Mass loss rate [kg/s], $\dot{q}_e^{''}$ = External heat flux [kW/m^2], A_s = Surface area of solid [m^2], $\dot{Q}_p$ = Heat of pyrolysis [kJ/kg]

These models have the advantage of being relatively simple to use. However, they have the disadvantage of relying on a critical temperature for the ignition and neglecting many chemical processes. The use of a critical temperature simplifies the fact that the chemical processes occur faster than the diffusion processes. This is only true in very high temperatures. However, the chemical kinetics play a big part at the lower temperatures.

2.2.2 Comprehensive models

The comprehensive models incorporate the chemical and diffusion processes that occur during the pyrolysis. They have thus overcome the fundamental nature of a simple thermal model. As a result, these comprehensive models can also include the thermal degradation processes. Furthermore, other processes like heat transfer, morphological changes, expansion, shrinkage, char formation, chemical reactions, and in-depth radiation are also frequently included in the models [16]. The examples of the comprehensive models are Gypro, ThermaKin, Pyropolis, and FiresCones [16]. Because of the complexity of these models, numerical solution methods such as finite difference or finite volume are almost always required to solve the equations.

The comprehensive models are classified as follows by the reaction scheme,

- One-step global reaction schemes
- One-step multi-reaction schemes
- Multi-step semi-global schemes

The simplest one is the one-step global reaction scheme which only considers a primary reaction like the conversion of virgin timber into products as given in Equation (1). In this model, the thermal degradation products are considered as lumped materials. The pyrolysis rate is calculated by the Arrhenius expression given in Equation (5), which is proportional either to the weight residue or the weight loss of the fuel [13]. The input parameters for the equation need to be defined experimentally.

The one-step multi-reaction scheme is a more detailed reaction scheme than the previous one. Here also, each component undergoes only one independent reaction, but this time the timber is not modelled as a lumped material but made out of several components. Each of these components goes through a different reaction that occurs in parallel. In this case, the pyrolysis rate is the sum of the reaction rates of each component weighted by the percentage of each component. The subsequent reaction that some of these products can undergo is the next step in the complexity. These are known as the secondary reactions [10], and one example is the char oxidation. Multi-step semi-global schemes are the models that take such reactions into account.

Some comprehensive models can also consider the effect of moisture presence in the pyrolysis process. However, a disadvantage of these comprehensive models is that many input parameters are needed even with a simple reaction scheme. That number increases drastically if more complex reaction schemes are used.

2.3 FDS PYROLYSIS MODEL

The Fire Dynamics Simulator (FDS) developed by the National Institute of Standards and Technology (NIST) is a Computational Fluid Dynamics (CFD) software package which solves simplified forms of Navier-Stokes equations numerically. The FDS can be used to simulate low-speed thermally driven fluid flow with the smoke plume. FDS is a powerful tool to predict heat generation and transfer from a fire [17]. The main models in FDS are hydrodynamic, combustion, and radiation transport models [18].

The combustion model is mainly used as a single-step, mixing-controlled chemical reaction. The combustion reaction includes air, fuel and products which are treated as lumped species and explicitly tracked in the simulations.

2.3.1 Pyrolysis model

FDS has the option to include different types of pyrolysis models, ranging from simple thermal ones to complex models based on the kinetics [18,19]. This study will use

the complex pyrolysis model from FDS. The complex pyrolysis model needs to define one or several chemical decomposition reactions and input data to calculate the reaction rate as explained in the previous section. The FDS definition of the pyrolysis reaction rate $r_{\alpha\beta}$ is a combination of solid and gas phase conditions and defines the reaction rate depending on the temperature of the solid T_s. The definition in the FDS contains the following sub-terms, Equations (3)–(5) [19]. In this study, only the reactant dependency and the Arrhenius function were used to define the reaction rate.

$$r_{\alpha\beta} = Reactant\ dependency \times Arrhenius\ function \times Oxidation\ function \times Power\ function \quad (3)$$

$$Reactant\ dependency = \left(\frac{\rho_{s,\alpha}}{\rho_{s(0)}}\right)^{n_{s,\alpha\beta}} \quad (4)$$

$$Arrhenius\ function = A_{\alpha\beta} exp\left(-\frac{E_{\alpha\beta}}{RT_s}\right) \quad (5)$$

where α = Material component in material layer, β = Name of reaction, $\rho_{s,\alpha}$ = Solid density of material component α [kg/m^3], $\rho_{s(0)}$ = Initial solid density of material layer [kg/m^3], $n_{s,\alpha\beta}$ = Partial reaction order for material component α in material layer and reaction β, $A_{\alpha\beta}$ Pre-exponential factor [1/s], $E_{\alpha\beta}$ = Activation energy [J/mol], R = Gas constant [J/K·mol], T_s = Temperature of solid [K]

Furthermore, the heat transport through the depth of the solid is calculated by the conduction in FDS. In this study, the heat conduction is only considered as one-dimensional into the solid.

2.3.2 Gas combustion model

The gas combustion model is a single-step mixing controlled combustion based on the Eddy Dissipation Concept where the mixing is approximated as having been burnt [19] and where only one fuel can react [18]. The chemistry model relies on a reaction of the following form as in Equation (6).

$$C_xH_yO_zN_v + v_{O_2}O_2 \rightarrow v_{cO_2}CO_2 + v_{H_2}H_2O + v_{co}CO + v_sSoot + v_{N_2}N_2 \quad (6)$$

Therefore, the user needs to specify the chemical equation of the burning fuel along with the yield of CO, soot and the volume fraction of the hydrogen in the soot. The enthalpy of formation of the gaseous fuel can either be specified directly for each gas or can be calculated from the (specific) heat of combustion of the reaction if the enthalpy of formations of all the other molecules in the reactions are known [19]. This second approach will be chosen in this study for the definition of the enthalpy of formation.

3 PYROLYSIS MODELLING WITH TIMBER IN FDS

3.1 INPUT PARAMETERS FOR THE FDS PYROLYSIS MODEL

The pyrolysis model used in this study was a one-dimensional heat transfer model with a simple, one-step global reaction scheme. To be compatible with the experimental data described in the section 3.4 "Experiment description", spruce was selected as the wood type. As shown in Equation (7), the chemical reaction was defined as the conversion of spruce into char and pyrolyzate.

$$Spruce \rightarrow char + pyrolyzate \quad (7)$$

In the experimental setup, the spruce sample had a moisture content of 12%. However, the simulations were started with dry spruce to keep the reaction scheme simple. Subsequently, the moisture content was added to the simulation. Only the reactant dependency and the Arrhenius function are used to calculate the reaction rate (Equations (3)–(5)). The oxidation function and power function of the FDS pyrolysis model were not studied further during this study. The default FDS values were used for those terms in the analyses.

For estimating the material and kinetic properties of spruce and char, the values were based on the research of Rinta-Paavola and Hostikka [20]. Thermogravimetric analysis (TGA) was used in the aforementioned study to estimate the yield of char and pyrolyzate, as well as the activation energy and pre-exponential factor [20]. This work provided the input parameters for the pyrolysis of spruce for simple and parallel reaction scheme in FDS. Further, these input parameters were validated and optimised against the cone calorimeter experiments at different heat fluxes. The value for the heat of combustion was derived from the micro-combustion calorimetry (MCC) experiments [20].

The heat of combustion is the effective heat of combustion, which is also the default definition in the FDS [18]. The heat of reaction for this simple reaction is defined as endothermic and is the optimised value by model fitting for a heat flux of 35 kW/m^2 in a cone calorimeter test [20]. Table 1 summarises the input parameters that were used for the decomposition process in the FDS simulation.

Table 1: *Input parameter for decomposition process [18,20]*

Parameter	Value
Number of reactions	1
Yield of char	0.16
Yield of pyrolyzate	0.84
Activation energy (J/mol)	190'500.00
Pre-exponential factor (1/s)	4.691×10^{13}
Absorptivity (1/m)	50'000.00
Reaction order	1
Heat of combustion (kJ/kg)	14'000.00
Heat of reaction (kJ/kg)	19

https://doi.org/10.52202/069179-0231

Other material properties for spruce, char, and pyrolyzate should be defined in addition to the pyrolysis parameters. These parameters for the two materials are shown in the Table 2 and in the text following the table. The next section will provide the information on the gaseous product "pyrolyzate".

Table 2: *Material properties for spruce and char [20,21]*

Parameter	Spruce	Char
Density (kg/m^3)	408	59
Emissivity (-)	0.9	0.85
Conductivity (W/m K)	0.09	0.22

The conductivity for spruce was the optimised value by model fitting for a heat flux of 35 kW/m^2 in a cone calorimeter test. The char density of 59 kg/m^3 was in the same range as reported in the literature, where the initial char density is 10–20% of that of the dry wood [22]. The value for the emissivity of char was from Chaos [21].

The last input parameter needed is the specific heat for spruce and char. They were defined as temperature-dependent in the publication of Rinta-Paavola and Hostikka [23]. The specific heat capacity of spruce ($C_{p,spruce}$) was defined as a linear growth from 30°C with 920 J/(kg·K) to 230°C with 1800 J/(kg·K). The specific heat capacity was assumed to be constant below and above that temperature. The specific heat of char ($C_{p,char}$) was defined by Equation (8).

$$C_{p,char} = 1430 + 0.355 \cdot T - \frac{7.32 \times 10^7}{T^2} \qquad (8)$$

where T = Temperature [K]

3.2 INPUT PARAMETERS FOR THE FDS GAS COMBUSTION MODEL

The main fuel for the gas combustion is the gaseous product pyrolyzate produced by the decomposition reaction in Equation (1). The input parameters for the gas combustion in the FDS were defined as follows; the chemical composition of the burning gas of spruce (C:1, H:3.584, O:1.55, N:0), the soot yield (0.015), the effective heat of combustion (14 MJ/kg), the viscosity (0.00059 kg/m·s) and the diffusivity (4.3×10^{-7} m^2/s) [20],[23][24].

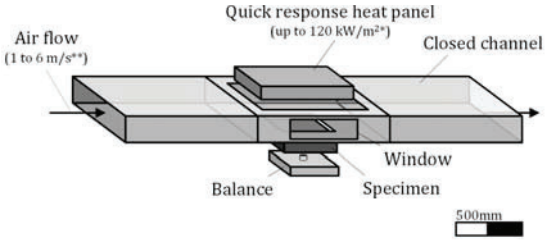
For the conductivity, the value for the spruce was used [20], the diffusivity was the axial diffusivity for dry ash [23] and the viscosity was for wood [24]. For the surrogate molecule of the thermal radiation, FDS has a predefined list to choose from [18]. From there, a chemically similar molecule to the gaseous product was chosen, which was 'METHANOL'. Additionally, the default FDS values were used for the other parameters in the gas combustion model.

3.3 ANALYSING METHOD TO DETERMINE THE CHARRING DEPTH AND CHARRING RATE

The temperature profile inside the timber specimen was used to calculate the position of the charring front in the simulations. It was defined as the 300°C isotherm [25]. The distance from the surface of the timber specimen to the position of the charring front at the end of the simulation was then defined as the charring depth. The charring rate was calculated by dividing the charring depth by the simulation time when the charring front reached that depth. An experimental setup was followed to create the simulation environment to model the timber pyrolysis and to evaluate the performance of the simulation.

3.4 EXPERIMENT DESCRIPTION

The Fire Apparatus for Non-standard Heating and Charring Investigation (FANCI) [4] was chosen as the experimental setup. It enables the investigation of the charring behaviour, the char layer surface regression, and the temperature distribution in a timber specimen, among other things. The experimental environment is called non-standard as the application of an airflow from 1 to 6 m/s is possible with a variable incident heat flux up to 120 kW/m^2 from a quick response heat panel to ignite the specimen [4]. Figure 2 and Figure 3 show the experimental setup used for the fire apparatus.



* variable external heat flux

** reference velocity at normal temperature

Figure 2: *Schematic view of the FANCI experiment setup [4]*

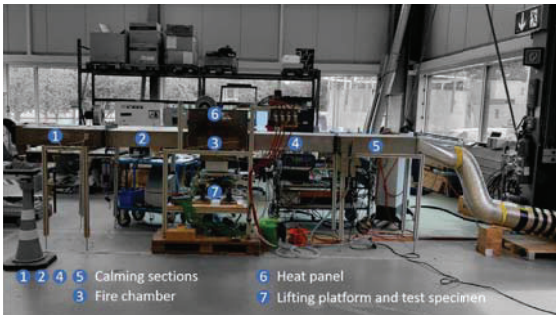


Figure 3: *FANCI test setup with the different components [27]*

The apparatus consisted of a long tunnel made of five sections, each section with a length of approximately 0.9 m, a width of 0.5 m and a height of 0.15 m as shown in Figure 3 [27]. The total length was approximately 4.5 m. Steel plates with a thickness of 1.5–3.0 mm were used to make these sections. The airflow was from the left

to right with respect to Figure 2. The timber specimen was placed in the section 3, called the fire chamber and positioned on the floor opposite a heat panel on the ceiling. The specimen had a length of 260 mm, a width of 225 mm and a thickness of 120 mm. The wood type was spruce, with a moisture content of around 12%.

For the comparison with the simulation results, the test JF00 from the FANCI test series was chosen [26]. In this experiment, a timber specimen was placed in the apparatus at a prevailing velocity of around 2.5 m/s, and the heat flux panel was calibrated to produce an incident heat flux of 96.4 kW/m^2 on the surface of the timber specimen. The specimen was heated by the heat panel for 20.1 min. The ignition occurred after ca. 0.42 min. The reported charring depth was 24 mm which was reached after 20 min. The charring rate for this test was 1.21 mm/min and the surface recession was 0.22 min/mm.

3.5 FDS MODEL

3.5.1 Geometry and mesh

The length of the tunnel for the simulation was shortened to 2.2 m instead of the length of 4.5 m in the actual experiment to reduce the computational time during the simulations. This was chosen after a sensitivity analysis to investigate the influence of the mesh size (1.25 cm, 1.0 cm and 0.625 cm) and the tunnel length on the airflow. Following the mesh sensitivity analysis, a mesh size of 1 cm was selected for the simulation. As there were no significant differences in the flow fields between the two geometries for all the simulations, a shortened geometry of the FANCI tunnel appears to be reasonable and capable of incorporating all the measurements that were measured in the FANCI-test experimental setup. The Figure 4 compares the geometry of the experiment and the simulation.

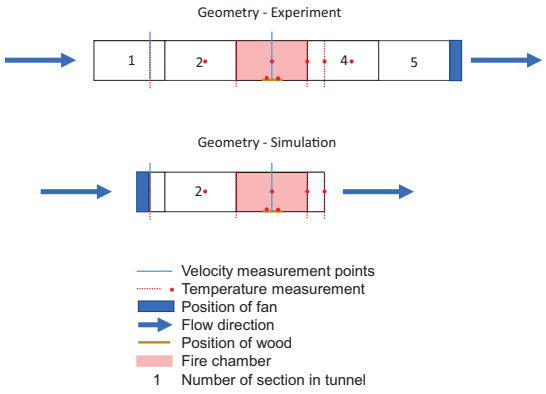

Figure 4: *Comparison of the geometry of the experiment and the simulation*

3.5.2 Temperature measurement

Following the experimental setup, gas temperature values were measured on the centre line of the tunnel. In the simulation, the temperature devices were distributed between the start of the fire chamber and the outlet, as shown in the Figure 4. Similar to the experimental setup, additional temperature measurements were done on the surface of the timber specimen and inside the solid.

3.5.3 Implementation of the mesh inside the timber specimen

For further analysis of the properties inside a solid, FDS has a special output recording option called &PROF [18]. This provides in-depth profiles of physical properties such as inlaid temperature, overall density, or density of different solid material components. The spacing of the solid grid defines the recording positions of these properties, which is done automatically by FDS unless changed manually [18].

Equation (9) defines the size of a solid phase cell or, in the case of one-dimensional heat transfer, the thickness of one layer inside the solid in the FDS. The simulation thickness is less than or equal to the calculated value.

$$\sqrt{\frac{\tau k}{\rho c}} \tag{9}$$

where τ = time constant [s], k = thermal conductivity [W/m·K], ρ = density [kg/m^3] and c = specific heat [J/kg·K].

By default, the distance between layers is smaller at the solid's surfaces and increases towards the middle by doubling their size to reduce the computational resources. They begin to shrink again as they approach the mid-depth. To some extent, the user can modify this solid grid by making the node spacing more uniform or by changing the mesh cells. The code line STRETCH_FACTOR, which is set to 2 by default, is responsible for the non-uniform spacing. This STRETCH_FACTOR was set to 1.0 for all the simulations to achieve a uniform spacing after a solid mesh sensitivity analysis. This resulted in approximately 248 layers inside the solid with a maximum thickness of 0.5 mm.

It should be noted that the spacing in Equation (9) is dependent on the thermal properties of the materials. when one of these changes, the number of layers also changes. Furthermore, if the burning causes the material to shrink or swell, resulting in a change in material thickness, FDS rechecks the total number of layers and adds or removes the layers as necessary.

3.6 OVERVIEW OF THE SIMULATIONS

The information available from the experiment for heating the timber specimen was an estimate of the incident heat flux on the surface of the timber specimen. Two heating methods were tested to achieve a similar incident heat flux on the timber surface in the FDS simulations.

The first option involved simulating an external heat flux with the same intensity as the experimental incident heat flux over the timber specimen. This simulation is named "S1-exHF" in this paper. In this method, the heat flux functions similarly to a perfect radiant panel or conical heating unit [18]. Option two involved defining a heat

https://doi.org/10.52202/069179-0231

panel on the tunnel ceiling above the wood specimen and calibrating it so that the amount of incident heat flux measured on the timber specimen surface has the same intensity as the one estimated in the experiment. This simulation is named "S2-HP". Dry timber specimens were simulated in these simulations using the temperature-dependent specific heat and the other input parameters listed in Section 3.1 and considered as the "standard simulations".

Additional simulations with modified input parameters were run apart from the standard simulations. One modification was introducing the moisture content to the timber specimen into the standard simulations ("S1-exHF-moisture" & "S2-HP-moisture"). This change also agrees with the experimental information, where the spruce had a moisture content of 12%. The goal was to see whether a more complicated pyrolysis model adds additional value to the output.

The other modification was to see the influence of the temperature-dependent input parameters on the simulation results. Instead of a temperature-dependent parameter, constant values were used for the specific heat of spruce and char in the standard simulation. This simulation is called "S1-exHF-cp". The simulation time was similar to the duration of the experiment, which was 20.1 (min).

4 RESULTS

4.1 COMPARISON OF THE IGNITION METHOD

The two methods which were used to ignite the timber specimen, once by a constant external heat flux over the specimen ("S1-exHF") and once by a heat panel ("S2-HP") showed similar results as shown in the Figure 5. The surface temperature measurements are slightly higher for the heat panel than the heat flux.

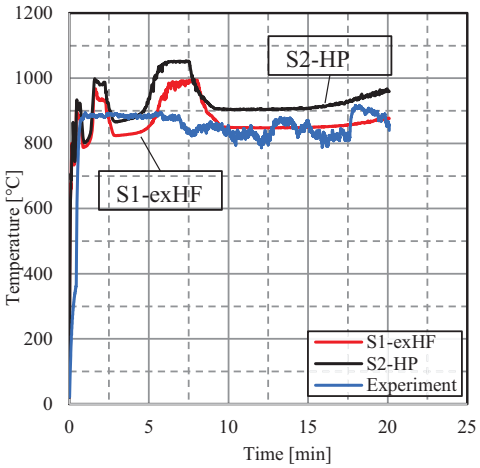

Figure 5: *Comparison of the surface temperature for experimental and modelling results for two ignition methods (S1, S2)*

The comparison of the mean surface temperatures shows temperature measurements of simulation to be very close to the experimental measurements but slightly higher. Taking into account that the measurements in the simulation were done by direct temperature measurements where the higher measurements were expected than those in the experiment where thermocouples have been used with a thermal inertia. Overall, it is visible that the temperature measurements in the simulation are in a good range. The external heat flux over the specimen is the best method to simulate the incidence heat flux on the specimen to compare with the experiment.

4.2 SURFACE TEMPERATURE MEASUREMENTS

The Figure 6 shows the comparison of the surface temperature of the specimen for different simulations compared to the experimental temperature values. The mean surface temperature for the experiment was 834.7°C, and the simulation values for the standard case and modified simulations are within 5% of this experimental mean value. These findings show that the surface temperatures in the experiment and simulations were very similar, indicating that the simulations had a similar fire exposure to the experiment. The modifications to the standard cases in the simulations have no significant effect on the results when compared to the experimental values.

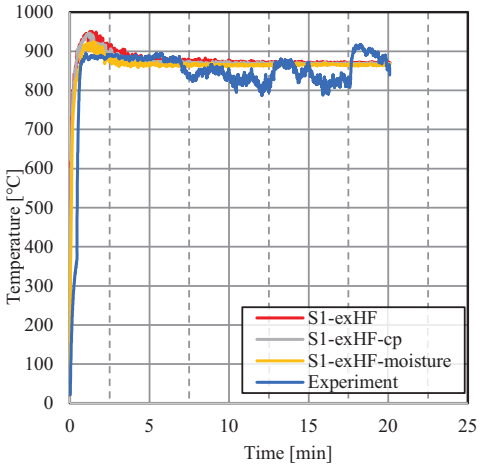

Figure 6: *Comparison of the surface temperature for experimental and modelling results for three specimens: dry, with constant specific heat and moist*

4.3 INLAID TEMPERATURE MEASUREMENTS

The temperatures inside the timber specimen from the experimental data are compared with the simulated results at various depths in the Figure 8. The thermocouple positions correspond to the depths measured in the experiment from the exposed surface as shown in the Figure 8.

Overall, the comparison indicates that the simulation temperatures are generally higher than the experiment. The above-mentioned trend was observed throughout the entire time, particularly at the deeper depths from the exposed surface. On the other hand, at the 6 mm and the

https://doi.org/10.52202/069179-0231

12 mm, the simulation temperatures close to the exposed surface are higher at the beginning of the test, but the experimental values gradually increase and become higher than the simulation values during the tests, as shown in the Figure 8. Further, at a depth of 18 mm, the simulation and experimental results end up in a similar temperature range. The comparison of the experimental and simulation results with ignition by a heat panel revealed the same pattern.

The reasons for the above difference could be diverse and might be related to the simplified definition of the charring process in the simulation or due to the inertia of the thermocouples in the experiment. Furthermore, the reaction parameters that were given as an input need to be optimised to define a realistic heat transfer into the solid for a non-standard fire exposure.

4.4 CHAR PROPERTIES

The graph in the Figure 7 compares the progression of the charring front through the timber specimen using the 300°C isotherm profile, where timber might char for the three simulations where the ignition was simulated by an external heat flux and for the experimental data. The charring rate has calculated using a linear regression in the experimental analysis. The data points in the simulations, on the other hand, show a logarithmic behaviour for the progression of the 300°C isotherm.

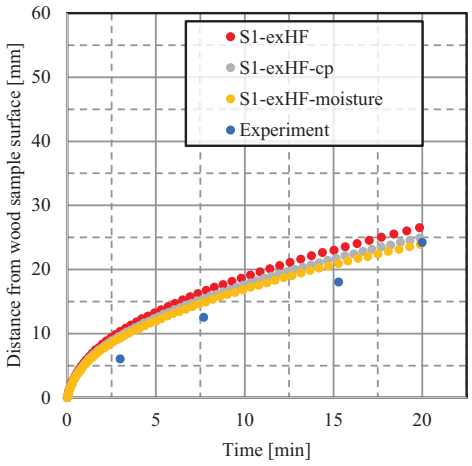

Figure 7: *Comparison of the char layer progression for experimental and modelling results for three specimens: dry, with constant specific heat and moist*

The Table 3 presents the charring depth and calculated charring rates for the simulations and the experiment at the end of the test. The comparison shows higher charring rates for the simulations with the dry specimen. The maximum difference in the charring rate for the simulations with the dry specimen is a 15.7% deviation from the experimental charring rate. On the other hand, the results for the charring rates with the moisture are very close to the experimental value.

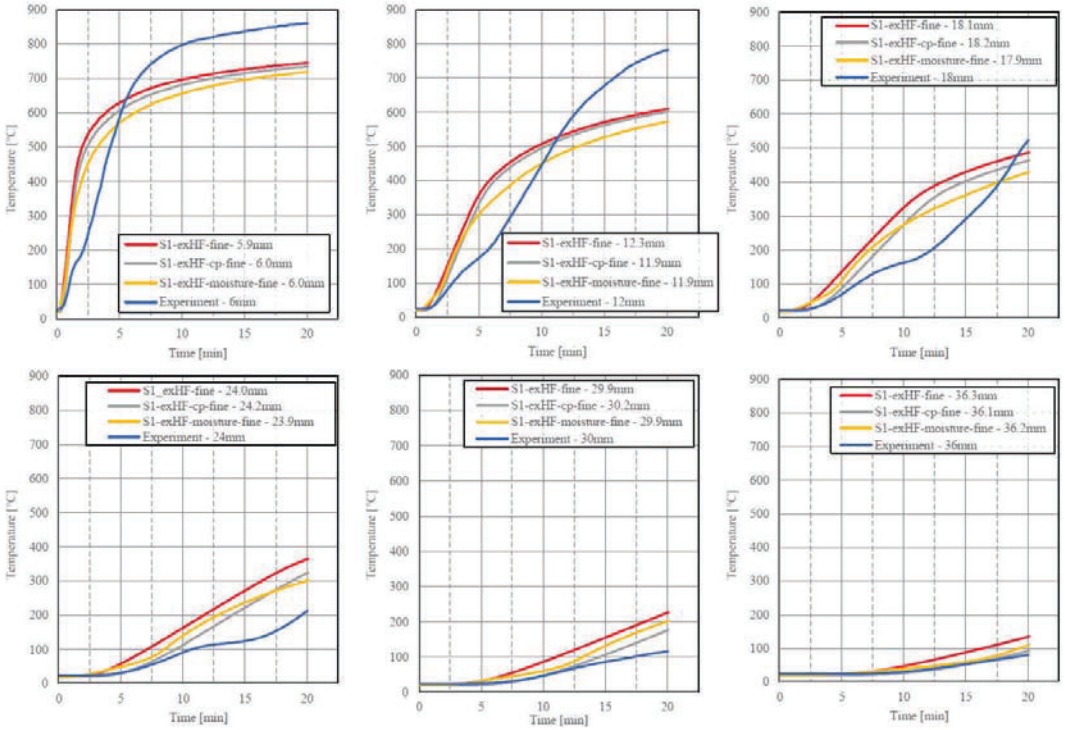

Figure 8: *Comparison of the temperature profile inside the timber specimen for experimental and modelling results at different depths for three specimens: dry, with constant specific heat and moist*

https://doi.org/10.52202/069179-0231

Table 3: *Charring depth and charring rate comparison after 20 minutes*

Parameter	Charring depth (mm)	Charing rate (mm/min)
S1-exHF	26.5	1.33
S1-exHF-moist	23.9	1.20
S1-exHF-cp	24.9	1.25
S2-HP	28.0	1.40
S2-HP-moist	25.4	1.27
Experiment	24.2	1.21

When the moisture is added to the specimen in the simulation, the charring rate decreases. This is because the moisture slows the heat transfer to the solid, resulting in a lower charring depth and rate. The simulation for moist specimen with the external heat flux accurately predicted the charring rate observed in the experiment. The difference is only 0.01 mm/min for the charring rate and 0.3 mm for the charring depth. Moreover, when the heat panel ignites the specimen in the simulation with moisture, the charring depth shows a 4.9% difference from the experimental value and the charring rate has a variation of 0.06 mm/min. Furthermore, it is visible that the simulation with a constant specific heat leads to a lower charring rate compared to the dry specimen and a higher charring rate compared to the moist specimen.

5 CONCLUSIONS

The purpose of the study was to simulate the burning behaviour of a timber specimen using the field model FDS. The simulation coupled the gas and solid phase processes in a fire. The focus was given to predicting the charring depth and the charring rate.

The comparison of the simulation and experimental results revealed a relatively good agreement for the charring rate and surface temperature measurements. The comparison of the temperature profiles inside the timber specimen revealed that the simulation temperatures are generally higher than the experiment temperatures. However, this trend was different close to the exposed timber surface.

The presence of moisture in the pyrolysis model of the timber specimen resulted in lower surface and inlaid temperatures compared to the results with the dry specimen. Further, the moisture influenced the charring rate and it is recommended to include that in the simulation for accurate results. On the other hand, using a constant specific heat instead of a temperature-dependent value also resulted in a slightly smaller charring depth. This shows the dependency of the simulation on the user input data and the importance of selecting accurate inputs for the model. The modified simulations with the constant specific heat showed only a 0.08 mm/min difference in the charring rate compared to the simulation with the temperature-dependent values. Therefore, in the initial simulations it is possible to use a dry specimen with constant specific heat to reduce the computational time while achieving reasonable results for the charring properties. Later, the moisture and temperature-dependent properties can be added to the simulation to achieve a higher level of accuracy.

Even though the simulations showed good agreement with the experiment for the solid phase measurement, there were few variations in the gas phase measurements. Therefore, further research is necessary to improve the simulations and to produce accurate gas phase results. Furthermore, to study the surface regression of the char, a more complex pyrolysis model is needed, including char oxidation.

EXPLICIT FIRE SAFETY FOR MODERN MASS TIMBER STRUCTURES – FROM THEORY TO PRACTICE

Laura Schmidt[1,2], Ryan Hilditch[1], Adam Ervine[1], Joshua Madden[1]

ABSTRACT: A holistic methodology for explicit fire safety strategies for buildings with mass timber structures has been developed based on theoretical frameworks outlined in the literature and the current state of published research on the fire behaviour and safety of mass timber structures. This paper presents the four main pillars of this methodology: tenability for occupant evacuation; heating of the mass timber structure and loss of loadbearing capacity; external flaming; and assessment of the potential for self-extinction of the mass timber structure after burnout of the movable fuel load. The application of the methodology to three case study buildings showed the need for interdisciplinary collaboration throughout the design and planning of mass timber buildings. Engineering and design decisions including structural design options, the extent of exposure of the timber, façade type and construction and general building layout influence the resultant level of fire safety to an even greater extent for buildings utilising structural mass timber elements than for buildings with non-combustible structures. All practitioners collaborating on design projects with mass timber structural elements require a contemporary understanding of the persisting limitations around timber fire safety strategies and research as anyone whose work affects or limits the fire safety measures on such a project will carry a certain ethical or legal responsibility for the outcomes and consequences of a fire.

KEYWORDS: Mass timber structures, exposed engineered timber, fire safety strategy, holistic fire engineering

1 INTRODUCTION

The construction industry is faced with increasing pressure from different stakeholders to integrate mass timber structures into modern designs. Specifically, fire engineers are expected to support these designs in their many forms. The main hazard of mass timber structures is the potential for the structure itself to contribute to the fuel load in a fire, potentially affecting the fire severity and duration. Exposure to fire and heat will also result in reduced structural capacity of structural mass timber elements. The consequence associated with loss of structural capacity is a local or global structural failure, leading not least to breach of compartmentation, potentially endangering occupants by not providing sufficient time to safely evacuate the building and fire brigade personnel by not providing sound structural conditions for search and rescue operations and intervention.

Fire safety strategies must consider the inherently different fire performance of combustible structures: from the ignition of the timber structure, fuel contribution, and altered fire dynamics to self-extinction. However, traditional frameworks and calculation methods currently available for fire and structural engineering have been originally developed for non-combustible structural materials.

This paper presents a theoretical methodology developed for fire engineering practice. It will discuss the shortcomings and knowledge gaps hindering the application of the developed methodology and report further challenges encountered in the practical realisation of real-life timber building designs.

Fire safety engineers must carefully assess which tools originally developed for non-combustible structures, like reinforced concrete or steel structures, remain applicable and where new frameworks and methodologies are required when materials and geometries change. Historically, most research has been focused on small compartments in the order of 10 m2 [1]. Consequently, most existing frameworks for assessing fire safety have been developed for small compartments. Research into the fire dynamics governing fire evolution in large, open-plan compartments has only begun to receive focus in the last few decades [2]. Until very recently [3], this work again assumed the use of non-combustible structures.

The characteristics of the local temperature profiles and fire dynamics become more complex in fires that involve combustible structures [4]. This complexity is especially due to the in-depth heating affecting both the loss of loadbearing capacity and production of flammable pyrolysis gases for combustible structures: The energy released by the combustion of the movable fuel load causes heat transfer into the timber structure. At elevated temperatures, pyrolysis of the timber structure results in combustible gases adding additional fuel to the combustion reaction. A char layer may form on the timber surface. The production and combustion of combustible gases contributed by the structure itself affect the local and global energy balance, which, in turn, has an impact on the pyrolysis reaction within the timber. In summary, the burning of the movable fuel load and the thermomechanical degradation and burning of the combustible structural elements are coupled [5].

[1]WSP Australia Pty Limited, Australia
[2] WSP UK Limited, United Kingdom,
laura.schmidt@wsp.com

https://doi.org/10.52202/069179-0232

The complexity of assessing combustible timber elements' degradation and fuel contribution is further increased since the degradation is thermomechanical, i.e. it depends on the mechanical and thermal loading. Phenomena like char fall-off have the potential to further weaken the structure [6] [7].

The possible impact of the burning of the timber structure itself on the fire growth is presented in Figure 1, in direct comparison with the fire development expected in a compartment with a non-combustible structure. The fire could grow more rapidly following the onset of pyrolysis and ignition of mass timber elements as they contribute additional fuel to the fire. The additional fuel may lead to higher heat release rates inside the compartment of origin, causing a faster transition to flashover, i.e. a fire involving all available fuel. Moreover, external flaming is expected to become more severe if an increased amount of gaseous fuel burns outside the compartment openings [3].

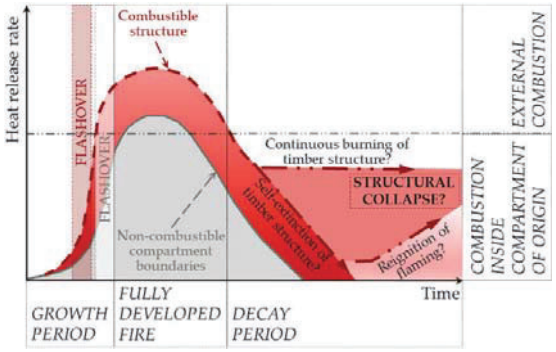

Figure 1: *The expected impact of a combustible structure (dashed red curve) on the fire development following ignition of the structure in comparison to non-combustible compartment boundaries (solid grey curve) in small compartments: increased total heat release and faster transition to flashover, changed heating conditions and thermo-mechanical degradation of the structure, potential for more severe external flaming and the possibilities of continued burning of the structure until collapse or self-extinction (adapted from Drysdale [8] and Hidalgo [9]).*

Fire safety strategies for high-rise buildings generally rely on structural integrity being maintained for longer than the duration of a fire. High-rise buildings require extended evacuation periods, during which occupants must be provided with adequately safe conditions. Moreover, the structural capacity must be sufficient to provide safe conditions for emergency personnel, who may need to enter the building for search-and-rescue operations or internal firefighting. The fire – referring to the combustion of the moveable fuel load (building contents) as well as the combustible structure itself – must eventually cease if sufficient structural capacity is to be retained.

A sound fire engineering methodology must assess if a given design (geometry, ventilation, exposed timber surface area, engineered timber products and other factors) allows for self-extinction to be achieved. In this context, self-extinction refers to the total burnout of the structural fuel. Self-extinction of the mass timber structure shortly after burnout of the movable fuel load is critical to avoid loss of load-bearing capacity until structural collapse [4].

It is important to differentiate between the extinction of flaming combustion and the extinction of smouldering combustion. Smouldering combustion may occur after flaming combustion [10]. While the heat generation of smouldering combustion is generally lower than flaming combustion, smouldering has been seen to continue for hours with prolonged heating leading to structural collapse hours after the extinction of visible flaming combustion [11] [12].

Most existing frameworks, including standard fire resistance tests, were originally developed for non-combustible structural materials, products, and elements. The additional energy generation from exposed combustible members is not accounted for [13]. Standard methods and calculations have been shown to potentially underpredict the loss of structural capacity [11] [14]. Moreover, calculating a Fire Resistance Level (FRL) using the existing frameworks does not allow a holistic assessment of fire safety and in no way supports the prediction of the potential for self-extinction of the combustible structural elements. For timber, some guidance documents describe so-called char depth or zero strength layer calculations to assign FRL to building elements. However, these calculations generally do not consider the fire dynamics and the importance of the incident heat flux. Therefore, existing frameworks are not able to assess the fire safety of mass timber structures to the level of existing knowledge around the complexities and relevance of the critical phenomena.

This paper aims to present the four key areas of fire safety that need to be addressed in the design of any building with combustible structural elements through a holistic fire safety strategy:

1. Influence of the burning of combustible structural elements on fire growth and tenability conditions;
2. Loss of loadbearing capacity of the heated combustible structural elements, considering the impact on the fire intensity and duration;
3. Potential impact on external flaming;
4. Self-extinction of the combustible structure after burnout of the movable fuel load.

The boundary conditions, compartment configuration, ventilation and other design decisions greatly influence the fire behaviour of combustible structures but vary considerably between buildings. Therefore, any fire safety strategy for buildings with mass timber elements needs to be performance-based. However, to the knowledge of the authors, currently, no prescriptive framework exists that addresses all of the above.

A holistic methodology based on concept steps proposed in previous literature [4] has been developed. Through practical application to several real building designs, critical knowledge gaps and limitations around key design variables have been identified and will be discussed in the following. In practice, a collaborative approach between all involved disciplines and stakeholders has proven critical to the development of fire-safe mass timber buildings.

https://doi.org/10.52202/069179-0232

2 PROPOSED METHODOLOGY

A four-part methodology is proposed to enable a holistic review and assessment of mass timber structures (see Figure 2). This methodology addresses the key elements of any fire safety strategy (fire growth and extinction; evacuation and tenability; heating of structural elements and structural stability; smoke spread and external flaming) with a special focus on the hazards introduced by the use of combustible structural timber.

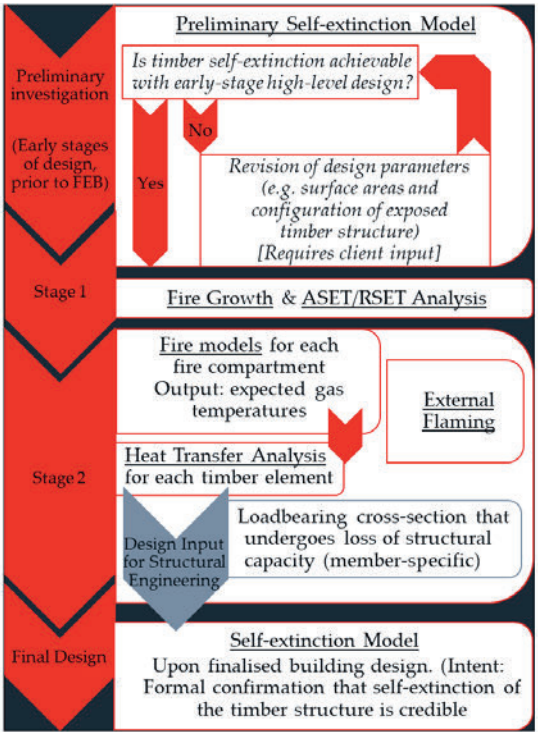

Figure 2: *Proposed fire engineering analysis of mass timber structures in the context of performance-based design.*

The order in which the different assessments are performed is based on the flow of projects encountered in construction practice, involving several stakeholders and interdisciplinary design decisions influencing the fire safety strategy, as well as the outputs of certain frameworks feeding into the calculations performed thereafter. The assessment of self-extinction is performed in the conceptual stage and informs important design decisions. The refined design is then assessed with different design fires regarding evacuation and tenability criteria.

It is not possible to accurately predict the nature of an accidental fire (fire source, spread directions, spread rate, etc.). This is especially true for large, open-plan compartments since the boundary conditions play a significant role in the fire development. Therefore, design fires for the assessments of tenability and heat transfer to the structure (see below) need to be chosen to provide upper and lower bounds, possibly working backwards using a worst-outcome approach.

The evacuation and tenability criteria are mostly identical to those that would be used in a building of the same occupancy and design but with a non-combustible structure. However, for the analysis of a mass timber structure, an additional criterion considering the ignition of the combustible structure needs to be considered. The structure's loss of loadbearing capacity due to heating is then assessed considering the thermal environment inside the compartment during different design fires. The output feeds into the structural design which can then provide sufficient sacrificial depth for the considered design fires on the one hand and optimise the material use on the other hand.

2.1 SELF-EXTINCTION

The potential of a proposed design to achieve self-extinction is the most critical design parameter and hence is suggested as the first step in the early design stages. Structural collapse will occur eventually if extinction of all combustible structural elements is not achieved. Once the continuous heat transfer from self-sustained combustion of the structure has reduced the structural capacity sufficiently to cause local collapse, the loss of compartmentation is a likely consequence, allowing for fire to spread outside the compartment of origin and violating the basic principles of most fire safety strategies. Therefore, the potential for self-extinction must be assessed by any fire safety strategy relying on the integrity of combustible structural elements. The framework for self-extinction of the timber structure is therefore proposed to assess indirectly the potential to retain adequate structural stability after burnout of the movable fuel load, for which self-extinction of the combustible structure is critical.

The term *self-extinction* must refer to the complete cessation of both flaming and smouldering combustion in this context. It is important to note that many publications report *self-extinction* as the cessation of flaming, regardless of smouldering combustion. As such, most of the criteria presented in literature which can be used as a design basis are limited to flaming extinction alone. Only after all combustion and therefore heat generation has stopped, the transfer of additional heat into the structure will cease and the elements can begin to cool down. Therefore, both flaming and smouldering combustion must self-extinguish or be actively extinguished and not continue self-sustained after burnout of the movable fuel load. Continued smouldering can also lead to the reignition of flaming. However, significant knowledge gaps around the smouldering of solid timber persist, especially with regard to its self-extinction.

The period of interest for consideration of timber self-extinction is during the fire decay phase after the flaming combustion of the moveable fuel has ceased within the compartment. Numerous focused studies [5] [15] [16] have observed that self-extinction of exposed timber, i.e. cessation of flaming combustion involving the exposed timber itself, can occur gradually within a compartment if well-ventilated conditions are present after the burnout of the moveable fuel load.

The proposed framework assesses a design fire scenario in which flashover has resulted in the ignition of all

exposed mass timber elements which continue to combust and emit heat simultaneously immediately after the movable fuel load has burned out. At this point, it is critical to understand the energy balance across the compartment, and whether the heat losses from each structural timber element are sufficient to result in the self-extinction of the member in this worst-case scenario in terms of ignition of available combustible structural fuel load. Adequate assumptions regarding the boundary conditions are critical as they impact the global energy balance of the compartment.

If the model shows that the incident heat flux into the timber is lower than the critical heat flux for sustained combustion while all surrounding mass timber elements are radiating, this means that these conditions cannot be self-sustained, i.e. permitting eventual self-extinction. If the received heat feedback results in a local positive energy balance sufficient to promote further pyrolysis beyond the char layer, the timber element can continue to undergo and promote combustion and will eventually lose structural integrity.

Computational Fluid Dynamics (CFD) modelling of each fire compartment can determine the theoretical potential heat feedback between burning timber surfaces. Therefore, each fire compartment is modelled with the proposed dimensions and other relevant characteristics. For the assessment, the surfaces of the remaining timber members are considered to be at elevated temperature and continuously undergoing exothermic reactions transferring heat into the compartment. A burning rate per unit area and temperature are assigned to the surface of each combustible structural element as proposed by Sahoo et al. [17]. Radiation modelling in CFD models is very sensitive to input parameters such as the soot yield, radiative fraction, radiation solid angles and path length. The incident heat received by each exposed mass timber surface as feedback from the other radiating timber surfaces must be below the critical incident heat flux for self-sustained burning. Otherwise, design parameters like the orientation and extent of exposed timber members need to be adjusted. The factors affecting the potential for self-extinction of the mass timber structural elements (geometry, configuration and view factors between timber surfaces, choice of materials, compartmentation, ventilation, etc.) must be considered in major design decisions, which are generally made in the early stages of a project. It is therefore advisable to perform a preliminary self-extinction assessment including a sensibility study in the early conceptual design stage to ascertain the credibility of timber self-extinction. The design limitations posed by the need for self-extinction can then inform the project going forward. The final self-extinction assessment can be carried out as the last step of the holistic fire safety assessment of the refined design.

2.2 EVACUATION AND TENABILITY

Life safety is the underpinning principle of any fire safety engineering effort. Safe conditions must be maintained for the required evacuation duration. Evacuation and tenability are often quantitatively assessed through a comparison of the Available Safe Egress Time (ASET) with the Required Safe Egress Time (RSET) with adequate safety factors for a range of primary and secondary fire scenarios.

The onset of untenable conditions for evacuating occupants, i.e., the end of the ASET, can be defined as and assessed via a range of criteria, e.g. sufficiently low temperatures not endangering human life, visibility levels that allow identification and navigation of evacuation routes, and adequate toxicity levels. These criteria can be applied to buildings with and without combustible structural materials.

In buildings with combustible mass timber structures, the ignition of the mass timber elements must be introduced as a further criterion to mark the potential onset of untenable conditions. The time between the initial onset of the burning of the movable fuel load and the ignition of the mass timber structure will vary between different fire scenarios and fire compartments.

In the context of tenability and evacuation, the expected critical impact of the burning of the timber structure is a potential decrease in the time until the onset of flashover conditions and a potential increase in the heat release rate within the compartment. All these effects can negatively impact the ASET.

Once a timber ceiling has ignited, it is expected that fire spread across the ceiling will occur rapidly [3] [12] [18]. The fire spread across combustible ceilings has been experimentally observed to support a rapid transition to flashover conditions [3] [12] [18], the rate of which is also affected by the ceiling profile. During flashover, all combustible materials within the compartment are on fire and more combustible gases are released than can burn within the compartment, which leads to combustion occurring outside the openings of the compartment. Occupant survival within a flashover compartment is considered impossible. Notably, the fire compartments with timber ceilings in our case studies were up to three times larger than the compartments in the subject experimental studies (see Section 4).

2.3 HEATING OF THE STRUCTURE

The temperature evolution within each structural mass timber element affects its loss of loadbearing capacity throughout the fire growth, fully developed fire, and decay phase. The remaining structural capacity needs to adequately support at least the design loads in the fire case which must be assessed in collaboration with the structural engineer. The selection of temperature criteria for the reduction of loadbearing capacity of heated timber members needs to be well documented to provide transparency and be based on relevant literature.

Heat transfer modelling to theoretically determine the in-depth temperature of the mass timber structure requires knowledge of the boundary conditions, including the incident heat flux or surface temperature of the timber element over time, as well as material properties. Expected maximum timber surface temperatures during the fully developed fire could theoretically be obtained from the modelling of a set of fire scenarios. The burning of the movable fuel load and combustible structural elements are coupled, as

https://doi.org/10.52202/069179-0232

explained previously [5]. Hence estimations of the expected burning duration must consider the coupled burning of the movable fuel load and mass timber structure, the compartment geometry, and ventilation.

If fire-protective layers are installed, it must be assessed when critical temperatures are reached within the timber underneath, causing loss of loadbearing capacity and contribution of combustible gases to the global fuel load (pyrolysis). Passive fire protection like protective non-combustible layers (e.g. plasterboard) are sometimes installed to delay the heating in depth of the timber and prevent involvement of the combustible structure in the fire. It is important to recognise the duration of the protective function provided and to consider the possibility of plasterboard failure as observed in large-scale experiments after which the formerly protected timber surfaces experience significant heat transfer [5] [10].

In the context of structural heating, the potential impact of the burning of the timber structure is firstly to increase the heat release and heat release rate and secondly to extend the burning duration by increasing the total available fuel load. Not only the increased total energy release but also the extended duration of heating can increase the in-depth heating of the timber structure, which is expected to result in increased and prolonged thermal degradation. Given the coupling of the combustible structure's thermal degradation and the fire dynamics, increased in-depth heating of the timber results in increased fuel contribution to the fire, which results in a feedback loop between the structure and the ongoing fire. This process can theoretically continue until all combustibles are consumed, unless sufficient char is formed and retained to allow for self-extinction of the timber, or firefighting intervention occurs.

Numerical models of burning timber must consider complex temperature-dependent processes like drying, pyrolysis and char oxidation. A finite difference model that accounts for the change in properties between virgin timber, dried timber and char was presented by Osorio [19] together with a review of existing models. Models like this can be used to estimate the in-depth temperatures in timber using a simplified energy balance accounting for the incident heat flux at the surface by summing the external heat flux and heat losses based on material properties and the thermal environment [7]. Heat transfer modelling to determine the temperature profiles within the timber complement the calculations performed by the structural engineers.

Due to the laminated nature of engineered timber, parts of the timber product can detach from the underlying structure [5] [6] [7]. In a fire, this phenomenon can add fuel, delay or prevent self-extinction and decrease residual structural capacity.

To account for the possible separation of lamella or loss of charred sections, it is proposed to consider the material properties of the proposed timber type and species, and to define failure, i.e. fall-off of lamellae and subsequent exposure of the underlying timber sections in the heat transfer model.

Prediction of debonding in heated engineered timber would require further research on the combined thermal and mechanical loading, and presents a highly complex problem. Publications that investigate the loss of charred sections from burning timber [6] [7] report no direct correlation between temperatures at the adhesive-timber interface and char fall-off. Therefore, it must be assumed that charring as well as char loss may occur.

A sensitivity study could be employed to assess the potential impact of the volume of charred lamella detaching from the exposed mass timber structure on the heat release within the compartment. Additional heat release from smouldering or flaming combustion of the detached char and partly charred sections needs to be considered as additional fuel load after falling to the compartment floor. The impact of the heat release of these materials on the potential for self-extinction of the mass timber structure after burnout of the movable fuel load must also be analysed as heat generation from smouldering combustion of charred timber has been observed to possibly continue for extended durations [12]. This additional heat release may have the potential to increase the incident heat to the exposed combustible structural elements beyond the critical limits for self-extinction.

For structural purposes, it is proposed to fully discard the depth of the cross-section that heats above a critical temperature. The additional required depth of timber has to be added to the cross-sectional depth of any load-bearing timber member as required for structural purposes.

2.4 EXTERNAL FLAMING

The potential for external flame spread to other floors, fire compartments, and neighbouring buildings must be assessed. External flaming radiates heat back at the façade of the building. Sufficiently high incident radiant heat received by other floors above and below the floor of fire origin can result in glazing breakage and ignite combustible materials within adjacent fire compartments, potentially resulting in uncontrolled vertical fire spread throughout the building, as seen in fires like the Grenfell Tower Fire in 2017 [20].

The potential severity of external flaming is expected to initially increase with increasing fuel load. Governed by the ventilation conditions, the combustible gases will partly burn inside and partly outside the fire compartment after partial or full window glazing failure. Increased heat release within the compartment can result in a larger effective height of the flames external to ventilation-controlled compartments. The assessment of external flaming must therefore consider the contribution of fuel provided by the timber structure itself over time, as well as several other factors such as available ventilation, opening orientation, compartment layout and the like.

Some local boundary conditions are especially difficult to predict and account for, yet could have an impact on the external flaming in a real fire. For example, wind conditions or the burning of a column located at the external compartment boundary are qualitatively understood to influence the intensity of the flame protruding but are difficult to quantify based on existing knowledge. Published scientific literature currently

lacks experiments assessing flame extension from uncontrolled fires in very large compartments of 100 m² or more, especially for buildings with mass timber structures [2] [8]. For example, the experimental work that underpins the Eurocode flame extension calculation was based on compartments with an area of less than 100 m². However, many modern designs aim for compartment areas in the order of 1000 m². This introduces further uncertainty into the external flame length calculation for such complex spaces.

When using the Eurocode calculation method to evaluate the impact of increasing the quantity of available fuel, a fuel load density quantity is reached after which increasing the fuel load density further ceases to increase the external flame height. This is understood to be because once a constant/maximum temperature is reached inside the compartment, the production of pyrolysis gases is then considered limited by the surface area of available fuel, and the combustion by the availability of oxygen based on the size of the compartment openings. These complex mechanisms bound the rate of combustion internally and, to some degree, control the impact of the contribution of the timber fuel to the internal combustion. The complex compartment fire dynamics that the combustible timber contributes to are responsible for affecting the resultant heat fluxes within the compartment and, by extension, the pyrolysis of the timber throughout the fire duration. These complex actions contribute to the resultant quantity of unburnt combustible gases escaping the compartment, and upon reaching fresh oxygen, undergoing flaming combustion externally.

3 CASE STUDIES

The methodology presented above was applied theoretically to three buildings with exposed mass timber structures, following the sequence as presented in Figure 2. Detailed design plans were attained and the buildings were assessed in line with Australian national building codes and regulations. Application of the methodology to the theoretical projects emphasised the limitations of existing guidance documents and persisting knowledge gaps around most of the design variables discussed previously.

3.1 DESCRIPTION OF THE BUILDINGS

The design plans utilised for the case study assessment represented three buildings with varying degrees of open-plan compartmentation; two were office buildings with typical open floor plates in the order of 1,000 m^2, one with seven and the other with three storeys, and an education building with large open areas adjacent to a series of smaller classroom configurations (total floor plate also in the order of 1,000 m^2, four storeys).

The designs of the mass timber structures of each building were seen to be generally similar: glulam columns, cross-laminated timber (CLT) beams and floor slabs, non-combustible internal partition walls (typically stud walls finished with plasterboard), and slab-to-slab height in the order of 3.8 m. Each building included storeys interconnected via an open stair or atrium configuration (never more than two storeys at a time). All buildings were provided with fire-isolated stairs and fire sprinklers. Other safety systems were provided in accordance with the prescriptive requirements of the Australian National Construction Code. The undersides of the CLT floor slabs were exposed in most areas (no suspended ceilings). The floors were provided with non-combustible, raised floor systems. Some exposed timber floors were also proposed in isolated locations.

The extent of glazing in the external walls in the case studies differed substantially from the compartments in studies published to date. Each case study building included 50-70 % glazed curtain wall, generally in a slab-to-slab design, whereas the majority of timber structure fire research to date has utilised external walls with a series of smaller windows, normally occupying the upper half of the wall [2] [3] [10] [12].

3.2 FIRE GROWTH & TENABILITY

The Stage 1 model assessed the onset of untenable conditions during occupant evacuation using CFD fire/smoke modelling and an empirical evacuation model to compare the Available Safe Egress Time (ASET) until untenable conditions were reached with the Required Safe Egress Time (RSET) for occupants to safely evacuate.

The fire scenarios modelled the movable fuel load with an initial t-squared fire growth rate based on the subject project and took account of the impact of the involvement of any of the exposed mass timber by conservatively assuming that rapid fire spread across the ceiling would occur should the timber ceiling reach the critical temperature for ignition (taken as 300°C [8]) in any location. This also accounts for the variable ceiling spread rate observed across experimental works.

Research [3] [12] has shown rapid fire spread horizontally under combustible ceilings where fire sprinklers are generally deemed ineffective and vertically on combustible walls. It is understood that flashover conditions occur soon after ignition of the combustible surfaces where significant or sustained pre-heating has taken place prior. Therefore, ignition of the exposed timber was considered as a failure criterion, meaning occupants must evacuate the fire floor before timber ignition.

It is important to note that the fire sprinkler system was considered to have failed on demand for all fire scenarios. This is considered to be reasonable based on our internal review of the available sprinkler statistics. Broadly speaking, it is prudent to assume that one out of ten fires results in an uncontrolled fire scenario, meaning that sprinkler failure must be considered as part of a holistic fire engineering assessment.

The impact of setting timber ignition as 300°C versus a traditional t-squared fire was significant. The available safe egress time is normally assessed with criteria such as the smoke temperature at a given height and the resultant radiant flux to the floor with the capacity to cause injury to occupants, with the time required for smoke layer build-up being the mechanism of interest. By contrast, the exposed timber ceiling, most likely directly above the fire plume, is at risk of igniting in a

https://doi.org/10.52202/069179-0232

fraction of the time of unacceptable smoke layer build-up. Across our models, this time was in the order of half. However, the time to timber ignition depends on the building layout, structural member configuration and orientation, slab-to-slab height, beam layout and opening location.

3.3 HEAT TRANSFER & CHAR DEPTH

Different design fire scenarios were developed to attain temperature curves near the ceiling that were then used as inputs for the heat transfer model. The aim was to develop temperature curves representative of a fire involving the structural timber in the real space as designed. Different bounding fire growth scenarios were developed, including rapid growth to a high HRR resulting in a shorter burning duration, to assess short hot fires, and slow fire development with extended fully developed and a decay phase. Various opening configurations, building layouts and exposed timber configurations were considered, and could be similarly assessed as part of a collaborative design approach with the architect and structural engineer in real projects.

The finite difference heat transfer model [7] [19] with the estimated heating curves in the subject compartments was then applied to a range of timber members with different lamella layups to estimate the thermal gradients in depth of the CLT or glulam. The model attempted to account for the potential impact of loss of charred section on CLT members by assuming failure at consecutive glue lines, which is understood to be an oversimplification. However, no methodology exists which can account for all relevant coupled causal factors such as mechanical and thermal loads throughout the timber and in particular affecting the bond between lamellae. Thicker outer lamella were generally understood to provide preferable outcomes as the glue lines were seen to receive less heat later. However, failure of heated bonded lamellae and various adhesive types is not well understood (also see Section 4.5) [6].

Uncertainty persists around required input values such as thermal conductivity, specific heat capacity, and heat transfer coefficients that are functions of temperature, species and other factors. Assumptions for these variables were made based on available scientific literature. However, the available data does not support rapid and robust application of this approach to real timber designs.

This theoretical approach assesses the heat transfer for compartment-specific design fire scenarios. The in-depth heating rate depends on a range of variables including the compartment design and ventilation. The incident heat may be less, similarly or significantly more onerous than that from a standard fire curve.

3.4 EXTERNAL FLAME HEIGHT

The fully-developed design fire could amount to a ventilation-controlled or fuel-controlled fire, depending on the available ventilation through compartment openings. In a ventilation-controlled fire (A), the expected impact of adding more fuel gas is to prolong or increase the intensity of the external flaming, i.e. the combustion of unburnt fuel gases that exit the compartment. The addition of the mass timber fuel possibly has little impact upon the HRR achieved within the compartment if all of the available oxygen is already consumed by the moveable fuel combustion. If the burning of the moveable fuel load is not ventilation-limited but fuel-controlled (B), some of the additional mass timber fuel is considered to burn within the compartment, up to the limit permitted by the available ventilation, and increase the heat released within the compartment.

While modelling the range of buildings and various compartments, both ventilation-controlled (A) and fuel-controlled (B) cases were observed. During the case studies, a flame extensions review was undertaken in accordance with BS EN1995-1-2 to assess the impact of the additional fuel load provided by the timber structure on external vertical flaming. A range of fuel load densities was assessed and the fuel provided by the mass timber structure was added. The calculation assessed a scenario in which an uncontrolled fire had occurred (sprinkler failure) and enough glazing broke to sustain a post-flashover fire. The external heat release rate increased by 15-17 % when the timber fuel was added to each fire scenario. The ratio of the maximum HRR attributable to the moveable and timber fuel in each scenario varied, as did the number of available openings.

Experiments assessing flame extension from uncontrolled fires in very large compartments are lacking from the scientific literature, especially for the case of a building with a mass timber structure. The experimental work that underpins the Eurocode flame extension calculation studied compartments with an area of less than 100 m^2. Therefore, the case study calculations were run for typical small compartments in the order of 3 x 3 m and also at the limits of applicability of the calculation method (ca. 100 m^2), despite the floor plate of the case study building compartments generally were in the order of 1,000 m^2. The impact of increasing the room size from 9 m^2 to 100 m^2 (i.e. one order of magnitude) was to increase the incident flux by 0.5 kW/m^2 to ca. 16.5 kW/m^2.

Upon review of the range of results, the external flame was evaluated as the radiant flux back to the building at 2.0 m above the opening. In the case studies, the incident radiant flux received by the glazing of the floor two storeys above the fire floor was deemed too low to induce thermal glazing failure. A review of the limited available literature on heat-induced glazing failure determined that laminated glazing is not likely to fail when exposed to an incident flux of up to 25 kW/m^2. The unknowns regarding extrapolation test results with specific designs to real design cases needs to be assessed in future work.

3.5 SELF-EXTINCTION

The assessment involved CFD modelling of fire compartments with dimensions as designed, and varying extent and configuration of exposed mass timber surfaces. The timber surfaces were assigned a burning rate per unit area (heat release rate per unit area) and temperature. The boundary conditions for the

compartment at the point of extinction of the moveable fuel load were defined to assess the scenario of minimum heat losses.

The incident flux received across all exposed timber surfaces calculated by the model was then compared with the critical incident heat flux for self-extinction reported in published research to determine if self-extinction was credible. The critical incident flux for flaming combustion reported in the literature is in the order of 30 to 42 kW/m2 for a series of lab and compartment experiments [15] [21]. However, the critical incident heat flux for self-extinction is a function of the experimental environment and conditions, including the char layer thickness [21]. Consequently, the critical heat flux for self-extinction will vary on a case-by-case basis depending on compartment boundary conditions, such as the available ventilation (quantity and size of openings) or the configuration and orientation of internal surfaces. The unknowns regarding extrapolation of experimental values for a range of compartment sizes and configurations needs to be assessed in future work.

4 DISCUSSION AND LIMITATIONS

The proposed methodology including the finite difference heat transfer model is a fundamental approach to mass timber design for fire safety. However persisting scientific knowledge gaps require to be filled to improve confidence and enable reduced inherent error in this fundamental approach. The key limitation of the proposed methodology relates to data availability and applicability, predominantly in the areas discussed in the following.

4.1 BURNING AND HEAT RELEASE RATES IN OPEN-PLAN COMPARTMENTS

The rate of energy released by the burning movable fuel load changes over time as a function of the thermal environment within the fire compartment. Higher heat feedback to the fuel increases the energy release rate and reduces the fire duration due to energy conservation.

The heat feedback to the fire changes with changing compartment geometries. The assumptions based on ventilation-controlled regimes no longer apply once the compartment becomes sufficiently large and well-ventilated. Spatial and temporal distributions of temperatures and incident heat fluxes on compartment boundaries are determined by the fire spread mode [2]. The heterogenous temperatures throughout a large compartment can lead to longer burning durations of the movable fuel load compared to compartments in which uniform burning of all fuel can be assumed [2]. As a consequence, the duration of thermal exposure to structural members increases.

Both the heat received over time and the burning duration affect the heat transfer into structural elements within the fire compartment. A high HRR over a short duration can be more favourable from a structural perspective than a longer lower HRR.

Different fire scenarios have to be assessed considering the movable fuel load and the burning rates expected for the compartment at hand. However, burning rates for large compartments, especially those with combustible compartment boundaries, form a critical research gap.

4.2 BURNING OF CEILINGS AND WALLS

The fire dynamics in a compartment with combustible boundaries are expected to differ once the compartment boundaries become involved in the fire. In traditional scenarios, all fuel is located on the compartment floor. The impact of burning combustible ceilings and walls on the fire dynamics are currently understudied.

4.3 THERMAL PROPERTIES AND EXTINCTION

The applicability of material properties required as input parameters for fire safety assessments of timber structures is uncertain and has not been sufficiently validated. Therefore, the results which can be obtained with any framework hold high uncertainty. Values determined in bench-scale experiments for a limited number of timber species may not scale up to full-scale applications and likely vary between timber species. The critical heat flux for self-extinction is conditional on the char layer thickness, which may differ substantially between timber species and application scales.

In addition, Sahoo et al. [17] determined best-fit results between a CFD model and an experimental study on small-scale compartments made of Radiata Pine CLT [16]. However, the modelling approach to assess self-extinction by Sahoo et al. [17] was not benchmarked against large-scale experiments. The incident heat flux obtained using fire CFDs are very sensitive to fuel (e.g. radiative fraction) and scale-dependent (e.g. path length) parameters from the radiation solver.

4.4 CONTINUOUS SMOULDERING

Numerous studies [5] [15] [16] have reported gradual self-extinction of flaming of exposed timber after the burnout of the moveable floor fuel load and following cessation of flaming combustion involving the exposed timber within well-ventilated compartments. However, large-scale experiments observed hotspots which continued smouldering for hours or days after flaming combustion was considered to have self-extinguished [12]. This is a fundamental safety problem for the long-term viability of timber building design that cannot be addressed with improved input parameters and calculations. A collective stakeholder approach involving the design team, first responders and other stakeholders must assess the potential consequences of continuous smouldering.

The methodology outlined in Section 2.1 allows qualitative identification of areas likely receiving increased heat feedback or losing insufficient heat critical for total self-extinction. However, the method cannot quantify the phenomenon or predict the consequence of these hotspots potentially undergoing self-sustained smouldering for extended periods of time. Critical heat fluxes and other critical variables (geometry, lamella thickness, air flows, etc.) regarding

https://doi.org/10.52202/069179-0232

the extinction of smouldering combustion of charred solid timber form a critical research gap.

The qualitative consequence of localised hotspots that do not undergo self-extinction can be low but prolonged heat generation, gradually weakening nearby loadbearing elements and eventual re-transition to flaming combustion. Kotsovinos et al. [12] observed the smouldering burn-through of an exposed CLT ceiling over a 40-hour period in a large-scale open-plan compartment after a flaming fire that lasted under 23 minutes. In a real building, this would have resulted in the loss of compartmentation. Kotsovinos et al. observed hotspots primarily at the interface between the CLT ceiling and concrete beams, i.e. where the two surfaces radiated back and forth over a short distance.

The observations of local hot spots suggest that even with conditions that appear generally favourable for self-extinction of exposed mass timber, localised heat generation can continue and spread through the structural timber members. The impacts thereof that need to be considered in structural design in practice is, to date, unknown. Partial evacuation seems unadvisable in buildings with combustible structural elements as delayed structural collapse and compartmentation by smouldering cannot be quantitatively assessed. Furthermore, it emphasises the importance and complexity of fire brigade intervention to ensure the complete extinction of structural timber members. The practical considerations of fire brigade intervention in post-flashover compartments with load-bearing timber are beyond the scope of this paper but must urgently be addressed in an open dialogue between the fire brigade, building authorities, researchers and fire engineers.

4.5 LOSS OF CHARRED CROSS-SECTION

Loss of charred timber section due to fall-off is a complex, currently unpredictable phenomenon that can cause iterative self-enhancing loss of loadbearing cross-section and affect compartment fire dynamics. It can delay or prevent self-extinction and enhance the in-depth heating of the timber structure [7].

The laminated nature of engineered timber products results in a potential for lamellae detaching once the capacity of their bond is exceeded. Temperatures like those expected in compartment fires can negatively affect the bond strength. The loss of charred timber sections through phenomena like delamination or char fall-off exposes the underlying timber and adds additional fuel to the fire. Char fall-off was visually observed to be followed by flaming combustion of the newly exposed, previously protected timber surface in full-scale compartment experiments with mass timber walls, and temperature devices recorded a local temperature increase in local temperatures [22].

A theoretical possibility to account for the loss of load-bearing cross-section to char fall-off is to perform a heat transfer calculation and continuously discount lost cross-section exceeding a critical state. Experimental research has observed char fall-off to occur over a wide range of temperatures as low as 140 ºC [6] and to be a thermomechanical phenomenon, i.e. a function of the local absolute temperature and mechanical loading [7]. Therefore, current knowledge does not support the use of a critical temperature criterion for char fall-off.

4.6 HEAT TRANSFER & COOLING PHASE

Fire curves in real compartment fires do not resemble the standard curve. In fire safety engineering practice, the standard curve is generally assumed to encompass all most reasonably foreseeable fire cases. It is not the scope of this paper to discuss the adequacy of standard furnace testing for non-combustible structural members. However, for designs using combustible structural members, the fundamental difference between furnace tests of combustible versus non-combustible elements becomes problematic and the real timber-involved fire may in fact fall well outside of what was once considered the reasonably foreseeable fire cases, and this occurrence is lost by relying only upon the furnace test to support timber structural member design.

In a standard furnace test, structural members are tested against standard temperature-time curves with gas burners providing heat [13]. Unlike non-combustible members, combustible elements like structural timber members themselves add to the fuel load in a furnace test, leading to reduced heat supply from the gas burners [13]. The timber's energy contribution is effectively deleted by the furnace recalibration procedure.

The peak temperatures in-depth of mass timber elements can be reached later than peak compartment temperatures due to thermal lag. The temperature evolution within a compartment after burnout of the movable fuel load depends on the heat losses from the compartment through compartment boundaries and openings and is influenced by fluid flows and, in the case of mass timber, the additional heat generation from combustible elements and their self-extinction.

4.7 WINDOW GLAZING FAILURE

Currently existing knowledge does not allow prediction of the timing, amount and locations of glazing breakage in compartment fires, especially in open-plan compartments. However, the amount of glass breakage can have critical importance regarding the energy balance in a post-flashover compartment, which can be especially critical for self-extinction of combustible structures. Therefore, the sensitivity of the assessments to varying amounts and configurations of intact and broken glazing must be analysed for the design at hand.

5 CONCLUSIONS

An explicit fire safety strategy for mass timber buildings with different compartment geometries has been developed based on theoretical frameworks proposed in existing literature. The four frameworks address self-extinction, tenability, adequate structural capacity in fire and external flaming. A review presented the applicability of available research as well as the remaining knowledge gaps. This approach highlights the need for research that addresses the fundamental questions including self-extinction, compartment fire dynamics and the material response to fire required for the safe design of modern mass timber structures.

https://doi.org/10.52202/069179-0232

A lot of responsibility lies with fire safety engineers to determine whether the existing knowledge of the profession, the design tools available and their individual knowledge and skills are sufficient to deliver a holistically adequate fire-safe design when faced with the challenge of a project that is proposed to include a mass timber structure. It is critical to clearly communicate limitations and potential consequences related to fire safety in mass timber buildings with all stakeholders as a part of executing due diligence.

FIRE CHARACTERISTICS OF A COMPARTMENT WITH EXPOSED CLT WALLS: AN EXPERIMENTAL INVESTIGATION USING THE STANDARD ISO 834 CURVE

Andrianos E. Koklas[1], Dionysios I. Kolaitis[2], Maria A. Founti[3]

ABSTRACT: Cross Laminated Timber (CLT) panels are increasingly used for building construction; in specific cases, the indoor surface of the CLT panels is required to be "exposed", thus making adequate fire protection of these elements a significant challenge. The main aim of this work is to experimentally determine the impact of an exposed CLT panel, in this case a ceiling, to the characteristics of a compartment fire. Experiments using either fire-resistant panels or a CLT exposed ceiling are performed in a test rig, corresponding to the 1/3 scale of the standard ISO 9705 compartment; a broad sensor network is installed to determine the main characteristics of the developing thermal- and flow-fields inside the compartment. In order to overcome certain limitations associated with achieving adequate levels of repeatability when a "realistic" time-dependent fire curve is used, a PID controller-based gas burner is employed; the ISO 834 standard temperature-time curve is used in all fire tests. The experimental results suggest that, as expected, when a CLT ceiling is used, the total fuel consumption at the burner is significantly lower. The thermal field inside the compartment exhibits certain differences, while the opening velocities were largely unaffected by the installation of the CLT ceiling.

KEYWORDS: Compartment fires, CLT, charring, fire engineering, measurements

1 INTRODUCTION

Wood construction is known to exhibit a range of advantages, compared to "conventional" construction methods (e.g. using concrete), in terms of seismic performance, cost and environmental footprint. However, due to the combustibility of wood, its fire behaviour is a major limiting factor in the development of new wooden buildings. Cross laminated timber (CLT) elements are load bearing elements, used either in vertical walls or slabs. In both of these cases, in order to enhance their fire performance, CLT elements can be encapsulated, i.e. covered by fire-resistant panels (e.g. gypsum plasterboards); however, due to aesthetic reasons, it is commonly required to leave "exposed" as much timber as possible. In the latter case, the adequate fire protection of the CLT elements poses significant challenges.

In order to investigate the fire behaviour of construction products, compartment fire tests are commonly used [1-5]. In these tests, the temporal evolution of the Heat Release Rate (HRR) usually follows either a "constant value" or a "time transient" profile. However, when a timber construction element is involved (e.g. an exposed CLT wall), the HRR inherently varies with time, due to the combustion process occurring in the wood, thus imposing an additional, time-varying fire load [1]. In the majority of fire tests using a "time transient" HRR profile, the fire source used is usually a wooden crib [2, 3, 4] or, in some rare cases, pertinent to large-scale compartments, actual furniture items [5]. However, both these options do not provide adequate levels of controllability and repeatability. In this context, this work presents a novel approach, where a series of fire tests are performed in a medium-scale compartment, equipped with a CLT wall, where the standard ISO 834 [6] time-temperature curve, commonly used in fire resistance furnace tests, is employed, aiming to ensure acceptable levels of repeatability.

This work is mainly aimed at investigating the effects of exposed CLT panels on the thermal characteristics of the fire developing inside a typical compartment. In this frame, two series of fire tests are performed in a medium scale compartment, one using an inert (non-combustible) material and the other using exposed CLT panels; the obtained measurements are then qualitatively and quantitatively compared.

2 EXPERIMENTAL SETUP

2.1 COMPARTMENT GEOMETRY

The fire compartment dimensions correspond to a 1/3 scale of the ISO 9705 [7] standard compartment, representing a typical room. The compartment's internal dimensions are 1200 mm (length) × 900 mm (width) × 900 mm (height); the door-type opening's dimensions are 266 mm (width) × 666 mm (height).

In the first test series, all sides of the compartment envelope (floor, walls, ceiling) were constructed using 20 mm thick fire-resistant ceramic boards; in the second

https://doi.org/10.52202/069179-0233

series, the ceiling was replaced with a 3-layered (30 mm / 20 mm / 30 mm) 80 mm thick CLT panel (Figure 1), corresponding to a "fully exposed" CLT ceiling scenario.

***Figure 1**. Indicative photos of the test compartment with inert (left) and CLT (right) ceiling installed.*

2.2 FIRE SOURCE

In the majority of medium-scale and small-scale laboratory fire tests, the fire source used is either a gas burner, operating in "steady state" conditions, or a pool/crib fire burning freely. Both of these test methods exhibit certain drawbacks, i.e. the first is rather "unrealistic", while the latter is significantly lacking in repeatability. Aiming to investigate the possibility of using a gas burner (thus allowing adequate repeatability) in conjunction with a "realistic" time-temperature profile, a PID controller was developed in-house. In the fire tests presented here, the standard ISO 834 [1] curve was employed in order to comparatively assess the characteristics of the thermal- and flow-field developing inside the compartment, when an "inert" or a "combustible" (CLT) ceiling is used.

***Figure 2**. Indicative photo (top view) of the burner and the installed sensor network inside the compartment.*

A rectangular porous burner was used as the fire source. The burner dimensions were 125 mm (length) × 125 mm (width) × 60 mm (height) and it was positioned at the centre of the compartment's floor. The burner was fed with commercial propane (C_3H_8) (Figure 2). A digital mass-flow controller (Bronkhorst F-203AV-1M0-RGD-55-V) was used to measure and control the propane flow rate. More specifically, the average of the upper gas layer temperature and the ISO 834 standard temperature were estimated every second. The measured average upper gas layer temperature corresponded to the input of the PID controller, while the latter quantity was the set-point of the PID, changing every second; the PID controller's output was the signal to the mass flow controller. In this way, when the compartment temperature was higher than the corresponding ISO 834 value, the mass flow controller was instructed to reduce the fuel flow and vice versa.

2.3 SENSOR NETWORK

A broad network of measurement sensors was installed inside the test compartment to determine the main characteristics of the developing flow and thermal fields. Overall, 81 K-type thermocouples, 4 bi-directional velocity probes, 2 Pitot-static tubes, 4 heat flux meters, 1 continuous gas analyser and 3 digital flow meters were used.

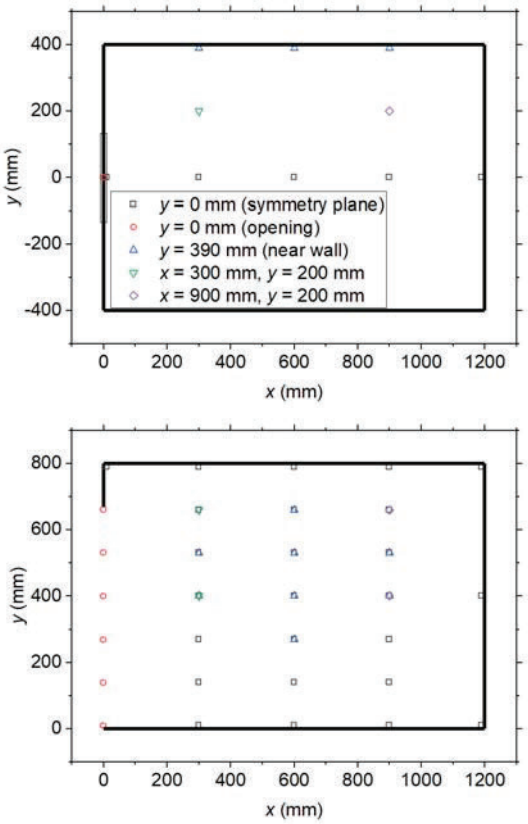

***Figure 3:** Spatial distribution of gas temperature and velocity measurement sensors, top view (top) and side view (bottom).*

The thermocouples were installed both inside the compartment (c.f. Figure 3), thus allowing measurement

https://doi.org/10.52202/069179-0233

of the gas phase temperature, as well as "inside" the ceiling (c.f. Figure 4) and compartment walls (c.f. Figure 5), at various locations across the thickness of the compartment envelope, aiming to record the temporal evolution of the thermal field developing "inside" the solid boundaries. When a CLT ceiling was tested, thermocouples were installed at the back (unexposed) side of each lamella (layer), corresponding to a distance of 30 mm, 50 mm and 80 mm from the exposed side, across the thickness of the CLT panel. The coordinate system used employs an axis origin that is located in the centre-line symmetry axis of the compartment (y = 0 mm), at the opening (x = 0 mm) on the floor level (z = 0 mm) (c.f. Figure 3).

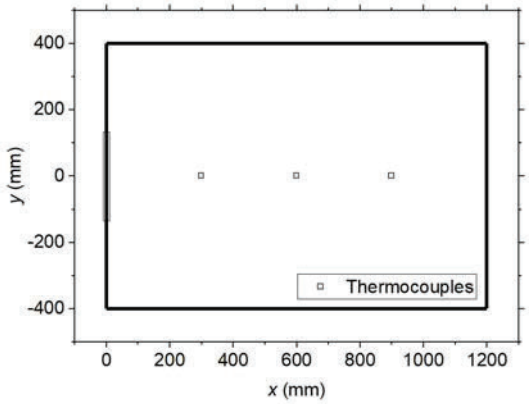

Figure 4: *Spatial distribution of the ceiling temperature measurement sensors.*

The gaseous combustion products were collected and a sample was fed to the gas analyser, where the oxygen, carbon dioxide and carbon monoxide concentrations were recorded. These measurements were later used to estimate the overall heat release rate, using the oxygen consumption calorimetry method (Equation 1) [8], where φ is the oxygen depletion factor, calculated using Equation 2. A brief description of all parameters that appear in Equations 1 and 2 is given in the Nomenclature.

$$\dot{Q} = \left[E_{O_2}\varphi - \left(E_{CO} - E_{O_2}\right)\frac{1-\varphi}{2}\frac{X_{CO}^{A^e}}{X_{O_2}^{A^e}} \right] \times \times \frac{\dot{m}_g}{1+\varphi(\alpha-1)}\frac{M_{o_2}}{M_a}\left(1-X_{H_2O}^{a}\right)X_{O_2}^{A^a} \quad (1)$$

$$\varphi = \frac{X_{O_2}^{A^a}\left(1-X_{CO_2}^{A^e}-X_{CO}^{A^e}\right)-X_{O_2}^{A^e}\left(1-X_{CO_2}^{A^a}\right)}{\left(1-X_{O_2}^{A^e}-X_{CO_2}^{A^e}-X_{CO}^{A^e}\right)X_{O_2}^{A^a}} \quad (2)$$

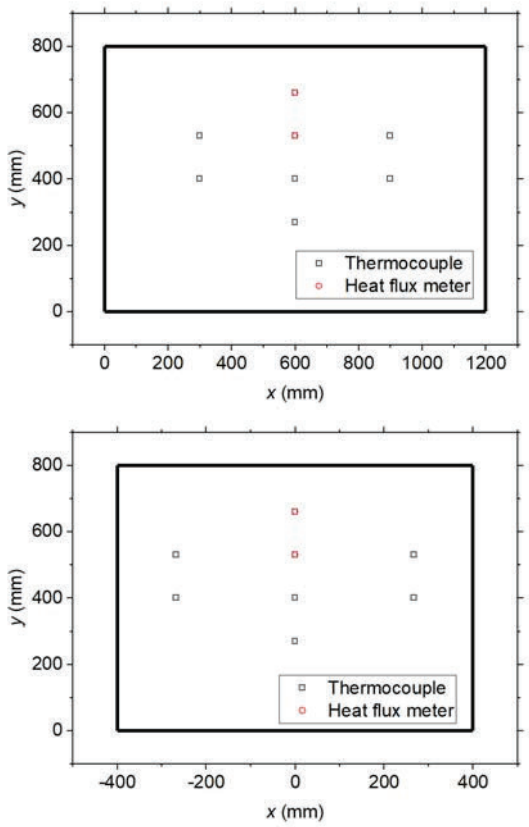

Figure 5: *Spatial distribution of the temperature and heat flux measurement sensors, at the side (top) and back (bottom) wall.*

2.4 MEASUREMENT UNCERTAINTIES

The gas temperatures were measured using K-type thermocouples connected to the signal acquisition system via extension wires. The systematic uncertainties of the thermocouples were a standard calibration uncertainty of ± 2.2°C or ± 0.75% of the measured value (the largest value is taken into account) for a 99% confidence interval (3σ), an uncertainty due to the wires and their extension of ± 2.2°C and a conversion uncertainty of ± 0.5%. The opening velocities were measured using bi-directional velocity probes and Pitot tubes. In terms of the systematic uncertainties, the bi-directional velocity probes exhibited a flow approaching uncertainty of ± 10% [4], a conversion uncertainty of ± 1% of the maximum pressure of the pressure sensor (10 Pa). The heat flux was measured using SBG01 water cooled heat flux meter. The calibration error is ± 3% of the measured value and the non-linearity error is ± 4% of the maximum heat flux (200 kW).

https://doi.org/10.52202/069179-0233

3 EXPERIMENTAL RESULTS

3.1 INERT ENVELOPE - REPEATABILITY

In the first series of fire tests, all sides of the compartment envelope were constructed using 20 mm thick ceramic boards. The standard ISO 834 time-temperature curve was used; the duration of each fire test was 3600 s. Measurements obtained at the upper gas layer of the compartment ($z \geq 660$ mm) were used to estimate the "average" temperature used in the PID controller to determine the required increase or decrease in the fuel flow.

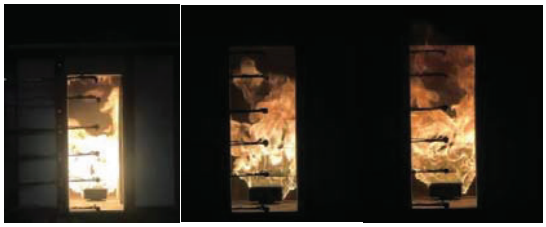

Figure 6: *Photos of a typical "inert" fire test, 600 s (left), 1800 s (middle) and 3600 s (right) after ignition.*

Initially, three identical fire tests have been performed, aiming to assess the "repeatability" of the test setup, based on the obtained measurements. In Figure 6, indicative images of the first "inert" (non-combustible envelope) fire test, using the standard ISO 834 time-temperature curve, are shown for three characteristic time instances, 600, 1800 and 3600 s after ignition. It is evident that the size of the developed flame covers a significant part of the compartment's height; in fact, the fuel mass flow rate at the 3600 s mark corresponds to a HRR value roughly equal to 100 kW.

Figure 7 depicts the temporal evolution of the standard ISO 834 fire curve against the experimentally measured values at the upper gas layer for the three "inert" experiments. It is evident that in all cases, the compartment temperature follows closely the standard ISO 834 curve.

Figure 8 depicts the temporal evolution of the gas temperature measurements obtained at three characteristic height levels, at a distance of x = 300 mm from the opening. The relatively small discrepancies observed among the three tests suggest that the developed test setup is capable of reaching increased levels of "repeatability".

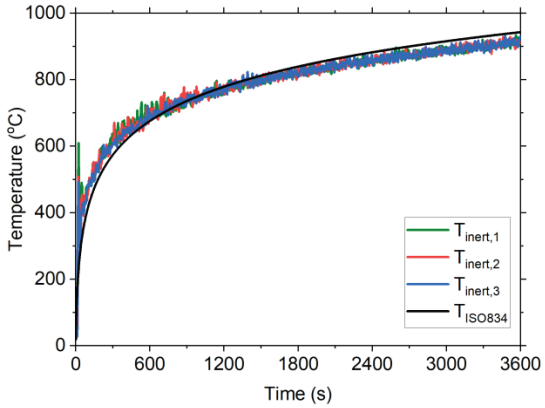

Figure 7*: Temporal evolution of average upper gas layer temperatures compared against the standard ISO 834 fire curve for the three "inert" experiments.*

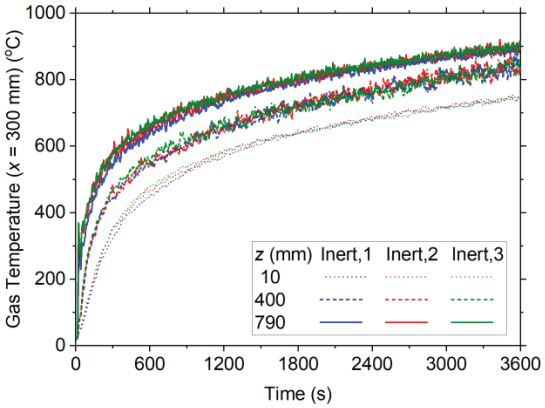

Figure 8*: Temporal evolution of indicative gas temperatures at a distance of x = 300 mm from the opening, for the three "inert" experiments.*

Figure 9 illustrates the spatial distribution of gas temperatures at the central symmetry plane ($y = 0$ mm) of the compartment, at three different time instants ($t = 600$ s, 1800 s and 3600 s). The grey box corresponds to the burner location, whereas the open rectangle (on the left, $x = 0$ mm) depicts the position of the compartment's door-type opening. As expected, the highest temperatures are observed near the centre of the compartment (above the burner) and at the upper gas layer (ceiling jet). Low temperatures close to the bottom part of the opening suggest the inflow of cold ambient air, providing oxygen for the fuel combustion process. Since standard ISO 834 curve imposes a monotonically increasing temperature profile, average compartment temperatures are gradually increasing with the elapse of time.

https://doi.org/10.52202/069179-0233

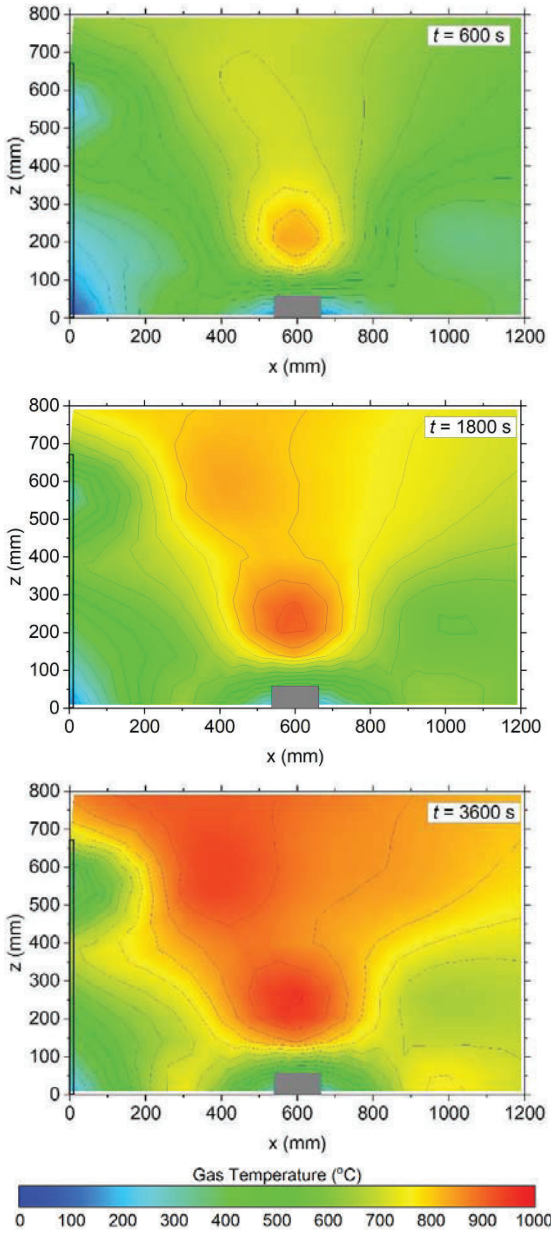

***Figure 9**: Spatial distribution of gas temperatures inside the compartment, 600 s (top), 1800s (middle) and 3600 s (bottom) after ignition.*

3.2 "EXPOSED" CLT CEILING

In the second series of fire tests, a Cross Laminated Timber (CLT) ceiling is installed in the test compartment, aiming to assess the impact on the fire characteristics. An 80 mm thick three-layer (1st layer 30 mm, 2nd layer 20 mm, 3rd layer 30 mm) CLT was used (Figure 10). Thermocouples were installed at the unexposed side of each layer, at two different axial locations (c.f. Figure 5).

The fire test was terminated after 55 minutes, due to the collapse of the ceiling.

***Figure 10**: Inner view of CLT panel, installed at the compartment ceiling.*

Figure 11 shows characteristic views of the compartment where the CLT ceiling is installed, using the ISO 834 fire curve, at three distinct time instances. Although the temperature inside the compartment is similar in both test cases, in the CLT case the flame ejects from the opening faster than the non-combustible ceiling case. This is due to the additional pyrolysate gases released through the CLT ceiling. Since the upper gas layer is oxygen-lean, the pyrolysate gases cannot be burnt promptly; they have to exit the compartment, through the opening, in order for their combustion to be completed in the ambient air. By comparing Figures 6 and 11, it is evident that in the CLT case, flames appear also in the upper part of the compartment, due to the partial combustion of the pyrolysate gases released through the ceiling.

***Figure 11**: Photos of the "exposed CLT ceiling" fire test, 600 s (left), 1800 s (middle) and 3300 s (right) after ignition.*

In Figure 12, the temporal evolution of the average upper gas layer temperature in the two investigated test cases is compared against the standard ISO 834 curve. The "CLT" case exhibits some initial perturbations (due to inertia of the PID system that prevented the rapid adjustment of the fuel controller to the additional heat release due to CLT pyrolysis and combustion); however, after the 900 s mark, both cases follow closely the ISO 834 curve.

https://doi.org/10.52202/069179-0233

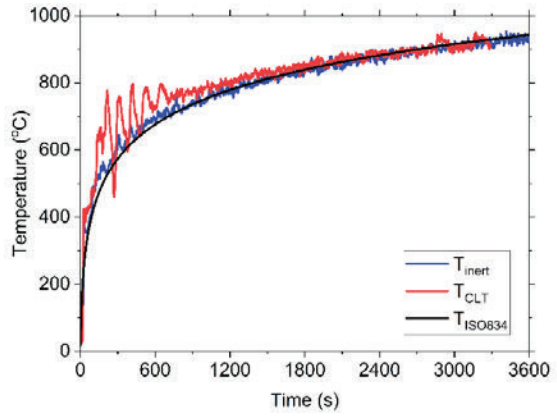

***Figure 12**: Temporal evolution of average upper layer gas temperatures compared against the standard ISO 834 fire curve.*

Figure 13 depicts the temporal evolution of the total fire HRR, corresponding to the sum of the HRR due to propane combustion and the HRR due to timber combustion, which was estimated using the oxygen combustion calorimetry method. After the initial period of fuel flow perturbations (t < 600 s), both cases result in similar HRR values. However, after the 2700 s mark, the total HRR in the CLT case is increased, thus suggesting that the increased HRR due to timber combustion cannot be counterbalanced anymore by the decreasing fuel flow to the burner; in fact, the gradually intensifying combustion of the CLT ceiling resulted in its partial collapse at 3300 s, thus prompting the early termination of the test.

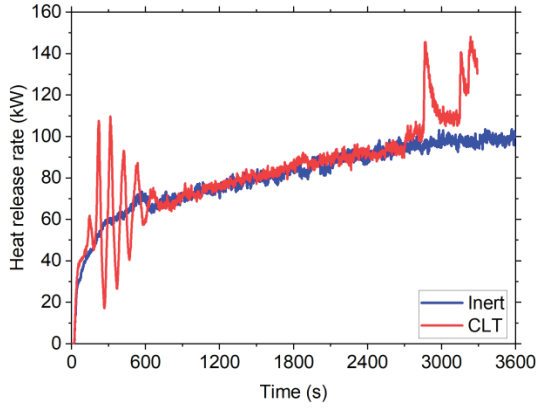

***Figure 13**: Temporal evolution of HRR for the "inert" and "CLT" test cases.*

Figure 14 illustrates the volumetric flow rate of the fuel, which was regulated by the PID controller; in Figure 15, the difference between the fuel flow rate in the "CLT" case, compared to the "inert" case is quantified. As expected, in order to achieve the ISO 834 curve, the "CLT" case requires a reduced fuel flow rate; in general, the reduction in the required fuel flow was more than 50% (Figure 15).

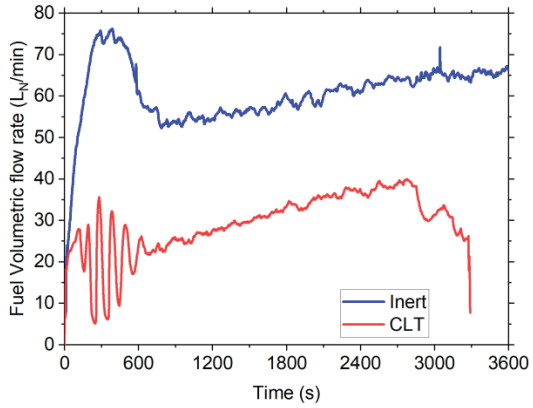

***Figure 14**: Temporal evolution of fuel volumetric flow rate for the "inert" and the "CLT" test cases.*

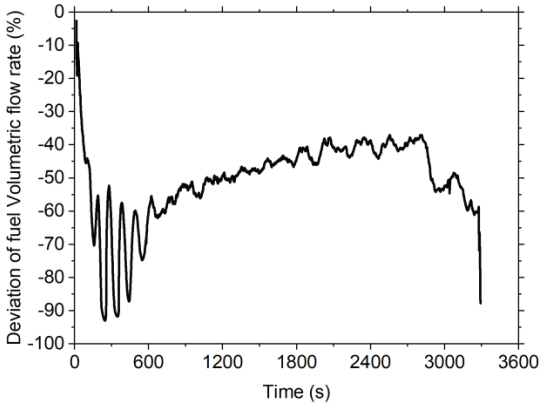

***Figure 15**: Temporal evolution of the deviation between the fuel flow rate between the "inert" and the "CLT" test cases.*

Figure 16 illustrates the spatial distribution of the gas temperature at the central plane of the compartment for three different time instances (t = 600s, 1800s and t = 3300s). Compared to the respective experimental results for the "inert" case (Figure 9), the "CLT" case results in a more "extended" region of higher temperatures close to the ceiling, due to the additional timber combustion processes that occur in this region.

https://doi.org/10.52202/069179-0233

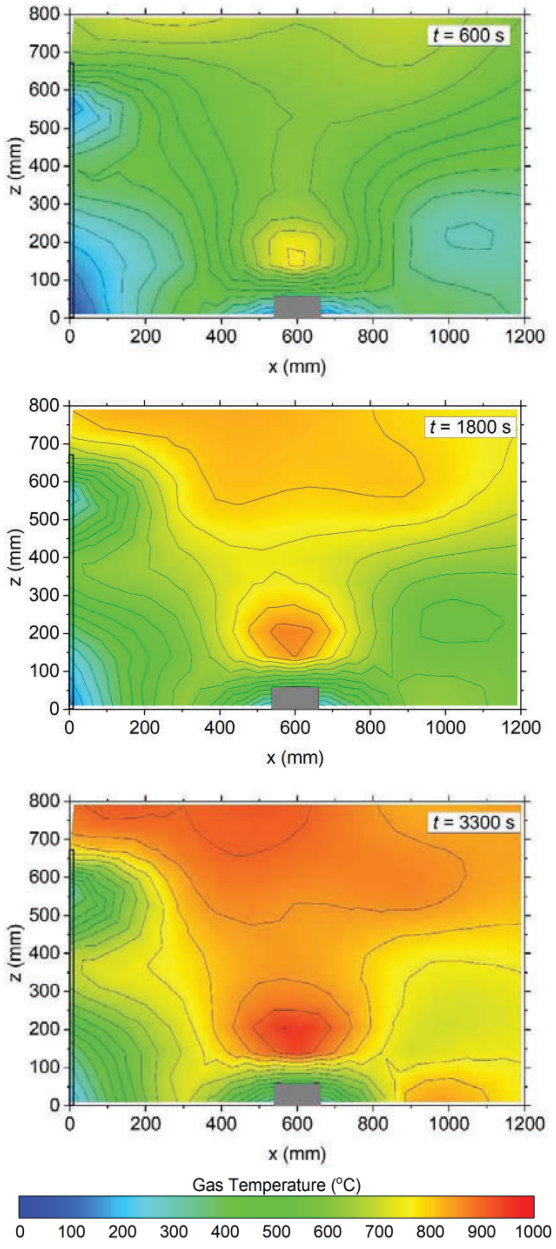

***Figure 16**: Spatial distribution of gas temperatures inside the compartment, 600 s (top), 1800s (middle) and 3600 s (bottom) after ignition.*

Figures 17-19 depict the temporal evolution of the gas temperature inside the compartment at three characteristic height levels (z = 140 mm, 400 mm and 660 mm above the floor); the measurements are provided for three locations across the compartment's symmetry axis, the first (x = 300 mm) close to the opening (Figure 17), the second at the centre (x = 600 mm) of the compartment (Figure 18) and the last close (x = 900 mm) to the back wall (Figure 19).

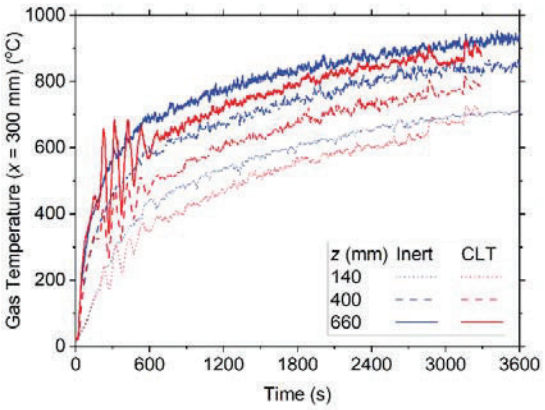

***Figure 17**: Temporal evolution of gas temperatures at three characteristic height levels, near the opening (x = 300 mm).*

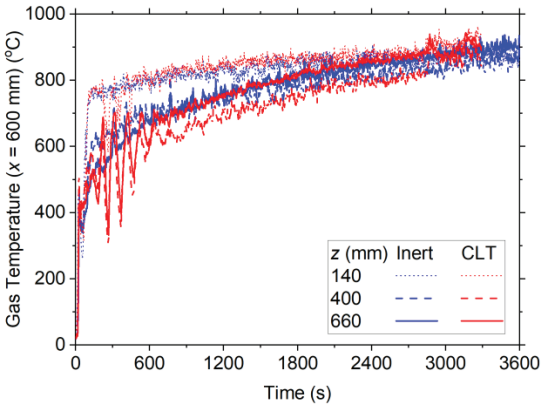

***Figure 18**: Temporal evolution of gas temperatures at three characteristic height levels, at the centre of the compartment (x = 600 mm).*

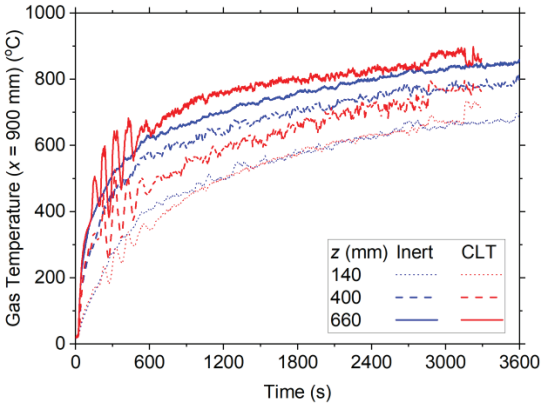

***Figure 19**: Temporal evolution of gas temperatures at three characteristic height levels, near the back wall (x = 900 mm).*

As expected, due to thermal buoyancy, gas temperatures are generally increasing with increasing height, with the

sole exception of gas measurements obtained just above the burner (z = 140 mm, Figure 20) which correspond to the peak temperature values inside the compartment (c.f. Figures 10 and 18). Since the pyrolysate gases close to the opening are ejected to the ambient air before being completely burnt, the average temperatures of the "inert" case are slightly higher than the corresponding values of the "CLT" case (Figure 19). However, at the "back" of the compartment (Figure 21), the thermal feedback from the burning CLT ceiling, in conjunction with the longer residence times of the produced pyrolysate gases allow a more "complete" combustion, thus leading to higher temperatures near the ceiling (z = 660 mm) for the "CLT" case.

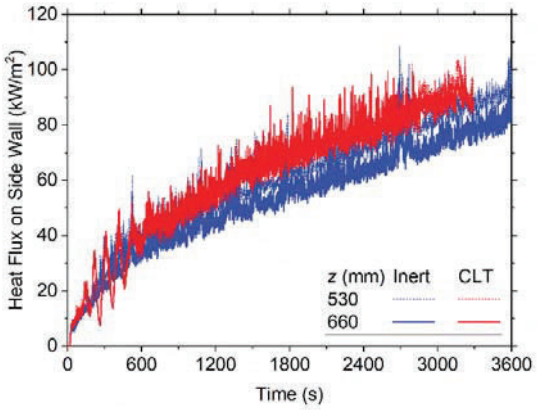

***Figure 20**: Temporal evolution of heat flux at the side wall (y = 400 mm).*

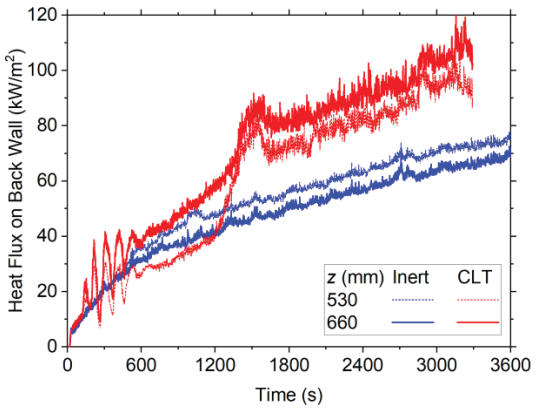

***Figure 21**: Temporal evolution of heat flux at the back wall (x = 1200 mm).*

Figures 20 and 21 show the temporal evolution of the incident heat flux at the side and the back wall, respectively. As expected, in all cases the measured heat flux values are increasing with time. For the "inert" test case, peak heat flux values are observed at a lower height level (z = 530 mm), due to the shorter flame developing in this case (c.f. Figures 6 and 11). However, in the "CLT" case, higher heat flux levels are recorded closer to the ceiling (z = 660 mm), where timber combustion takes place. In general, higher heat flux levels are observed in the "CLT" case compared to the "inert" case, due to the additional radiation from the flames appearing close to the ceiling (c.f. Figure 11).

Figure 22 depicts the effects of the combustible ceiling on the temporal evolution of the flow field developing at the opening plane. Positive velocity values suggest ambient air entering the compartment, whereas negative values signify combustion products exiting through the opening.

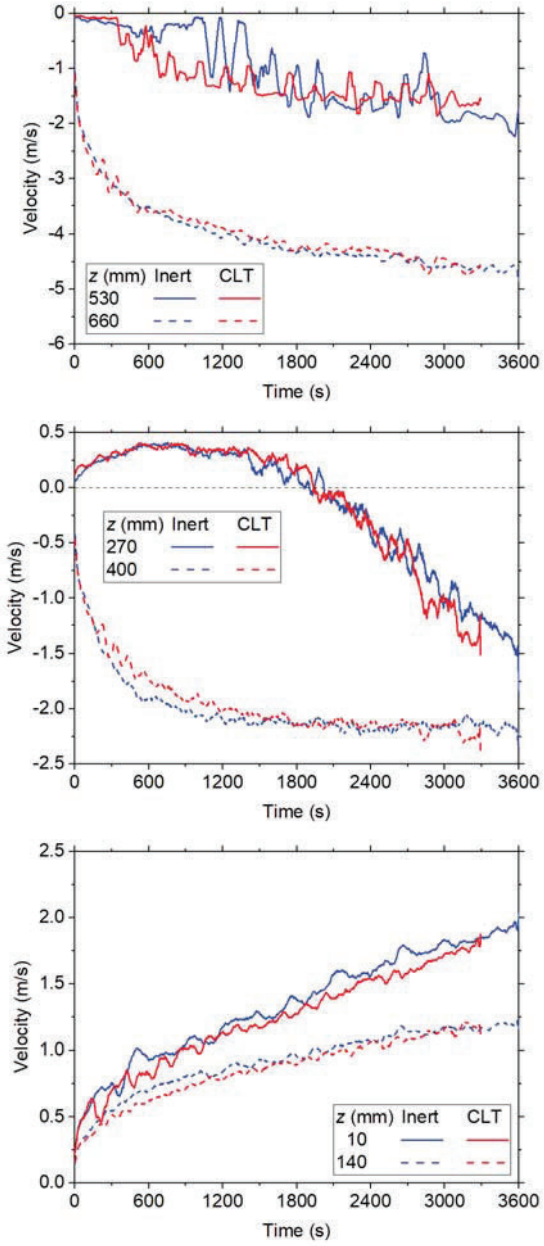

***Figure 22:** Temporal evolution of gas velocities in the upper (top), middle (middle) and lower (bottom) layer of the opening.*

https://doi.org/10.52202/069179-0233

As expected, at the top section of the opening (Figure 22, top), only negative velocity values are recorded, thus suggesting that the hot combustion products, concentrated under the ceiling, escape through the opening's lintel. The gradual increase of the compartment's temperature and, therefore, of the HRR, results in an increasing mass flow rate of the combustion products; as a result, the absolute values of the corresponding velocities are also increasing. Negative velocity values are recorded at the top half of the opening ($z > 300$ mm). During the first half of the fire test ($t < 1800$ s), velocity measurements obtained at a height of $z = 270$ mm (Figure 22, middle) suggest that ambient air is entering the compartment. However, as time goes by and the HRR is increased, the increasing mass flow rate of the hot combustion products results in a "reversal" of the flow direction at this specific height, thus leading to negative velocity values. At the lower part of the opening (Figure 22, bottom), the velocity of the incoming ambient air is monotonically increasing, due to the increasing HRR and, therefore, the need for oxygen.

In general, the CLT ceiling does not seem to significantly affect the measured velocity values. This is also evident in Figure 23, where the vertical velocity profiles at the opening, for three characteristic time instances, are shown. It is interesting to note as time goes by, due to the increasing HRR, the absolute values of both the incoming air and the outgoing combustion products are increased.

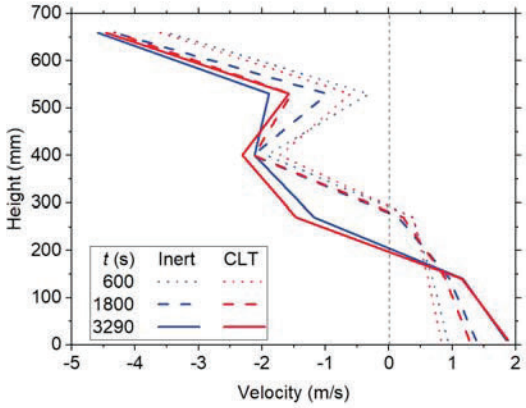

Figure 23: *Gas velocity profile in the opening at 600 s, 1800 s and 3600 s.*

Figure 24 depicts the recorded solid-phase temperatures across the thickness of the CLT ceiling. The distance from the opening ($x = 600$ mm vs. $x = 900$ mm) does not seem to significantly affect the CLT temperatures. According to the recorded temperatures at the unexposed side of the 1st layer, the charring front did not reach the second layer of the CLT ceiling. Near the 3000 s mark, the first CLT layer started to fall-off and the temperatures between the first and second lamella started to rise. The fall-off did not affect significant the temperatures measured between the 2nd and 3rd lamella.

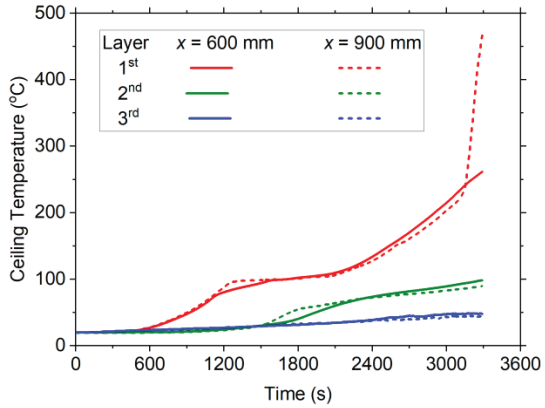

Figure 24*: Temporal evolution of solid-phase temperatures at the unexposed side of each lamella (layer) of the CLT panel.*

4 CONCLUDING REMARKS

In this work, two different series of laboratory experiments were conducted, aiming to assess the impact of installing an exposed CLT panel at the compartment's ceiling, on the characteristics of the thermal- and flow-fields developing inside the compartment, when the ISO 834 standard fire curve is used.

Based on the experimental observations made during the tests, the main effects of installing an exposed CLT ceiling are summarized below:

- The flames eject from the opening quite earlier, a fact that should be taken into account during the building design phase, e.g. suggesting potential additional requirements for the fire protection of façade systems.
- The fuel needed to reproduce the standard ISO 834 fire curve was about 50% less compared to the "inert" case. This fact highlights certain concerns, regarding the use of time-temperature curves for classification purposes, e.g. fire-resistance tests of combustible materials.
- Although the average compartment temperature was kept constant, in the case of the CLT ceiling, higher temperatures were observed at the back of the compartment (and, consequently, lower temperatures near the opening) compared to the respective measurements obtained for the non-combustible ceiling.
- The heat flux levels recorded inside the compartment were significantly higher in the case of the exposed CLT ceiling.
- The addition of the CLT ceiling does not seem to have any significant affect to the exhaust gas and the incoming air velocities.

The presented experimental campaign will be extended in the future, aiming to investigate the effects of alternative exposed CLT panel configurations, i.e. exposed ceiling, one exposed side wall, two exposed side walls, exposed ceiling and one side wall and exposed ceiling and two side

https://doi.org/10.52202/069179-0233

walls, as well as the effects of different fire curves (e.g. temperature-time, HRR-time).

FLAME SPREAD CHARACTERISTICS IN LARGE COMPARTMENTS WITH AN EXPOSED TIMBER CEILING

Panagiotis Kotsovinos[1*], Eirik G Christensen[1] Harry Mitchell[2], Rikesh Amin[2], Mohammad Heidari[3], Guillermo Rein[2], David Barber[4], Judith Schulz[1]

ABSTRACT: In the pursuit of the net-zero agenda set by the global community to fight climate change, more architects and engineers have turned their attention to heavy/mass timber as an alternative structural material to concrete and steel which are the materials predominantly used in building construction. Current evidence from fire experiments is primarily limited to small compartments with an area of 84m^2 or less. To address the lack of knowledge in this area, Arup, CERIB and Imperial College London completed the CodeRed experiments in a 352m^2 open-plan compartment with an exposed CLT ceiling and glulam columns. Four experiments were undertaken in total in 2021, with three of them focusing on fire dynamics. The facility was a replica of the previous largest experiment with a non-combustible ceiling undertaken to date, such that a direct comparison on the impact of the timber ceiling can be made. This paper presents an overview of these experiments, and specifically presents the experimental outcomes relating to flame spread rates observed on the fuel bed, and the influence of the timber ceiling on fire dynamics when compared to experiments completed similar non-combustible compartments. These experiments show that a timber ceiling significantly accelerates the fuel-bed flame spread rates compared to a comparable non-combustible compartment. This has implications for means of escape of occupants, fire-fighting interventions as well as structural response.

KEYWORDS: timber ceiling, large-scale compartment fire experiment, flame spread rates, fire safety

1 INTRODUCTION

In the pursuit of the net-zero agenda set by the global community to fight climate change, more architects and engineers have turned their attention to mass timber as an alternative structural material to concrete and steel which are the materials predominantly used in building construction. Understanding he response of mass timber to fire is critical to delivering safe and sustainable building designs. Two key parameters that must be considered with respect to structural fire protection in mass timber buildings are: a) the size of the fire compartment and b) the materials of construction exposed to the fire compartment.

Our experience indicates that architects are increasingly considering mass timber as the primary structural material for buildings designed for office, retail, and assembly occupancies. These buildings often have large open-plan floor areas (e.g. >1000m^2) with aspirations of maintaining as much timber exposed as possible to meet sustainability goals (reducing use of applied cladding materials) and improve aesthetic appeal for occupants and stakeholders. The exposed timber surfaces in open-plan office buildings are often desired to be in the form of a CLT or glulam ceiling (soffit) supported by a glulam frame.

Traditional fire safety design for structural fire resistance (termed "loadbearing capacity" in UK guidance) is based on small compartments. The 'travelling fire' design concept (see Figure 1) has been developed over the past 10 years, and is increasingly applied to large open-plan compartments. However, existing experimental evidence for travelling fires is based on compartments constructed from largely non-combustible materials. Travelling fires are assumed to cover a limited area of a compartment ("near field") and spread across the floorplate. The burning area is defined by the leading edge (front of the fire) and the trailing edge of the fire, where the fuel has been consumed leading to burn-out of the fire. Both the leading and trailing edges spread until the total available fuel is consumed [1].

A review by Rackauskaite et al. [2] has highlighted previously that compartment fire experiments with exposed timber surfaces published at the time of the authors' review were limited to a compartment area of 84m^2. This limits the understanding of fire regimes that can occur in larger compartments, such as characteristics of flame spread, which are less significant in small compartments. Furthermore, temperatures in large compartments can vary significantly both spatially and temporally. This is important because there is a potential that traditional structural fire protection design may lead to under- or over-provision of protection materials to large compartments. The former is potentially unsafe, while the latter is unwelcome in terms of sustainable development.

https://doi.org/10.52202/069179-0234

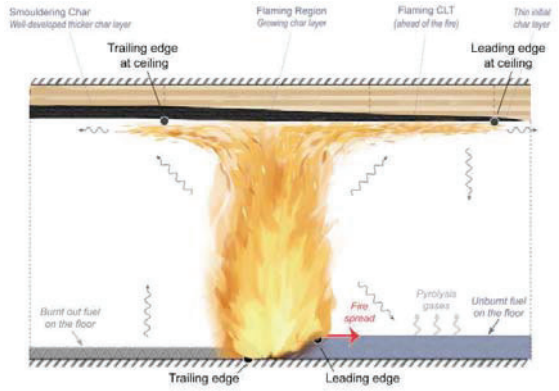

***Figure 1**: The travelling fire dynamics phenomena expected in a large scale open-plan compartment with exposed mass timber ceiling. Arrows indicate radiation from fire and heated surfaces preheating fuel and timber ahead of the flames, and continuing heating of charred timber behind the flames in addition to the heating from smoke (not indicated in this figure for clarity).*[2]

Therefore, there exists an important gap in knowledge around understanding fire dynamics in large timber compartments. This gap must be filled to establish credible design fire scenarios and to inform fire safety design methods for timber buildings that adequately mitigate risks introduced by the timber construction.

To address this knowledge gap, a consortium comprising Arup, Imperial College London and CERIB completed the CodeRed experimental series[3].

This paper presents an overview of the outcomes from the CodeRed experiments. It focusses on the impact of the timber ceiling on fire dynamics, and specifically how this influences flame spread rates within the compartment. Detailed results from each experiments are published separately for each experiment in [4]–[6] &[9].

2 THE EXPERIMENTS

A series of full-scale fire experiments in a purpose-built, compartment of 352m^2 was conducted in 2021. These experiments aimed to capture fire dynamics in large compartments with exposed timber. The experiments examined different parameters such as ventilation, encapsulation and the provision of a water mist system.

The facility used for the CodeRed series was built at CERIB's site in Epernon, France. The CodeRed experiment configuration was constructed to match as closely as possible that of an existing non-combustible building used in a series of experiments, known as *x-ONE* [7] and *x-TWO.1* [8]. These prior experiments studied travelling fire dynamics in open-plan compartments of non-combustible construction. The CodeRed experiments were design to enable, so far as was practicable, direct comparison of the impact of exposed timber on fire dynamics.

2.1 THE NON-COMBUSTIBLE COMPARTMENT EXPERIMENTS (x-ONE and x-TWO.1)

Compartment configuration

x-ONE and xTWO.1 were carried out in an existing building near Warsaw, Poland. The building had one floor that was mostly open plan with thick external masonry walls. The beam and block concrete slab ceiling was supported by reinforced concrete columns, beams, and external masonry walls. The experiments were carried out in the open-plan section of the building which had a floor plan of approximately 384 m^2. The compartment was 10.8m wide, 35.5m in length, and height ranging from 2.93m to 3.19m.

Ventilation was provided via fixed open holes in the concrete perimeter walls of the experimental building. See Table 1 for the % perimeter area of ventilation provided.

Fuel load design

The fuel load used in x-ONE and x-TWO.1 constituted of a continuous wood crib to encourage a natural spatial and temporal fire growth. The fuel load density of was approximately 370 MJ/m^2 (19.4 kg/m^2) and covered a floor area of 174 m^2 (6 m x 29 m).

The fuel bed was not covering the whole length of the compartment, and started approximately 6m from one end. This was the part of the fuel bed that was ignited.

The fuel setup consisted of 11.5 layers of a continuous wood crib (4 sticks each layer). In x-ONE two layers of 4 mm fibreboard were included within the crib build-up and across the whole fuel area to facilitate a faster flame spread. In x-TWO.1 the additional fibreboard was provided only to the first metre of the fuel load.

The previous experimental series had one further case, *x-TWO.2* [8] that had a reduced fuel load density. In this case the flames did not touch the ceiling, and therefore this experiment is not included in the comparisons set out in this paper.

2.2 THE COMBUSTIBLE COMPARTMENT EXPERIMENTS (CODERED)

Compartment configuration

The details of the CodeRed compartments are set out below and in Figure 2 to demonstrate their equivalence to the previous experiments described above.

- 10.27 m wide,
- 34.27 m long and
- 3.1 m high,

The building was constructed from aerated concrete blocks (365 mm thick, 350 kg/m^3). The ceiling was composed of 14 CLT panels supported by hinge connections on the perimeter walls and a central concrete beam. The CLT consisted of 5 ply (40-20-20-20-40 mm) spruce wood with MUF adhesive; the CLT was not treated with any fire retardant. The CLT ceiling been tested by

https://doi.org/10.52202/069179-0234

the manufacturer not to experience char fall-off (no glue line integrity failure in fire) in a long duration fire exposure (120 minutes to the ISO 834 standard fire). As the primary focus of the experiments was to observe the fire dynamics, the structure was supporting self-weight only and was not substantially connected mechanically. Figure 1 describes the building layout and Figure 3 describes typical instrumentation provided.

Ventilation was provided via fixed open holes in the concrete perimeter walls of the experimental building. See Table 1 for the % perimeter area of ventilation provided.

Fuel load design

All three CodeRed experiments reported in this paper matched the x-TWO.1 fuel load design. See the yellow area in Figure 2 for the extent of the fuel bed. This was designed to match the fuel bed of x-TWO.1.

Instrumentation

The fire development in the *CodeRed* experiments, inside and outside the compartment, were captured via thermocouples, plate thermometers, as well as fixed and drone mounted cameras, as seen in Figure 3.

Parameters varied in each experiment

The four experiments comprised:

- *CodeRed #01* – arrangements similar to that of non-combustible experiments, but with an exposed CLT ceiling and glulam columns [4]
- *CodeRed #02* – same as *CodeRed #01* but with 50% of the ventilation [5]
- *CodeRed #03* – looking at the effectiveness of a water mist system with timber ceilings (outside the scope of this paper) [9]
- *CodeRed #04* – same as *CodeRed #01* but with ~50% of the timber encapsulated in fire resisting cladding. The extent of encapsulation is shown in the blue box in Figure 3. [6]

Overview of fire response

CodeRed #01, *#02* and *#04* had no suppression or firefighting intervention, allowing the fires to grow, spread and decay naturally and enabling smouldering to be observed. Combustion of the wood cribs was observed as follows:

- #01 – Flaming ended: 22 min 30 s after ignition. Smouldering observed for 48 hours;
- #02 – Flaming ended 26 min 30 s after ignition, smouldering observed for 60 hours; and
- #04 – Flaming ended 45 mins after ignition, smouldering was observed for 24 days.

As indicated above, after the flames had ceased in the crib, smouldering and intermittent flaming was observed in the CLT of all experiments in multiple locations. In many instances the smouldering spread through the thickness of the CLT panel leading to the formation of holes in the CLT slab.

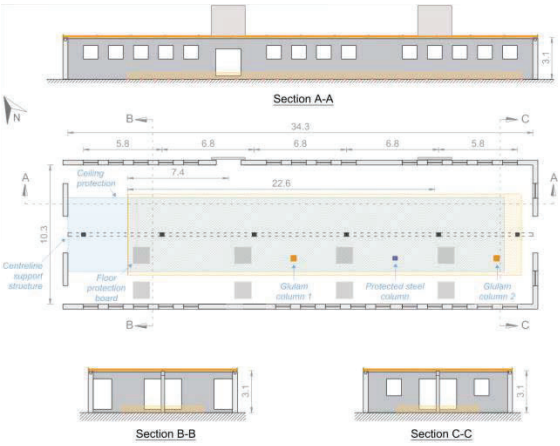

Figure 2: *Floor plan and sections of the compartment used for the CodeRed experiments. Units in metres.*

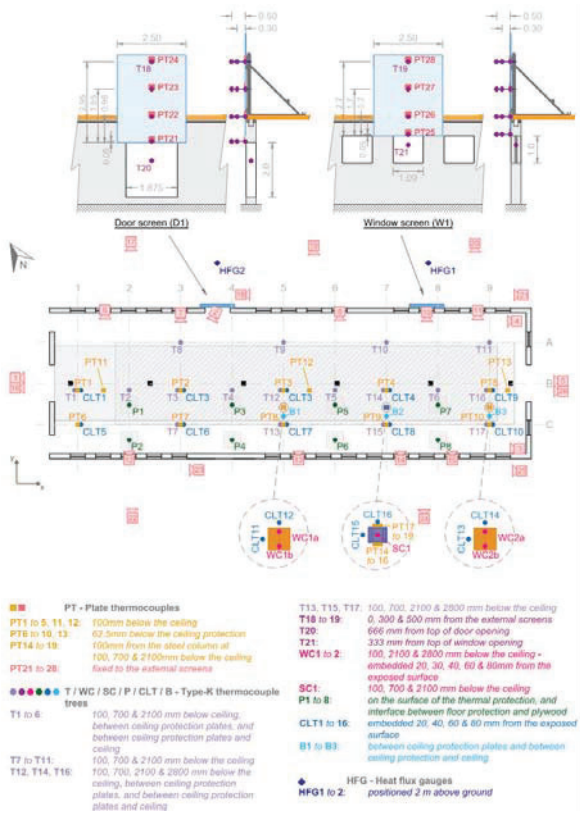

Figure 3: *Typical instrumentation in the CodeRed experiments.*

2.3 COMPARISON OF FEATURES

With regards to the specific objectives of this paper, footage from all recovered cameras were used to measure the locations of the leading (i.e. flame front) and trailing (i.e. burn-out) edges of the fire as in *x-ONE* [7] and x-*TWO.1* [8]. Cameras located inside the compartment and at compartment openings were placed in heat and

https://doi.org/10.52202/069179-0234

radiation-resistant containers to protect the instrumentation and data collected.

See Table 1 for a comparison of the relevant experiments.

Table 1. Summary of the differences in the key parameters of interest between the previous non-combustible travelling fire experiment and the CodeRed experiments. CodeRed #03 is not included in the table as its aim is not related to this study.

Parameter	x-ONE [7], x-TWO.1[8]	*CR#01* [4]	*CR#02* [5]	*CR #04* [6]
Ceiling	Non-combustible	*Fully exposed ceiling (CLT)*	*As CR #01*	*52% exposed*
Ventilation	20%	*21%*	*10%*	*As CR #01*
Width x length	10.8 m x 35.52 m	10.27 m x 34.27 m	*As CR #01*	*As CR #01*
Height	2.93 m to 3.19 m	3.1 m	*As CR #01*	*As CR #01*
Area	384m^2	*352m^2*	*352m^2*	*352m^2*
Type of fuel – wood sticks	Wood sticks 0.03m x 0.03m x 1m	Same as x-ONE and x.TWO.1	Same as x-ONE and x.TWO.1	Same as x-ONE and x.TWO.1
Fibreboard	Wood fibreboard throughout (x-ONE) and only in first meter (x-TWO.1)	Same as x.TWO.1	As x.TWO.1	As x.TWO.1
Size of fuel bed	6 m x 29 m	As x-ONE and x-TWO.1	As x-ONE and x-TWO.1	As x-ONE and x-TWO.1
Fire duration (cessation of flaming of wood cribs)	25 min (x-ONE) 32 min (x-TWO.1)	22.5 min	27 min	46 min

3 IMPACT OF EXPOSED TIMBER ON FLAME SPREAD

The CodeRed experimental set-up mimicked previous "travelling fire dynamics" experiments undertaken in a non-combustible compartment to allow for direct comparison between each experiment series. For reference purposes the extracted locations of the flame and spread rates of the flames for x-TWO.1 are shown in Figure 4 [8].

3.1 FLAME SPREAD IN NON-COMBUSTIBLE COMPARTMENTS

In x-TWO.1 the flame spread rate showed two main conditions. For the first 5m of the fuel bed, flame spread 4.16 mm /s (0.25 m/min). this took approximately 14 minutes. As the flames passed the large ventilation opening that was present in this location, the flame spread rate then increased to an average value of almost 58.3 mm/s (3.5 m/min) until reaching the end of wood crib. After 5 min from the ignition, a clear trailing edge of fire started to move along the compartment, with the spread rate of ~ 4.2 mm /s (0.25 m/min) almost the same as the leading edge. After 13 minutes from ignition of the fuel bed, the spread rate of the trailing edge of the flames accelerated to a maximum value of 41.7 mm/s (2.5 m/min). The spread of the trailing edge stopped at around 25 minutes. In the locations where the trailing edge has passed the fuel had experienced burn out. See [8] for more information on the experimental results.

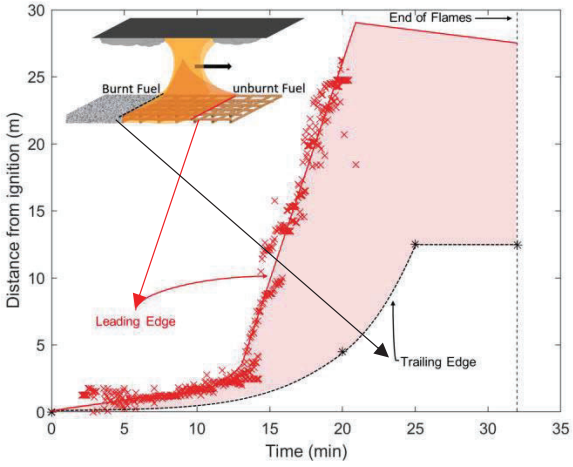

Figure 4: Locations of the leading and trailing edges of flame spread across the compartment for x-TWO.1.[8]

3.2 FLAME SPREAD IN CODERED #01

As shown in **Error! Reference source not found.** in *CodeRed #01*, the flame spread along the crib was observed to follow two main burning regimes. For the first 2.5 minutes of spread, the leading edge spread rate was approximately steady at 11 mm/s, 2.5 times the rate of the x-TWO.1 experiment. The spread rate accelerated substantially at the point the CLT ceiling surface ignited, spreading across the full fuel bed within 5 minutes of ignition. Noting that it took the x.TWO.1 experiment 20 minutes for the leading edge to reach the far end of the fuel bed.

After the leading edge reached the end of the fuel bed, it was also observed to regress into the compartment as the crib was consumed from both ends. This was not observed in the x.TWO.1 experiment.

The trailing edge, was identifiable and began to substantially traverse the compartment at approximately

https://doi.org/10.52202/069179-0234

12 min (comparable to x.TWO.1) and steadily spread across the compartment with an average spread rate of 37 mm/s (2.2 m/min). This is at the higher end of the trailing edge spread rates observed in x.TWO.1.

The distinct and identifiable movements of both the leading and trailing edge are characteristic of a travelling fire. This demonstrates that it is valid to consider travelling fire conditions in compartments of this size.

The average spread rate of flames across the CLT, based on the time between the ignition of the CLT and the flames reaching the far end of the compartment, was 200 mm/s (12 m/min) spreading 30 m in 2 min 29 s. This is approximately 3.5 times faster than the x-TWO.1 test results.

The fire was at its maximum size between 6 and 12 min when the full extent of the crib and CLT were burning simultaneously. This was not observed in the x.TWO.1 experiment, as the trailing edge had spread before the leading edge reached the far end of the fuel bed. This meant that the fuel at the start of the compartment had already burnt out as the fire was travelling.

3.3 FLAME SPREAD IN CODERED #02

As shown in **Error! Reference source not found.**, in *CodeRed #02* as in *CodeRed #01* flame spread across the ceiling was rapid once the CLT ignited. At 7 min 25 s the leading edge of both the crib and the ceiling arrived simultaneously to the far end of the compartment as seen in **Error! Reference source not found.** The crib at the far end of the compartment was observed to quickly burn out, resulting in the leading edge receding back through the compartment at approximately 13 min 30 s after ignition. The trailing edge appeared to progress much slower than the receding leading edge.

Based on the timing of the ignition of the CLT and the arrival of the flames at the end of the compartment the average flame spread rate across the CLT in CodeRed#2 was 153mm/s (9m/s) compared to 200mm/s (12m/s) for *CodeRed #01.* The spread rate across the crib was less impacted than the CLT, with an average spread (after CLT ignition) of ~147 mm/s (0.15 m/s), compared to 161 mm/s (0.16 m/s) in *CodeRed #01*. As such the reduction in ventilation appeared to have a greater overall impact on the spread rate of flame across the CLT (-23%) than the crib (-8%). Similarly to CodeRed #01, in CodeRed #02 the crib was burning simultaneously for the majority of the fire duration unlike x-TWO.1

3.4 FLAME SPREAD IN CODERED #04

Overview of difference with other tests

In *CodeRed #04* ~50% of the ceiling was encapsulated, mostly above the fuel bed. In this experiment there was an initial delay of 20 minutes until the exposed CLT ceiling ignited (see Figure 7. This delay was because of the encapsulation preventing flames and hot gasses impinging on the CLT directly above the fuel bed, where CodeRed #01 and #02 ignited first. Instead of direct flame impingement from the wood crib fire onto the CLT ceiling, the fire in the wood cribs instead heated up the encapsulation instead, driving out the moisture in the board protection. Additionally, the moisture of the wood cribs was higher than the earlier experiments due to environmental conditions during *CodeRed #04* which took place in December. This effect is discussed in detail below.

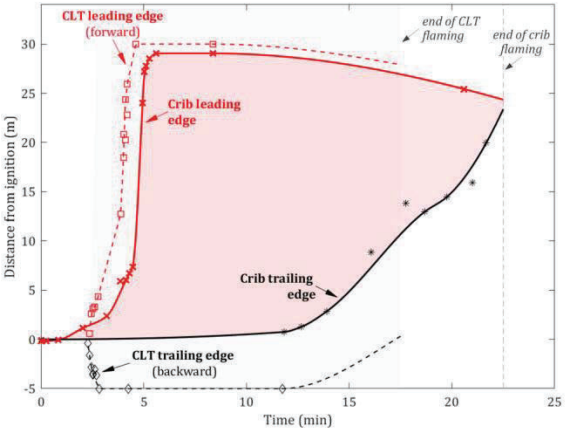

Figure 5*: Locations of the leading and trailing edges of flame spread across the CLT (dashed lines) and the wood crib (solid lines) for CodeRed #01. The time of end of observed flaming combustion of the CLT (17.5 min) and crib (22.5 min) are marked with vertical shaded area and dotted line, respectively.*[4]

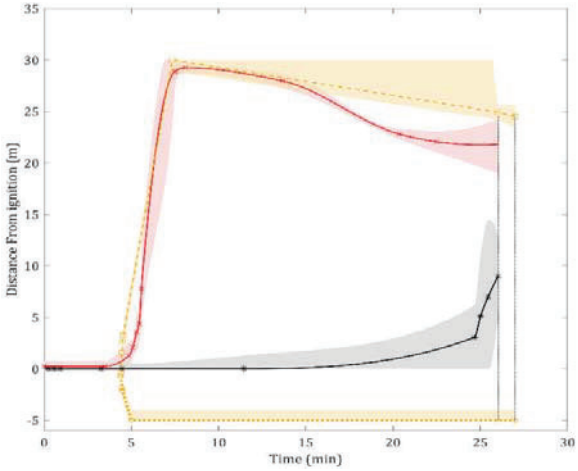

Figure 6: *Leading and trailing edges of flame spread along the wood crib, and leading flame edges both forwards and backwards under the CLT ceiling for CodeRed #02. Error cloud indicates deviations in edge location along the width of the crib, as edges are not constantly parallel to compartment width.* [5]

Fire spread observations

Figure 7 presents the positional data of the leading and trailing edge gathered from image analysis for *CodeRed*

#04. Before the first ignition of the CLT, the leading edge spread linearly with an average spread rate of 3 mm/s (0.18 m/min). By comparison, in *CodeRed #01* this spread was 11 mm/s (0.66 m/min), over a shorter duration, and while the fire was spreading through the section of the crib with fibreboard. When the CLT ignited, the leading and trailing edges had already travelled 4.4 m and 3.0 m respectively. As a result, a smaller extent of the crib was involved during the peak fire period in *CodeRed #04* compared to *CodeRed #01*and *#02*.

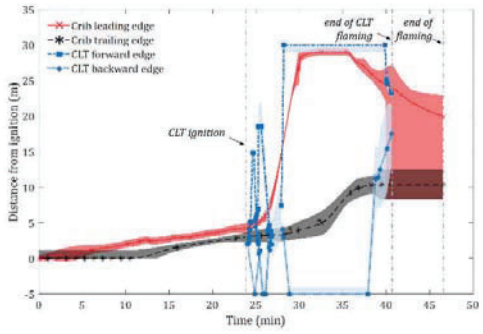

***Figure** 7: Locations of leading and trailing edges of flame spread across the cross-laminated timber (CLT) (dashed lines) and the wood crib (solid lines) for CodeRed #04. The time of end of observed flaming of the CLT (40 min 59 s) and crib (46 min) are marked with vertical dotted lines.* [6]

Following the sustained ignition of the CLT, the spread rate of crib fire grew to an average of ~107 mm/s (6.4 m/min), taken between the time of sustained CLT ignition and when the flame spread was observed to spread the length of the crib. The average spread across the CLT was ~222 mm/s (13.3m/min), measured from the point of sustained ignition of the CLT. In *CodeRed #01,* the spread rates were 161 and 200 mm/s (9.6 and 12m/min) for the crib and CLT, respectively.

Impact of encapsulation

The encapsulating boards were observed to largely remain in place over the whole flaming period, preventing flaming from the surface of the protected CLT ceiling. The last layer failed in some instances during decay but the encapsulation met its objectives in preventing flaming.

The decrease in flame spread rate in *CodeRed #04* across the crib is likely due to the effects of the calcium silicate board protection and different moisture content in the *CodeRed #04* crib. The encapsulation of the CLT delayed ignition of the CLT and instead resulted energy being absorbed in driving out moisture from the board protection [10]. The encapsulation also reduced radiative feedback from the ceiling to the fuel bed. The flame spread across the CLT was broadly within the same range, as in *CodeRed #01* once the CLT ignited.

Impact of moisture content

The greater moisture content within the wood crib of *CodeRed #04* (17.7%) compared to that in *CodeRed #01* (13.5%), and the presence of the board protection is expected to have reduced the spread rate of the leading edge, as greater energy and time are required to dry the wood. This difference in moisture content in the crib equates to an approximately 34% increase in energy required to dry the wood, and an approximately 32% increase in the overall energy required to combust the timber which also includes heating (to 350 ℃, specific heat capacity = 2.3MJ/kgK [11]) and pyrolyzing the timber (1.82 MJ/kg [12]).

Therefore, when comparing the results of *CodeRed #04* with those of *CodeRed #01*, the increased moisture and resulting increase in energy required to heat the timber, needs to be taken into consideration as it a significant influence on the results, particularly in the initial stage of the fire. The energy required to dry the moisture from the encapsulation system may have also played a role.

The results from CodeRed #04 suggest that in partly encapsulated compartments the flame spread over the fuel bed will be slower than fully exposed ceilings but faster than non-combustible compartments. However, when ignited, the exposed CLT ceiling spread flame at the same rate as a fully unprotected CLT ceiling.

3.5 FIRE SIZE OF WOOD CRIBS

The amount of fuel load burning at one time is important to the understanding of how quickly a severe compartment fire may grow and spread. Therefore, the amount of the fuel bed burning simultaneously was compared between all the tests.

As discussed earlier the same wood crib configuration was used in the x-ONE, x-TWO.1 and CodeRed experiments. All experiments had the same number and arrangement of wood sticks. A wood fibreboard throughout the fuel load was also included in x-ONE and but only in first meter for x-TWO.1 and CodeRed.

Figure 8 plots the length of the wood cribs on fire simultaneously as a comparison across all the compared experiments. Comparing the fire length on the fuel bed allows to establish the extent of flaming within the compartment at any given time and be able therefore to compare the relative impact of the timber ceiling in affecting the extent of flaming of the cribs. The crib fire size results are presented for the duration of each test after CLT ignition occurred (CodeRed) or flames touched the ceiling (x-ONE & x-TWO.1) for a more representative comparison over time.

Based on the results it can be seen that the CodeRed #01 and #02 experiments resulted in a larger extent of the cribs burning simultaneously compared to x-TWO.1, even though the fuel load configuration was identical. The fully exposed timber ceilings of CodeRed #01 and #02 also resulted in a larger extent of the wood cribs flaming

https://doi.org/10.52202/069179-0234

simultaneously compared to the presence of the fibreboard in the x-ONE experiment. Comparing CodeRed #04 with x_ONE and x-TWO.1, a similar peak size of flaming was reached between the three experiments but in the case of CodeRed #04 that was reached more quickly than the non-combustible experiments.

Therefore, the CodeRed experiments support a conclusion that exposed CLT ceilings are likely to lead to more severe fire conditions earlier in a fire.

The CLT ceilings also had an influence on external flaming as discussed further by [13].

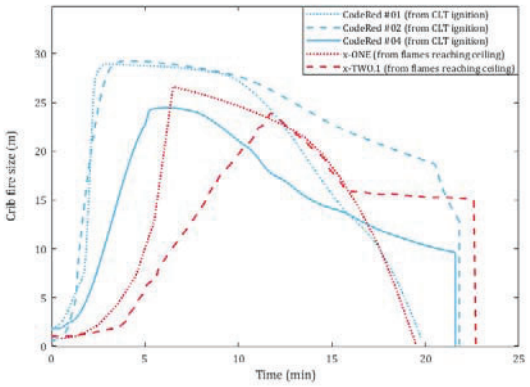

***Figure 8**: Fire size of the wood cribs – comparison of all the experiments.*

4 DISCUSSION

This section discusses the impact of introducing the CLT ceiling on flame spread rates, fire duration and Design fires.

4.1 IMPACT ON FLAME SPREAD RATES

In all CodeRed experiments the leading and trailing edges were observed to initially spread across the compartment, characteristic of travelling fires. However, once the timber ceiling was ignited, the flames spread at a rate much faster compared to the equivalent non-combustible compartments x-ONE & x-TWO.1.

Flame spread rates for the experiments across the wood cribs in the non-combustible compartments, and across the wood cribs and the CLT in the combustible compartments are summarised in *Table 2*.

Table 2. Flame spread rates in [mm/s] for the x-ONE and x-TWO.1 and CodeRed experiments. CodeRed #03 is not relevant to this study.

Parameter	*x-ONE*	*x-TWO.1*	*CodeRed #01*	*CodeRed #02*	*CodeRed #04*
Crib spread rate before flames touch the ceiling (x-ONE and x-TWO) or before CLT ignites (CodeRed)	3.3	1.9	11	2.1	3.3
Crib spread rate after flames touch ceiling / after CLT ignites	67	34	161	147	68 (first ignition) 107.5 (sustained ignition)
CLT spread rate	N/A	N/A	200	153	95 (first ignition) 222.1 (sustained ignition)

For the first two CodeRed experiments the presence of the timber ceiling resulted in a much more rapid flame spread in the wood cribs compared to the equivalent non-combustible structure, and consequently also a relatively shorter fire duration.

This increase in flame spread rate of the wood crib with the presence of the timber ceiling is most likely due to radiative heat transfer from the flaming of the CLT preheating the crib, resulting in a faster fire growth than in previous experiments with the same configuration in a non-combustible enclosure.

As expected, the overall fire dynamics experienced in *CodeRed #04*, fall between the characteristics observed in *CodeRed #01* and the reference non-combustible experiments, *x-TWO.1* that had identical fuel load arrangement. x-ONE that has a different fuel load arrangement with the addition of fibreboard led to similar spread rate with *CodeRed #04* when taking the time for first ignition (but slower when taking the taking the time from second ignition). Despite the initial delay for the protected CLT ceiling to ignite, once the CLT had ignited, flames spread rapidly over the timber ceiling albeit not at the same rate as in the cases with a fully exposed ceiling. The slower spread rate across the CLT ceiling in *CodeRed #04* is substantially influenced by 1) the CLT directly above the wood crib being protected with the encapsulation; and 2) some energy was absorbed in driving out the moisture content of the wood crib and board protection covering half of the CLT.

https://doi.org/10.52202/069179-0234

The observed CLT flaming spread rates in the CodeRed experiments are rapid. It should be considered however that the

4.2 IMPACT ON FIRE DURATION

The impact of the timber ceiling on flame spread and overall fire duration is an important consideration as it informs the fire severity that the structure is expected to withstand.

The experimental results suggest that the presence of substantial CLT linings do not substantially reduce the wood crib flaming period due to the more rapid flame spread across the ceiling. This is unlike experience from small compartments where increased fuel load would be expected to result in an increased flaming duration.

Table 3 presents the comparative results on flaming duration. The fire in *CodeRed #01* was growing more rapidly during its initial stage before flames touched the ceiling (11 mm/s) than x-ONE and X-TWO (3.3 mm/s and 1.9 mm/s respectively). In addition, in *CodeRed #04* there was a delay in sustained CLT ignition. Therefore, time differences in the overall wood crib flaming duration are not solely due to the presence of the timber ceiling. Instead considering the duration after flames have ignited the combustible ceiling or when the flames touched the non-combustible ceiling allows for more direct comparisons of the relevant metrics.

Table 3. Fire durations for each experiment

Parameter	*x-ONE*	*x-TWO.1*	*CodeRed #01*	*CodeRed #02*	*CodeRed #04*
Total fire duration from ignition of the wood cribs	25 min	32 min	22.5 min	27 min	46 min
Fire duration after flames touching the ceiling (x-ONE & x-TWO.1) or CLT ignition (CodeRed)	19 min 30 s	23 min	19 min 43 s	22 min 49 s	22 min 07 s (first ignition) 19 min 30 s (sustained ignition)

4.3 IMPACT ON DESIGN FIRES

The CodeRed experiments showed that an exposed timber ceiling leads to a rapid spread of the fire that exhibits both – rapid - travelling behaviour and simultaneous burning across the entire a compartment. It was shown that the increase of fuel load (and therefore heat release rate) in the compartment through the addition of the timber ceiling did not result in a subsequent increase in overall fire duration.

The flame spread across the cribs was 4.3 to 4.7 times faster in the compartment with a fully exposed timber ceiling compared to the equivalent non-combustible experiment (x-TWO.1), measured from the point of CLT ignition / flame impingement on the ceiling. With 50% encapsulation the flame spread rate across the wood cribs was 2 times faster when taking time from first ignition and 3.2 times faster when taking time from sustained ignition.

While travelling fire characteristics were observed in all experiments, the rapid flame spread rates suggest that uniform flashover conditions may be a good approximate for large compartments with exposed timber ceilings for the characterisation of the internal thermal environment.

Applying such uniform flashover conditions to large compartments for some types of structures that are sensitive to non-uniform compartment temperatures such as steel frames may yield unconservative structural responses [14]. This means it will be necessary to further develop travelling fire analysis models [1] that are suitable to represent fire dynamics in large compartment with exposed timber, and provide adequate design fires for structures under uneven heating conditions.

Barber et al. [15] indicate the importance of assessing thermal penetration in loadbearing timber elements as peak temperatures in mass timber elements occur long after flaming combustion in the compartment has ceased, often several hours later. Columns are particularly vulnerable.

Further analysis is necessary for timber framed structures to investigate the impact of non-uniform burning seen across large compartments with exposed timber surfaces.

It is noted that taking an approach of uniform temperatures across the entire compartment may be overly conservative where heat transfer is evaluated to the floor (i.e. fire exposure from above); this is discussed in more detail in [19]

The presence of the CLT on the ceiling produced more rapid flame spread rates compared to those assumed in the travelling fire methodologies in the literature [16] that assume non-unform burning which have been developed for non-combustible ceilings.

The existing methods do not incorporate the contribution of additional combustible surfaces to the overall energy release inside the compartment, or the role of combustible surfaces in increasing spread rates.

Further research and development is required to incorporate these fire dynamics phenomena into travelling fire design fire methods to make them appropriate for application in large CLT compartments.

Nevertheless, the travelling behaviour occurs so rapidly that further review is also needed to determine under

https://doi.org/10.52202/069179-0234

which scenarios design fires based on simpler flashover assumptions would yield sufficiently conservative results from a fire safety engineering perspective for mass timber structures.

The timber ceiling also affects external flaming outside the compartment that is not captured by current design methodologies [13]. Further research is needed to understand heat release rates in compartments with an exposed timber ceiling and how this additional combustion is influencing fire severities outside and inside the compartment (% of combustion inside vs outside).

4.4 IMPACT ON MEANS OF ESCAPE AND FIRE-FIGHTING ACTIVITIES

The CodeRed research has shown that once a timber ceiling is ignited flame spread can be rapid.

The recorded flame spread rates over the untreated CLT ceiling are high, with up to 200 mm/s (0.2m/s) where there is a fully exposed ceiling, from the point that the ceiling becomes involved in a fire.

It is acknowledged that in practice, untreated timber surface, which would commonly be assigned a reaction to fire classification of Euroclass D, would not be permitted in large open spaces; common fire safety standards used in e.g. the UK, BS9999 [17], and Approved Document B [18], would expect a Class B reaction to fire finish, unless the rooms are very small.

It is important however to consider how close these observed flame spread rates are to evacuation speeds adopted in fire engineering practice (0.5-1.2 m/s), particularly when considering that people may initially move towards the fire to investigate the cause, and attempt to extinguish it.

The ability of surface treatments to improve the reaction to fire performance of timber to slow fire growth and flame spread in more severe fire conditions would benefit from further study.

The observed increase in flame spread rates and subsequent earlier and larger maximum heat release rate reduced the time available for fire-fighting activities in mass-timber buildings to commence while a fire is still growing. Fire fighting tactics also need to take account of risk of ongoing smouldering e.g. in junctions that can continue for multiple days under the right conditions.

Designers need to take these into consideration when determining fire safety strategies for large compartments with exposed timber ceilings.

5 CONCLUSIONS

The CodeRed series of experiments conducted in 2021 had as one of its fundamental objectives to study the impact of timber on fire dynamics in large open-plan compartments.

This paper specifically focuses on flame spread rates within compartments, comparing CodeRed to previous non-combustible compartment experiments that were used as prototype for CodeRed.

Rapid flame spread was observed across the CLT ceiling once the ceiling ignited (~153 to 220 mm/s). Compared to the reference non-combustible enclosure experiments the flame spread across the wood cribs was also significantly faster (3.1 to 4.7 times faster considering the time from sustained ignition of the CLT ceiling).

In all CodeRed experiments, leading and trailing edges observed, characteristic of a travelling fire, transitioning to full flashover fire where the fire was burning across the entire wood crib and CLT ceiling simultaneously.

The rapid flame spread rates suggest that uniform flashover conditions may be a good approximate for larger compartments with exposed timber ceilings.

However for structural systems sensitive to non-uniform compartment temperatures such as steel frames, and very large compartments, such simplified design fires may yield unconservative structural responses.
There may be a range of different design fires that a combustible structure needs to be evaluated against.

Travelling fire analysis models that are suitable to represent fire dynamics in large compartment with exposed timber are therefore necessary to provide adequate design fires for structures sensitive to uneven heating conditions, and for large compartments where uniform flashover conditions may be unconservative.

6 Further work

The observed CLT flaming spread rates in the CodeRed experiments are rapid. It should be considered however that the experimental configuration may have played a role on the observed flame spread rates in the experiments. In particular the availability and position of ventilation compared to the location of ignition of the fire in both the CoreRed and x-ONE and x-TWO.1 experiments may have influenced the early fire growth period and therefore influenced the outcomes.

Future tests should establish if the observed CLT flame spread rates observed in CodeRed would also apply to other compartment and ventilation arrangements.

ACKNOWLEDGEMENT

This research has been fully funded by Arup and was undertaken in partnership with Imperial College London. The experiments were carried out in a bespoke facility built at CERIB's Fire Testing Laboratory site in France.

ACCOUNTING FOR POST-PEAK COMPARTMENT TEMPERATURE THERMAL DEGRADATION OF MASS TIMBER

David Barber[1], Eirik Christensen[2], Panos Kotsovinos[3], Mohammad Heidari[4], Judith Schulz[5]

ABSTRACT:

Mass timber load-bearing members need to be assessed for structural adequacy in fire. For high-rise buildings their strength has to be determined once the fire has completely decayed and the timber member is no longer impacted by the heat of the fire. For a decaying fire, the thermal penetration into a timber member continues well after the peak compartment temperature, resulting in timber strength degradation, which is not typically assessed and accounted for. From a review of experimental data sets for exposed mass timber members and using the glulam column data from the CodeRed large scale compartment experiments, an assessment of the issues for thermal penetration and heat diffusion has been carried out. Initial studies have shown that peak temperatures in a timber column will occur well after the end of flaming and that thermal loss from the member in the decay phase of the fire is slowed by the char layer built up. Assessment of structural adequacy of columns has shown that the reduced cross-section needs to account for the compartment post-peak temperature thermal penetration, or the engineering design may be non-conservative.

KEYWORDS: Mass timber, structural fire engineering, heat transfer, fire resistance, columns

1 INTRODUCTION

Buildings constructed with mass timber continue to increase in popularity globally. Low and medium rise buildings with exposed mass timber can generally be designed to meet fire safety goals of local regulations, codes or standards. Where mass timber is exposed within a high-rise building, the structure needs to be able to withstand a range of design fires, that includes both the standard fire and natural (physically based) fires. The structural adequacy of mass timber elements that resist loads in a fire is based on determining an effective cross-section, after exposure to a design fire. Where large areas of mass timber are exposed, design fires are influenced by that exposed timber and changing ventilation, a highly complex assessment. The effective cross-section is determined from a reduced initial cross-section, based on a char layer and the reduced strength of the wood ahead of the char, due to thermal impact. Simple design rules are based on the effective cross section supporting the applied loads for the period of fire exposure, such as EN 1363-1 [1] or ASTM E119 [2].

For a timber member exposed to a natural fire, the heat flux received varies with time and as the external heat flux reduces from a peak, the resultant thermal penetration (thermal wave) will continue to cause timber degradation after the compartment peak temperature has been reached. The resultant strength reduction in-depth after the peak exposure temperature has had limited research, is not normally assessed by engineers and is highly relevant for high-rise mass timber structures exposed to longer duration and decaying fires, and in particular, vertical load-bearing elements such as columns.

This paper presents the initial work carried out in literature reviews, background theory and summary of results from the CodeRed series of large-scale experiments. Work is on-going and further updates are to be published later in 2023 that includes finite element modelling and developing an engineering method to predict the impact of thermal degradation on timber strength for the decay phase of natural fires.

2 BACKGROUND

Timber exposed to a heat flux has three distinct zones, as was first described by Schaffer [3], being a charred layer where the temperature is in excess of 300°C, a transitional zone (pyrolysis zone) between 300°C and ambient temperature, typically called the thermal penetration depth, and ambient temperature timber (assumed to be 20°C). The position of the char front is set by the 300°C isotherm and under standard fire exposure (such as to EN 1363-1 or ATM E119), is predicted using a nominal char rate (β_o) of 0.65mm/min. The structural adequacy (capacity) of an exposed timber member reduces when exposed to fire based on the time of exposure, with the constant char rate (β) and a fixed zone of timber behind the char with no strength (zero strength layer, ZSL), to determine where the cross-section has full strength (effective cross-section). This is based historical fire

testing to the standard fire. The fixed char rate and ZSL are only valid for standard fire exposure.

2.1 Relevance of Timber Strength Proportional to Temperature

The strength of timber reduces at relatively low temperatures. The mechanical properties of timber are reversible if temperatures are lower than 100ºC. For timber of temperatures higher than 100ºC, the properties are permanently degraded [4]. Research indicates that wood between 100ºC and 200ºC is considered to be in transition, with thermal breakdown occurring at temperatures past 200ºC. Once fully charred at 300ºC, timber is considered to have lost all strength. The transitional zone between the fully charred and ambient temperature timber therefore has three parts - the timber at a temperature between ambient and 100ºC which has a reversible strength reduction; temperatures of 100ºC and 200ºC where temperature effects are not reversible, though temperatures are not elevated enough to start pyrolysis; and the timber between 200ºC and 300ºC, where pyrolysis occurs and the mechanical properties degrade to zero [4, 5, 6].

From an engineering point of view, the question to be addressed in the design of a timber member is at what point of the thermal penetration of timber between 100ºC and 300ºC does temperature matter? Eurocode 5 (EN 1995-1-2) [7] provides data for the reduction in mechanical properties for timber proportional to temperature. This data is only applicable for standard fire exposure. Schmid et al [8] shows this data for strength and stiffness, with f_c representing compression, f_t for tension and f_v for shear (see Figure 1).

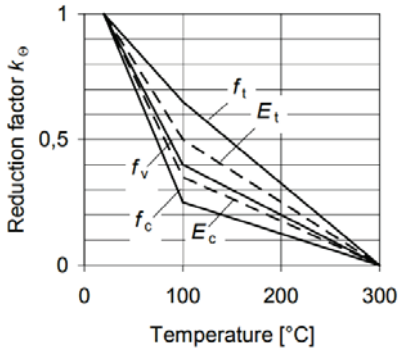

Figure 1: *Reduction factors for strength and stiffness properties from adapted from Eurocode 5, for standard fire exposure [8]*

Of most relevance is how sensitive compressive strength is to temperature. Timber at 140ºC has lost 80% of its compressive strength. At the same temperature timber has lost only 40% of its tensile strength. For columns that are under load and have timber that has reached 140ºC, whether the impact of thermal strength degradation is reversible or not, losing 80% of compressive strength is very significant. The 140ºC isotherm may not need to penetrate too far into a column before the member would lose structural adequacy, typically through buckling. Once structural adequacy has been lost, the reversibility of the timber strength loss is moot.

2.2 Relevance of Zero Strength Layer and Thermal Penetration Depth

The ZSL is an engineering approximation for the thermal penetration depth and is used to account for the area of reduced strength behind the char layer, given the temperature range is between 300ºC (charred wood) and ambient, for standard fire exposure. The thermal penetration depth has been researched for over 40 years with data from fire testing on solid timber and glulam being analysed [9]. Janssens and White [10] summarised test data and provided a method to determine the temperature at any point and showed that temperatures reached ambient at 40mm behind the char layer, for various softwood timber species. Frangi and Fontana [11] estimated 25mm to 50mm (see Figure 2).

These temperature correlations were used to determine the ZSL as 7mm behind the char zone, as an approximation for engineering design, to account for thermal penetration depth. The use of 7mm has been reviewed for many years as not reflecting known mechanical properties of timber and is revised in the current Eurocode 5 update [12], with higher values for the ZSL, depending on the forces being resisted in the timber for compression, tension or shear, reflecting actual timber mechanical properties.

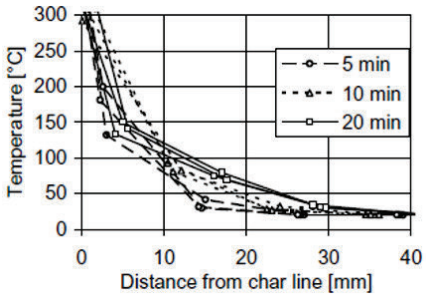

Figure 2: *Temperature profiles in a timber beam, behind the char, for 60min standard fire exposure [11]*

The experimental results above for thermal penetration depth are only accurate for standard fire exposure and not applicable for a natural fire, or the decay phase of a fire. To determine the thermal penetration depth for a natural fire, the temperature through the timber cross-section needs to be assessed, which requires the heat transfer into the timber to be analysed. This can be completed by experimental work or finite element modelling.

2.3 Determination of Thermal Penetration Depth for Natural Fire Exposure

There have been over 40 different compartment experiments with exposed mass timber and a natural fire. Temperature growth and decay curves are shown in Figure 3 from a Canadian experimental series [13], showing the relatively slow decay phase due to the extent of exposed mass timber, with limited ventilation.

https://doi.org/10.52202/069179-0235

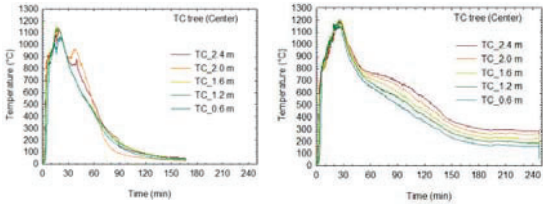

Figure 3: *Temperature profiles from an exposed mass timber compartment fire, with no timber exposed (left) and CLT exposed on one wall (Test 2) (right). The difference in temperatures at 120 mins can be seen. The change in rate of cooling near 700°C can also been seen. The CLT had proven glue line integrity in fire [13]*

A natural fire will decay (ignoring fires that do not decay due to CLT glue line failure or encapsulation failure) and the fire heat release will trend to zero and room temperatures trend to ambient. The lack of fire and thermal exposure will result in the charring of any exposed mass timber to stop. While the charring may stop, the thermal wave from the compartment fire and the glowing and smouldering residual fuel on the floor, will continue to penetrate the mass timber element. A review of experimental data shows that the thermal penetration continues to occur well after the peak compartment temperature has been reached and through the full decay phase of the fire. Determining where the thermal penetration is between 300°C and 100°C behind the char layer in a timber member, during the fire decay phase, becomes essential to determine structural adequacy.

3 REVIEW OF RELEVANT EXPERIMENTAL WORK

To determine the extent of experimental data that shows how thermal waves penetrate timber members in the decay phase of fires, over 60 experimental works were reviewed. The following is brief summary of the most relevant work.

The experimental series "Fire Testing of Rooms with Exposed Wood Surfaces in Encapsulated Mass Timber Construction" [13] was based on natural fire tests with exposed CLT, with in-depth thermocouples in the CLT, recording temperatures during the decay period through to four hours after ignition. Using Test 2 as an example (see Figure 4), the peak compartment temperature occurred at 28 to 31 mins after ignition and did not drop below 200°C. The peak temperatures in the CLT at depths of 35mm and 52.5mm are at initially near 120mins after ignition, then continue to rise through to the test being extinguished at four hours. Char depths of the CLT wall measured after the fire was extinguished ranged from 50mm to 95mm, with high values located near the floor. Ignoring the values at the base of the panel where charring was deeper due to the burning of the residual fuel on the floor, the average char depth was 62mm.

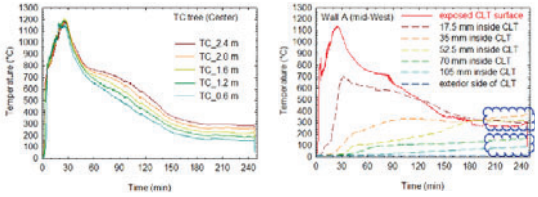

Figure 4: *Temperature profiles from Test 2 with an exposed mass timber wall (left). Temperature profiles within the CLT wall with increasing temperatures in-depth clouded [13]*

When compared with the temperatures recorded in-depth of the CLT wall, at 70mm from the exposed surface the temperature reaches 140°C at approximately 210 mins after ignition. At 105mm depth from the exposed surface the temperature is just over 100°C at 240 mins after ignition and was still increasing. These thermocouple readings indicate that thermal penetration occurred through to 70mm and up to 105mm deep into the CLT, compared to the char depth recorded that was between 50mm and 85mm, with an average of 62mm, with thermal penetration still increasing at 240 mins when the experiment was stopped. The char depth would indicate structural adequacy could be assessed using a reduced cross section in the order of 62mm, whereas the in-depth thermocouples would indicate that thermal degradation impacting timber strength occurs past 70mm and likely 105mm into the CLT.

In the "Compartment Fire Testing of a Two-Story Mass Timber Building" by the US Forest Service [14], natural fire tests with exposed CLT were completed, with temperatures recorded at depth within the CLT. The recorded post-experiment char depth in the panels was measured at approx. 30 to 35mm. For the experiment with CLT walls exposed, the delay in peak temperatures in-depth in the CLT are significant when compared to the time of the temperature peak for the natural fire. Figure 5 shows the peak temperatures in the living room and bedroom were at approx. 15 to 25 mins after ignition.

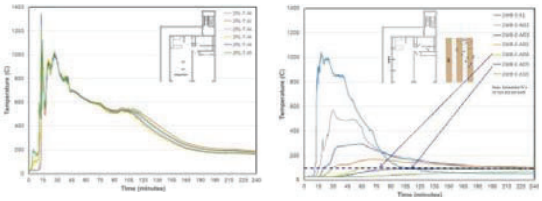

Figure 5: *Temperatures from the USFS Test 3 compartment fire with CLT walls part exposed. Living room temperature profile (left). Temperature profiles within the living room CLT wall, with 100°C line annotated (blue line) (right) [14]*

Within the living room the temperature at 35mm from the exposed surface is between 140°C and 160°C at 75 mins after ignition; and at 58mm depth between 100°C and 120°C between 60 mins and approx. 180 mins. Within the bedroom the temperature at 47mm from the exposed surface is between 120°C and 140°C at 105 mins after ignition; and at 58mm depth between 100°C and 120°C between 105 mins and approx. 180 mins. Hence, the in-depth thermocouples show that thermal penetration in the timber occurs through to a depth of 47mm and up to

https://doi.org/10.52202/069179-0235

58mm in the fire decay phase but measured char depths only record about 35mm. The additional depth of thermally degraded timber (approx. 12 to 23mm) that would have reduced strength, is not accounted for.

Harada's tests on a 100mm thick glulam timber wall [15] were exposed to a 60 min ISO834 fire and allowed to cool within the furnace, while in-depth thermocouple data was recorded. The glulam wall was 800mm by 800mm of exposed area, with thermocouples located at 20mm, 40mm, 60mm, and 80mm from the exposed surface. The exposed surface temperatures decay steadily but slowly due to the furnace enclosure and at 240 mins range from 120ºC to 350ºC (see Figure 6).

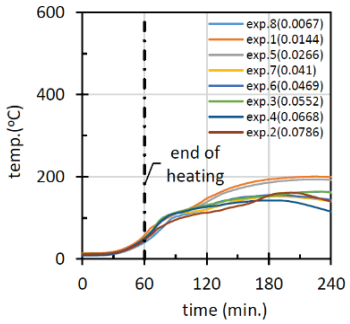

Figure 6: *In-depth temperatures measured at 60mm from the exposed surface [15]*

Based on the 60mm in-depth thermocouples, thermal degradation occurs through to 4 hrs of exposure, with thermocouples measuring between 120ºC to 200ºC. The data indicates the timber strength would be permanently impacted past 70mm depth. Charring post-test was recorded at approx. 52mm, showing the thermal degradation in-depth was deeper than the post-test char measurements.

Zeng et al [16] completed experiments on 3 and 5 ply CLT floors, exposing them to both standard and a simulated natural fire. In-depth CLT temperatures were recorded through the decay period for some of the experiments. The researchers recorded char depths of 37mm to 41mm after the test. Test (F5-20-N) shows thermocouples TC7 at a depth of 49mm and TC8 at a depth of 56mm from the exposed face recorded temperatures greater than 250ºC and 140ºC respectively through the fire decay period, and the temperatures were still increasing at the end of the test (see Figure 7). Thus, the timber at a depth of at least 56mm was thermally degraded, but char depths recorded were only up to 41mm, noting temperatures were still increasing when the experiment was stopped.

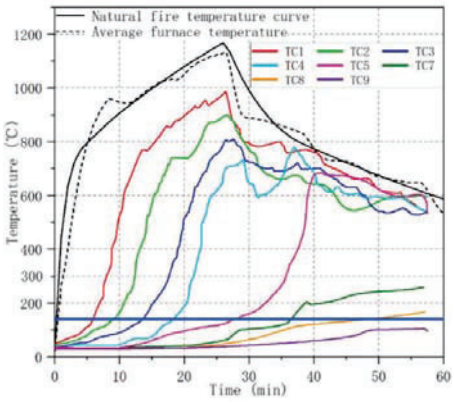

Figure 7: *Temperature profiles in a 5 ply CLT floor exposed to a natural fire (F5-20-N). Blue line indicating 140ºC [16]*

3.1 Summary of Review

A review of experimental work indicates there are only a limited number of useful data sets that provide information on in-depth temperatures during fire decay within timber. There are few experiments that have a decaying fire, where data is recorded for multiple hours without firefighting intervention. Of those experiments, many do not have thermocouples located deep enough to record useful data.

What the above useful data shows is that in the fire decay period, whether that be natural fire or a form of decaying fire within a furnace, that temperatures do not decay quickly in-depth and that temperatures can still be increasing when the experiment stops. The in-depth temperatures are also elevated enough to degrade strength. Where char depths at the end of an experiment are recorded, the in-depth thermocouples indicate that strength degradation occurs to a much greater depth than the recorded char layer.

4 IMPACT OF THERMAL PENTRATION DURING NATURAL FIRE DECAY – APPLICATION

For high-rise buildings with exposed mass timber (timber not encapsulated so exposed to the full heat of a fire), engineers need to determine the strength of a load-bearing timber member for the full duration of a fire. The strength of the timber member has to include the period through fire decay, such that the timber member is no longer impacted by the heat of the fire. In the growing phase of a fire the timber member chars, with the char providing insulative protection, with the char layer typically at temperatures between 300ºC and 600ºC. Once the fire reaches its peak temperature and starts to decay the timber member is exposed to a reducing heat flux. In a compartment with large areas of exposed mass timber, the fire decays more slowly, compared to a non-combustible compartment (see for example experiments from [13], [14]).

The reviewed data has shown that for a decaying fire, the thermal penetration into a timber member behind the

https://doi.org/10.52202/069179-0235

depth of char continues well after the peak compartment temperature and during the fire decay phase. As the compartment cools, the timber member starts to dissipate heat back to the compartment, as the char will be at a higher temperature than the surrounding compartment. This heat dissipation from the member occurs slowly given there are four possible impediments to rapid cooling: (1) thermal waves still penetrating the timber member from the peak heat flux; (2) the received radiative heat flux from the cooling compartment boundaries; (3) the char being a heat source, and (4) the insulative properties of the char preventing heat dissipating from the timber member back to the cooler compartment. The same insulative properties of char that prevent the timber from being damaged by the fire in the growth stage of a fire then become problematic as the char slows the timber member from cooling, as the compartment cools.

Thus, designing timber structures assuming the thermal impact in the timber member ceases when the fire peak temperature is reached, such as for a standard fire; or when the flaming ceases, such as for a natural fire, can be non-conservative. These approaches do not account for the ongoing heat transfer into the timber member and the associated thermo-mechanical degradation to the timber. This is relevant for high-rise timber structures and disproportionally impacts compressive members such as columns and load-bearing walls.

4.1 Implications

Columns are most vulnerable for the assessment of thermal penetration post-peak compartment temperatures, given there are few paths for heat dissipation given the four-sided charring. Their base can also be surrounded by smouldering residual fuel, continuing to conduct heat into the lower part of the column. Beams are normally exposed on three sides with the fourth side fixed to a floor system allowing for heat dissipation to a colder non-fire compartment. Hence, the slow heat dissipation that will occur in columns, and the significant reduction in compressive strength with elevated temperatures above 100°C (see Figure 1), results in columns being highly vulnerable to thermal penetration in the fire decay phase. Given the lack of sufficient data sets, it was determined by the project team in the formation of the CodeRed experimental series that glulam columns were to be included within all experiments to provide a novel data set [17, 18].

5 DATA AND FINDINGS FROM THE CODERED EXPERIMENTAL SERIES

The CodeRed large scale compartment experiments were set up to provide a detailed data set on thermal degradation in-depth of the timber, and data was recorded for a period in excess of 24hrs after fire ignition. The compartment had an internal floor area of 352 m^2. The fuel bed was identical in all experiments and consisted of continuous wood cribs with a fuel load density of ~380 MJ/m^2 over a floor area of 174 m^2. Two glulam columns were included within the CodeRed series of experiments and instrumented with thermocouples to collect in-depth data. The CLT panels located at the ceiling were also instrumented with in-depth thermocouples. The columns were 400mm x 400mm and the CLT panels were 5 ply (40-20-20-20-40 mm) spruce wood with MUF adhesive. Information presented below is from the first two experiments CodeRed #01 and #02 [17, 18]. A full description of the experimental setup, fuel load, ventilation, instrumentation, fire dynamics and charring behaviour in the timber members is within the referenced papers.

Figure 8 shows temperatures in-depth within Column 1, with thermocouples at depths of 20, 30, 40, 60 and 80mm. The variance of temperatures over column height is also shown through three different heights of thermocouple locations. Similar data was obtained for column 2 and also from experiment CodeRed #02, which had 50% less ventilation to the compartment. The data shows a delay to reaching the peak temperatures within Column 1 (centrally located) with peak of just over 300°C at 60 mins after ignition at 30mm depth; and a peak of just over 200°C at ~70 mins at 40mm depth. At 60mm depth, the peak temperature of just over 100°C is not reached until close to 90 mins after ignition (see Figure 9). Column 2 had similar results, though slightly lower temperatures as this column was closer to the building end. The measured char depth at the end of the experiment was 23mm for column 1 and 18mm for column 2 (weighted average).

Based on the temperatures recorded within the columns, thermal degradation occurs at a greater depth than the post-test char recordings show. At a 40mm depth the timber is thermally degraded with temperatures ranging from 139°C to 207°C and average close to 180°C. The peak temperatures occur 43 mins after the end of wood crib flaming. At a depth of 60mm, temperatures are very closely aligned with a range of 92°C to 106°C, with a peak occurring approx. 60 mins after the end of wood crib flaming. Based on the thermocouple data and using a temperature limit of 140°C (as discussed in Section 2.1 above), there is thermal degradation through to 52mm of column depth. This differs significantly from the post test charring with an average of 23mm deep. The data is also shown in Figure 10, represented by plotting at different column heights, the delay to reach peak temperature and the temperature reached. Further data is shown in Table 1. This data shows that the temperatures in the columns continue to increase well after the peak fire temperature (20 mins after ignition) and after the flaming has stopped (27mins after ignition). The additional timber that is thermally impacted behind the char layer needs to be accounted for in engineering design.

https://doi.org/10.52202/069179-0235

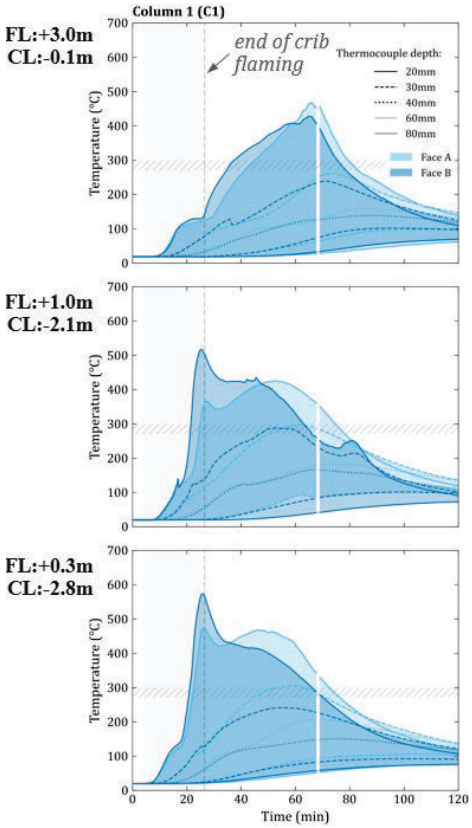

Figure 8: *Column C1 temperatures at various depths from CodeRed #01, at three different heights from ceiling (FL +3.0m) to floor (FL: +0.3m). End of crib flaming is shown. Peak compartment temperature was at 20 mins*

TC depth	Column 1	Column 2	Delay to Peak
20 mm	426 - 574°C	460 - 632°C	25 - 66 mins
30 mm	238 - 304°C	164 - 467°C	42 - 73 mins
40 mm	139 - 207°C	110 - 215°C	61 – 88 mins
60 mm	92 - 106°C	75 - 96°C	76 – 251 mins
80 mm	65 - 80°C	58 - 82°C	124 – 297 mins

Table 1: *Summary of Column 1 and 2 in-depth peak temperatures, based on thermocouple depth. Range shows the difference in peak temperatures depending on thermocouple location. Third column shows range of time to reach peak*

5.1 Relevance of the Delay of In-depth Peak Temperatures

The data from CodeRed illustrates an important factor in the engineering design and assessment of mass timber elements exposed to fires, being the delay in reaching peak temperature in-depth within the timber member. The thermal penetration into a timber member takes significant time to occur, relative to the growing and decaying fire, which has not received discussion in the literature reviewed. The CodeRed data for columns 1 and 2 show delays in peak temperatures that are relevant for thermal degradation of up to 88 mins after ignition (40mm depth), with the end of flaming of all flaming occurring at 27 mins. A graph of the delay to peak temperature is shown in Figure 11, indicating the trend.

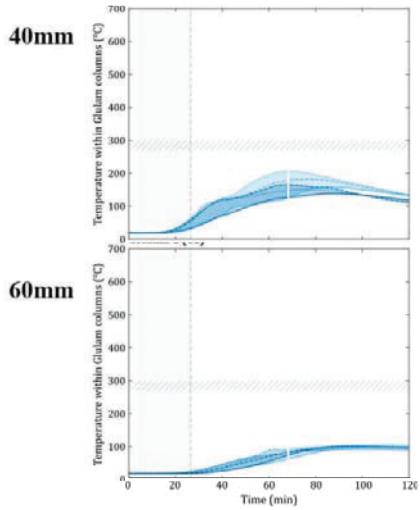

Figure 9: *Column C1 temperatures at 40mm and 60mm deep from CodeRed #01, with vertical dotted line showing the end of crib flaming. Peak compartment temperature was at 20 mins*

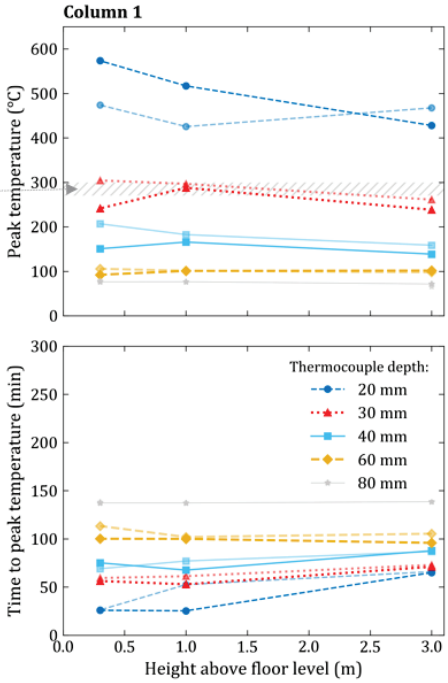

Figure 10: *Column C1 peak temperatures and time to reach that peak temperature at each depth, based on height above floor, for two differing sets of thermocouples at each in-depth location.*

A collated graph of the delay to peak temperature for both the exposed CLT and columns is shown in Figure 12. Whilst there is a range of scatter, the data shows a definite trend that the peak temperatures at the same depth in CLT are lower than in the columns. The time to reach the peak temperature is also slower in the columns.

https://doi.org/10.52202/069179-0235

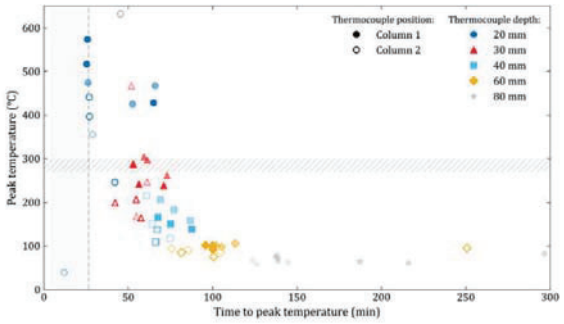

Figure 11: *Columns 1 and 2 from CodeRed #01 showing the peak temperature and time after ignition of that peak temperature, for differing thermocouple depths. Timber with temperatures above 100°C will have reduced strength that is not reversible*

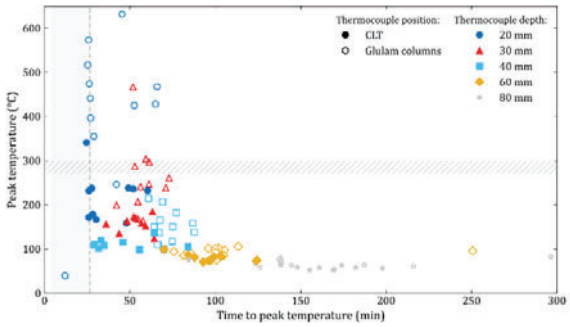

Figure 12: *Column and CLT temperature data from CodeRed #01 showing the peak temperature and time after ignition of that peak temperature, for differing thermocouple depths.*

This data indicates how a CLT floor benefits from having a cool surface on the non-fire surface (topside). This ambient temperature surface assists in reducing the overall temperatures in the CLT and allowing for faster heat dissipation, when compared to columns that are heated on four sides and also have insulative char build-up on all four sides. This difference in time to peak temperature at depth and relative hotter or cooler temperatures between CLT and the columns is undergoing further study, with finite element analysis. It should be also noted that the thermal impact is different to that caused by smouldering, which occurs in a localised area. The thermal penetration occurs throughout the whole column and as the CodeRed data shows, across the whole height of the column.

6 Using Code Red Results - How Is Structural Adequacy Impacted?

A code based approach for the assessment of structural adequacy for a column exposed to a 60 or 120 minute standard fire would be based on a char rate and zero strength layer (as described above in Sections 2.1 and 2.2). Using the EC 5 approach would result in 84mm of charring plus a 7mm zero strength layer, for 120 minutes of standard fire exposure. The cross section would be reduced by this char depth on all four sides to determine structural adequacy.

For engineering design, the CodeRed data (and the other data sets reviewed) shows that the end of flaming for a timber member cannot be taken as the end of the fire. The end of flaming or cessation of flaming is often referred to as "self-extinguishment" of a timber element [see 19, 20 as an example]. Of concern is that engineers and designers are using the end of flaming of a timber member as an indicator that the impact of heating and thermal penetration from the fire has stopped. The data sets reviewed within this paper clearly show that the cessation of flaming or self-extinguishment of timber cannot be used as an indicator for the end of thermal impact on strength for timber members, especially columns. If the cessation of flaming is used as the basis for engineering design of timber members, this will lead to non-conservative results.

Under exposure from a natural fire, the char depth can be calculated by assessing the radiative heat flux from a time-temperature curve and resultant char depth determined, for the growing and decaying fire. From the temperature data presented above, the reduced cross-section where the strength would be adequate for the full duration of the fire exposure is at 60mm depth (for CodeRed #01), given the temperatures are at or just above 100°C and thus thermally impacted strength reduction is reversible. If a limiting temperature of 140°C is used, where 80% of compressive strength parallel to the grain is lost, and this is used to determine effective cross-section, i.e. timber inside this isotherm still has load-carrying capacity, timber outside this does not, this would be at depth of approx. 52mm (based on interpolating average temperatures). If the design was based on the column section having full compressive strength timber, then the depth would be 60mm. As noted above, the CodeRed #01 char depths were 23mm for Column 1 and 18mm for Column 2 (weighted average). Figure 13 shows the percentage reduction in compressive strength for the timber located up to 40mm deep (88% reduction) and 60mm deep (76% reduction) in Column 1 from CodeRed #01.

As a further indication of the impact, column design for a building is highly proportional to the slenderness ratio and cross-sectional area. Using the CodeRed 400mm x 400mm column, with a length of 3.1m, as a design example and following the methodology within Eurocode 5: *Design of Structures. Part 1-1: General – Common Rules and Rules for Building* [21] Section 6.3.2 *Columns subjected to either compression or combined compression and bending*, and choosing typical glulam characteristic compressive strength of the timber parallel to the grain, $f_{c,0,k}$, gives the following comparison (GL30 grade glulam): Using a post-test measured char depth of 23mm + 7mm zero strength layer, could resist an applied load (factored for the fire load combination) of up to 247kN. Using the thermally impacted depth of 52mm, the same column can only resist an applied load (again factored for the fire load combination) of 63kN, i.e. the same column can safely resist only 26% of the load that is estimated from measuring post-test char depth. This indicates that the transient thermal wave has a significant impact on the

https://doi.org/10.52202/069179-0235

reduction in column capacity, even with this conservative assessment. Assuming column capacity based on measured char depth alone overestimates the column capacity to adequacy resist loads and is non-conservative.

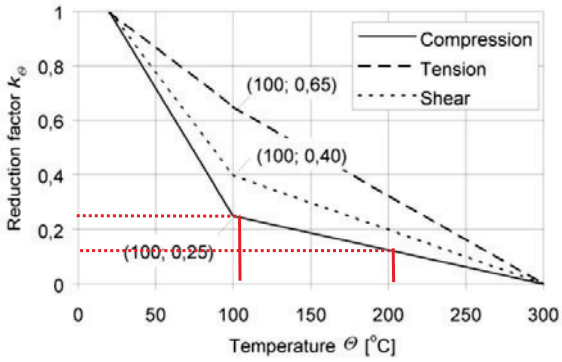

Figure 13: *Reduction factor for strength parallel to grain of softwood from Eurocode 5 [7], with Column 1 peak temperatures at 40mm (207°C) and 60mm (106°C) annotated showing compression strength reduction*

From an engineering viewpoint, the factor of time of thermal exposure is also important. As highlighted earlier in the paper, the in-depth temperatures within the column stay elevated for a relatively long duration, compared with the fire duration. For example, the fire duration in CodeRed #01 to the end of flaming is 27 mins. At 40mm depth, the column is at a temperature of 100°C or more for 90 mins. Experimental data reviewed shows elevated temperatures (above 100°C) can occur in-depth in timber members for three or more hours. This duration of elevated temperature needs to be considered from an engineering design viewpoint, given that fire is seen as an instantaneous load duration condition, and not a short-term loading condition. There is no real guidance available to engineers as to how the duration of exposure to elevated temperatures from a fire should be assessed in the determination of load factors and reduction factors for mechanical properties (impacting k_{mod}). Load duration between short-term and instantaneous is considered the difference between up to a week versus minutes (respectively). As an illustration, the compressive strength parallel to the grain f_c is reduced by 50% at 75°C and in the very short duration CodeRed #01 fire, Column 1 has a temperature at a depth of 40mm higher than 75°C for 2 hours. At 60mm depth the temperature above 75°C occurs for over an hour. Can these elevated temperatures be considered as instantaneous load conditions? Engineers do need to make their own judgements as to whether this thermal degradation duration is important, or not.

6.1 Impact on the assessment of time-equivalence

This information is also important for assessment of time equivalence, an important engineering design analysis needed for building construction. A typical approach would be to equate the 23mm of char depth back to an equivalent fire char depth based on a standard fire exposure, which would be 43 mins (at 0.7mm/min, standard fire exposure plus 7mm). For a heat impacted depth of 52mm, this would equate to 74 mins of standard fire exposure (no zero strength layer would be included). Hence based on the CodeRed data, the column exposure as determined from the post-fire char depth measurement would be adequate to achieve a 60 min fire resistance. But based on the thermocouple data for thermal penetration where (excluding cross-sectional area of timber that has lost 80% of its compressive strength parallel to grain), the column would not achieve 60 mins of fire resistance.

7 DISCUSSION – EXPERIMENTAL DATA

The data reviewed, including the data from the CodeRed series, shows that the peak temperatures in-depth with the timber members are often not recorded within experiments or tests as these occur well after the test has been stopped. In many of the experiments reviewed, the in-depth temperatures are still increasing at the end of the experiment and hence the actual peak temperature at depth are not actually recorded. The data reviewed does not provide suitable sets of data that can be used because thermocouples are not deep enough within the timber, the thermocouples are spaced to far apart and lead to coarse measurements, and the experiments are not being carried out long enough to allow all relevant data to be collected. In hindsight, the CodeRed data also could have benefited from more in-depth thermocouples at locations of 50mm and 70mm.

The review of data shows that more experimental series are required to understand the in-depth temperatures and requires timber members, preferably columns, exposed to a natural fire, with thermocouples embedded in-depth at no more 10mm spacings and the experiment is run to allow temperatures within the timber member to reduce from their peak back to ambient, most likely running the experiment for four to six hours after ignition.

8 NEXT STEPS - ASSESSMENT METHOD

The reviewed and CodeRed data indicates that there are three issues to be considered for the assessment of thermal penetration into a timber column during a natural fire. The first is the depth within a timber member for thermal penetration to occur that results in temperatures that will cause permanently reduced timber strength. The second is the duration of time that the elevated temperature occurs, which can also be measured as the delay until the temperature returns to less than 100°C. The third is whether the reversible strength reduction below 100°C is relevant to the design for the timber column, given that at 75°C, the compressive strength parallel to the grain is reduced by 50% and a column may be exposed to these elevated temperatures in-depth for multiple hours and hence, could actually fail under buckling given this reduction in compressive strength due to the longer-term nature (hours rather than minutes) of the thermal wave. The longer-term nature of this thermal impact is also relevant for fighting actions, which can still be occurring multiple hours after the fire has occurred and been extinguished.

https://doi.org/10.52202/069179-0235

The next steps with the CodeRed data are to carry out detailed finite element analysis of the columns to attempt to accurately model the recorded data and to then be able to determine methods for engineering design, based on a range of natural fires.

To design a timber column within a high-rise building exposed to a natural fire, the engineer needs to assess the impact of the thermal penetration and heat dissipation within the timber member, what should be a relatively straight-forward assessment of heat transfer. A changing external heat flux for compartment fire growth and decay, means the timber only reaches an equilibrium heat transfer state well after the compartment fire has decayed. Heat transfer analysis of the thermal penetration in the timber can be estimated with the timber element considered as a semi-infinite three part solid, with an outer layer of char and an inner layer of ambient temperature timber and a transition layer. Fourier's law for heat transfer through solids is normally adequate for most heat transfer problems in engineering [22], but the assessment becomes more challenging when the properties of the char are changing with temperature and the dissipation of the heat is not straight forward.

The methodology currently being attempted for a column is to determine the thermally impacted effective cross-section by segmenting the column into thin slices, assessing the temperature and residual strength (reduced mechanical properties, based on temperature of each slice). Modelling the physical properties of char is demanding as timber physical properties are not accurately known for natural fires and modelling the dissipation of heat from a heated timber member is also difficult to verify. As the thermal penetration is assessed through the timber member, the reduction in load-carrying capacity can then be determined, through to the full dissipation of the heat.

The engineering design of columns cannot just be based on designing to withstand a fire until flame cessation (self-extinguishment) or even compartment burnout (fire has decayed to less than 1MW or temperatures have returned to ambient). The method for designing columns must be based on assessing thermal degradation in-depth and determining the strength reduction to that depth to determine structural adequacy (maintaining stability).

8.1 Limitations and further work

There are a number of limitations in the current modelling and design approach. This includes the thermomechanical properties of timber being effective properties based on the standard fire temperature-time curve, which have limited accuracy for other thermal exposures or decaying fires.

More research is needed to understand the strength properties of timber at the 100ºC to 200ºC range and how permanent strength reductions are. This temperature range has received little research or attention as wood pyrolysis has not been reached, which is of interest to fire scientists. The thermomechanical properties of wood above 100ºC, where moisture migration determines the impact requires revisiting given the work by researchers such as Schaffer [9] and Gerhards [23] is 40 years old and is not reflective of modern mass timber members.

The relatively slow decay that occurs in fires with large areas of exposed timber and the resultant duration of thermal penetration in the timber member is also worthy of further research. Determining the importance of the slow thermal dissipation of in-depth heat and the depth of impacted timber is important from an engineering design perspective. In standard fire testing the thermal heating is relatively quick in the first 20 mins and then slowly increases, leading to thermal penetration through the timber that is fairly uniform, given the slowly increasing temperature after 30 minutes of exposure. The thermal gradient between the back of the char layer at 300ºC and ambient temperature therefore occurs over a relatively small thickness of approx. 40mm. For an exposed mass timber compartment, the extended fire decay phase leads to a temperature gradient over a much deeper thickness of timber than 40mm, between 300ºC and ambient.

9 CONCLUSIONS

Experimental data from a range of mass timber studies have shown that thermal penetration continues in a timber member after peak temperatures from fire exposure have been reached. This thermal penetration reduces structural capacity of a timber member in-depth. In the decay phase of a natural fire, the built-up char layer also slows heat dissipation from the timber member. Columns are particularly vulnerable given they have four-sided charring and compressive strength parallel to the grain reduces quickly at elevated temperatures above 50ºC.

Analysis of structural adequacy of timber columns in high-rise buildings where a range of natural fires has to be assessed, needs to account for the loss of structural capacity from the thermal penetration and the slow heat dissipation due to the char layer. Using experimental results from the CodeRed series of experiments, the authors have made progress in the understanding of the engineering issues. Further work is currently being undertaken with finite element modelling to develop engineering methods to predict the impact on structural capacity of timber columns for the full duration of a fire.

To address this issue, possible means of mitigation include (1) increasing the member cross-sectional area to account for the thermal wave, based on a heat transfer analysis; (2) including non-combustible protection to the timber member to prevent heating by fire exposure (3) if columns are to be exposed (not encapsulated), these should be located near windows where the compartment temperatures and thermal impact is reduced.

ACKNOWLEDGEMENTS

This research would not have been possible without all the hard work and attention to detail by those involved with the CodeRed experiments at Arup, CERIB and Imperial

College London, especially Fabienne Robert (CERIB) and Guillermo Rein (Imperial College London).

PROTECTION AND THERMAL EXPOSURE OF CLT CEILING AND FLOOR SURFACES

Eirik G. Christensen[1]* , Benjamin Khoo[2], Panagiotis Kotsovinos[3], David Barber[4], Judith Schulz[5]

ABSTRACT: Timber is increasingly used in buildings because of its favourable embodied carbon credentials compared to traditional materials such as steel and concrete. However, due to it combustible nature, encapsulation products are frequently used to prevent or limit the timbers contribution to a fire. These encapsulation products introduce additional weight, cost and carbon to project, which limit the benefit of timber construction. The performance of these products in natural fires and the relative fire severity experienced by products placed near the ceiling and the floor has received little attention. Here we present data on the performance of encapsulation applied to the timber ceiling and floor elements within the *CodeRed* experiments – a series of large-scale timber compartment experiments with varying ventilation and extent of exposed timber. Compartment temperatures were measured at the ceiling and near the floor, indicating a lower temperatures at floor level; the time temperature curve 'seen' by the floor encapsulation is dependent on whether or not there is residual glowing embers on the floor. Both the 25 mm calcium silicate encapsulation to the floor, when located below the wood crib and when adjacent to it, and the three layers of 12.5 mm gypsum fibreboard board applied to the ceiling were shown to be adequate in preventing the ignition of the underlying timber. However, smouldering was observed to sustain remote to encapsulation, but eventually spread beneath the encapsulation which facilitated continued smouldering. This highlights that smoulder can progress behind encapsulation. A 1D Finite Difference Model (FDM) was used to explore the temperature development of timber surfaces beneath simulated encapsulation details using the gas temperatures measured near the ceiling and floor. Converting the modelled peak temperatures to time equivalent times revealed an 23% average reduction in time equivalent fire severity near the floor level for natural fires with a severity equivalent to a 30 min standard fire. When considering greater fire severities, this reduction remained similar, indicating that applying the same fire protecting rating to the floor as to the ceiling is likely overly conservative. The study represents the first step in quantifying a more refined protection required at the floor and to the ceiling; with further research it may be possible to justify a reduction in the required fire protection performance of floor level encapsulation for long duration fires compared to that on the ceiling, taking into account the observed distribution of compartment gas temperatures in large compartments. Ultimately this offers an opportunity to reduce the embodied carbon, costs, and weight of the structural design.

KEYWORDS: encapsulation, timber, *CodeRed*

1 INTRODUCTION

The construction industry is quickly turning to timber as construction material as a solution to achieving the net-zero carbon agenda. However, as the influence of exposed timber on fire dynamics creates new hazards, is complex and subject to extensive research still, timbers surfaces are encapsulated to limit or eliminate the involvement of timber in a fire [1]. This in turn, reintroduces additional embodied carbon, cost, construction time to the project. BS EN 13501-2:2016 defines the performance of an encapsulation system to protect a substrate, with the designation of a K2 classification [2]. The standard requires the encapsulation system to limit the temperature increase at the surface of the substrate to below 250 ℃ on average or 270 ℃ in any location while preventing the pyrolysis of the protected material when exposed to a "standard fire". In addition, there can be no collapse of the covering during the test. However, this standard makes no distinction between the requirements of a floor or ceiling element. The temperature distribution within real fires is such that the thermal severity of a floor may be expected to be less than that of a ceiling in a timber compartment. Studies found that, in a ventilation controlled fire, gas temperature near the floor are on average 100 – 200 °C lower than near the ceiling [3–7], as shown in Figure 1. As such applying the same fire protection for encapsulation on both the ceiling and floor may result in excessive conservative encapsulation, inflating the mass, embodied carbon, and cost of a building. It is valuable to understand not only the performance of encapsulation system in real fire scenarios but also understanding the

extent of protection required for the protection of CLT floor slabs.

This paper presents data from *CodeRed #01*, *#02* and *#04*, experiments from a series of large-scale timber compartment experiments which varied ventilation, and extent of exposed mass timber/encapsulation. We analyse the performance of the encapsulation of the CLT and floorboards to improve the understanding of such measures.

Additionally, this paper presents a first proposal in quantifying relative fire severity experience near the ceiling and floor. This is done in the following way:

- An idealised calcium silicate board protection over CLT is modelled to establish the timber surface temperatures, for both ceiling and floor arrangements, for the respective time- temperature profiles near the floor ceiling observed from the *CodeRed* experiments; this is done using a 1D Finite Difference Model (FDM).
- Using those peak temperatures at the surface of the encapsulated timber, the time equivalent 'fire protection' rating is derived that would deliver the same surface temperature in a standard fire test; this is done to convert the results into a commonly used fire safety performance metric.
- A ratio of those time equivalent values between the ceiling and floor is calculated to quantify the relative fire severity between the ceiling and the floor.
- A simplified design fire is created, informed by the *CodeRed* temperature measurements, to extend the analysis to fires of greater severity.

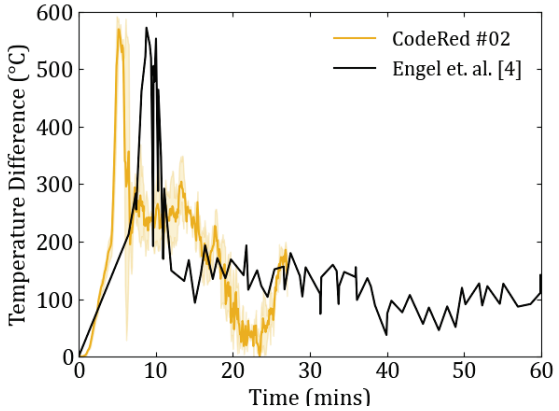

Figure 1: *Gas temperature difference measured near the ceiling and the floor, averaging at around 200 °C while the fire is ventilation controlled. At minute 18, the fire becomes more akin to fuel controlled in CodeRed #02.*

2 *CODERED* EXPERIMENTS

The *CodeRed* experiments were conducted in a purpose-built structure at CERIB's site in Epernon, France. The compartment measured 10.27 m wide, 34.27 m long and 3.1 m tall. The experimental set up is shown in Figure 2. A detailed description of the experimental set up is available in [6–8]. The compartment included a CLT ceiling and continuous wood crib (6 × 29 m) with a fuel load of around 380 MJ/m^2. The crib was ignited along its full width at one end, and the fire then allowed to naturally spread.

Thermocouples were distributed within the compartment at 100 mm, 700 mm, 2100 mm and in limited locations 2800 mm (T12, T14, T16) below the ceiling level to study the fire dynamics. The thermocouple measurements were corrected using the β-method [9] to account for radiative heat flux from the fire. In *CodeRed #02* and *#04*, eight, 18 mm plywood floorboards (P1-P8) where placed within the compartment as indicated in Figure 2, which were then protected with a single layer of 25 mm thick calcium silicate board encapsulation. These were instrumented with thermocouples on the surface of the board and at the interface between the plywood and the encapsulation.

In *CodeRed #04*, just under 50% of the CLT ceiling was encapsulated using a proprietary $K_2$60 protection product comprising 3 layers of each 12.5 mm thick gypsum fibreboard.

Thermocouples were placed between each layer of boarding and at the interface with the CLT. Data from *CodeRed #02* and *#04* are used to study the performance of the encapsulation of the CLT and floorboard.

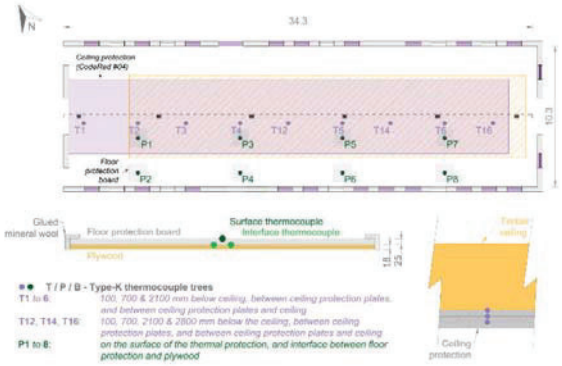

Figure 2: *Floor plan of the CodeRed experiments, sections of the encapsulation build ups, and instrumentation. Ceiling protection was only provided in CodeRed #04. Units in metres.*

The key differences between the *CodeRed* series are summarised in Table 1.

Table 1 *Summary of the differences in the key parameters between the CodeRed series*

Parameter	*CodeRed #01*	*CodeRed #02*	*CodeRed #04*
Ceiling	Fully exposed	Fully exposed	48% encapsulated
Ventilation	20.5%	10%	20.5%

3 NUMERICAL METHODS

A simple 1D heat transfer model was implemented using FDM which used two layers: an encapsulation layer and a timber layer. This model does not consider the contact resistance between the layers. Figure 3 shows a cross section of the floor encapsulation system as an example. The first layer represents encapsulation with a thickness is modified between analysis, while the second layer represents the 140 mm thick timber. The timber thickness was taken as 140 mm (the thickness of the CLT) instead

https://doi.org/10.52202/069179-0236

of 18 mm (the thickness of the plywood floorboards) to avoid modelling additional layers, and to reduce error at the internal boundary.

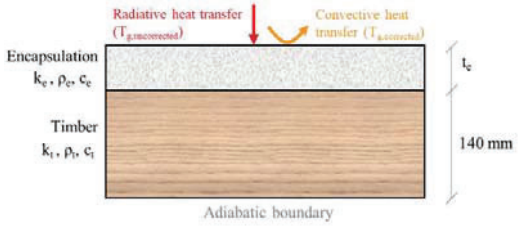

Figure 3 *Cross section of the model build up.*

The thermal model uses a simple finite difference scheme that calculates temperature at each internal nodes using the following equation:

$$T_n^{s+1} = Fo(T_{n-1}^s + T_{n+1}^s) + (1 - 2Fo)T_n^s \quad (1)$$

Where T is the temperature of a given node, n is the space step level, *s* is the time step level and *Fo* is the Fourier number.

For the temperature at the interface between the encapsulation and the timber, the calculation is given by:

$$T_n^{s+1} = Fo_1(T_{n-1}^s - T_n^s) - Fo_2(T_n^s - T_{n+1}^s) + T_n^s \quad (2)$$

Where Fo_1 and Fo_2 is the Fourier number of the encapsulation and CLT respectively. The distribution of grid nodes needs to be arranged accordingly such that Fourier number for both layers are similar. This is to reduce errors, especially at the internal boundaries for multilayer thermal modelling as noted by Waters et al [10].

The boundary condition for the exposed surface is given by:

$$T_0^{n+1} = \frac{2dt}{\rho_1 c_{p_1} dx_1}(h_c(T_g^s - T_0^s) + q_{rad} + 2Fo_1(T_1^s - T_0^s) + T_0^s \quad (3)$$

Where *dt* is the time step, ρ_1, c_{p_1} and dx_1 is the density, heat capacity and node size of the encapsulation respectively, T_g is the gas temperature at the exposed side corrected with the β-method [9] , T_0 is the temperature at the exposed surface, h_c is the convective heat transfer coefficient set at 25 and 35 W m^{-2} K^{-1} , for furnace conditions and natural fires respectively in line with EC1, and q_{rad} is the radiative heat transfer.

The radiative heat transfer is estimated using *eq* 4, and uses the uncorrected thermocouple (T_u) measurement as this captures the influence of radiation so provides a more accurate measure of the radiative temperature.

$$q_{rad} = e\sigma(T_u^{s4} - T_0^{s4}) \quad (4)$$

Where e is the surface emissivity set at 0.8 as recommended by EC1 and σ is the Stefan-Boltzmann constant.

For the back boundary of the CLT is assumed to be adiabatic and the temperature at the boundary is formulated as:

$$T_n^{s+1} = 2Fo_2(T_{n-1}^s - T_n^s) + T_n^s \quad (5)$$

To ensure numerical stability, *Fo* and *Fo*(1+*Bi*) is limited to 0.5 by limiting time step, *dt* to 0.1 s.

3.1 MATERIAL PROPERTIES

The material properties are that are used for the simulations are described in Table 2. These properties are provided by the manufacturer or material handbook and are assumed to be constant with varying temperature. As the thermal property is expected to change with temperature, which is not accounted in this work, some modelling errors are expected to be introduced.

Table 2 *Material thermal properties obtained from the product literature.*

Materials	Thermal conductivity, κ (W m^{-1} K^{-1})	Density, ρ (kg m^{-3})	Specific heat capacity, c_p (J kg^{-1} K^{-1})
Plywood/CLT [11]	0.126	380	2300
Gypsum fibreboard [12]	0.32	1150	1100
Calcium silicate board [13]	0.20	900	960
Light weight concrete [14]	1.00	1600	840
Normal weight concrete [14]	1.60	2300	1000

4 RESULTS

4.1 CLT CEILING ENCAPSULATION

In the *CodeRed* experimental series the encapsulation was generally found to be effective in preventing the ignition of timber both at the ceiling and the floor. The temperature development measured between the layers of encapsulation is presented in Figure 4. The average peak temperature measured at the ceiling encapsulation (across all locations apart from T1) was 106°C, 104°C, and 94°C for thermocouples between layer three and two, two and one, and at the interface of the CLT respectively. The similarity of the peak temperatures at all depths below the exposed surface may be due the formation of gaps between the encapsulation panels preventing heat transfer through the encapsulation, reducing the temperature within the encapsulation system as well as the evaporation of moisture content. However, no rigorous investigation on why such observation was made as it is outside the scope of the *CodeRed* experiments.

https://doi.org/10.52202/069179-0236

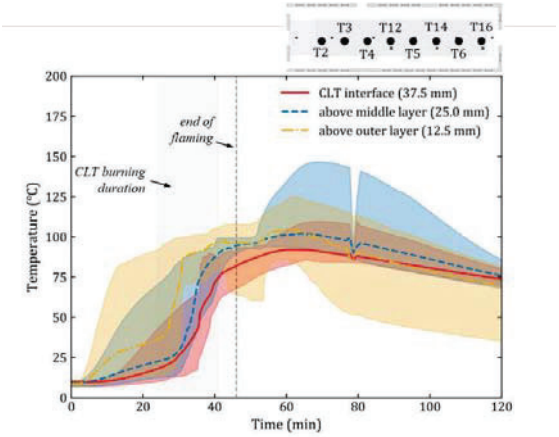

Figure 4: *Temperature development within between the layers of encapsulation. Solid line represents the mean temperature development, while the cloud should the range of measurements.*

The ceiling encapsulation was observed to remain in place until near the end of the fire at which point cracks started to form and portions of the outer layer of the encapsulation began to fall off. However as this occurred during the cooling period, after the cessation of flaming, it never exposed any of the underlying CLT. However, this highlights the benefits of a multilayer encapsulation system whereby the failure of a single layer does not result in the exposure of the underlying timber.

At the perimeter of the ceiling encapsulation some charring was observed beneath the encapsulation, but smouldering did not appear to sustain or spread. The damage was limited to within 40 mm of the end of the encapsulation.

Some smouldering occurred at the junction between one perimeter wall and the ceiling, over the course of several days without any firefighting intervention, which spread approximately 1.3 m beneath the encapsulation. The encapsulation provided a seemingly hospitable environment for the smouldering despite the test being completed in the winter, as it spread and consumed a larger extent than was seen in previous experiments (see Figure 5). This can, in part, be explained by the longer period of time to deconstruct CLT ceiling during without any firefighting intervention.

Hence, encapsulation can potentially hide smouldering; which means that it may be necessary for firefighters to remove encapsulation to identify any residual pockets of smouldering so they can be supressed.

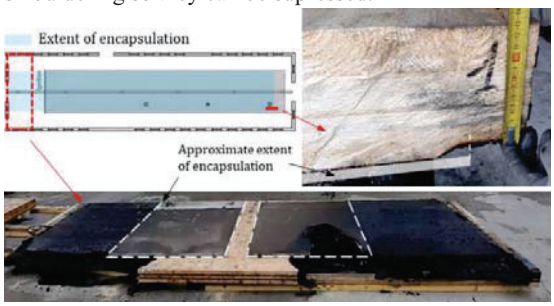

Figure 5: *Char and smouldering beneath encapsulation. figure in the top right shows a cut through the CLT slab, and the extend of charring. bottom image shows the underside of the first CLT panel in the compartment.*

4.2 FLOORBOARD ENCAPSULATION

Floorboards comprising a layer of 18 mm ply protected by 25 mm calcium silicate board were placed below and alongside the wood crib to represent the potential encapsulation of a CLT floor from a fire from above. The average peak temperatures measured at the surface of the encapsulation and the interface with the timber are presented in Table 3 for both *CodeRed #02* and *#04*. No floorboards were used in *CodeRed #01*.

Temperatures at the surface of the plywood below the protective board did not exceed 200°C, and there was no evidence of ignition of charring. Notably, this is greater than the temperature measured beneath the outer layer (12.5 mm) ceiling encapsulation, despite the locally lower measured temperatures. It is unclear why the performance of the ceiling encapsulation appeared to perform better than that on the floor. It may be due to the characteristics of the specific encapsulation product, moisture content within the encapsulation and inclusion of multiple layers which may introduce insulating air gaps.

Table 3: *Peak temperatures measured at the floor protection at the surface and the interface with the timber below.*

Experiment	Position	Peak temperature (°C)	Time to peak (min)
Temperature at surface of protective boards			
CodeRed #02	Below crib	497	28
	Next to crib	576	20
CodeRed #04	Below crib	330	37
	Next to crib	431	44
Temperature at surface of plywood (below protective board)			
CodeRed #02	Below crib	193	59
	Next to crib	187	47
CodeRed #04	Below crib	155	68
	Next to crib	147	60

The experiment showed that 25 mm calcium silicate board provided adequate protection for a fire with similar severity as the *CodeRed* experiments. However, with a more severe fire, it is expected that the same board thickness may not be sufficient.

In all cases the peak temperature occurs after the cessation of flaming, due to the effect of thermal lag, as the thermal wave continues to propagate through the encapsulation. The temperature development of the floorboard in *CodeRed #02* and *#04* is illustrated in Figure 6.

While the peak temperatures measured at the interface with the timber surface are similar for floorboards located below and along the crib, the time at which the peak occurs happens later where the boards are below the wood crib.

The peak temperatures measured at the surface of the encapsulation was, on average, 90°C hotter beside the crib compared to those under the crib. However, for the floorboards under the crib, the surface of the encapsulation remained around 300-500°C for longer,

https://doi.org/10.52202/069179-0236

well after the end of flaming, while beside the crib the temperatures decreased towards the end of flaming. This difference is likely due to the burning wood crib initially shielding the floorboards beneath from some of the radiation within the compartment but, before the remnants of the glowing embers of what is left of the wood crib continued smouldering after the end of flaming, and conducting heat towards the floor.

The similarity in the average peak temperature of the timber floorboard is noted, despite the differences in the temperature profiles measured at the surface of the encapsulation; it may be coincidental. It highlights the importance of considering the impact of smouldering of fuel remnants on the floor in the consideration and design of floor build up and section thickness, as this will contribute to the continued conductive heating through the encapsulation to the timber below.

Further research is needed to understand the heat transfer into floor elements from above, and the significance of a smouldering fuel bed heating the floor slab after the end of flaming.

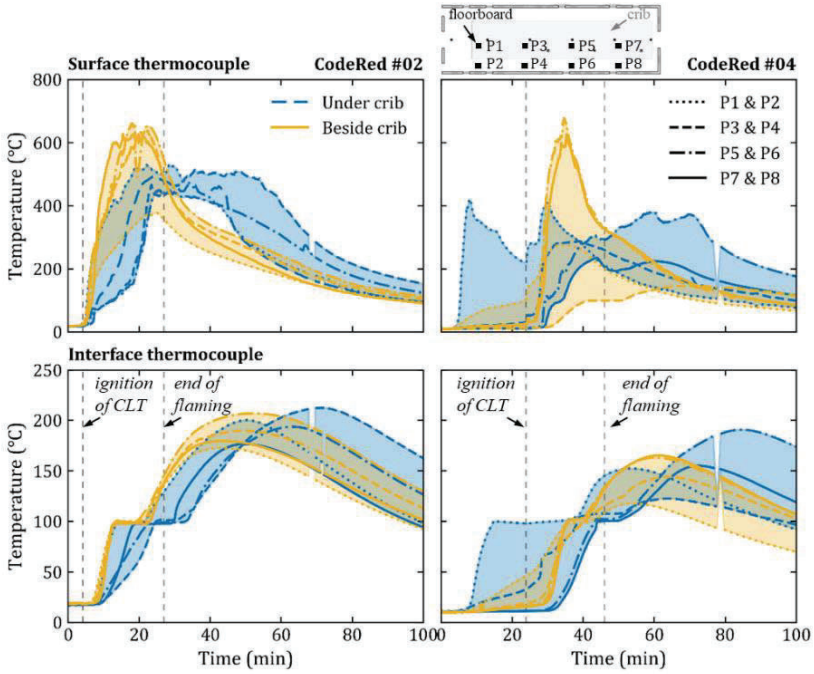

Figure 6: *Temperature development of eight plywood floorboard samples P1 to P8 each protected by a 25mm thick layer of calcium ciliate in CodeRed #04. Gas temperature given for reference.*

4.3 NUMERICAL ANALYSIS

The different encapsulation systems used at the floor and the ceiling makes direct comparison of their thermal response difficult. Therefore, to study the relative fire severity experienced by an encapsulation product fixed the ceiling and floor based on the different temperature distribution observed in *CodeRed*, a 1D FDM model was used to represent the thermal response of a hypothetical single layer encapsulation system fixed to the floor and ceiling. The model output was then compared to the measured results found from the *CodeRed* experiments to assess its performance.

4.3.1 Modelling floor protection vs experimental observations

The floorboard arrangements in *CodeRed #02* and *#04* were modelled, using the temperatures measured by the T12 thermocouple tree as the input for the boundary conditions on the basis that gas temperature were measured both near the ceiling (Ceiling level (CL) -100 mm) and near the floor level (floor level (FL)+300 mm). These locations also represent the worst-case temperature profile as indicated by the deepest char depth measured in *CodeRed #02* and *#04*. The modelled results are then compared against the temperatures measurements at the interface at floorboards P3 and P5 as they are the closest floorboards to T12, located approximately 3.7 m away.

An example model prediction of the floorboard temperature development is presented in Figure 7. The temperature at the interface between the encapsulation and plywood is overestimated in both *CodeRed #02* and *CodeRed #04* by an average of 39.9 % and 19.4 %, respectively.

The interface temperature prediction for *CodeRed #02* shows a larger discrepancy than *CodeRed #04* despite similar average and peak temperatures being recorded in both experiments. The likely explanation for this discrepancy is moisture content in the encapsulation and/or timber. The moisture content the temperatures at the interface between the encapsulation and the plywood stagnates at 100 °C for approximately 10 and 5 min for *CodeRed #02* and *#04*, respectively, which is not captured by the model. Other potential errors include: not

considering varying thermal properties with temperature, contact resistance, and modelling the ply layer as 140mm thick CLT rather than ply on a concrete screed.

Despite these errors, the model is suitable to provide a comparative analysis of the relative fire severity near the ceiling and floor level using the local temperature measurements and considering an idealised and simplified single layer encapsulation product.

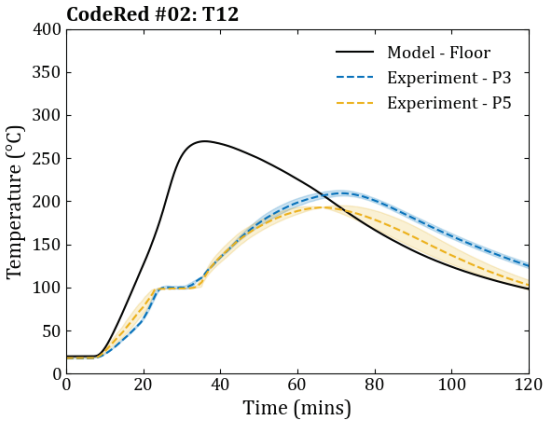

Figure 7: Comparison between the model of the interface temperature and the measured value in the experiment. Temperature over prediction is likely due to not modelling moisture content

5 INVESTIGATING RELATIVE FIRE SEVERITY AT THE CEILING VS AT FLOOR LEVEL

5.1 MODEL CONFIGURATIONS INVESTIGATED

The different encapsulation systems used at the floor and the ceiling makes direct comparison of their thermal response difficult.

Therefore, to study the relative fire severity experienced by an encapsulation product fixed to the ceiling and floor, the thermal response of the following hypothetical scenarios were further studied, comprising:

- a single layer of 25 mm thick encapsulation system fixed to 140 mm thick CLT, exposed to
- the temperature-time curves measured at T12 near the ceiling and floor in the *CodeRed #01*, *#02* and *#04* experiments (to simulate the exposure of encapsulation at the floor and ceiling), and
- The standard fire curve.

The analysis was undertaken using the FDM model and associated input parameters described in section 4.3 above, using calcium silicate boarding as encapsulation product.

The resulting modelled peak timber temperatures using the *CodeRed* time temperature curves were then converted using the time equivalence method. For the purposes of this study it is defined as the modelled exposure duration to a standard fire (in line with Eurocode 1 (EC1)) required to achieve the equivalent peak timber surface temperature found using the *CodeRed* fire curves.

5.2 RESULTS FROM *CODERED* FIRE CURVES

The model predicted timber surface temperatures beneath the ceiling encapsulation to be 75 °C (34 %), 66 °C (24%) and 52 °C (28%) greater compared to the timber surface temperatures below the floor encapsulation, using fire curves of *CodeRed #01*, *#02* and *#04*, respectively.

The simulation results suggest that in terms of fire exposure to the encapsulation system, *CodeRed #02* is experienced the most severe condition (i.e. least reduction out of all three), followed by *CodeRed #01* and *CodeRed #04*, as shown in Figure 8Figure 8.

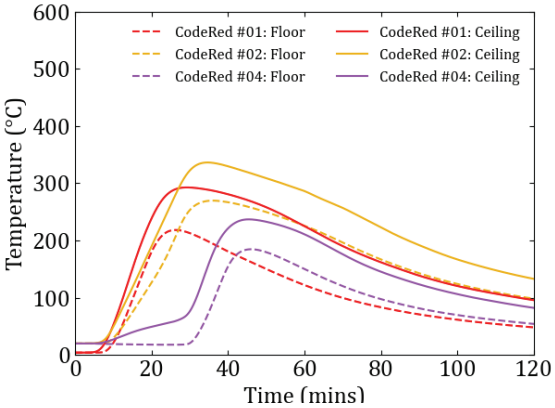

Figure 8: *Comparison of the modelled timber surface temperatures of the hypothetical encapsulation build ups position of the floor and ceiling when exposed to the CodeRed temperature curves. Model comprised of 25 mm calcium silicate encapsulation fixed to 140mm CLT .*

This is likely due to the increased burning duration in the ventilated-controlled fire of *CodeRed #02* which resulted in a more severe fire. As such the simulation results are consistent with previous observation where the average char depth is higher in *CodeRed #02* than *CodeRed #01* [6], suggesting a more severe fire in *CodeRed #02*. The slow temperature increase in *CodeRed #04* is due the gypsum fibreboard encapsulation preventing the CLT ignition until 23 min 53 s after the ignition of the crib compared to 2 min 47 s and 4 min 11 s in *CodeRed #01* and *#02* respectively.

5.3 TRANSLATION TO TIME EQUIVALENT VALUES

These results were then translated to a “time equivalent” value (TE), which is a standard metric used by fire engineers to compare fire severity. Here it is considered to be the time required for the timber surface temperature beneath the encapsulation to reach the peak temperature (modelled using the *CodeRed* fire curves) when exposed to a standard fire test. This is practice is often used for protected steel members.

Table 4 summarises the peak temperature at the timber surface following the *CodeRed* fire curves at each position, the time equivalent value, and the ratio between the time equivalence of the ceiling and floor, calculated as TE_{floor} / $TE_{ceiling}$.

Table 4: *Peak timber surface temperature and associated time equivalence calculated for the three CodeRed fire curves, at the floor and ceiling respectively, and the ratio found between them.*

https://doi.org/10.52202/069179-0236

CodeRed fire curve	Location	Peak timber surface temperature - *CodeRed* (°C)	TE (min)	TE ratio (-)
#01	Floor	218	26	0.74
	Ceiling	293	35	
#02	Floor	270	30	0.79
	Ceiling	336	38	
#04	Floor	185	21	0.78
	Ceiling	237	27	

The predictions shows that the time equivalence is, 26%, 21% , 22% lower at the floor than at the ceiling when using fire curves derived from *CodeRed #01, CodeRed #02* and *CodeRed #04* respectively.

This indicates that a lesser fire protection rating may be sufficient for the floor encapsulation to achieve an equivalent performance to that on the ceiling.

These results are based on a short fire, achieving time equivalences severity of around 30 min. Further analysis was completed to examine how the time equivalence ratio might change in fires with greater durations.

5.4 EXTRAPOLATING TO INVESTIGATE LONGER DURATION FIRES

To understand how more severe fires could affect the time equivalence ratio, a simplified time temperature profile was derived from the *CodeRed* data in the absence of available data for long duration large compartment fires.

To derive the time-temperature profile for longer duration fires at the floor and ceiling, the maximum temperature during the peak flaming period (as defined in [6–8]) in the most severe fire (*CodeRed #02*) was used, namely 912 °C measured near the ceiling and 617 °C near the floor. These temperatures are rounded to 900 °C and 600°C respectively and are applied as fixed boundary conditions to the encapsulation build up.

The time equivalent ratios between encapsulation on the ceiling and floor exposed to fires of greater severity were calculated as follows:

Step 1 - Calculate the minimum thickness of encapsulation necessary to keep the timber surface temperature at or below 270°C (one of the acceptance criteria for the K_2 protection in BS EN 13501-2:2016) for 30, 60, 90 and 120 min of standard fire exposure.

Step 2 - Calculate the equivalent '*CodeRed* fire duration' using the *ceiling temperature* curve (i.e 900°C) to achieve the 270°C at the timber surface temperature (see Figure 9) using the minimum thicknesses calculated in step 1.

Step 3 - Calculate the timber surface temperature of the same encapsulation build up established in Step 1, for the '*CodeRed* fire duration' established in Step 2, using the *floor temperature* curve (i.e 600°C) (see Figure 9).

Step 4 - Calculate the time equivalence for the timber surface temperature established in Step 3 by modelling the same encapsulation thickness found in step 1 exposed to the standard fire.

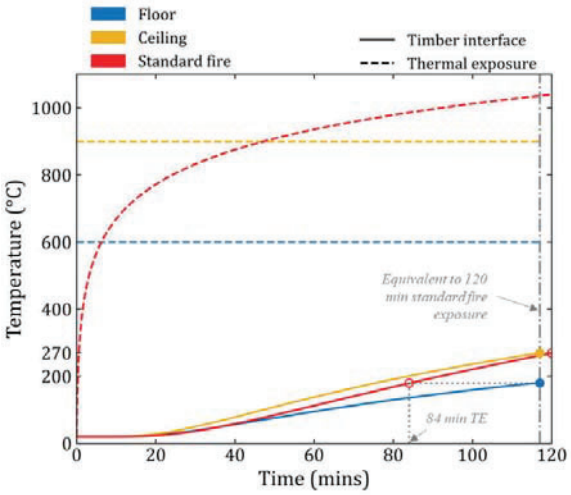

Figure 9: *Simplified time temperature development within modelled ceiling and floor encapsulation to 120 min equivalent exposure based on averaged temperature data from the CodeRed #02 fire curve, and resulting temperatures at the timber interface below the encapsulation.*

5.4.1 Example calculation

For instance, to find the ratio time equivalence ratio for a fire of 120 min fire severity the steps outline above are illustrated in Figure 9 and performed as follows:

Step 1: The minimum thickness of encapsulation necessary to keep the peak temperature of the timber surface protected after 120 min standard fire exposure to 270°C is 60.5 mm of calcium silicate board (noting again that this analysis is simplified with limitations that have been discussed earlier in this paper, and that actual thicknesses must be demonstrated by testing to the relevant standard as the likely failure mechanism will be fixings which cannot be modelled).

Step 2: The duration of exposure to the *ceiling temperature* curve to achieve the same timber surface temperature (270°C) as 120 min standard fire exposure is 117 min.

Step 3: Modelling the temperature development within the build-up using the near floor temperature condition of 600°C for 117 min, yields a predicted peak temperature of 180°C.

Step 4: This, in turn, equates to an 84 min time equivalence value. The time equivalence ratio is 0.7. As such the relative fire severity near the floor is 30% less than near the ceiling for a 120 min fire.

5.4.2 Time equivalent ratios for longer fire durations

The relative fire severity near the floor and ceiling and was similar for 90, 60 and 30 min equivalent exposure, as shown in Table 5. As expected, the ratio calculated for an equivalent 30 min exposure is similar to that calculated using the *CodeRed* temperature profiles which had time equivalent severity between 21-38 min. This may suggest the use of the 900 and 600°C temperature conditions is a reasonable approximation.

To explore this further, the critical thickness calculated for 90 min standard fire exposure is modelled with the floor level thermal condition (600°C) for 117 mins

https://doi.org/10.52202/069179-0236

(equivalent to 120 min fire exposure using the near ceiling condition, 900°C). The peak interface temperature was predicted to be 228°C. Similarly, the predicted interface temperature for a 60 min and 30 min rated floor encapsulation in a 90 and 60 min equivalent standard fire exposure was 248 °C and 298 °C, respectively. This indicates that reducing the floor encapsulating fire rating by one step may be possible for 120 and 90 min fire exposure but not for 60 min fire exposure and as this results in a temperature rise greater than the 270°C required for K_2 protection. On this basis there may be an opportunity to reduce the prescribed protection required to the floor while maintaining the intended performance. However, due to simplification taken in these models, more research must be undertaken before any conclusive guidance can be given.

Table 5: *Summary of extended fire duration exposure of encapsulation on floor and ceiling. Results are modelled using ceiling (900°C) and floor (600°C) temperatures to model peak timber surface temperature, associated time equivalence values and time equivalence ratios.*

Standard fire duration (min) [encapsulation thickness (mm)]	Location	Peak timber surface temperature (°C)	TE (min)	TE ratio (-)
120 [60.5]	Ceiling	892	120	0.70
	Floor	589	84	
90 [51.0]	Ceiling	891	90	0.70
	Floor	587	63	
60 [39.5]	Ceiling	888	60	0.68
	Floor	583	41	
30 [25.0]	Ceiling	882	30	0.70
	Floor	574	21	

5.4.3 Limitations

It is important to emphasise that there are significant uncertainties regarding the temperature development and heat transfer for long duration fires.

Also, the results are modelled based on a primarily ventilation-controlled fire which in CodeRed were observed to have more variation across the vertical temperature profile. Vertical temperatures in a fuel-controlled fire have been found to be more uniform. However, it is expected that a fuel-controlled fire will typically have a shorter duration and is less likely to require significant fire ratings.

The preliminary results presented here indicate that the concept of setting different fire protection levels for the ceiling compared to the floor may be viable, subject to further study.

While the assumptions used here are deliberately simplified to test the viability of the idea of prescribing different fire protection performance for the ceiling compared to the floor, they provide a model which produces reasonable results when applied to both the natural fire as well as the standard fire as an initial study into the relative fire severity near the floor and ceiling.

The idea is promising, however the time equivalence ratios determined here should not be used to justify a reduction in encapsulation specification. However, it does suggest that such reduction may be possible provided further experimentation or more advanced models.

6 DISCUSSION

The current analysis suggests that due to the post flashover temperature gas differences near the ceiling compared to near the floor level it may be possible to reduce the fire protection requirements of the encapsulation provided to the top surface of timber floors to protect them from fire from above, while still achieving a similar performance to the ceiling encapsulation of the mass timber ceiling in case of fire from below. The analysis presented also indicate that this reduction may be more likely and reasonable where greater fire resistance / fire protection is required.

To examine the value such a reduction in fire resistance may bring, the estimated mass and embodied carbon of toppers is summarised in Table 6. The FDM was utilised to approximate the critical thicknesses of typical materials available as floor topping to prevent the surface of the timber igniting, as done previously. The critical thickness was calculated for 30, 60, 90 and 120 min of standard fire exposure (see Table 6). These are conservative thicknesses as the model does not account for such things as moisture, thermal contact resistance, or temperature dependent thermal properties. This was similarly modelled by [15], and has good agreement.

Table 6 emphasises the potential significant contribution of the encapsulation system to the total mass and embodied carbon of the structural system. For instance, the reduction from 120 min to 90 min protection to the topside of the floor slab, with normal weight concrete, would results in a 17.6% decrease in required material. This translates to a reduction of 2074 kg of embodied carbon and a 20.1 tonnes in total mass, for a 500 m^2 compartment. This reduction in mass may also return additional reductions in the section of the structural members.

In the interest of reducing carbon in the construction industry further research is needed to evaluate the relative thermal severity experienced near the floor level compared to near the ceiling in more detail.

Table 6: *Critical thickness of CLT floor toppers to limit the temperature of the timber below 270°C, in line with a K2 classification according to BS EN 13501-6:2016 and using a standard fire. Boundary conditions used are in line with Eurocode 1*

Topper material	Critical thickness (mm) [embodied carbon (kg CO_2e/m^2)]				Embodied Carbon (kg CO_2e/m^3) [Reference]
	120 min exposure	90 min exposure	60 min exposure	30 min exposure	
Calcium Silicate board	60.5 [7.1]	51.0 [6.0]	39.5 [4.6]	25.0 [2.9]	117 [16]

https://doi.org/10.52202/069179-0236

Light weight concrete	105.5 [32.1]	88.0 [26.8]	67.0 [20.4]	40.5 [12.3]	304 [17]
Normal weight concrete	99.5 [23.6]	82.0 [19.4]	62.0 [14.7]	35.5 [8.4]	237 [16]

7 CONCLUSIONS

This paper investigated the performance of encapsulation in protecting the timber floor and ceiling in the *CodeRed* experimental series, a series of large-scale timber compartment fires. Both the 25 mm calcium silicate floorboard encapsulation and the three layers of 12.5 mm gypsum fibre boarding applied to the ceiling was shown to be adequate in preventing the ignition of the underlying timber. However, while smouldering beneath the encapsulation was not sustained immediately after the cessation of flames, smouldering was observed to sustain remote from the encapsulation and beneath the ceiling protection, where it burned an area of timber approximately 3 × 1.3 m in extent in one location. This suggests that while encapsulation may be effective in preventing the ignition of CLT, it is not 100% effective in preventing smouldering which can occur and spread behind the encapsulation.

Gas temperature measurements from the *CodeRed* experiments have showed that the temperatures near the floor are significantly lower (~300 °C) than near the ceiling in ventilation-controlled conditions. The significance of the difference in gas temperature near the ceiling and floor on the fire protection performance of encapsulation products in these positions was studied using a 1D FDM model. A single layer of 25mm calcium silicate encapsulation protecting a 140 mm CLT was modelled, using the measured gas phase temperatures near the ceiling and floor from the *CodeRed* experiments as the boundary condition of this model.

The predicted peak temperature at the surface of the timber was converted to time equivalent values. The ratio between the time equivalent value modelled for the encapsulation positioned on the floor and ceiling revealed, on average, a 23% reduction in the fire severity on to the encapsulation on the floor compared to the ceiling. This suggests that a reduced fire protection performance may be sufficient to protect a CLT floor, compared to the fire protection required for a CLT ceiling.

While the CodeRed experiments are estimated to have the approximate time equivalent fire severity of a 30 min standard fire, fires of greater severity and duration were also modelled to study the influence its influence on the time equivalence ratio.

This was done by developing simplified design fires for near ceiling and floor level exposure based on measurements taken from *CodeRed #02* and applying them to encapsulation thicknesses which were optimised to achieve the K_2 encapsulation standard (270°C at the surface of the encapsulated timber) after 120, 90, 60, and 30 min standard fire exposure. Comparing the standard fire time equivalent values of the encapsulation exposed to the ceiling and floor level design fires revealed a 30% reduction in fire severity to the encapsulation on the floor compared to the ceiling for severities up to 120 min.

Modelling an optimised encapsulation thickness exposed to a fire duration of 120 and 90 minutes standard equivalent fire for the ceiling respectively revealed that 90 and 60 min encapsulation performed adequately when positioned on the floor and exposed to the floor level design fires. However, applying a 30 min optimised encapsulation thickness to a 60 min standard fire equivalent floor level design fire yielded temperatures greater than the 270°C required for K_2 protection.

There may be an opportunity to develop a protection regime for mass timber compartments where the prescribed protection required to the floor is lower than that applied to the ceiling while maintaining the intended performance. This reduction offers an opportunity to reduce, the mass, embodied carbon and cost associated with encapsulation products. It should be noted that the results found here should not be directly applied to justify a reduction in prescribed fire resistance requirements. This study is the first step in quantifying the relative standard fire resistance requirements required at the floor and to the ceiling to help guide practitioners on designing and constructing safe and sustainable buildings and highlight the need for further research to enable better characterisation of fire severities at ground level of large compartments with a timber ceiling.

ACKNOWLEDGEMENT

This research has been fully funded by Arup and was undertaken in partnership with Imperial College London. The experiments were carried out in a bespoke facility built at CERIB's Fire Testing Laboratory site in France.

COMPARATIVE PERFORMANCE OF PROTECTIVE COATINGS FOR MASS TIMBER STRUCTURES

Lorna Johnson[1], David Morrisset[2], Antonela Colic[3], Luke Bisby[4]

ABSTRACT: The use of engineered mass timber in large scale structures is increasing due to the demand for low carbon, sustainable building design. The potential for structural timber to combust and contribute to a fire event adds hazards and complexity to the design of mass timber buildings. To address these issues, various surface treatments are available aiming to protect or alter the reaction to fire behaviour, relevant during early stages of a fire, and charring behaviour of fire exposed timber which is relevant during the developed stage of a fire. The performance of three specific commercially available fire protective coatings for timber was studied by exposing coated 95mm x 95mm x 45mm horizontal softwood samples to radiant heat flux of 35 and 60 kW/m^2 in a cone calorimeter from above, a level of radiation representative of a developing fire. Ignition time, heat release rate, mass loss rate, gas species emissions, in-depth temperatures, and char progression were recorded to study sample performance when compared against uncoated timber. Results indicate that two of the protective coatings used successfully developed a protective intumescent char layer, while one product did not. The former two displayed significantly reduced mass loss and heat release rates, as well as reduced in-depth thermal penetration when compared to uncoated timber. One coating did not intumesce and performed similarly to uncoated timber. These results illustrate the importance of not extrapolating from reaction to fire classifications to make assumptions about improved fire performance outside the scope of such classifications, without substantial further testing and validation of those assumptions.

KEYWORDS: Protective coatings, intumescent coatings, fire performance, mass timber, cone calorimeter

1 MOTIVATION AND BACKGROUND

1.1 INTRODUCTION

The use of engineered mass timber in large scale structures is rising due to the demand for low carbon, sustainable buildings [1]. Mass timber offers benefits such as being lightweight and less constrained by size or shape in comparison to concrete and steel. However, the potential for structural timber to ignite and contribute fuel to a fire, as well as timbers comparatively higher susceptibility to reductions in mechanical properties at elevated temperatures, necessarily adds complexity to the design of mass timber buildings. To address these issues, surface treatments are available aiming to alter the reaction-to-fire [2-4] and/or the charring behaviour of fire exposed timber to achieve a higher fire resistance period than untreated timber. Unlike structural steelwork, with which intumescent coatings are more commonly used, timber structural elements will char and can fail at comparatively low temperatures due to thermal decomposition (i.e., pyrolysis) and timber strength degradation at elevated temperatures when exposed to sufficient heating. Intumescents are passive fire protection coatings that react when exposed to heating and swell to form a protective char layer which can reduce heat transfer to the substrate materials [5] and hence, in the case of a timber substrate, reduce mass flow of pyrolysates from the exposed surface. Intumescent coatings are typically specified to achieve a better reaction to fire classification than untreated timber would achieve, but may also be relied upon to reduce charring rates which would be determined by the relevant standardised testing method. Transparent protective coatings are appealing for mass timber designers, compared with rigid encapsulation alternatives, due to the aesthetics of exposed timber surfaces. However, experimental data (as opposed to compliance classifications) for such coatings are extremely scarce for a range of relevant heating scenarios. A greater understanding of intumescent products for mass timber is therefore required since many such products are already in widespread use in the built environment. The study presented in this paper aims to quantify and compare the behaviour of timber specimens coated with three different commercially available transparent fire

protection coatings, achieving European reaction to fire Class B, under various heating conditions. These coatings have been independently obtained, and the authors make no attempt herein to endorse (or otherwise) any of them; we simply present and discuss experimental outcomes under the scenarios investigated.

1.2 PROTECTION OF WOOD

Key concerns for safe structural design of timber are related to the potential fuel contribution of timber elements in a fire (fire dynamics), in combination with reductions in mechanical properties on heating (fire resistance). In order to specify the dimensions of timber structural components, whilst complying with building stability, integrity, and insulation requirements, multiple forms of passive fire protection are available to designers [6-7]. These passive protection measures may include board/encapsulation products, intumescent coatings, and impregnation treatments, all of which aim to reduce the heat transfer to the underlying timber. Gypsum plasterboards are a common, albeit often architecturally undesirable, passive fire protective measure where the thickness or number of layers of board can be adjusted to provide differing levels of protection. Intumescent coatings have the advantage that they can be applied in thin layers whilst maintaining the aesthetic qualities of the unprotected mass timber; however, may require re-application to maintain their performance, and may not function as intended when combined with other surface treatments.

1.3 INTUMESCENT COATINGS

When sufficiently heated, intumescent coatings swell and form a protective char layer [5]. These coatings commonly incorporate various chemical components which react to ensure intumescence and char formation [5,8] under standardised heating scenarios. The interactions of these components in the "correct" sequence is key to ensuring successful formation of an intumescent char, and therefore to the protection of the substrate from fire [5]. A char begins to form when the intumescent compounds decompose and release gases within the melted substance, forming a 'multi-cellular' char layer [5]. Trapped bubbles provide a low density, protective char layer which reduces heat transfer to the structural member and therefore postpones the conditions (i.e., temperatures) favourable for timber to pyrolyze. The mixture of chemical compounds used in intumescent coatings formulated specifically for wood is likely to be unique to each specific commercially available product. Hence, the speed of intumescent char growth, thickness, density, and porosity distribution within the intumescent char all depends on the specific product formulation (and, critically, on the heating conditions). Due to the different chemical compositions of intumescents, and therefore different activation temperatures of their chemical groups, there is a critical temperature required for an intumescent coating to react, char, and provide altered properties that are relevant to the intended substrate material [9].

Possibilities for transparent or coloured coatings make intumescents aesthetically desirable, and their thin, lightweight nature minimises additional structural loads and structural member sizes. However, care must be taken that coatings are applied appropriately; relevant conditions as specified by the manufacturer are required in order to ensure products perform as intended. Factors such as humidity, moisture, and thickness must be considered to ensure their durability, longevity, and performance in fire.

1.4 INTUMESCENT COATINGS FOR WOOD

Popescu et al. [10] describe that in addition to insulating a timber element, intumescent coatings can enhance fire performance by 'reducing the amount of heat released during the initial stages of fire, by retarding the spread of flame and by limiting the production of smoke and flammable volatiles'. The effectiveness of the intumescent coating also depends on the thermal boundary conditions, including the temperatures of the substrate material. A challenge for intumescent coatings applied to timber is that they must have a lower critical temperature (i.e., the temperature that initiates the expansion of the intumescent) than those used for other materials, such as steel, in order to provide protection before significant pyrolysis occurs. This may mean that intumescents for timber are quickly impaired at a higher temperatures [10].

The performance of intumescent coatings (in terms of reaction-to-fire response) is typically determined using standard test methods such as European reaction to fire 'single burning item test' and 'single flame source test' (BS EN 13501-1, BS EN 13823 and BS EN ISO 11925-2 as described in Section 2.2) [2-4]. However, some variables of potential importance in fire are not directly measured or reported in most standard tests, including gas species generation, char depths and rates, mass loss rates, and toxicity. This limits a holistic understanding of the fire performance of intumescent coatings generally, and specifically for those used to provide fire protection of wood [7].

Experimental studies involving intumescent coatings for wood have been presented by, for example, Wladyka-Przybylak, Hassan et al., Bahrani et al., Hartl et al., Lucherini et al. and Xu et al. [8, 11-15] in relation to different coating formulations, durability and the effects of external weathering, and their performance when compared to other passive fire protection methods (e.g., gypsum plasterboards). However, there remains a need for rigorous fire science data regarding the fire performance of existing timber intumescent coatings under a range of relevant heating conditions. This is in order to better understand the performance of reaction to fire coatings, coatings seeking to impact on the resultant fire dynamics and/or slow char rates to improve fire resistance of timber under more severe fire conditions, and to establish their reliability under natural fire conditions.

This paper aims to characterise the fire performance of different reaction to fire treatments under a range of

https://doi.org/10.52202/069179-0237

relevant heating conditions so as to better understand a broader range of impacts of some commercially available coatings when placed under more onerous heating regimes.

2 METHODS

The performance of three commercially available intumescent fire protection coatings for timber was studied by exposing coated samples of softwood to radiant heating. The coatings were then compared against untreated wood to quantify their influence on ignition and burning behaviour. This was done qualitatively by visual observation and quantitatively in terms of heat release rate (HRR), in-depth temperatures, mass loss rate (MLR), and gas species production.

2.1 TEST SAMPLES

Timber samples tested were cut from solid Norway Spruce and had 95 x 95 mm cross sections with 45mm thickness. Three in-depth 1.5 mm diameter K-type thermocouples were installed from the side of the sample and were positioned at 5mm depth intervals from the exposed surface to allow for in-depth temperature measurements at depths of 5, 10, and 15 mm.
All samples were surrounded by aluminium foil and ceramic fibre paper to mitigate mass transport, reduce pyrolysis gas escape from the sides, and reduce heat transfer to the sides of the sample (see Figure 1).

Figure 1: *Coating A timber sample preparation.*

2.2 INTUMESCENT COATINGS

The three products used in this study are commercially available in the UK and designed for the fire protection of timber; advertising a "reduction of ignitability" and to "insulate against heat", "prevent propagation of fire and spread of flame" and "suppress emission of deadly smoke & gases" whilst providing a reaction to fire classification and/or fire resistance period [16-18].
Each coating system consists of an intumescent base coat and top coat. No primer was used for application of these coatings, as specified by manufacturers for clean softwood. The respective coating systems were applied in thin layers and allowed to dry between each application, as per the respective manufacturers' instructions.

It was noted that despite all coatings being described as transparent, each had a slightly different appearance once all layers had been applied and dried (Figure 2).

Figure 2: *Comparison of intumescent coating appearance. From left to right; Coating B, C, A and uncoated.*

Coating A (sold as HW Envirograf) is a water-based intumescent system which is advertised on their website as achieving European classification B-s1, d0; on the basis of testing to the 'single burning item test' and 'single flame source test' [2-4, 16]. Such tests are designed to measure production of heat, production of smoke, horizontal flame spread, ignition, and the falling of flaming droplets and particles in controlled fire conditions. The product is also advertised for application e.g. on fire doors for fire resistance periods using standard furnace tests, for 30 and 60 minute fire resistance ratings based on BS 476-20 and BS 476-22 tests for non-/load-bearing elements, and 66 minutes integrity is claimed with reference to a BS EN 1364-1 wall test [16]. No fire classification or fire test reports were available for download from the website to provide further detail and limitations of the fire performance of the product.

Coating B (sold as Sika Pyroplast) is a water-based intumescent system advertised to achieve European classification B-s1, d0 [17]. The manufacturer does not advertise any ability to provide fire resistance with their product.

Coating C (sold as Thermoguard Fire Varnish) is a combined resin-acid catalyst and white spirit based intumescent system. This coating is advertised to achieve European reaction to fire classification B-s2, d0 (thus greater smoke production than coatings A and B) [18]. Coating C's manufacturer also state that fire resistance classifications are possible using their product but that this requires further consultation.

Each of the coatings used in the current study are sold on the basis of improving the fire performance of timber, either in relation to the reaction to fire classification or fire resistance classification.
The proprietary nature of each product likely results in different reactions under heating and therefore different intumescent performance in real fire scenarios.

https://doi.org/10.52202/069179-0237

2.3 APPARATUS AND MEASUREMENTS

Each sample was exposed to a constant radiant heat flux in a cone calorimeter for 30 minutes, since initial investigations determined that this provided sufficient time to develop the protective char layer. Experiments were performed at two nominal incident heat fluxes (35 and 60 kW/m^2) aiming to span a range of heat fluxes that is broadly representative for a compartment fire scenario. Gas species, heat release rate, mass loss rate, and in-depth temperatures were recorded. Measurements of ignition, char thickness (i.e., swelling), and char depth were also recorded so as to further characterise the coating response. Guidance for the testing was taken from BS ISO 5660-1. The surface of the sample was separated from the lowest point of the cone heater by 50 mm to prevent contact between the intumescing coating and the cone heater [19]. However, due to the use of intumescent coatings and their unpredictable behaviour, the samples were not placed in a standard sample holder and instead wrapped (as previously described) and then placed directly onto a load cell [19].

3 RESULTS

3.1 IGNITION

Ignition times for each product are given in Table 1. Both the uncoated and coated samples were observed to ignite under the heat flux conditions used in this work. The uncoated samples experienced continued flaming, after ignition, throughout the experiments, while Coating B and Coating C treated samples experienced extinction shortly after ignition. Later re-ignition was observed for coating B and C samples exposed to 60 kW/m^2; however, this was not observed for 35 kW/m^2. The ignition times for Coating C samples were found to be less than for the uncoated samples at both heat fluxes used. Coating A was found to delay ignition compared to the uncoated sample, however this product displayed continued flaming, after ignition, throughout the experiments.

The earlier ignition of Coating B and Coating C appeared to result in the formation of a protective char *before* the majority of the underlying wood surface reached its pyrolysis temperature, hence protecting the wood substrate once the swollen intumescent layer had formed.

Table 1: *Times to ignition, extinction, and re-ignition of flames for each coating and heat flux tested.*

Coating Type	Heat Flux (kW/m^2)	Time to Ignition (s)	Time to Extinction (s)	Time to Re-Ignition (s)
Coating A	*35*	71	n/a	-
	60	6	n/a	-
Coating B	*35*	39	61	n/a
	60	9	28	152
Coating C	*35*	12	63	n/a
	60	3	37	159
Uncoated	*35*	65	n/a	-
	60	6	n/a	-

3.2 VISUAL OBSERVATIONS

Observation of the intumescent coatings during testing suggested that only two of the three coatings expanded significantly when exposed to the heat flux conditions used in the current study. Coating B and Coating C, both of which swelled, produced insulating char layers with maximum depths of 12 mm from the exposed surface of the sample. Thus, each of these two coatings grew to approximately 10 times the original applied dry film thickness. Coating A did not swell.

Although successful at extinguishing flames shortly after early ignition, both coatings B and C demonstrated different char growth phases (uniform/non-uniform as further explained), presumably due to their unique chemical formulations. Given the proprietary nature of these products, the exact formulations and hence reactions that occur upon exposure to heating are not known.

The differing swelling phases of the intumescents can, however, be visually correlated to phenomena that were observed during the experiments. Phases of intumescent coating thermal resistance correspond to the growth and decay phases of the char layer; thermal resistance being the ratio of expanded thickness to thermal conductivity of the intumescent layer (Li et al. and Lucherini et al.) [14,20].

COATING B

The growth of Coating B slowly developed as an unevenly distributed white char across the sample surface (Figure 3a), which then blackened (Figure 3b). Ignition of the volatiles produced during coating pyrolysis occurred soon after heating (see Section 3.1).

Once ignited (Figure 3c), surface flaming then contributed additional heat feedback to the surface, which increased the rate of pyrolysis (evidenced by the mass loss rate in Section 3.3). This accelerated pyrolysis rate also accelerated the rate at which the intumescent char layer developed. The growing char layer served to reduce the rate of heat transfer to the underlying timber substrate, and thus to a decrease in the pyrolysis rate. The pyrolysis rate then decreased below the critical rate to sustain flaming and the flame extinguished (Figure 3d).

Upon completion of the swelling of the intumescent and the oxidation of its char, its thermal resistance peaked [14]. Hence, this was the upper limit of its insulating capability (Figure 3e). Regression of the intumescent char then slowly occurred, resulting in a reduction in thermal resistance. This coating reached a maximum char thickness of 12mm above the surface of the sample.

https://doi.org/10.52202/069179-0237

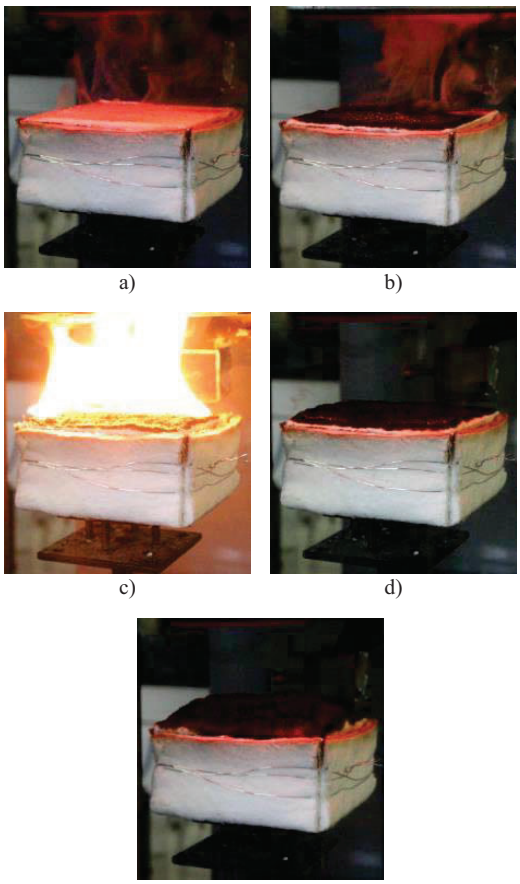

Figure 3: *Phases of Coating B (Sika Pyroplast) intumescent growth at 35 kW/m^2.*

Coating B displayed significant variation in intumescent blister shape and distribution across the surface; this can be seen clearly in Figure 4.

Figure 4: *Intumescent char formations for Coating B (Sika Pyroplast) sample removed from apparatus at 35 kW/m^2.*

COATING C

Coating C did not behave as expected based on the existing literature [7,14]. Before growth of the char bubble matrix, an outermost layer of the coating appeared to trap a portion of intumescent pyrolysis gases and formed a single large (approximately 16mm deep) bubble over the entire surface of the coated sample. Ignition of volatiles released from this bubble caused a large initial flame on ignition, resulting in significant heat feedback to the sample surface. The coating then entered a transient phase by forming a multitude of small bubbles that developed into a protective char layer. This coating reached a maximum char thickness of 8mm, and then – as for Coating B – it gradually regressed.

COATING A

When exposed to heating, Coating A immediately melted, pyrolysed, and changed to a blackened colour. Upon ignition however, this coating appeared to immediately disintegrate, cracking, and peeling away in thin curling leaves to reveal the underlying substrate. Little initial bubbling and no obvious intumescent growth were observed. The timber then began to char and fracture as if uncoated. Flaming of Coating A samples continued until the end of the experiments.

3.3 BURNING BEHAVIOUR

The heat release rate (HRR) for the samples was measured using oxygen consumption calorimetry. The mass loss rate was also determined via cone calorimetry and provides an indication of thermal decomposition of the samples. Mass loss can evidence drying of timber, decay by pyrolysis, or oxidation of the carbon-rich char [21]. The heating process that causes the greatest loss of timber substrate mass is pyrolysis, generating ash and gaseous products. Both the time-resolved HRR data and MLR data are given in Figure 5 to Figure 9.

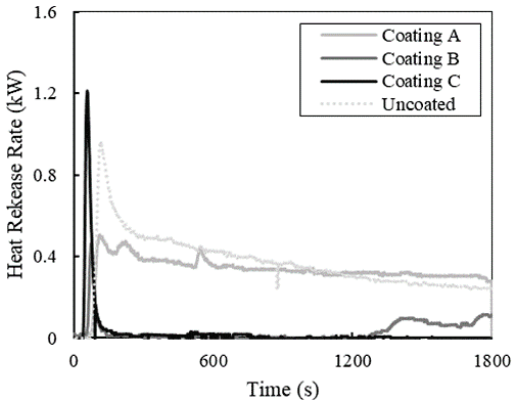

Figure 5: *Stages of intumescent burning at 35 kW/m^2.*

https://doi.org/10.52202/069179-0237

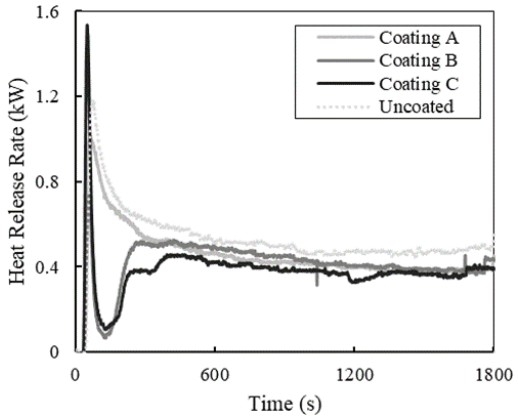

Figure 6: *Stages of intumescent burning at 60 kW/m^2.*

Across the exposure conditions used, the two coatings that swelled (coatings B and C) displayed distinctly different burning behaviour as compared with uncoated wood. The time resolved HRR data for an uncoated sample exposed to 60 kW/m^2 is given in Figure 7. The early stages of the experiment displayed high rates of pyrolysis prior to ignition, then a rapid increase in the HRR after ignition. The HRR then increased to a peak value which gradually decreased as the char layer developed and heat transfer was reduced in-depth in the timber (as expected).

The HRR with time for a typical intumescent coating (Coating C) exposed to 60 kW/m^2 is given in Figure 8. A peak HRR value was observed soon after ignition of the intumescent coating. The HRR then reduced to well below the value recorded for uncoated timber. For trials at 60 kW/m^2, the intumescent char then began to degrade after about 150 seconds; the surface then eventually reignited, with commensurate increase in the HRR (Figure 6).

For experiments conducted at 35 kW/m^2, re-ignition did not occur and HRR did not increase after the initial peak (Figure 5). The discrepancy between the behaviours across the two heat fluxes illustrates the potential importance of the heating conditions when studying the performance of intumescents, as previously suggested in the available literature [13-14]. The heat fluxes to which such coatings are subjected when assessed via regulatory tests is therefore potentially very important in terms of the credibility of assessment for performance in real (rather than regulatory) fire scenarios.

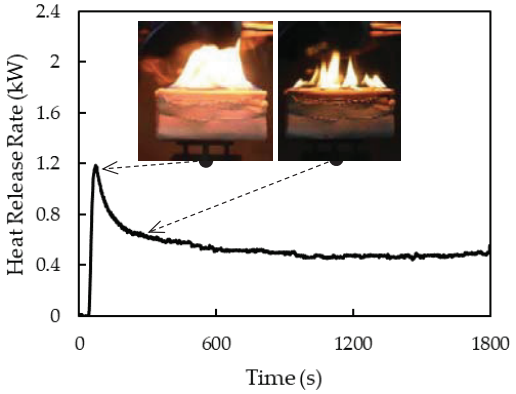

Figure 7: *Phases of flaming and heat release rate at 60 kW/m^2 for uncoated samples.*

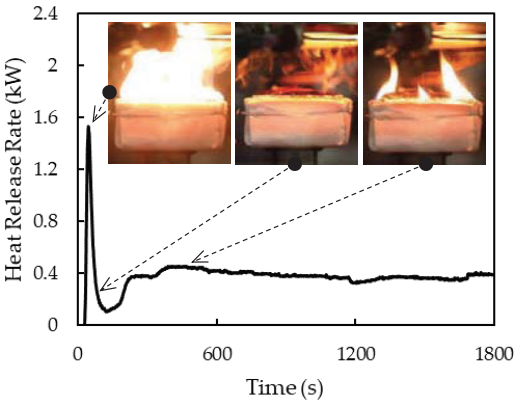

Figure 8: *Phases of flaming and heat release rate at 60 kW/m^2 for Coating C (Thermoguard Fire Varnish) coated samples.*

Figure 5 to Figure 9 show that Coating C had the fastest and largest HRR and MLR peak for all coatings and heat fluxes. This peak occurred in less than 20 seconds at 35 kW/m^2 and less than 10 seconds at 60 kW/m^2. HRR then declined rapidly, suggesting there was a sudden release and then ignition of combustion products – this aligns with the observation of a single large bubble on the surface of the Coating C samples. After this initial growth the intumescent char layer protected the timber and therefore HRR and MLR declined. After approximately five minutes, the HRR behaviour for trials conducted at 60 kW/m^2 was observed to converge to similar general behaviours as the samples transitioned into a regime of predominantly char oxidation. All ignition, extinction, or re-ignitions occurred within the first three minutes of each experiment.

https://doi.org/10.52202/069179-0237

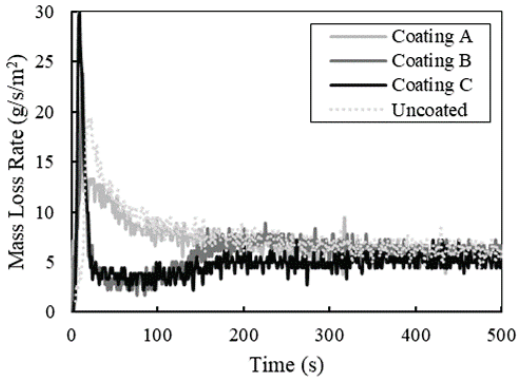

Figure 9: *First 500 seconds of mass loss at 60 kW/m².*

Despite the behaviour of each sample within the first 500 seconds being distinctive, all data began to converge to a mass loss rate of approximately 4 g/s/m² at 35 kW/m² and 5 g/s/m² at 60 kW/m², once 1500 seconds had elapsed.

The results for heat release rate and mass loss rate correlate well, as expected given that both are manifestations of the burning rate. The trends of mass loss therefore correspond to those described for HRR, i.e., the initial mass loss rate is higher due to the added presence of more volatile products.

For coatings B and C which swelled, the peak in mass loss rate occurred as the intumescent blisters were forming. This occurred more quickly than for Coating A or uncoated samples and can likely be attributed to the reduced reactional temperature of the intumescent in comparison to the pyrolysis temperature for timber. The reduced mass loss and heat release rate after the initial peak supports the idea that the intumescent char layer does protect the underlying timber.

3.4 GAS SPECIES

Recorded values of carbon monoxide (CO) and carbon dioxide (CO_2) in the cone calorimeter flue gases provide insight into the emissions from both the timber substrate and each of the protective coatings; the CO results are shown in Figure 10. The pyrolysis and burning of timber can be expected to produce CO, CO_2, and various other products. The intumescent coatings will also contribute combustion products, including CO and CO_2. The rate of CO and CO_2 generation will vary with the presence of a flame or with the presence of solid phase char oxidation. Therefore, the measurement of CO and CO_2 lend insights into the global combustion conditions of the tested specimen. Periods of high CO_2 generation tend to indicate periods of sustained flaming, as a result of the flame sheet rapidly oxidizing CO produced during pyrolysis to CO_2 [22]. The CO values found in this study, however, varied significantly between coatings and heat fluxes, following differing trends throughout the 30 minute exposures.

High generation of CO has been associated with both pyrolysis and solid phase char oxidation [23]. The CO production for samples coated with coatings B and C were significantly higher than for uncoated wood, suggesting that the increased CO yield may be a result of the oxidation of the intumescent char. Intumescent products commonly incorporate carbonising agents, and it is possible that decomposition of these elements leads to the production of CO in the early stages of intumescent growth [8]. It is also likely that char oxidation dominates the production of CO in the later stages of the experiments presented herein [24].

For coatings B and C exposed to 35 kW/m², the CO value grew significantly after an initial peak, peaking for a second time after 20 minutes and 30 minutes, respectively. At 60 kW/m² the initial CO peak was much higher, and production then rapidly decreased. This variation of gas species generation between the two heat fluxes supports the idea that different chemical reactions may occur within the intumescents at different temperatures. It is also noteworthy that production of these gases only occurred after the thermal decomposition of the protective layer had been initiated.

The CO_2 and CO concentrations varied considerably between each Coating B repeat test. This suggests that even with the same application of coating and heat flux, the behaviour of this intumescent may differ in terms of both char formation and reaction products.

As with the previous results, the Coating A samples behaved similarly to uncoated wood in relation to both CO_2 and CO concentrations at both 35 and 60 kW/m².

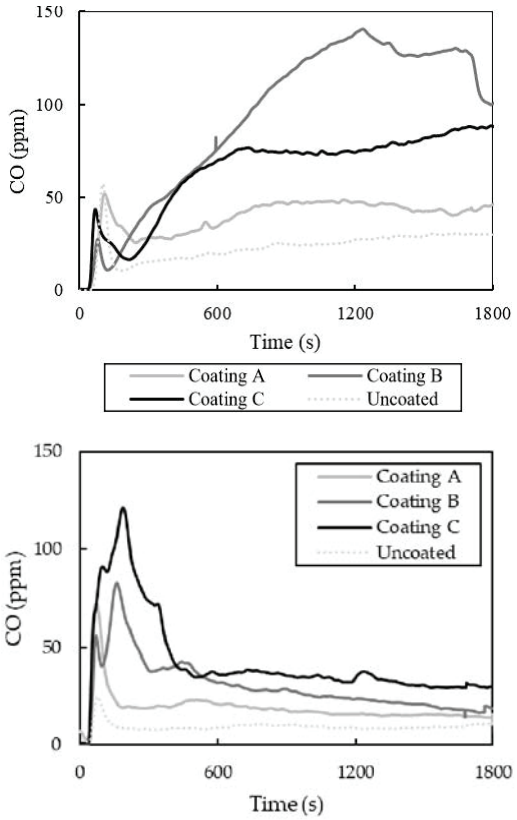

Figure 10: *CO gas concentrations in exhaust gases at 35 kW/m² (top) and 60 kW/m² (bottom), respectively.*

https://doi.org/10.52202/069179-0237

3.5 TEMPERATURE AND CHAR DEPTH

The in-depth temperature gradients in the samples provide indications of the degree of thermal penetration in the timber. Dominating burning regimes correlate with different temperature bounds, therefore, a profile of temperature through the depth of the sample can elucidate the processes occurring at any one time and suggest the degree to which the overall strength of the timber section would have been reduced due to in-depth heating. At approximately 100ºC moisture vaporization and transport will occur variably throughout a timber cross section, causing dehydrated wood to become more brittle and saturated wood layers to soften [21]. At 100ºC, timber is typically assumed to lose 75% of its flexural strength [25]. At about 200ºC, the timber will begin to pyrolyze [26] which not only further reduces the structural capacity of the member but also produces flammable gases which may ignite. At temperatures in the range of 400-600ºC, any char is likely to experience solid phase char oxidation. The 300°C in-depth isotherm is typically assumed to represent the effective depth of the "char layer" (i.e., the position at which timber has lost effectively all of its mechanical strength). However, mechanical properties are also lost in thermally-affected regions at temperatures below 300°C [25].

The samples that most rapidly reached 300°C, both at the surface and at locations in-depth, were the uncoated samples. These were closely followed by samples with Coating A.

Coatings B and C, both of which insulated the timber as already discussed, resulted in consistently lower in-depth temperatures compared against uncoated trials.

At 35 kW/m^2, the surface of the timber protected by Coating C was up to 300°C less than for uncoated timber samples. The char depth after 30 minutes of exposure was reduced by 4-7 mm for coatings B and C.

Figure 11 shows the thermal gradients developed through the depth of exposed uncoated and Coating B specimens. This thermal gradient can then be compared across products to assess the rates and degree of thermal penetration experienced.

In addition to in-depth temperature results, the impact of each coating on final char depth of the timber was evaluated by visual examination of the samples after testing. Samples were cut vertically in half to observe the char depth and unpyrolysed wood, where distinction was made by qualitatively reviewing the colour change of the cross section. By measuring the remaining depth of wood, the loss of material was quantified in thickness (as well as mass from the mass loss readings).

As should be expected, the greatest loss of timber substrate was found for the uncoated timber when tested at 60 kW/m^2.

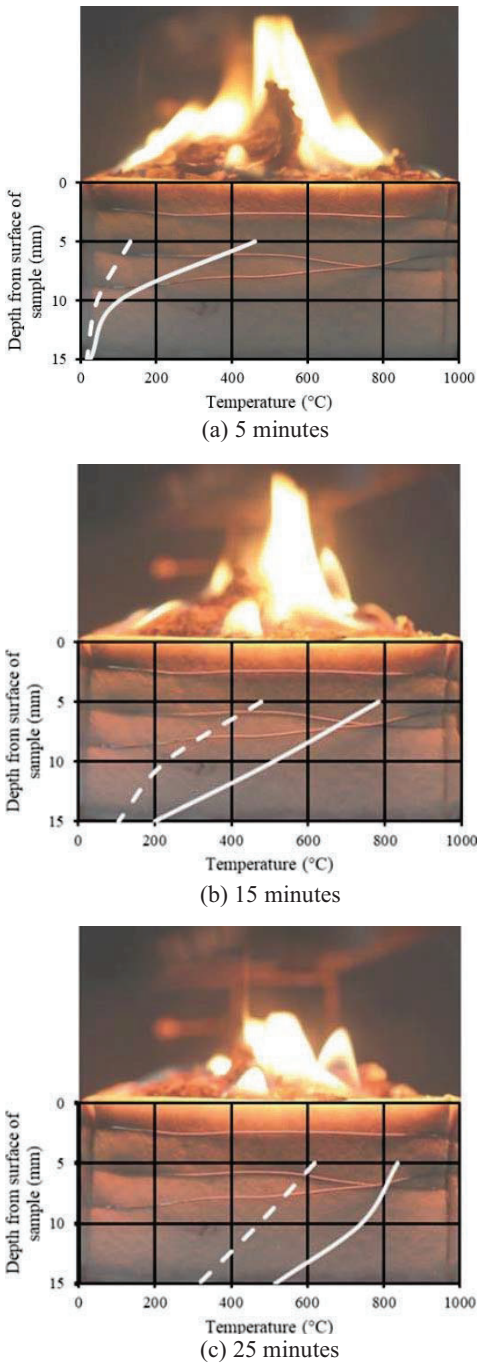

Figure 11: *Temperature distribution through the depth of samples at 60 kW/m^2. Solid line: uncoated sample. Dashed line: Coating B (Sika Pyroplast) (TCs at 5, 10, 15 mm).*

4 DISCUSSION

The data presented in the preceding sections provide insights into timber and intumescent coating response when exposed to radiant heating at small scale. The behaviours observed allow a comparison of the coatings' performance in terms of the intumescent growth phases, burning behaviour, products of combustion, thermal penetration, and char depth. These measurements allow for the evaluation of the product performance alongside

https://doi.org/10.52202/069179-0237

claims made by each product manufacturer, and hence their potential effectiveness in regard to a range of potential applications in mass timber buildings.

4.1 HEAT FLUX

All samples were tested at both 35 kW/m^2 and 60 kW/m^2 and it was confirmed – as expected – that a higher initial incident heat flux consistently resulted in earlier ignition, greater heat release rates, greater mass loss rates, acceleration of in-depth temperature increase, greater in-depth temperature, and greater final char depth. This was seen both in uncoated and coated samples (all other factors being equal).

4.2 COATING A

The data presented consistently suggests that the performance of Coating A samples resembled that of uncoated wood. It was observed that instead of the intumescent layer growing from the surface of the timber when exposed to heating, the coating peeled away to reveal the timber underneath. Albeit time to ignition was mildly extended using this coating.

It is possible that the comparative ineffectiveness of this coating has been caused by the uncontrolled moisture content of samples before application. The manufacturers 14% maximum moisture content, however, is extremely difficult to achieve for existing structural elements which the coating is advertised for, suggesting that successful protection using this intumescent would be very difficult to attain if conditioning is absolutely necessary.

4.3 COATING B

The data for Coating B confirmed that it performed as expected for a typical intumescent coating, forming a cellular char layer that extinguished flames at both heat fluxes tested. The depth of the intumescent char was the greatest of all coatings tested; this resulted in decreased HRR, MLR, flaming, in-depth temperatures, and char depth in comparison with uncoated wood.

The behaviour of this coating during testing confirms that it has beneficial impacts on the HRR and insulation of underlying timber.

The inconsistent performance of Coating B across the surface of the sample and between repeat tests may be an indication that the product protection may be prone to variation in practice. It is suggested that further repeat experiments are completed to ensure the overall performance of Coating B is quantified. Furthermore, large scale and realistic orientation tests should be completed to observe whether the variation of intumescent growth is significant over larger surface areas and whether it maintains intumescent char structure when vertical.

4.4 COATING C

Coating C was successful in reducing HRR, MLR, flaming, in-depth temperatures and char depths in comparison with uncoated wood. Moreover, Coating C samples demonstrated the least amount of flaming after the initial peak in heat release rate, and consistently gave the lowest in-depth temperatures amongst all coatings.

Early ignition in comparison to uncoated wood was observed for Coating C; however, as early ignition then promoted the rapid growth of the intumescent char layer, early ignition is not necessarily in itself a negative result in terms of fire performance. Large scale testing at various orientations is recommended to understand the consequences of ignition and flame spread over an intumescent coated surface and hence fire growth rates for timber surfaces within realistic fire compartments in buildings.

5 CONCLUSIONS

The research presented within this paper serves as a preliminary study investigating the reaction-to-fire performance of three transparent passive fire protective coatings for wood, when exposed to more severe heat flux conditions from above, with the sample in a horizontal orientation. The testing results indicate that Coating A did not swell and therefore performed similarly to that of uncoated samples. The two remaining intumescent coatings (B and C) produced multi-cellular char layers that reduced the heat release rate, mass loss rate, CO_2 concentrations, in-depth temperatures, and char depths under the experimental conditions used in the current study. The potential for these products to improve the reaction-to-fire and burning behaviour and wood is therefore promising. However, their widespread application in mass timber buildings with exposed timber surfaces requires further study to better understand the influence of e.g. scale, orientation and much higher heat fluxes seen in natural fire conditions in large timber-lined compartments [27].

Research and experimentation has highlighted the importance of a range of parameters for evaluating the effectiveness of an intumescent product for wood. Additional research is needed to determine the suitable applied surface treatments across the relevant range of fire safety strategy considerations, where they are intended to improve e.g. char rates, or be used as a justification for slower fire spread rates in large compartments. The current fire classifications of reaction to fire classification and fire resistance derived from standard tests are unlikely to be suitable for that purpose.

To accurately predict the behaviour of an intumescent in a real fire scenario, further experimentation involving the exposure of intumescent coatings to transient heat sources, (e.g., increasing heat flux, interactions within a real compartment, etc.) in a realistic orientation that accounts also for the impact of gravity (as products are usually applied to walls or ceilings) would be necessary to better represent the changing conditions.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the support of the University of Edinburgh School of Engineering, Edinburgh Fire Research Centre, and the supplier of the intumescent coatings (not the manufacturer). The authors

would like to thank and acknowledge Michal Krajcovic for his technical support and advice.

FIRE DESIGN OF GLULAM CONNECTIONS WITH TIMBER-TO-TIMBER BEARING INTERFACES

Hans-Erik Blomgren[1], David Barber[2], Graham Montgomery[3]

ABSTRACT

High-rise mass timber buildings require beam end connections to maintain the fire resistance rating of the beam. Connections where a glulam beam ends bear directly onto a supporting glulam column are commonly utilized because they reduce cost, require only simple CNC fabrication, meet the desired architectural aesthetic, and have high load carrying capacity. In addition, a properly designed bearing connection can achieve a 1hr-to-2hr fire rating. A beam to column bearing connection designed and fire tested for a high-rise building project in the United States is presented in this paper. An assessment of the bearing area required to support the load under fire conditions required detailed review of the scientific literature to understand how the thermally impacted timber ahead of the char front reduces the perpendicular-to-grain mechanical properties at the bearing interface. An estimate of the reduced perpendicular-to-grain stiffness and strength at the bearing area was used to design the connection. Two 2hr fire tests to ASTM E119 were performed to experimentally validate the design assumptions. This paper concludes with a discussion of how engineering guidance for bearing type connections exposed to fire can be further developed.

KEYWORDS: Mass Timber, Connections, Fire Engineering, Structural Engineering, Bearing Behavior, Joints, Intersections, Interfaces

1 INTRODUCTION

The construction of large-scale multi-story mass timber buildings is rapidly expanding across the world as developers, architects, and contractors become more experienced with the new construction type. To market these buildings, there is a strong desire to expose the wood surfaces as the architectural finish. Building Codes require the primary structural frame to be fire rated between 1hr and 2hr depending up on the height and floor area of the structure [1]. The principles of engineering glulam beam and column member cross-sections for fire resistance through a protective charring layer of the timber have been well established in building codes for decades [2]. However, design methods for engineering exposed glulam connections for fire are limited.

This paper provides background, analysis, fire test information and post-test assessment for the fire performance of exposed timber beam-to-column bearing connections. These designs have been employed by the authors on some of the first projects in the US that require up to a 2hr fire resistance rating (Figure 1).

2 FIRE RATED BEARING CONNECTION REQUIREMENTS

Bearing connections are commonly used in North American timber construction and many historic heavy timber buildings utilize this connection type. Traditionally, the beams bear onto the column through an external steel metal cap that provides sufficient support for the beam and direct load transfer to the column while also allowing the column load above to transfer to the

column below in direct end-grain bearing at the cap plate as shown in Figures 2 and 3.

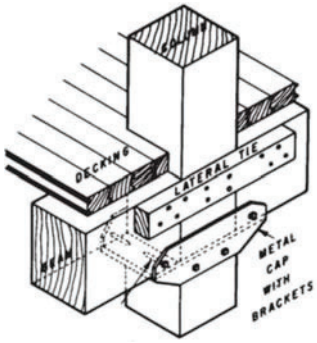

Figure 2: *Heavy Timber beam to column bearing connection with exposed metal cap plate [3].*

Figure 3: *Historic heavy timber beam to column bearing connection with exposed metal cap plate (credit: DeStefano & Chamberlain).*

In modern mass timber construction, beams commonly bear directly on cut-outs or notches in the columns with screws providing the positive fixing as shown in Figure 4. This bearing connection type is utilized because it provides the benefit of reduced cost, simple CNC fabrication, desirable aesthetic, and high load carrying capacity.

When the exposed beam and its end connection are required to have a fire-resistive rating, the use of an external cap plate connection is prohibited because the external steel parts are not protected from the fire exposure temperatures. The bearing capacity of the beam end supported on the column is determined by calculating the reduced bearing area due to char and a zero-strength layer ahead of the char front multiplied by an allowable perpendicular-to-grain bearing stress for fire exposure conditions.

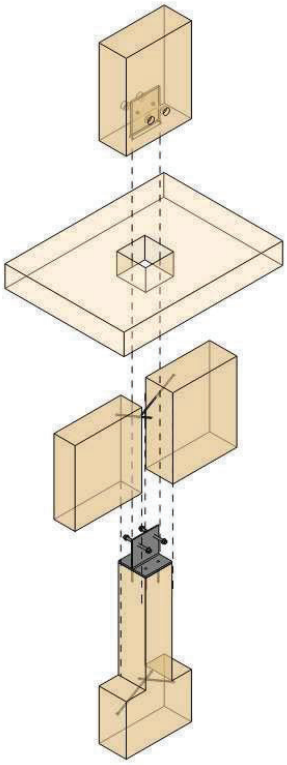

Figure 4: *Exploded view of notched column glulam beam bearing connection (credit: Timberlab).*

3 NOTCHED COLUMN BEARING CONNECTION

A glulam beam end can be designed to bear directly onto a notch fabricated into the column face as shown in Figure 4 to create an efficient connection. The glulam beam end is loaded in perpendicular to grain bearing and the column is loaded parallel to the grain at the contact surfaces. At the vertical abutted interface between the beam end and face of notched column, a small gap is detailed to allow for construction tolerances, and when required by building codes, to accommodate rotations due to the building horizontal seismic design drift [4]. These vertical end gaps are typically in the order of 2 to 6 mm. Fire protection of these interface gaps are discussed in Section 6 of this paper. Note that fire sealing of the fire rated floor assembly (typically CLT panels with a non-combustible topping) around the notched column that penetrates the floor is beyond the scope of this paper.

4 BEARING BEHAVIOR

Before investigating bearing connections under fire exposure, is it warranted to review the behavior of perpendicular-to-grain bearing for the non-fire load case. Perpendicular-to-grain bearing strength is a distinct limit state for timber design because strength is established based on a deformation (serviceability) limit and short

https://doi.org/10.52202/069179-0238

term (time-dependant) loading stress increases are not applicable.

In the United States, the nationally adopted model code is the International Building Code (IBC) [1], with the 2021 edition the current latest publication. The IBC references the National Design Specification for Wood Construction (NDS) [2] which includes the allowable stress design (ASD) values for various species and grades of timber. The perpendicular-to-grain bearing stress in the NDS is determined from ASTM D143 [5] testing that utilizes small 50mm x 50mm x 150mm clear green wood specimens subjected to compressive pressure from a 50mm x 50mm steel block on the top face and uniform support below on the full specimen surface area. The measured stress at 1mm of deformation for each specimen is measured and the resulting 5th percentile strength is calculated. To convert the tested value to the ASD reference design value, the 5th percentile value is divided by 1.5 for a factor of safety and duration of load. This value is then multiplied by a strength ratio of 1.0 and multiplied by 1.5 for and adjustment for dry use.

From time-to-time the validity of using the small-scale ASTM D143 test method for real large scale building structures has been questioned. Testing in the 1990s by Madsen [6] investigated the behavior of full-scale perpendicular-to-grain bearing of dry-use glulam members for a range of bearing plate sizes from 25mm x 25mm to 177mm x177mm. Bearing at the middle and ends of glulam were tested. Figure 5 presents a representative graph from Madsen's work for the average load-deformation relationship of a 125mm x 125mm bearing plate at the end of a dry use Douglas fir glulam beam. This graph exhibits a gradual transition or "proportional limit" between deformations of 1mm and 2mm where the deformation becomes non-linear resulting in permanent indentation (deformations) in the wood. The occurrence of this transition between 1mm and 2mm was found to be consistent across all tests performed by Madsen.

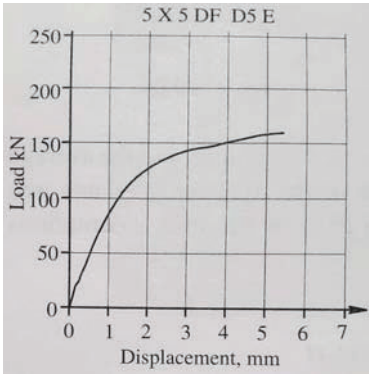

Figure 5: *Perpendicular-to-grain load-deformation plot for a 125mmx125mm plate located at the end of a Douglas Fir glulam, Madsen [6].*

Based on these tests, Madsen proposed a design method that accounted for the effects of i) bearing on the contact surface area ii) the length of bearing edge parallel to grain, and iii) the length of bearing area perpendicular to grain. When the proposed design method is applied to a large bearing plate condition (178mm x 350mm) it is shown that a 2mm indentation in the glulam (deformation) is required to attain the factored design strength calculated using the ASD reference design load multiplied by the LRFD format conversion factors documented in the NDS [2]. This example indicates there is reasonable correlation of strength and deformation between the two design methods for perpendicular-to-grain bearing on large bearing areas.

5 WOOD PROPERTIES AT ELEVATED TEMPERATURE

To properly engineer mass timber elements under the conditions of fire exposure, the change in strength and stiffness of the material as a function of temperature between ambient conditions (20C) and the char temperature (300C) must be quantified. Research in this area has been available for decades and is based on exposing wood samples to a standard fire, such as ASTM E119 [7]. For temperatures in this range, Eurocode 5 [8] provides graphs for parallel to grain tension and compression loads. The reduction of strength and stiffness is characterized by bi-linear lines that exhibit strength losses of 75% (Compression) to 35% (Tension) at 100C and then reducing linearly to zero at 300C. Where timber is heated up to 100C, the strength losses are reversible on cooling. Above 100C, the strength losses are not reversible on cooling [9].

As timber chars due to fire exposure, a thermal penetration depth beyond the char front into the depth of the wood develops. Due to this heating, a portion of the moisture present in the wood is driven ahead of the thermal wave further into the wood. The increase in moisture content and wood temperatures up to 50mm beyond the char font have been experimentally measured by several researchers [10, 11, 12] and found the heat penetration and driven moisture have a combined effect on the immediate mechanical properties of wood. Figure 6 from Schaffer's work [10] plots the temperature and moisture content as a function of the distance from the surface of the charred wood.

https://doi.org/10.52202/069179-0238

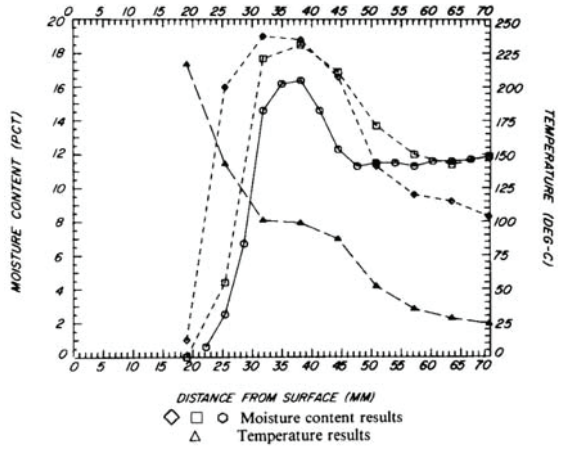

Figure 6: *Measured temperature and moisture content gradients beyond the char front for southern pine specimen with an initial MC of 10%. One face of wood exposed to 538C furnace temperatures for approximately 20mins, Schaffer [10].*

Schaffer's work [10] also experimentally measured the relative parallel-to-grain stiffness and parallel-to-grain compressive and tensile strength beyond the char front, as shown in Figure 7. The lines in this plot show the complexity of the combined effect that increasing temperatures and increasing moisture content have from 0mm to 50mm beyond the char front that need to be accounted for in the structural fire design of exposed timber members.

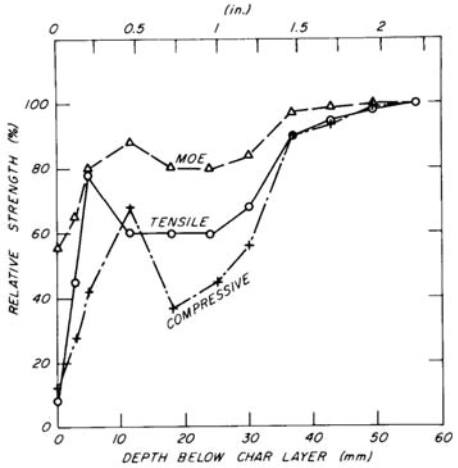

Figure 7: *Measured parallel-to-grain stiffness and compressive and tensile strength of softwood beyond the char front expressed in percent of that at 25C and initial moisture content of 12%. Schaffer [10].*

The strength reduction of wood due to fire exposure discussed so far in this section has only considered parallel-to-grain loading. For the fire design of bearing connections, the strength and stiffness reduction of wood perpendicular-to-grain at elevated temperatures needs to be quantified. The authors of this paper found limited published research on this subject. A report by Gerhards [13] provides a summary of experimental testing that studies the immediate effects on the mechanical properties of wood due to changes in moisture content and temperature. His report includes all mechanical properties for wood including perpendicular-to-grain compressive loading. Gerhards' summary shows that for a relative change in temperature from 20C to 70C the compressive stiffness and strength perpendicular-to-grain decreases by approximately 35%. This reduction is reported at an MC greater than 10% with the trend being clear that a higher MC in combination with higher temperatures increase the reduction in strength and stiffness.

It is noted that Gerhards' report is limited to maximum wood temperatures of 70C creating a gap in knowledge about the mechanical properties of wood in compression perpendicular-to-grain at temperatures from 70C leading up to the 300C char front where strength diminishes to zero. Limited experimental testing on full scale perpendicular-to-grain bearing interface connections have reported large and rapid loss of strength and stiffness due to fire exposure. The publication by Buchanan and Ostman [14] provides a short discussion and photos showing large permanent perpendicular-to-grain deformations in the high stress contact area of test specimens that were dissected after fire testing.

6 JOINTS AND INTERSECTIONS

Notched bearing connection fire performance needs to consider both the horizontal and vertical joints between the beam and column. Figure 8 shows this typical condition where the column is notched on two faces to support beams framing in from each side. The remaining center portion of the column penetrates the CLT floor to support the column above in end-grain bearing. Both of these joints are discussed in the following sections.

Figure 8 *Photo of a beam to notched column bearing connection. This connection creates a horizontal bearing interface and vertical joint at the abutted members (credit: Timberlab).*

https://doi.org/10.52202/069179-0238

6.1 Fire protection of the Vertical Joint

The vertical timber joint requires a gap to be detailed to account, at a minimum, for fabrication and installation tolerances. Using state-of-the-art CNC equipment, a 2mm gap for tolerances is typically found to be satisfactory. For buildings in high seismic regions of the US, the IBC reference standards require the non-participating gravity system to accommodate seismic design story drifts [4]. This results in cyclic beam-column joint rotation deformations being imposed on the connection which means a larger vertical joint gap may be required. As well, wood shrinkage during the building operational life can also result in gaps forming.

IBC requirements for fire protection of timber-timber gaps such as this have only recently begun to be developed. In the US, the Fire Design Specification (FDS) [15] states that all gaps from 0mm up to 3mm have to account for char penetration into the joint that is 2 times the nominal char rate of timber. For gaps larger than 3mm, the FDS states surfaces within the gap are assumed to be fully exposed to fire for the full depth of the gap.

From a connection design standpoint, advanced charring into the vertical gap has to be prevented as any charring in this area rapidly reduces the beam bearing area and thus the load bearing capacity of the connection. As well the cross-section area of the notched portion of the column supporting floor loads from above is reduced. To address this problem, engineers in the US have begun to use intumescent fire tape products that are concealed in the depth of the vertical gap as shown in Figure 9.

Figure 9: *Photo of a glulam beam end with fire tape seal applied in a vertical joint before it is installed onto a supporting glulam column (credit: Blomgren)*

Under fire exposure and temperatures in the order of 200C, the intumescent tape activates and expands across the joint providing an effective and durable seal that slows or prevents fire penetration into the joint that is greater than the advancing char depth of the parent timber material. Manufacturers of these tape products have begun to demonstrate the fire protection performance of these products for these applications by testing to ASTM E1966 [16].

6.2 Fire Protection of the Horizontal Bearing Interface

The bottom of the beam delivers its load in perpendicular-to-grain bearing to the end grain of the supporting column. This interface is in compression and assuming accurate fabrication tolerances, the load is applied as a uniform pressure across the full bearing area. To confirm char penetration into this interface does not occur which would severely undermine the bearing capacity of the connection, the American Wood Council (AWC) managed a testing program of these loaded connection types exposed to ASTM E119 furnace temperatures. The testing applied a relatively low pressure to the bearing interface to represent a lower bound lightly loaded beam connection. The AWC reported that thermocouple data from these tests found no advanced char line penetration into the compression bearing joint [17].

7 ENGINEERING CALCULATION

For a 2hr fire rated mass timber building on the east coast of the US, the authors of this paper, designed and fire tested a large timber beam-to-column bearing connection. To efficiently support the beam end loads to the column, they are directly seated onto the column, with each incoming beam end sharing one-half of the column end area. To support the column load from above in end-grain bearing, a steel post with end plates is located within the timber beam depth. Small notches are formed in each abutted beam end to provide space for the post. Photos of the connection specimen being assembled at the testing laboratory are shown in Figure 10. The joint at the vertically abutted beam ends are protected with fire tape as shown above in Figure 9.

Figure 10: *Photos of the test specimen glulam beam ends to column support test specimen being assembled. A steel post to support the column above was included to replicate the actual project detail (credit: Blomgren).*

https://doi.org/10.52202/069179-0238

The design of a bearing connection is a very simple calculation where the applied bearing pressure is compared to the design bearing resistance pressure that includes an appropriate safety factor. However, for a fire condition, design guidance for the engineer is lacking. To design the first test the authors referenced the NDS [2] for timber that states the char depth at 2hrs of fire exposure is 66mm. Following with the NDS provisions, an effective char depth was determined by increasing the char depth by 20% to 79mm to account for the pyrolysis zone and zero strength layer for parallel to grain loading (i.e. bending, axial tension, and axial compression). Charring was assumed to occur on the three faces of the column under the supported beam end, and concurrently the three faces of the beam. This results in a 66% reduction in bearing area as shown in Figure 11. For this design the steel post and base plate were detailed with a minimum wood cover of 89mm which provides sufficient thermal protection for 2hr.

Continuing with the design, the published allowable perpendicular to grain bearing stress for the glulam product used is 4.13MPa. For fire conditions the NDS [2] allows allowable stresses to be increased to account for short term loading and adjusting the 5th percentile strength to an estimated mean strength. Using this method, the perpendicular-to-grain bearing stress increase adjustment for fire design was calculated to be 1.67 x 4.13=6.9MPa.

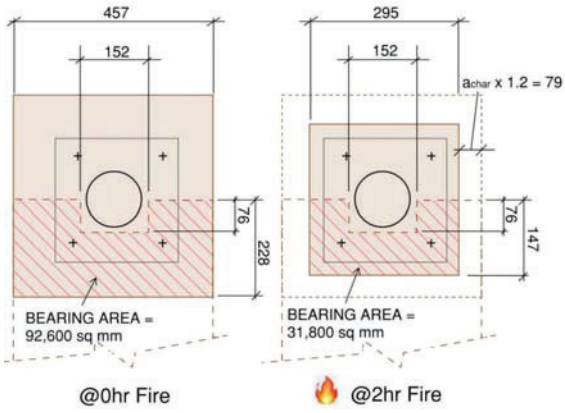

Figure 11: *The calculated bearing area for Test 1 at zero hour and 2hr.*

With the bearing stress design values and bearing area areas calculated, it is evident the fire condition at 2hrs controls the design by limiting the maximum allowable beam end reaction to 6.9MPa x 31,800mm^2 = 219kN.

8 ASTM E119 FIRE TESTING

8.1 Test 1

To justify the use of an exposed 2hr fire rated timber bearing connection for the building project, the mass timber supplier chose to perform full scale testing in general accordance with the ASTM E119 fire test standard. Testing is a specific code compliance pathway provided in the 2021 IBC [1] that has adopted new provisions for mass timber high-rise buildings. Project-specific testing was chosen, rather than analysis methods, due to the lack of existing testing data to justify the timber-timber bearing connection design under large loads. Building permit approvals were also more straightforward and efficient with a successful fire test rather than an analysis approach. It should be noted that ASTM E119 does not have a specific section in the standard for the fire testing of connections. The methodology for testing a connection was therefore based on an approach consistent with the standard, based on advice from the testing facility and consistent with other full-scale fire tested connections (timber and steel).

The specimen was constructed and inserted into a self-reacting test frame with an actuator capable of applying a maximum 204kN load to the specimen as shown in Figure 12. The specimen was carefully designed and detailed to ensure the actuator load imposed compressive forces on the beam to column interface with no secondary load paths. To accomplish this, the CLT panel that forms the lid of the furnace was split into two parts with a shearing joint located over the end of the beam. In addition, the CLT perimeter was supported on the four edges of the furnace with multiply layers of compressible ceramic blankets.

Figure 12: *Glulam bearing connection specimen and test frame prior to being lifted and placed in the furnace (credit: Blomgren).*

Testing commenced by applying a 204kN load to the specimen. An immediate actuator extension of 8mm was measured which can be attributed to elastic compression of the specimen through the CLT and beam depth and some flex in the test frame itself. This measurement was zeroed out and the furnace was ignited. The deformation

https://doi.org/10.52202/069179-0238

grew slowly measuring 10mm at the 60min mark. Soon after this time, the deformation increased exponentially resulting in failure at 86min which was only 72% of the calculated 2hr fire resistance time discussed in Section 7. The actuator extension curve for the test is provided in Figure 13. At the final moment before the actuator force reduced to zero, the recorded actuator extension was 60mm. The actuator briefly extended up to 105mm due to the failed beam end sliding off the supporting column before the test was terminated.

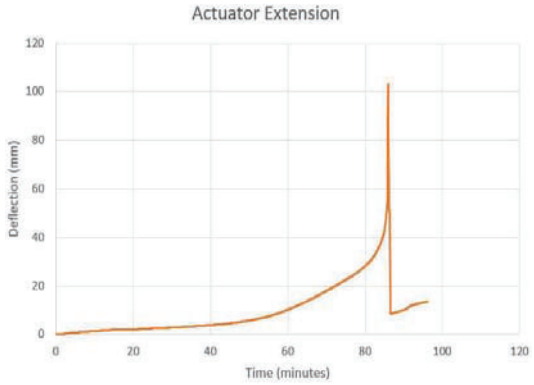

Figure 13: *Plot of the actuator extension vs. time for Test 1 showing test specimen failure at 86m.*

Although the results of the ASTM E119 fire test did not correlate well with the calculated prediction, it did provide a time-to-failure test to learn from. After the test, the data was reviewed, the disassembled specimen was visually observed, and other possible factors that may have caused the early failure time were investigated. After this effort, it was concluded the most likely cause of early failure was due to elevated temperatures in the bearing region that softened and weakened the wood more than anticipated resulting in excessive deformations and loss of strength allowing the beam end to slide off the column support. This result indicated that the 1.2x factor applied to the 2hr char depth to determine the effective bearing area in the engineering calculation discussed in Section 7 was unconservative.

At 86min of ASTM E119 fire exposure the calculated char depth per NDS [2] is 51mm. Using this char depth and the allowable fire design bearing pressure of 6.9MPa and bearing area of 31,800mm^2 derived in Section 7, an approximate 1.5x "zero strength layer" adjustment factor was back calculated.

8.2 Test 2

A second specimen was designed and ASTM E119 fire tested to 2hrs. To successfully pass this test the compression bearing area was increased by using a larger supporting glulam column. However, due to project design constraints on glulam member cross-section sizes, it was not possible to increase the bearing area by the full 1.5x adjustment factor determined from the Test 1 results. Only one edge of the column bearing length was increased from 228mm to 254mm. To account for this, the strength and stiffness of the bearing interface connection was supplemented with fully threaded compression reinforcing screws. Seven screws were installed into the underside of the beam with their countersunk heads installed flush and bearing over the bottom steel post base plate. The location of the screws in the connection area had sufficient wood cover to be thermally protected for the 2hr fire exposure as shown in Figure 14.

At a 2hr fire exposure, the screws were calculated to provide 76kN of supplemental ultimate bearing strength while the strength of the bearing area using a 1.5x adjustment factor was calculated to be 128kN. The resulting total calculated bearing capacity was 204kN. The calculated reduction in bearing area at 2hrs was 74% as show in in Figure 14.

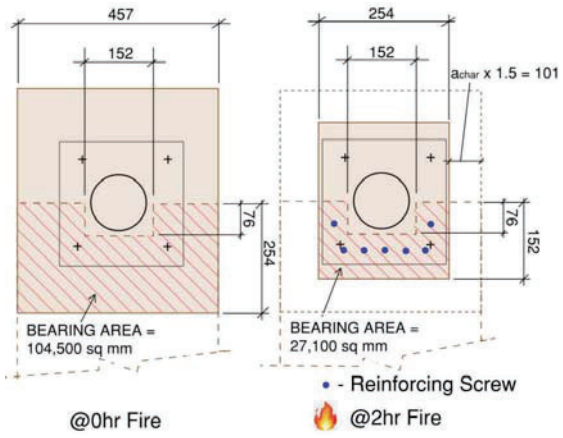

Figure 14: *The calculated bearing area for Test 2 at zero hour and 2hr using a 1.5x adjustment factor on achar.*

The Test 2 specimen successfully carried the applied 204kN actuator load for 2hrs. It is of note that in the last minutes of the test, the actuator extension increased exponentially from 10mm to 35mm indicating the connection was very close to its failure time. The actuator extension curve for Test 2 is provided in Figure 15.

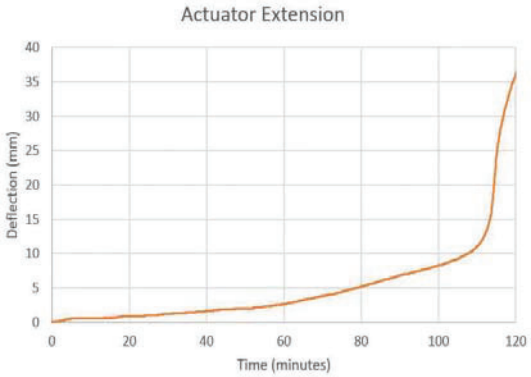

Figure 15: *Plot of the actuator extension vs. time for Test 2. The test was terminated at 120m.*

Figures 16 and 17 show the post-fire test disassembled beam exhibited significant perpendicular-to-grain crushing localized in the high bearing stress contact area. As well, the compression screws were observed to be permanently pushed into beam, providing visual evidence they supported load during the test.

Figure 16: *The disassembled specimen beam bearing area for Test 2. Note the localized permanent compressed wood at the high contact stress region (credit: Blomgren).*

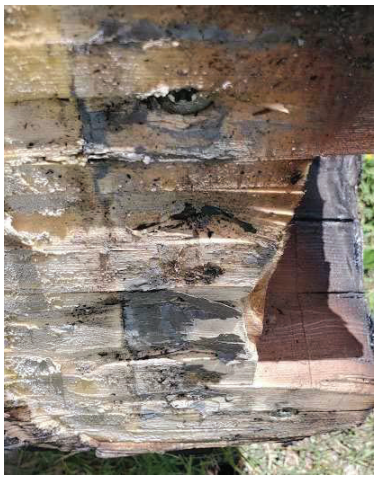

Figure 17: *A close up photo of the Test 2 beam bearing face shows the compression screw heads are permanently pushed into the wood surface (credit: Blomgren).*

9 CONCLUSIONS

Perpendicular-to-grain bearing for glulam beam-to-column connections are an efficient design option for building projects. To achieve a fire resistance rating through charring of the timber members, the bearing area needs to consider the reduced mechanical properties of the timber ahead of the char layer due to elevated temperature and moisture content and detail for construction tolerance gaps at the abutted surfaces. The fire testing in this paper has shown that engineering methods and guidance needs to be improved. A summary of observations and findings from this paper are as follows:

- ASTM D143 test methods and the testing by Madsen for non-fire conditions show that perpendicular-to-grain bearing strength of timber has a consistent transition or "proportional limit" between 1-2mm of indentation of the wood. For fire design, it is generally accepted that serviceability (deformation) limits states are not of concern. The fire tests presented in this paper measured deformations at time of failure that were an order of magnitude larger than for non-fire design conditions.
- Schaffer's research presented in Figure 6 shows temperatures up to 100C for a distance into the timber that is approximately equal to the char depth, when timber members are exposed to a fire temperatures such as ASTM E119. In the same region, the moisture content of the timber can also increase by 1.3x to 2x. Figure 7 from Shaffer's research shows the reduction in parallel-to-grain mechanical properties attributed to these effects.
- The summary report by Gerhards reported middle-trend immediate strength and stiffness loss for compression perpendicular-to-grain as high as 35% at 70C and MC>12%. These reductions are higher than those reported for parallel-to-grain and bending properties. There is a gap in the literature for perpendicular-to-grain mechanical properties greater than 70C.
- Joints and intersections need to be appropriately detailed with gaps to account for installation tolerances, shrinkage, and potentially rotation capacity of the connection due to design seismic drifts. Vertical abutted edges require fire protection products, such as intumescent fire tape to ensure the timber surfaces in the joint are not subject to charring.
- CNC fabrication and construction practices for the horizontal interface needs to assure uniform bearing of this joint. Testing performed by the American Wood Council and the testing presented in this paper found no evidence of accelerated charring at the bearing interface.
- Based on the testing presented in this paper, a 1.2x factor applied to the char depth for bearing strength calculations did not correlate well with Test 1 which failed at 72% of the targeted 2hr mark. Using the results of Test 1, it is possible to back calculate an approximate 1.5x adjustment factor applied to the char depth which correlates with the test outcome. This 1.5x factor has been adopted in the 2022 edition of the FDS for the design of bearing interfaces.
- Test 2 was redesigned based on the results of Test 1. Due to member size constraints for the building project a sufficient bearing area using the 1.5x factor could not be achieved. To provide supplemental connection strength and stiffness, fully threaded compression screws

https://doi.org/10.52202/069179-0238

were installed into the bottom of the supported beam over a steel post base plate. Test 2 successfully passed the ASTM E119 exposure by supporting the applied actuator load for 2hrs.

Engineering a mass timber bearing connection for fire resistance is more complex than just calculating a simple area of bearing based on ambient temperature strength. The area of weakened timber behind the char layer needs to also be addressed, given the reduced strength. A design approach has been recommended within this paper to address the fundamental issues.

FIRE RESISTANCE TESTING OF CLT-CONCRETE COMPOSITE FLOOR SLABS WITH STRIP NOTCH SHEAR CONNECTIONS

Javad Tashakori [1], Osama (Sam) Salem [2]

ABSTRACT: The latest edition of the National Building Code of Canada (NBCC 2020) permits wood products to be used as the primary material in constructing up to twelve-story buildings. This results in an enduring increase in the application of mass timber sections, such as glued-laminated timber (glulam) and cross-laminated timber (CLT). Timber floors in such tall mass timber buildings can be even more robust and span longer by adding a top concrete layer to allow the formation of timber-concrete composite (TCC) floor systems when adequate shear connectors are utilized. In TCC systems, notch connections can allow a gap between the timber and the concrete top layer to have a better floor system in terms of cost saving and acoustic characteristics.

This paper presents the experimental results of two full-size TCC floor slabs that have been examined under service load and standard fire exposure. Each test assembly had a 5300 mm total length with a 5000 mm clear span and 900 mm width. The composite sections were formed of a 5-ply CLT panel of 143 mm thickness and a 65-mm thick concrete layer on a 25-mm thick insulation layer. In those two fire tests, the performance of CLT-concrete composite slabs was achieved due to the nearly full composite action between the CLT panel and the concrete top layer, resulting from the utilization of 150-mm wide rectangular strip notch shear connections. Test results show that the failure of the composite slabs under standard fire exposure depends mainly on the reduction of the CLT section due to charring. However, due to the activation of the composite action, both composite floor slabs sustained the applied service loads for the 90 min duration of standard fire exposure. However, a whole-wide strip notch connection needs to be designed carefully to achieve acceptable fire resistance based on available design equations. In addition, having a whole-wide notch connection would influence the initial deflections of the supporting CLT panels while poured concrete is still wet if no shoring is provided in the middle of the slabs. Thus, to avoid excessive initial mid-span deflections and to meet the design serviceability requirements, intermediate support needs to be provided until concrete is hardened.

KEYWORDS: Timber-concrete composite sections, CLT panels, Strip notch shear connections, Fire performance

1 INTRODUCTION

Advantageously, engineered wood products, such as glued-laminated timber (glulam) sections and cross-laminated timber (CLT), have been utilized in tall wood building construction since they have less carbon footprint and construction costs than concrete and steel materials. Moreover, since mass timber panels, such as CLT panels, have high tensile strength and sufficient fire resistance, to be utilized in TCC floor systems, it is more likely that they provide flexural strength and stiffness comparable to concrete floor slabs. The current edition of the National Building Code of Canada (NBCC 2020) [1] permits wood products to be used as the primary material in constructing up to twelve-story buildings. This results in an enduring increase in the application of mass timber sections, such as glulam for beams and columns and CLT for walls and floors. Over the past few years, mass timber construction has been assembling momentum in North America since wood is an environmentally friendly and sustainable material with lower construction costs.

The CLT panels with structural polyurethane (PUR) adhesive conforming to ANSI/APA PRG 320 (up to its 2012 edition) were tested in several furnace experimental studies with the FPInnovations research programs [1-4]. Based on the outcomes of those studies, there has been one common observation, which is the falling of localized piece of the charred layers when the CLT lamination interface temperature reached 115 to 250 ºC. This phenomenon led the second and subsequent delamination to start earlier, which also was more pronounced for

[1] Javad Tashakori, Ph.D. Candidate, Dept. of Civil Engineering, Lakehead University, Ontario, Canada, jtashako@lakeheadu.ca
[2] Sam Salem, Professor and Chair, Dept. of Civil Engineering, Lakehead University, Ontario, Canada, sam.salem@lakeheadu.ca

https://doi.org/10.52202/069179-0239

thinner lamination. It is claimed that if it was desirable for greater fire resistance for CLT slabs, there should be no adhesive melting up to 300 ºC [5]. However, it was not a compulsory requirement for CLT manufacturers, that CLT products under fire conditions should be able to reach this temperature at the glue line without excessive delamination until the 2017 edition of ANSI/APA-PRG-320 [6] has been published.

TTC systems includes timber components which can be made of solid, glulam, laminated-veneer lumber (LVL), or CLT sections that are supporting and connected to a topping concrete layer (usually around 70 mm in thickness) utilizing a wide range of shear connectors. TCC floor systems own the advantageous characteristics of both materials (i.e., timber and concrete) if their shear connections are robust enough under service and ultimate design limits. In TCC sections, timber is used as the primary tensile load-carrying material due to its high strength-to-weight ratio. In contrast, concrete is used for its high compressive strength and advantages in terms of stiffness and acoustic characteristics.

The primary technique to provide a sufficient shear connection between the timber section and concrete layer in TCC sections is to use shear connections that come in various metal connectors, grooved connections, or adhesive connections. They include mechanical fasteners such as nails, screws, toothed metal plates, glued-in steel plates embedded into the timber, and notches cut from the timber or a combination of them. In order to estimate the composite strength of a TCC system with a well-recognized shear connection (stiffness and strength), Annex B of Eurocode 5 [7] provides the mechanically jointed beam theory (gamma method). In this method, a uniform distribution of shear connectors along the span of the floor is considered. Moreover, the flexural stiffness of both materials and the shear stiffness of the connection provides the composite flexural stiffness as well as the amount of axial and moment demands imposed on each material in such composite action.

The mechanical characteristics of various fasteners and connectors used for timber-to-timber joints are provided in Eurocode 5 [7]. Also, as far as the connection stiffness is concerned, for steel-to-timber or concrete-to-timber connections, the timber-to-timber joint stiffness might be multiplied by a magnifying factor. Salem and Virdi [8] experimented inclined self-tapping screw (STS) connections of CLT-concrete composite section through push-out direct shear tests. Tests results show that the stiffness of their STS shear connections was almost the same as that provided by Eurocode 5 [7].

As for determining the stiffness of notch connections, there has been no available analytical method so far and thus, only experimental evidences are used to predict its stiffness, otherwise the γ method strength predictions would not be accurate enough.

While the design of TCC sections with various mechanical shear connectors is well addressed in different design codes in the EU, there are no provisions in the current Canadian *Engineering design in wood* standard [9]. The only design guide that recently became available in Canada is the Design Guide for Timber-Concrete Composite Floors in Canada [10], which guides the design of TCC systems in ambient and fire conditions. Although several research studies were conducted to investigate the mechanical characteristics and structural behaviour of TCC floor systems under service and ultimate limit state conditions, there are still several uncertainties related to the influence of elevated temperatures on their structural fire performance. In general, TCC sections possess considerable fire resistance due to the large size of the timber cross-sections utilized in them; however, the type and design of the shear connectors in use significantly impact the actual behaviour of those composite systems when subjected to fire.

Van der Linden [11] introduced a relationship based on differential equations to define the more efficient composite action in which designers could avoid too thin concrete topping layer attached to mass timber beams and vice versa. In other words, an efficient composite action would be achieved with a concrete layer thickness that is more than 70 mm, which is common in construction. That ends up using a thicker concrete layer, which makes a TCC floor uneconomical. However, if there is a gap between the concrete top layer and the timber supporting component underneath, this would allow not only stiffer TCC sections but also economical floor systems. However, the fastener stiffness should be decreased by 25, 44 and 50% for gap/d ratio of 2, 3, and 4, respectively [12], where d is the diameter of the fastener based on Table 7.1 of Eurocode 5 CEN [7]. Therefore, it is significantly likely that a notch connection could accommodate this gap if the shear area of concrete at the notch is able to sufficiently transfer the shear forces at the interface between the concrete top layer and the supporting timber component with the existing constructional gap.

This paper presents the experimental results of two full-size, one-way TCC floor slabs that have been examined under service load and standard fire exposure. In the two fire resistance tests conducted as part of this current study, the performance of CLT-concrete composite floor slabs was achieved due to the nearly full composite action between the CLT panel and the concrete top layer resulting from the utilization of 150-mm wide rectangular strip notch shear connections with 25-mm thick gap in between the two materials to provide a more economical TCC floor system yet having considerable strength and stiffness.

2 EXPERIMENTAL PROGRAM

The main objective of the full-size testing of flexural TCC floor slab presented in this paper was to assess the performance of strip notch connections as they could accommodate the gap between the concrete top layer and the supporting CLT panel. Moreover, most tests done on

CLT-concrete composite systems experienced excessive ply fall off due to adhesive melting under fire conditions, while it is now an obligation requirement for CLT manufacturers to produce CLT panels that should be able to reach charring temperature without excessive delamination [6].

Therefore, designers might be able to have a low charring rate of 0.65 mm/min throughout the entire fire exposure time instead of the current design procedure assumption of 0.8 mm/min charring rate after the first major ply has burnt out. This assumption was based on ply fall-off phenomena which used to happen for CLT with polyurethane (PUR) adhesive in the past. The CLT panels utilized in the test specimens of this study were produced by Nordic Structures with the industrial name of Nordic X-Lam. This product is certified by APA (Product Report PR-L306C) per ANSI/APA PRG 320 standard [6].

2.1 TEST SPECIMENS DETAILS AND FABRICATION PROCESS

The fabrication of the two full-size TCC floor assemblies and their fire endurance testing were carried out at Lakehead University Fire Testing and Research Laboratory (LUFTRL). Each test assembly had a 5300 mm total length with a 5000 mm clear span and 900 mm width. The composite sections were formed of a 5-ply CLT panel of 143 mm thickness and a 65-mm thick concrete layer on a 25-mm thick insulation layer. The CLT panel in each test specimen was prepared with six rectangular strip notches each aligned in the transverse direction along the entire width of the panel, Figure 1. The insulation layer was deliberately added to enhance the flexural stiffness and the acoustic characteristics of the TCC floor assemblies and to maintain a reasonable cross-sectional moment of inertia with less weight, Figure 1.

The CLT panels utilized in fabricating the TCC floor assemblies tested in this study were Nordic X-lam cross-laminated timber that is certified E1 CLT stress grade, using 1950 Fb-1.7E Spruce-Pine-fir (S-P-F) MSR lumber in the longitudinal layers and No. 3/Stud S-P-F lumber in the transverse layers. This product is certified by APA (Product Report PR-L306C) per ANSI/APA PRG 320 standard [6] and shall be used in dry service conditions. As per the data published by Nordic Structures, the carbon balance is approximately -590.97 CO_2 of one cubic meter of Nordic X-Lam [13]. The concrete poured for the topping layer had a 28-day strength of 43 MPa and its strength on the fire test day was 46 MPa. Four 12-mm diameter lag screws were installed along each strip notch to allow more ductile performance for the TCC floor slabs in the ambient ultimate state.

The strip notch connections are normally strong enough connections to be implemented just at the far ends of a TCC element. However, such approach might not offer sufficient strength nor stiffness required for the fire resistance design based on the reduction of the structural integrity because of the cross-section loss due to charring. Therefore, with 800 mm spacing between the strip notches prepared in the CLT panels, there were six strip notches along the longitudinal direction of the floor slab to provide sufficient structural integrity during fire exposure, Figure 1. As far as the concrete depth along the span is concerned, in the three middle panels, a 65-mm thick concrete layer on top of a 25-mm thick insulation layer was considered to have sufficient composite action behaviour. However, in the two end panels from each end of the slab specimens, a full thickness (90 mm) of the concrete layer was cast to avoid any shear failure that could happened near the ends of the floor test specimens not during the fire tests but when the burned specimens are removed out of the furnace after fire testing, Figure 1.

2.2 TEST SETUP

Test specimens were loaded under four-point flexure bending using a steel spreader beam connected to the piston of a hydraulic cylinder that is attached above the furnace to the steel loading framed structure that is also supporting the fire testing furnace, as shown in Figure 1.

The load applied on each test specimen throughout the fire test consisted of 2.4 kPa dead load including self-weight and additional 2.4 kPa accounting for service live load. These loads were applied to the floor specimen at least 30 mins before the fire test started in conform to CAN/ULC-S101 [14]. Afterwards, the applied load was maintained constant throughout the entire duration of the fire test.

The vertical deflections of the test specimens were measured using draw-wire displacement transducers installed at three different locations along the length of the floor slabs: the midspan and under each point load (1667 mm apart and cantered along the specimen span).

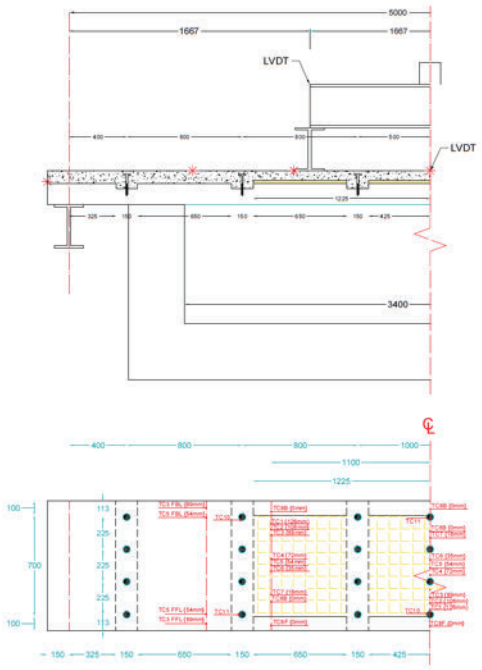

Figure 1: *A general test setup with a typical TCC floor test assembly with strip notch connections and thermocouples layout*

https://doi.org/10.52202/069179-0239

Each floor assembly was instrumented with 45 Type-K thermocouples that were inserted from the top inside pre-drilled tight holes with various depths into the CLT panels. A few thermocouples were placed at the interface between the CLT plys and at the mid-thickness of each ply. Other thermocouples were located at the interface between the concrete top layer and the CLT panel and at the coach screws. Figure 2 illustrates the distribution of thermocouples around one of the strip notches.

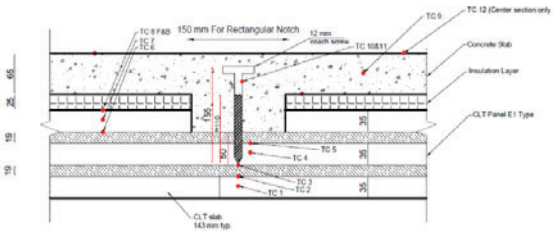

Figure 2: *Distribution of thermocouples around one of the strip notches*

3 DESIGN PROCEDURE

The current design method of timber structures is based on the limit states design (LSD) philosophy in Canada. It takes three design categories into account: Serviceability Limit States (SLS), Ultimate Limit States (ULS), and Fire resistance conditions. The serviceability limit states intend to guarantee the structural components be capable of sustaining the applied loads without any significant defects and/or service disruptions, including excessive deflection, vibration, permanent deformation, and local structural damage such as cracking [15].

3.1 NOTCH CONNECTION DESIGN

Design Guide of Timber Composite Floors in Canada [10] provides concrete crushing and shear failure strength capacity by Equations (1) and (2). These equations are much more conservative than their counterparts in the design guideline provided by Yeoh et al. [16]. Therefore, several strip notch connections need to be designed and implemented along the span of the TCC floor slabs tested in this study to achieve the targeted 2-hour fire resistance. However, cutting into the entire thickness of the utmost longitudinal ply of the CLT panel in the direction of major strength axis to accommodate the strip notch depth can reduce the overall flexural strength of the TCC section in fire conditions once the natural axis of the composite section escalates up and be relocated within the thickness of the concrete top layer. In addition, having a whole-wide notch connection would influence the initial deflections of the supporting CLT panels while poured concrete is still wet if no shoring is provided in the middle of the slabs. Thus, to avoid excessive initial mid-span deflections and to meet the design serviceability requirements, intermediate support needs to be provided until concrete is hardened. Alternatively, two-stage concrete casting procedure shall be followed. First, concrete shall be poured in the strip notch grooves prepared in the CLT panel until it reaches certain strength with rough surface condition and then, concrete could be poured over the entire floor CLT slab as a second stage.

$$V_{\mathrm{r,\,Conc.\ Comp.}} = \alpha_1 \phi_c f'_c d_n b_n, \quad \alpha_1 = 0.85 - .0015 f'_c \tag{1}$$

$$V_{\mathrm{r,\,Conc.\ Shear}} = 0.8P_{r,w} + 2.76\phi_c b_n(2d_n \tan(\theta) + L_n) \leq 0.5\phi_c f'_c b_n(2d_n \tan(\theta) + L_n) \tag{2}$$

Where, d_n is notch depth, b_n is notch width, $P_{r,w}$ is lag screw withdrawal resistance, L_n is notch length, and ϕ_c is the concrete resistance factor, Figure 3.

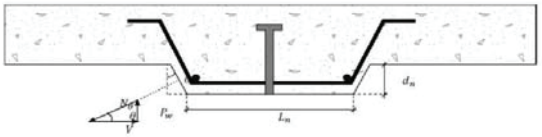

Figure 3: *Force equilibrium at notch connection*

3.2 ELASTIC DESIGN METHOD (γ-method)

As the shear connection performance determines the degree of composite action in a TCC floor systems, such sections shall be designed with this consideration whether the connection yielded before reaching the ultimate limit state condition or not. The γ method can predict the behaviour of TCC floor systems as long as the behaviour of the shear connection is still within the elastic region, such as those utilized nails, HBV steel plates, and notches. Alternatively, the Design Guide for Timber-Concrete Composite Floors in Canada [10] provides an elasto-plastic model (EPM) to capture the behaviour of TCC floor systems at the ultimate state limit with shear connections that can even sustain plastic deformations. However, since notch shear connections normally exhibit elastic behaviour, the γ method is accurate enough to estimate the flexural strength of TCC systems with strip notch shear connections.

4 RESULTS AND DISCUSSION

4.1 DEFLECTIONS

Figures 4 and 5 show the time-deflection curves developed based on deflection values measured at the midspan and left-side loading point for both floor assemblies, Slab 1 and Slab 2, respectively. Due to electronic malfunction in one of the displacement transducers, the floor deflections at the right-side loading point were not recorded. According to the presented time-deflection curves, both slabs experienced gradual increase in their vertical deflection until approximately 25 mins into the fire tests with a slop that is slightly higher than that experienced by both slabs for the next 25 mins (25 to 50 mins into the fire tests). It is worth mentioning that at 25 mins into the fire tests less than half the thickness of the first ply charred in both slabs according to the thermal measurements obtained. While at 50 mins into the fire tests the entire thickness of the first ply charred, which can

https://doi.org/10.52202/069179-0239

be correlated to the bounce back of higher slops exhibited by the time-deflection curves started at that time mark. Both slabs maintained that relatively linearly increased slop until almost the end of the fire tests when both tests were deliberately terminated a few mins after surpassing the targeted 90 mins fire resistance time mark.

At the termination time of the first tests (90 mins), the mid-span recorded deflections were 35 and 30 mm in Slab 1 and Slab 2, respectively, including the initial deflections due to the pilot loading applied before the start of the fire tests, Figures 4 and 5.

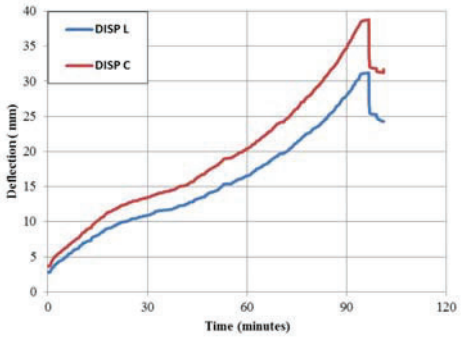

Figure 4: *Time-deflection curves of Slab 1*

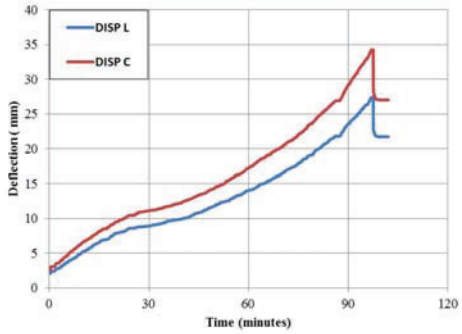

Figure 5: *Time-deflection curves of Slab 2*

Throughout the duration of the fire test, the char front progressed closer to the top plys. In particular, the top three plys in the CLT panel. The bottom of the middle longitudinal ply was the location of the thermocouple labelled TC3. The middle longitudinal ply was deemed critical for the targeted 90-min fire resistance under standard fire exposure if it burned away.

Figure 6 shows the time-temperature curves of the thermal measurements of the critical thermocouple (TC2) installed at the bottom of the first transverse ply and those measured by thermocouple TC3 installed at the bottom of the middle longitudinal ply at three different sections (L, M, and R) along the span of Slab 1. The left and right-side sections were 1100 mm offset from the midspan, as shown in Figure 1. As shown in Figure 6, as per the design of the TCC floor specimens, the bottom transverse ply began to char at approximately 55 mins as the temperature measured by TC2 reached 300 °C at this time mark. While the temperature measured by TC3 was less than 200 °C at the end of the fire test.

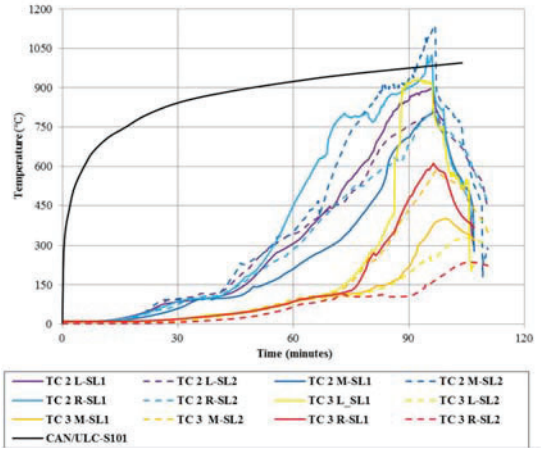

Figure 6: *Time-temperature curves of thermocouples TC2 and TC3 located at the three different sections in both slabs*

Figure 7 shows one of the floor test specimens (Slab 1) still burning right after the termination of the fire test and before extinguishing the specimen by spraying it with pressurized water mist.

Figure 7: *Slab 1 with its CLT panel still burning right after the termination of the fire test*

Table 1 presents the charring rate calculations based on the temperatures measured by the critical thermocouple (TC2) installed at the bottom of the first transverse ply and those measured by thermocouple TC3 installed at the bottom of the middle longitudinal ply at three different sections (L, M, and R) along the span of Slab 1. The average charring rates according to the calculations performed based on the thermal measurements of the selected thermocouples located at the three sections are 0.63 and 0.61 mm/min for Slab 1 and Slab 2, respectively. It is worth mentioning that there was no delamination observed due to adhesive melting in the CLT panel of any of the two test specimens. Thus, the calculated charring rates based on actual thermal measurements meet those rates provided in ANSI/APA-PRG-320 [6] as a requirement of reaching 250 ºC temperature at the glue line without excessive delamination.

https://doi.org/10.52202/069179-0239

Table 1: *Calculated charring rates based on measured temperatures at the three different sections in both slabs*

TC No.	Section along the span	Ply used for the charring rate calculations	Charring rate (mm/min) Slab 1	Slab 2
TC 2	Left	1st long. ply	0.59	0.64
TC 3		1st trans. ply	0.83	0.54
		1st long. & trans. plys	0.66	0.60
TC 2	Middle	1st long. ply	0.50	0.64
TC 3		1st trans. ply	0.85	0.63
		1st long. & trans. plys	0.58	0.64
TC 2	Right	1st long. ply	0.64	0.57
TC 3		1st trans. ply	0.67	0.66
		1st long. & trans. plys	0.65	0.60

5 CONCLUSIONS

Two identical full-size, one-way CLT-concrete composite floor slabs have been fire tested at Lakehead University Fire Testing and Research Laboratory (LUFTRL). Based on the design equations provided in the Design Guide for Timber-Concrete Composite Floors in Canada [14], the strip notch connections of the two test specimens were designed.

As a result of the activation of the composite action between the concrete top layer and CLT panel, both TCC floor slabs sustained the applied service loads for the 90 min duration of standard fire exposure. This show at least 30 mins added to the 1-hr fire resistance that those CLT panels with the same span (5000 mm) can have under the same applied load (4.8 kPa), as per the data provided by their manufacturer.

According to the outcomes of this new experimental research study, it is recommended that for strip notch connections in TCC floor assemblies like the ones examined under standard fire exposure in this study, at least one longitudinal ply in the major strength direction other than the utmost longitudinal ply that was cut due to the implementation of the six rectangular notches along the length of the CLT panel needs to stay unburned and remain in the residual section of the TCC after fire.

Another important observation is that having a whole-wide strip notch connection would influence the initial deflections of the supporting CLT panels while poured concrete is still wet if no shoring is provided in the middle of the slabs. Thus, to avoid excessive initial mid-span deflections and to meet the design serviceability requirements, intermediate support needs to be provided until concrete is hardened.

ACKNOWLEDGEMENT

This research project has been mainly funded using the Discovery Grant awarded to the second author by the Natural Sciences and Engineering Research Council of Canada (NSERC). The authors would like to thank Nordic Structures for their support and generous in-kind contributions in form of providing all CLT panels used to fabricate the large-size TCC floor test assemblies examined in this project. Thanks are extended to Pioneer Construction Inc., Miller Precast Ltd., and Harris Rebar (Thunder Bay) for their in-kind contributions. Thanks are due to lab technologist, Mr. Cory Hubbard for his great assistance during the experimental investigation stage of this project.

FIRE RESISTANCE TESTING OF CLT-CONCRETE COMPOSITE FLOOR SLABS UTILIZING GLUED-IN STEEL PLATES AS SHEAR CONNECTORS

Adam Petrycki[1], Osama (Sam) Salem[2]

ABSTRACT: Timber-concrete composite (TCC) sections have shown desirable mechanical characteristics for use in the structural design of mass timber buildings at both ambient and elevated temperatures. TCC sections have advantages over conventional steel-reinforced concrete elements or timber elements on their own. While some recent performance-based design guidelines have been developed to aid in the design of TCC sections, they primarily rely on experimental data from specific TCC arrangements with certain types of shear connectors (e.g., steel plates, metal screws, etc.). The study presented in this paper involves experimental testing of two full-size CLT-concrete composite one-way floor slabs that were exposed to elevated temperatures of the CAN/ULC-S101 standard fire time-temperature curve, while being subjected to four-point flexure bending that is equivalent to the moment developed by a uniformly distributed 4.8 kPa service load. Each TCC slab assembly had a clear, simply supported span of 5000 mm and a width of 900 mm. The CLT panel composition (5 plys) and thickness (143 mm) were chosen to investigate how its one-hour fire resistance under the applied service loads could be increased to two hours by developing the composite action with the added concrete layer (90 mm thick) that otherwise would impose |dead load on the CLT panel without contributing to the overall strength of the floor system. Shear connectors utilized in these two TCC floor assemblies were perforated steel plates installed in prepared longitudinal slots using epoxy.

KEYWORDS: Timber-concrete composite (TCC) sections, Glued-in steel plates, Shear connectors, Fire performance

1 INTRODUCTION

Timber-concrete composite (TCC) systems were initially developed and used before being replaced by reinforced concrete slabs several decades ago. Nowadays, such composite systems are experiencing increased use in new construction and rehabilitating existing timber structures. TCC systems are developed by creating a shear connection between a timber section carrying the tensile forces and a concrete topping layer to carry the compressive forces. The behaviour of a TCC section is defined mainly by the rigidity of the connection between the two materials. Failure in such composite systems can occur as brittle failure in the wood section or a brittle or ductile failure at the interface of the connection between the two materials [1]. While mechanical shear connectors, such as screws and steel plates, are approved for specific composite systems in the EU, there are no provisions in the current Canadian standard for *Engineering design in wood* [2]. The only guidance available for engineers in Canada is the recently developed *Design guide for timber-concrete composite floors in Canada* [3], which provides some guidance for the performance-based design of TCC systems at normal and elevated temperatures with mechanical connectors such as screws, plates, and notches in the timber section.

Recent changes in the National Building Code of Canada [4] have allowed for the construction of timber buildings up to 12 storeys if a solid core is designed for lateral loads, such as the recently completed Brock Commons building at the University of British Columbia [5]. The two-way CLT floor slabs were designed to be point-supported on glulam columns with a concrete layer on top in the said building. However, no composite action was developed between the two materials. Thus, the concrete's compressive strength was not fully utilized to increase the stiffness of the floor system or its fire resistance; both are observed benefits of TCC systems [6]. Due to the non-homogenous nature of timber, extensive testing is required on the shear connectors to determine their stiffness, strength, and ductility ratio. Once those characteristics are defined, large-size samples are tested to validate the small-size experimental results and then evaluate how the characteristics of the examined shear connectors can influence the overall behaviour of TCC systems. Ultimately, TCC systems with certain engineered wood products and selected types of shear connectors/connections undergo standard fire testing. The experimental results of a very limited selection of shear connections in CLT-concrete composite floor systems can be found in the available literature, especially in the context of large-scale specimens. The focus has been primarily on notched connections [7] or dowel type

fasteners and nailed plates [8-10]. Thus, there is a lack of studies on longitudinal connectors secured by adhesive in CLT floor panels, such as the glued-in steel plates utilized in the floor assemblies tested in the current study.

This paper presents the experimental results of two full-size CLT-concrete composite, one-way floor slabs exposed to elevated temperatures of CAN/ULC-S101 standard fire [11], while being subjected to four-point flexure bending that is equivalent to the moment developed by a uniformly distributed 4.8 kPa service load, are presented. The TCC floor slabs involved in this study utilized glued-in perforated steel plates as shear connectors.

2 EXPERIMENTAL PROGRAM

2.1 SPECIMEN DESIGN AND DESCRIPTION

For the design of the TCC floor test specimens of the present study, the gamma and elastoplastic methods were used to determine their flexure bending strength. Hence, their time to failure under standard fire exposure was determined before conducting the fire endurance experiments. Both test specimens were 5300 mm long x 900 mm wide, with a 5000 mm clear simply supported span. The TCC floor assemblies were composed of 5-plys CLT panels of 143 mm thickness, alternating between 35-mm thick lamina in the major axis direction and 19-mm thick lamina in the minor axis direction. A regular strength concrete layer, with a thickness of 90 mm and a 28-day strength of approximately 40 MPa was cast on top of the CLT panel and reinforced with the minimum required steel reinforcement to prevent shrinkage cracking. According to the design, the shear connectors utilized to develop the composite action in the TCC sections were longitudinal glued-in perforated steel plates that measured 254 mm long x 90 mm high. The plates were embedded inside 40-mm deep longitudinal kerf cuts of approximately 3 mm width prepared in the CLT panel. Steel plates were affixed to the CLT panel using a two-component epoxy. The remaining 50 mm depth of the steel plates was embedded within the concrete layer. It is worth mentioning that the mechanical characteristics of the utilized proprietary glued-in Holz-Beton-Verbund (HBV) steel plates are documented, and those types of shear connectors are already installed in a few mass timber buildings recently constructed in North America. A plan view of the layout of the longitudinal steel plate shear connectors in one of the TCC floor assemblies is shown in Figure 1.

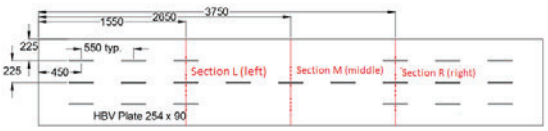

Figure 1: *Plan view of the layout of the steel plate shear connectors in a typical TCC floor assembly*

The relevant design and mechanical properties of the TCC components are summarized in Tables 1 through 3. Based on the listed values, the CLT slabs deflection under simply supported conditions (to mimic the in-site use of the CLT panels as form work) from the curing concrete was calculated and checked against the allowable deflection of *Span/360* and found to be within the allowable design serviceability limits.

Table 1: *Mechanical properties of the utilized CLT panels*

CLT floor panel properties	
M_r	65.0 kN.m
T_r	1780.0 kN
V_r	43.0 kN/m
EA	1480.0 x10^3 kN

Table 2: *Concrete properties*

Concrete slab properties		
	Test 1	Test 2
f'_c	36.94 MPa	40.43 MPa
ρ_c	2477 kg/m^3	2458 kg/m^3
Slump	90 mm	85 mm
Maximum aggregate size	13 mm	13 mm

Table 3: *Mechanical properties of the utilized steel plates*

HBV steel plate shear connector	
V_r	24.4 kN
k_s	209 kN/mm
k_u	139.3 kN/mm

Using the CSA-O86 Standard [2] and the FPI Design Guide for TCC Floors in Canada [3], the design of the TCC floor test assemblies was checked for vibration criteria and SLS and ULS limits under 2.4 kPa dead load (including slab's own weight) and 2.4 kPa live load combinations, and was found to be adequate. Also, based on an assumed notional charring rate of 0.65 mm/min, the TCC test assemblies were determined to safely achieve a 2-hr fire resistance time before failure.

2.2 INSTRUMENTATION

Each specimen had 37 Type-K thermocouples installed at varying depths at three sections (namely Sections L, M and R), as shown in Figure 1. The layout of the thermocouples installed at Section L (near the left side of the specimen within the maximum shear force zone) is shown in Figure 2. While Figure 3 illustrates the distribution of the thermocouples installed at different depths at Section M (at the middle of the specimen within the maximum bending moment zone).

https://doi.org/10.52202/069179-0240

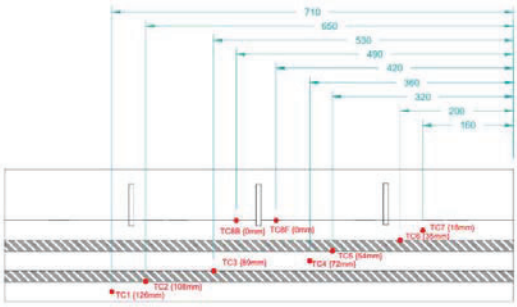

Figure 2: *Thermocouples layout at Section L, where the maximum shear exists (cross-section view)*

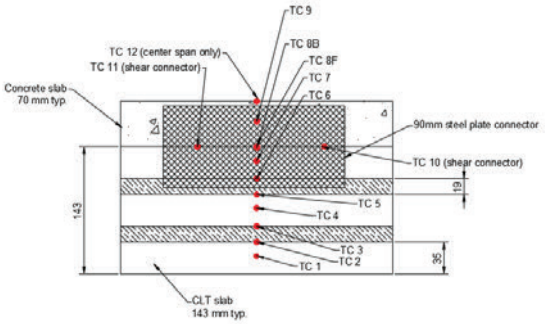

Figure 3: *Thermocouples layout at Section M, where the maximum bending moment exists (sectional-elevation view)*

Thermocouples were distributed to capture a representative sampling of the thermal measurements due to standard fire exposure over the width and along the length of the floor slabs. Also, careful attention was given to ensure that thermocouples were installed in their respective holes drilled to the correct depth, Figure 4.

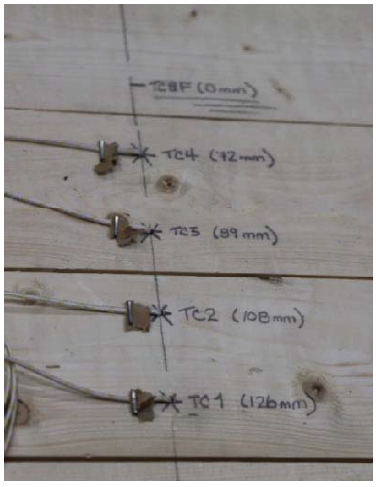

Figure 4: *Thermocouples installed and labelled in one of the two CLT panels*

The temperature readings were used to monitor the test specimens during fire testing and thus, thermal measurements were used to calculate the charring rates which were then compared to the thicknesses of the residual CLT sections measured after the completion of the fire tests.

In addition to the thermal measurements, it was essential to evaluate the mechanical behaviour of the test assemblies by measuring their vertical deflections at three different locations: at the midspan of the specimen and at each of the two applied load points. Thus, three draw-wire displacement transducers were installed above the furnace and safely connected to the top surface of each test specimen.

2.3 TEST SETUP

The two full-size TCC one-way floor slab assemblies were experimentally examined at elevated temperatures following the CAN/ULC-S101 standard fire time-temperature curve. During fire tests, floor assemblies were subjected to four-point flexure bending equivalent to a 4.8 kPa service load (2.4 kPa dead load including the slab's own weight, and 2.4 kPa live load). The loading equals the maximum service load applied to the CLT panels with the same span designed to have a 1-hr fire resistance. The study parameters and matrix of the fire experiments presented in this paper are summarized in Table 4.

Table 4: *Study parameters and matrix of fire experiments*

Test ID.	TCC-HBV-CC
Number of tests	2
Shear connector	254 x 90 mm, HBV steel plates
Wood material	900 mm wide x 143 mm thick x 5000 mm span (5-ply) E1-grade CLT
Concrete material	90 mm conventional concrete, ~ 40 MPa, with 6-mm dia. welded wire mesh
Designed fire resistance time	120 min

A sectional-elevation view of the test set-up applied for the fire experiments of this study is illustrated in Figure 5.

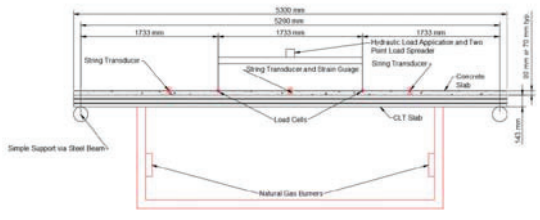

Figure 5: *A typical TCC floor assembly test setup and mechanical instrumentation layout*

https://doi.org/10.52202/069179-0240

TCC floor test assemblies were subjected to monotonic loading throughout the entire duration of the standard fire endurance tests. Shortly after each floor assembly achieved the 2-hr fire resistance time mark, test was deliberately terminated. Figure 6 shows one of the TCC floor test assemblies installed on top of the large-size furnace accommodated at Lakehead University Fire Testing and Research Laboratory (LUFTRL).

Figure 6: *A TCC floor assembly installed on top of the large-size furnace accommodated at LUFTRL*

Throughout the entire duration of each fire test, the applied transverse load was kept constant as the floor slab continued deflecting. Vertical deflections, applied load, and external and internal temperatures were all monitored and logged over the course of each fire test via a data acquisition system connected to a computer. Also, the test specimens were periodically monitored visually through the two observation viewports on the furnace front door. The underside of the first test specimen undergoing fire testing is shown via one of the viewports in Figure 7.

Figure 7: *The underside of a TCC floor assembly undergoing fire testing captured via one of the furnace's viewports*

After the termination of the fire tests, the underneath of the TCC slabs, which were still burning, were sprayed with pressurized water mist. Then, the specimens were removed out of the furnace for examination and visual inspection to determine the thickness of the remaining uncharred CLT section once the char layer was removed.

3 RESULTS

Test specimens were exposed to the CAN/ULC-S101 standard time-temperature curve for a few additional minutes beyond the two hours, exactly 126 minutes, to ensure satisfaction of the designed 2-hr fire resistance rating required by applicable building codes for the construction of tall timber buildings in Canada. Both samples sustained a 28.0 kN.m bending moment applied at their midspans under simply supported end conditions for the entire duration of the 2-hr standard fire exposure with no run-away deflection or any other characteristics of failure. This shows that a significant increase (more than 1 hr) in fire resistance time can be achieved for CLT floor slabs like the ones utilized in this study with the addition of a top layer of concrete that can work in composite action with the supporting mass timber section as a results of the utilization of the HBV glued-in steel plates as shear connectors between the timber and concrete elements in such TCC floor systems.

3.1 MECHANICAL BEHAVIOUR

After casting the concrete layer on top of the CLT slab, the initial mid-span deflections of the prepared test specimens due to the weight of wet concrete were measured and found to be 6.7 mm and 9.3 mm for Slabs 1 and 2, respectively. Afterwards, the test specimens were stored indoors for at least 28 days for full concrete curing, before each TCC floor assembly was installed on top of the furnace. Before the commencement of the fire test, a two-point load causing a maximum bending moment of 28.0 kN.m at the specimen midspan was applied in four increments, each of 25%, with the total applied load maintained stable for at least 30 minutes in conformity with CAN/ULC-S101. Then, the vertical deflections were measured due to the pilot loading prior to the start of the fire test. The applied bending moment maintained relatively constant throughout the entire duration of the fire test, while the gradually increased vertical deflections of the specimens were measured and recorded. The time-deflection curves for both floor slabs are shown in Figure 8.

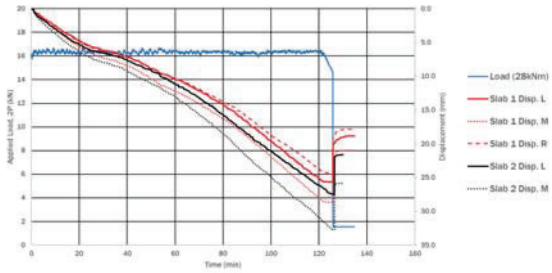

Figure 8: *Time-deflection curves for Slab 1 and Slab 2*

A summary of the maximum vertical deflections measured at the slab midspan and each point-load location is provided in Table 5. Readings for the right-side deflections of Slab 2 were not recoded due to a malfunction that occurred with the displacement transducer prior to the start of the fire test.

https://doi.org/10.52202/069179-0240

Table 5: *Summary of the maximum vertical deflections measured for Slab 1 and Slab 2*

Test specimen	Initial deflections due to weight of wet concrete (mm)		
Slab 1	6.7		
Slab 2	9.3		
	Deflections due to pilot loading (mm)		
	L	M	R
Slab 1	2.9	3.9	3.7
Slab 2	2.6	3.0	Error
	Final deflections right before terminating the fire tests		
Slab 1	29.1	32.1	28.4
Slab 2	32.7	38.7	Error

Generally, the vertical deflection values were found to be in good agreement with each other and consistent over the two slabs. From the time-deflection curves previously shown for both slabs in Figure 8, the floor slab deflection behaviour was more of a linear increase, which is characteristic of the reduction of the CLT cross-section over time due to charring. No exponential trend or run-away deflection was observed for the time-deflection curves for any of the two floor slabs throughout the entire duration of the 2-hr fire tests. It is worth mentioning that the deflection values rebounded a noticeable amount when the load was removed at the termination of the fire test. This behaviour is aligned with the TCC sections still undergoing elastic deformations and not exhibiting any plastic deformations in their shear connectors or brittle failure in the timber nor concrete components.

3.2 THERMAL BEHAVIOUR

Over the course of the 2-hr fire test, 37 thermocouples measured the internal temperatures of each test specimen at different locations with various depths. As the CLT bottom plys burned away, the exposed thermocouples were found to reach and follow the time-temperature profile of the followed standard fire as anticipated.

As the fire test progressed, the charring front moved closer to the more critical plys. These plys were the last two remaining plys in the CLT panel (one transverse with a 19 mm thickness and the very top longitudinal ply with a 35 mm thickness). The bottom of the last transverse ply was the location of the thermocouple labelled TC5. The transverse ply was deemed critical for the 2-hr standard fire exposure, not because the assembly could no longer sustain the load if it burned away, but for two reasons:

1) As per the composition of the utilized CLT panels, the transverse glued layer transfers the load to the remaining longitudinal plys, which were not edge glued. If the said transverse ply burned away, the CLT slab would no longer be in a composite action with the top concrete layer and thus, the behaviour of the remaining very top longitudinal ply solely supporting the concrete layer could no longer be as accurately predicted with either the gamma method or the elastoplastic method;

2) Since the HBV steel plate shear connectors were installed into the CLT panels using an epoxy material that is sensitive to elevated temperatures a minimum wood cover needed to be maintained to ensure the integrity of the adhesive and accuracy of the predicted behaviour of the shear connection with no failure in the adhesive due to fire exposure.

Figure 9 shows the time-temperature curves of the thermal measurements of the critical thermocouple (TC5) installed at the bottom of the top transverse ply and those of the thermocouple installed at the mid thickness of the said ply (namely TC6) in one of the slabs (i.e., Slab 1). As shown in the figure, as per the design of the TCC floor specimens, the top transverse ply began to char near the end of the fire test at approximately 123 minutes as the temperature measured by TC5 reached a temperature of 300 °C at this time mark.

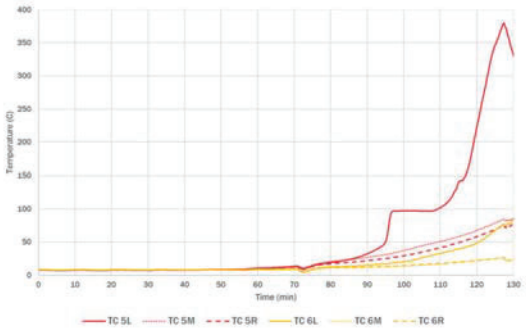

Figure 9: *Time-temperature curves of thermocouples TC5 and TC6 installed in Slab 1*

Generally, it was observed from the thermal results that the internal temperatures measured at the midspan of the floor slabs (Section M) increased with time to reflect a charring rate that is close to the notional rate of 0.65 mm/min that is standard for the utilized CLT panels. However, in the maximum shear zones of the floor slab, near the walls of the furnace, steeper temperature gradients were observed. Due to the non-combustible nature of the furnace insulated walls, fire vortexes formed at the corner where the furnace wall intersects with the underneath surface of the test specimen at each end. While this phenomenon unrealistically increased the charring rates near the left and right-side walls of the furnace, it did not affect the fire resistance of the test specimens or prematurely fracture the remaining longitudinal ply at the midspan where the maximum bending moment exists. This confirmed a continued composite action between the CLT plys remained after charring and the concrete layer until the termination of the fire resistance test at 126 minutes.

3.3 CHARRING RATE

After the TCC floor slabs were taken out of the furnace, they were securely positioned on their back longitudinal edge to allow for the removal of the developed char layer as shown in Figure 10 for Slab 1. The char layer was removed on the entire bottom surface of each test specimen using a wire brush on an electrical drill. Figure 11 shows the residual CLT section at the midspan of Slab 2 after removing the char layer.

Figure 10: *Char layer removed on the entire bottom surface of Slab 1*

Figure 11: *Residual CLT section at the midspan of Slab 2 after removing the char layer*

Once the char layer was removed, small holes were drilled into the CLT residual section at different locations until the drill bit touched the concrete slab. A digital calliper was inserted into the drilled holes to measure the residual thickness of the CLT section. The average thickness of the CLT residual section from various locations near the midspan of the test specimens were found to be 57 mm and 59 mm for Slab 1 and Slab 2, respectively.

The CLT residual thicknesses are reflective of a 2hr and 6-minute standard fire exposure, followed by approximately 5 minutes of a cool down phase before extinguishing of the test specimens started. Therefore, the charring rate was found to be between 0.65 mm/min and 0.68 mm/min assuming a time of either 131 minutes or 126 minutes, respectively. Based on the thermal measurements taken by the thermocouples implemented inside each test specimen (discussed in Section 3.2), the average charring rate was calculated at approximately 0.65 mm/min based on the assumption that the location of the char front in the CLT slab corresponded to a thermocouple reading of 300 °C.

4 DISCUSSION

The new results of the fire resistance tests of the two full-size one-way TCC floor slabs show that both test specimens achieved the targeted two-hour fire resistance time. Neither slab experienced failure while loaded with a total service load equivalent to 4.8 kPa over the course of exposure to two hours of a CAN/ULC-S101 standard fire. The CLT slab itself, under the same loading conditions, which could include a poured concrete layer without composite action with the supporting CLT slab, was only rated for a 60-minute fire resistance. The experimental results were found to be in good agreement with the predicted design calculations and the assumed charring rate used in the design of the CLT residual sections at the 2-hr fire resistance time mark were confirmed to be accurate. In addition, the fire performance of the HBV steel plates as the shear connectors used in the test specimens of the present study can be accurately predicted using the gamma method or the elastoplastic method based on the following two assumptions:

1. A minimum adequate thickness of a wood layer beneath the kerf saw cut in the CLT floor slab is maintained over the duration of the fire and thus, at no point the adhesive securing the steel plate connector into the timber is exposed to direct fire.
2. That the remaining plys of the CLT floor slab maintain its mechanical properties over the course of the fire. In the case of the CLT panels used in the experiments of the present study, the laminas were not edged glued and thus, it had the bottom underlying transverse layer (second ply from the bottom) burned away completely near the end of the 2-hr fire test. Accordingly, there would have been little to no interaction between the individual longitudinal lamina and the shear connectors would only be interacting with the longitudinal lamina they were embedded in and not

https://doi.org/10.52202/069179-0240

any adjacent longitudinal lamina without shear connectors in the wood

5 CONCLUSIONS

Using the HBV glued-in steel plates as effective shear connectors enhanced the fire resistance of the two CLT-concrete composite floor slabs tested in this study by creating a near-complete composite action that achieved a minimum fire resistance of two hours as required by applicable building codes for mid-rise residential buildings. The designed TCC floor slabs satisfied deflection limits during the initial concrete curing stage. Also, the stiff shear connectors increased the degree of composite action between the CLT and concrete layer and thus, reduced the mid-span deflections of the TCC slabs under the applied load, keeping the exhibited deflections within the allowable limits for SLS criteria. The TCC slabs were found to satisfy ULS criteria at both ambient and after a 2-hr standard fire exposure. The ambient and fire design outcomes based on the gamma and elastoplastic methods for the experimentally examined TCC floor slabs were found to be supported by the experimental results and thus, their fire behaviour was proven to be accurately predicted.

ACKNOWLEDGEMENT

This research project has been mainly funded using the Discovery Grant awarded to the second author by the Natural Sciences and Engineering Research Council of Canada (NSERC). The authors would like to thank Nordic Structures for their support and generous in-kind contributions in form of providing all CLT panels used to fabricate the large-size floor test assemblies examined in this project. Thanks are extended to Pioneer Construction Inc., Miller Precast Ltd., and Harris Rebar (Thunder Bay) for their in-kind contributions. Thanks are due to lab technologist, Mr. Cory Hubbard for his great assistance during the experimental investigation stage of this project.

FIRE RESISTANCE TESTING OF CLT-CONCRETE COMPOSITE FLOOR SLABS UTILIZING SELF-TAPPING SCREWS AS SHEAR CONNECTORS

Sarah Barclay[1], Osama (Sam) Salem[2]

ABSTRACT: In massive production, mass timber sections made of engineered wood, such as cross-laminated timber (CLT) panels, accelerated the pace of the construction of tall wood buildings in North America in the past few years. However, more stringent fire safety measures are applicable to tall timber buildings. Most critically, floor systems in mass timber buildings can be made more robust, span longer distances and exhibit enhanced fire resistance by adding a top layer of concrete to allow a timber-concrete composite (TCC) floor system when adequate shear connections are utilized. This paper presents the experimental results of the fire resistance tests of two full-size, one-way TCC floor slabs that utilized self-tapping screws (STS) as shear connectors. The main objective of this new experimental study is to investigate the enhancement of the fire performance when designing a CLT panel as a TCC floor assembly through achieving the required composite action with a top concrete layer at the interface between the two materials. Test results show that a minimum fire resistance of two hours required by applicable building codes for mid-rise residential buildings has been achieved for CLT floor panel by designing it as a TCC floor assembly, taking advantage of the composite action activated by the utilization of 45-degree inclined STS as shear connectors.

1 INTRODUCTION

A key aspect of structural engineering research and design is looking at the optimization of sections and finding more efficient solutions to fundamental behaviours. That is the primary motivation and reasoning behind the design of composite structural members. They are maximizing the strengths of materials and compensating for the weaknesses. While many composite members can be designed, timber-concrete composites (TCC) sections are of great interest, with the timber material resists the tensile stresses and concrete resists the compressive stresses.

TCC sections are an excellent solution for both designing new structures and restoring existing timber structures since a fundamental improvement is in service for vibration and drastic change possible for fire resistance rating requirements in current building codes and design standards. Thereby, increasing the possibility of not only building tall with timber but also leaving the material exposed, impacting the architectural concept of the structure, and increasing the use of engineered-wood products (EWPs) as a design solution.

As under current standards, the only possibility to design tall mass timber building is with incorporating a type of construction known as Encapsulated Mass Timber Construction (EMTC). This forms an alternative solution for tall wood buildings to meet the code objectives and functional statements pertinent to the requirements of the combustible construction [1]. EMTC is defined as a type of construction in which a degree of fire safety is attained using encapsulated mass timber elements with an encapsulation rating and minimum dimensions for the structural timber members and other building assemblies [2].

In recent years, there has been a new surge of interest and studies for the introduction of EWP in taller mass timber buildings. Such products include cross-laminated timber (CLT) panels, which has been gaining popularity since they were first introduced in the early 1990s in Europe. Not initially examined in Canada until 2007, and not until 2017 when it was fully implemented into CSA-O86 *Engineering design in wood* standard [3]. CLT panels are mass timber sections made by gluing and pressing wood lamellas with alternating fibre directions (±90°) [4]. The panels shall have an odd number of lamellae (Typ. 3, 5, 7, or 9) arranged symmetrically around the centre layer, with the thickness of each layer ranging from 20 to 45 mm.

It is typical in mass timber construction to pour a concrete layer on top of timber floor slabs to improve their vibration and acoustic characteristics as well as to provide a space for conduits to run electrical and plumbing

[1] Sarah Barclay, Ph.D. Student, Dept. of Civil Engineering, Lakehead University, Ontario, Canada, sbarclay@lakeheadu.ca
[2] Sam Salem, Professor and Chair, Dept. of Civil Engineering, Lakehead University, Ontario, Canada, sam.salem@lakeheadu.ca

https://doi.org/10.52202/069179-0241

utilities. However, this practice is a missed opportunity to improve the overall structural behaviour and fire resistance of such timber floor sections. TCC sections have the involved materials (i.e., timber, concrete, shear connectors, etc.) working together in each respective strength and thus, altering the location of the neutral axis of the composite section to achieve the maximum possible strength and stiffness.

Contrary to popular belief and hesitation when considering mass timber materials for construction, they have excellent fire resistance and perform well under elevated temperature conditions. Although without verified test results, it causes a limitation of the industry's progression and possibilities when considering building tall in timber and options to have structural elements left exposed.

2 LITERATURE REVIEW

2.1 CLT BEHAVIOUR UNDER FIRE

To design TCC sections utilizing CLT panels, it is essential first to understand the expected behaviour and performance of the mass timber panel as a standalone element. More extensive research programs have focused on CLT panels when exposed to fire. Most of the fire testing completed when studying the behaviour of CLT floor slabs followed standard fire testing conditions. It is the most straightforward approach for comparing results with different parameters or materials for equivalent fire severity. However, studying test specimens under natural fire conditions allows a more accurate representation of fire in a realistic setting. The key benefit of natural fire exposure is adjusting for different ventilation conditions. This mainly affects the fire growth rate, as when a fire reaches the point of flashover, this influences the duration of the steady state burning stage of the fire.

The studies conducted by Mindequia et al. [4] and Wiesner et al. [5] were both part of the Epernon Fire Test Programme, a multi-partner collaborative research project launched in 2017 and focussed in its studies on the comparison between natural and standard fires in their effects on buildings. For the studies conducted by Frangi et al. [6] and Wang et al. [7], the primary study parameter was changing the thickness and number of plys used in the composition of the CLT panels, as well as the corresponding changes in the temperature profile and charring rate of their test specimens. In the study conducted by Mindeguia et al. [4], the structural capacity of the CLT panels was investigated, while Wiesner et al. [5] examined the thermo-mechanical behaviour of the CLT panels.

As with studying the fire performance of any construction material, it is crucial to understand the development and progression of heat transfer within the material. It is even more critical with CLT panels and other engineered-wood products. Such products are not homogenous, and their composition involves adhesives, even in relatively small amounts. Having accurate temperature readings throughout the sections is critical, as this information is essential to determine the actual charring rates and depths.

When fire contacts wood, a charred layer on the side of contact is formed, and as the heat continues to grow, the thickness of the char layer increases. Advantageously, this char layer protects the remaining uncharred core of the cross-section that is not yet exposed to fire. However, there is still a reduction in the cross-section area sustaining the applied loads. When studying the fire performance of CLT panels, a significant difference in the cross-section overall fire resistance is whether the charred layer falls off or remains intact. If the charred layer falls off, the protective function it gives is lost; thus, a new char layer starts forming. When a layer falls off, there is an increase in the charring rate as the underlaying layer becomes exposed to elevated temperatures that are higher than its initial temperature at the beginning of the fire test. Falling off of those layers is described as a delamination effect. This can occur locally at isolated locations, or globally when most of a ply falls simultaneously from a CLT slab exposed to fire.

Charring rate is evaluated by determining the thermal progression throughout a fire test and then, comparing temperatures afterward to determine the time each point reached 300°C. In general, the nominal charring rate of solid and glued-laminated timber sections under one-dimensional standard fire exposure is 0.65 mm/min, given by Eurocode 5. While, in general, the values agree reasonably well with the standard value from Eurocode 5, there is still some differences. This suggests that the charring rate alone is insufficient for predicting the residual loading capability of CLT floor slabs.

Thermocouples are essential to monitoring temperature, but they are limited by their placement location and can only determine when that spot reaches the critical temperatures. By removing the charred thickness and measuring the remaining section, a more holistic view of the slab performance and the differences across the slab can be achieved. Therefore, the char layer depth recorded in each experimental study is an important parameter as it influences the residual sections of a CLT slab that remain after fire exposure to sustain the applied loads without collapse.

2.2 DESIGN OF TCC SECTIONS

For TCC sections, two key assembly types of sections can be used: beam-type assembly and slab-type assembly. First, the beam-type system consists of a concrete slab supported by timber beams made of either mass timber or EWPs. A thin wood layer can also be placed between the concrete and beams to act as permanent formwork. The second type is the slab-type assembly which consists of a concrete slab on top of a solid mass timber panel. An important distinction between the two assembly types, besides the timber components being in either the shape of beams or slabs, is the exposure of the concrete to fire.

When designing such TCC sections, there are two methods to follow, the γ-method and the Elasto-Plastic Method (EPM). The former is the more common and original design concept. At the same time, the latter is relatively new and explicitly implemented for ductile connectors as the γ-method assumes elastic behaviour before the point of yielding. When EPM is within the plastic range and afterwards, the shear connectors begin to yield. Both design methodologies need to be checked, but EPM is critical to the design of TCC sections for shear connectors with less stiffness, such as self-tapping screws (STS).

One of the three fundamental aspects of the design of TCC sections is the shear connectors used to connect the two materials, giving the location to transfer stresses between the different materials. This results in many possible connectors that can be used, with their pros and cons in quantity required, level of skilled labour for insulation, cost per unit, availability, and research studied with validated results and behaviour in ambient and fire conditions. Therefore, to advance the understanding of the behaviour of TCC sections more experimental examining of the various shear connectors in full-scale testing setup to capture in-situ conditions and the overall performance of the sections is needed.

STS are a commonly used type of metal fasteners in timber structures, whether used for connections or for strengthening structural elements and connections. They can either be fully or partially threaded; while in TCC sections, the fully threaded screws are the preference. This is mainly due to the more uniform load transfer between the fully threaded screw and the timber material, which results in better withdrawal resistance. Thus, enhancing the strength and stiffness of the shear connections developed by those STS in TCC sections. STS that are fully threaded is hardened to develop a high yield moment and tensile and torsional strengths, while their long threads provide reliable embedment in the timber elements [3]. A benefit of their inherit design is that typically no pre-drilling is required, meaning they are faster to install than their counterpart shear connectors. All that makes them cost-efficient shear connectors for TCC sections, which requiring significantly less quality control measures or skilled labour during installation.

2.3 TCC SECTIONS BEHAVIOUR AT AMBIENT TEMPERATURE

The majority of completed studies are on the behaviour of TCC sections at ambient temperature. However, only a few studies have been completed recently after streamlining to focus on sections utilizing CLT panels and STS as shear connectors. Many factors influence the design and strength of the screw-type shear connections: overall dimensions, embedment length, angle of inclination, and screw spacing. Those parameters alter the strength, stiffness, and overall behaviour of TCC sections.

The study completed by Gerber [8] included an extensive experimental program studying different types of connections used in different timber materials and testing variances of each type of shear connectors. TCC sections experimentally tested in that study included: (a) screws at 30-degree angle of inclination, (b) screw pairs at 45-degree angle of inclination, and (c) screw pairs at 45-degree angle of inclination with an interlayer. The research study also included different screw lengths and diameters. In a relatively recent study completed by Mirdad and Chui [9], three different parameters were investigated in different TCC sections: screw embedment length in the timber; thickness of the insulation layer used; and the screw angle of inclination with the horizontal.

Another experimental study completed by Salem and Virdi [10] examined the influence of three parameters on the shear strength of TCC sections: longitudinal screw spacing; number of screw rows in the transverse direction; and age of concrete. Study parameters involved reducing the longitudinal screw spacing from 200 mm to 150 mm; increasing the quantity per row from two to three screws; and increasing the concrete curing age from 14 to 28 days. Interestingly, results of that study show that reducing the screw longitudinal spacing or increasing the number of screws in the row resulted in a similar increment in the maximum load sustained by the different TCC sections. However, the authors of that study recommended increasing the number of screw rows over decreasing the screw longitudinal spacing as this allows a more uniform distribution of the shear stresses in the transverse direction of the TCC section.

As part of the previously mentioned study conducted by Gerber [8] and after completing the pilot testing phase which included a series of shear tests, four-point flexure bending testing on long TCC slabs was completed. Test specimens involved CLT slabs as the timber component with screws at 30-degree angle of inclination in the shear flow direction. The screw spacing in the longitudinal direction alters, with a spacing of 150 mm in the high shear zone near the supports increased to 300 mm in the low shear zone in the middle of the slab. Higgin et al. [11] also conducted flexure bending tests as a part of their experimental program. However, their samples were tested under three-point flexure bending, and they utilized 45-degree orientated screws in the shear flow direction with two different spacing arrangements. In the first arrangement, the screws were installed at a constant spacing equal to 305 mm along the length of the specimen. While in the second arrangement, screws were widely spaced at 610 mm within the low shear zone in the middle of the slab and spaced at only 305 mm in the high shear zone near the supports.

While each of the parameter investigated in the previously mentioned studies influences the strength and stiffness of the experimentally examined TCC sections, it ultimately affecting their performance in flexure bending and the corresponding flexural rigidity based on the load-

https://doi.org/10.52202/069179-0241

displacement relationships developed for the different TCC sections. Results from Gerber [8]

Typically, TCC sections, especially when considering a timber component that utilizes a CLT panel along with STS as shear connectors, exhibit brittle failure under extreme flexure bending. As observed in tests completed by Gerber [8], all specimens subjected to flexure bending and utilized STS into CLT panels exhibited brittle failure, specifically a timber tensile facture. However, the author of the said study noted that the specimens exhibited brittle failure modes (i.e., concrete crushing or tensile fracture) failed at more significant applied loads compared to those that exhibited ductile failure modes (i.e., connector yielding or screw withdrawal).

2.4 TCC SECTIONS BEHAVIOUR UNDER FIRE

While TCC sections, when under ambient conditions, is more extensivity researched and studied both in terms of experimental and numerical analysis, there is lacking information when the fire conditions are involved. As previously mentioned, the need for further investigation to study CLT panels under fire exposure; the same goes for TCC sections. As for any TCC slab-type assembly, the behaviour of the overall floor is highly dependent on the behaviour of the timber component and the shear connections.

In fire conditions, the material ability to resist forces is affected due to the increased temperature and reduced timber area due to charring. This loss in strength leads to a shift in the location of the cross-section neutral axis and thus, result in loss of the stiffness of the TCC section. Complex thermal and mechanical responses must be considered when examining TCC sections exposed to fire, thereby increasing the challenge to develop both simple analytical methods and advanced numerical procedures to quantify their fire resistance according to the relevant codes [6]. However, to develop such models, there is a demand for more reliable experimental results to run comparative analyses to verify their reliability. Considering the limited research focused on studying of TCC sections using STS as shear connectors and having the timber component made of CLT panels, more large-scale fire experiments on such slab-type TCC floor systems are highly needed [13].

In that regard, an experimental study on long span TCC floor slabs was conducted by Osborne [14]. In that study, three key depths were important to consider, which are the depths at the interfaces between the first three ply's (i.e., 35 mm, 70 mm, and 105 mm). The first ply charred at 60 min, beginning to fall at 90 min, giving a char rate of 0.52 mm/min. The second ply charred at 105 min, falling at 120 min, giving a charring rate of 0.68 mm/min. Then the third ply was charred at 150 min, falling at 180 min, giving a charring rate of 0.68 mm/min. Since the TCC slab reached failure due to mid-span deflection at 187 min, the testing was terminated. Therefore, the charring rate began like that of the accepted European standard of 0.65 mm/min, but as the ply fell and delamination occurred, the charring rate further increased. Another important measurement was the temperatures measured at the interface between the concrete top layer and the CLT panel, where there was only a slight increase of about 20°C and only 5°C at the mid-depth of the concrete layer by the end of the fire tests. Also, the temperature of the screws was important to be monitored, as it increased by 93°C by the end of the fire tests. However, this did not occur until the tip of the screw reached a temperature of 100°C. Afterwards, the heat quickly transferred through the screw from the tip to the head and increased much more rapidly once the wood fell around the tip of the screw and was directly exposed to the fire. It is worth noting that although the temperature in the screw was raised, there was negligible heat transfer to the concrete top layer.

Relatively similar thermal behaviour was seen for the TCC slab assemblies examined by Shephard et al. [13]. In that study, the heat transferred from the exposed side to the interface between the concrete and the timber component and raised the temperature at the interface to 59°C and the temperature at the mid-thickness of the concrete layer to 72°C by the end of the fire tests. Also, the charring rates determined in that study was 0.66 mm/min based on the burning of the first ply. However, it was determined at 0.8 mm/min based on the burning of the subsequent plys. Greater charring rates also lead to a greater loss of timber section with an average depth remaining of 25 mm, which would be only the very top ply of the CLT panel. Unlike the study conducted by Osborne [14], where both the fourth and fifth ply remained uncharred, one reason for the difference could be that the adhesive used in manufacturing the CLT panels utilized in the TCC specimens experimentally examined by Shephard et al. [13] affected the delamination occurrence. Although the placement of the screws and corresponding spacing were different between the TCC slabs of those two studies [13 and 14], this would cause a difference in their mechanical behaviour in terms of strength and stiffness, but not the charring rate of the CLT panels. Another possibility is the influence that the panel-to-panel joint affected the fire performance of the TCC floor assemblies examined by Shephard et al. [13]. This is a much-needed topic for further exploration, as the panel-to-panel connection is a very critical component in a mass timber floor system, especially in fire conditions.

3 EXPERIMENTAL PROGRAM

While TCC sections have been studied for many years across various countries, limited testing and verification are completed in Canada. This shows that the possibility of TCC sections being implemented into the Canadian *Engineering Design in Wood* standard [3] requires more extensive experimental testing, computer modelling, and numerical analyses. Currently, TCC sections have only been designed using performance-based guidelines, as the

prescriptive methods are still lacking in many published wood design standards.

Following typical fire resistance design procedures, TCC floor assemblies were subjected to monotonic loading before being exposed to standard fire. Each floor assembly was exposed to CAN/ULC-S101 standard fire time-temperature curve for the two fire tests of the research study presented in this paper. In Canada, a minimum fire resistance rating of 45 minutes is required for structural timber components. However, considering the new era of erecting tall wood buildings and the introduction of EMTC, the goal has been changed to achieve a minimum fire resistance rating of 2 hours for buildings more than six stories.

3.1 TEST SETUP

Fire endurance testing was carried out at Lakehead University Fire Testing and Research Laboratory (LUFTRL) located on Thunder Bay campus, Ontario. This state-of-the-art facility, accommodates a large custom-designed furnace with two natural-gas fed burners that can raise the furnace's temperature to 1300 °C. The furnace is equipped with a control panel that can be set to follow a programmable fire time-temperature curve.

The roof of the furnace is comprised of three separated strips that are joined together. As for this research, each of the 900-mm wide TCC floor slab was placed instead of the middle roof strip, thereby acting as part of the furnace roof. Thus, test slabs were exposed to standard fire only from underneath, which reflected one-dimensional heat transfer, Figure 1.

Figure 1: *Interior of the testing furnace with one of the TCC floor test assemblies installed*

The overall dimensions of any TCC floor assembly are 5300 mm x 900 mm, with a clear span of 5000 mm. As the furnace itself is not load-bearing, the TCC floor slab rests on simple supports placed on the transverse beams of the exterior loading/supporting steel framed structure. Thereby, not the entire span (5000 mm) of the floor slab was exposed to fire, but rather a middle length equivalent to the interior length of the furnace chamber (3750 mm) was exposed to fire. This allowed 75% of the floor slab length to be exposed to fire and guaranteed to keep the supports outside the furnace. Meanwhile, under the four-point flexure bending applied on the TCC floor slabs, the greatest shear, moment, and deflection locations were always within the furnace chamber.

To accomplish the objectives of this experimental study, measurements and experimental data were required to evaluate and quantify the performance of the TCC floor slabs when exposed to standard fire. It is essential to provide reference and insight to the recorded visual observations of the floor assemblies as they were designed to achieve a fire resistance rating of 2 hours. Thus, fire tests were terminated shortly after reaching this fire resistance time mark. As tests was duplicated, the first specimen (Slab 1) was exposed to fire for 125 min, while the second specimen (Slab 2) was deliberately exposed to fire for extended period (145 min). Thereby being able to show no sudden change or failure occurrence shortly after the 2-hour threshold.

Test assemblies were loaded to the design load, including 2.0 kPa dead load (in addition to self-weight) and 2.4 kPa live load, representing in situ loading for typical residential occupancy loading. Each specimen was designed to achieve a 2-hr fire resistance, thereby doubling the fire resistance of the CLT panel as a standalone element as reported by the manufacturer, Nordic Structures. The design of each TCC specimen and its shear connections was determined by adopting the clauses and equations in the Canadian Wood Design Handbook [2], Design Guide for TCC Floors in Canada [15], and European Design Code for screw capacity.

3.2 MATERIALS

3.2.1 CLT Panels

This research project utilized CLT panels supplied by Nordic Structures, Quebec, Canada. The principal mechanical properties of the sections were provided by the manufacturer and verified by the Canadian Construction Materials Centre (CCMC) in Evaluation Report CCMC 13654-L [16]. A 5-ply CLT panel was chosen when considering the experimental setup, overall specimen dimensions, and applied loading. Nordic Structures manufactures two different 5-ply CLT panels, one with all ply thickness being 35 mm, giving an overall depth of 175 mm; while the other is with the major strength direction plys of 35 mm thickness each and the minor strength direction plys of 19 mm thickness each, giving an overall depth of 143 mm. The slenderer one was chosen to align with the research objectives.

3.2.2 Concrete

The concrete used in this experimental study was normal strength concrete with 28-day compressive strength designed for 30 MPa. Coarse aggregates were dolomite based with a maximum aggregate size of 16 mm and a nominal diameter of 13 mm. Smaller-diameter aggregates are common in TCC sections as it allows for the mix to

https://doi.org/10.52202/069179-0241

flow and bond around the shear connectors adequately. Water-cement ratio used was approximately 0.56 and no additives were used in the concrete mix. Additionally, the minimum reinforcement ratio of 0.002 of the concrete cross-sections was achieved by placing a wire mesh with 150 mm grid of 6-mm diameter steel wires. This is mainly to control tension cracking due to concrete shrinkage.

3.2.3 Self-Tapping Screws (STS)

The type of STS used in this study were SWG ASSY VG plus cylindrical head, Figure 2. The properties of those screws include diameter (8 mm), total length (240 mm), embedment length in CLT (150 mm), insertion angle 45°, longitudinal spacing (150 mm), transverse spacing (350 mm), bending strength (1015 MPa), tensile strength (18.9 kN), and shear strength (641 MPa). The product evaluation report for the utilized STS provides the full technical specifications for the screws [17].

3.2.4 Insulation Layer

The seen benefit of including insulation layer at the interface with respect to increasing the moment arm between the timber and concrete components, decreasing overall weight, and increasing the thermal and vibration characteristics, a layer of insulation was added to both test specimens. However, due to the less desirable effects of placing STS directly through the installation layer with the decrease in strength and stiffness as the screw tends to twist and bend, the insulation was only placed between the rows of screws. Type of insulation was FOAMULAR CodeBord XPS Insulation cut to strips of 200 mm wide and placed intermediate between screw rows, Figure 3.

3.3 FABRICATION OF TEST SPECIMENS

Due to the detailed composition of TCC floor slabs, it is a multi-step process that must be followed to fabricate each test specimen. Special care was taken to ensure accurate measurements of the thermal data during fire testing. This step is vital as it directly reflects results and conclusions drawn.

High-temperature insulated Type-K thermocouples were installed at specific locations in the CLT panel, concrete slab, and on selected STS. In total, there were 37 thermocouples installed in each test specimen at specified depths, Figure 4. The thermal data measured by the installed thermocouples provides information on the transfer of heat through the specimen and the temperature of different components at a given time during the fire test. Thus, can be used to observe the relationship between time, temperature, and the depth into the floor assembly cross-section. As shown in Figure 4, thermocouples TC1 through TC7 were installed in the CLT panel, located at the interface between each ply and at the mid-depth of the major plys. TC8 was installed at the interface between the concrete and the CLT panel, TC9 at the mid-depth of the concrete layer, TC10 and TC11 around one of the STS, and TC12 on the concrete layer top surface.

4 RESULTS & DISCUSSION

4.1 MEASURED TEMPERATURES

During any fire testing on structural elements, it is essential to monitor and analyse their thermal behaviour, even more so when considering combustible materials like CLT to understand the rate of heat transferred and charring of the section. Unlike other materials where structural integrity is only diminished, with wood products, this occurs in addition to the loss of cross-section. Thereby, this significantly influences the ultimate strength and stiffness as well as the cross-section loss that is unrecoverable. Examining CLT when exposed to fire conditions is complex but extremely important to designing TCC with slab-type assemblies and providing adequate reliability in fire conditions.

Results were analysed in two distinct ways. First, compared the slabs against themselves by looking at the overall sections and studying the differences with the three separate thermocouple locations: left side, midspan, and right side. The left and right lines are just offset from the location of the point-loading application. Second, is comparing the slab against each other, tracking if duplicate specimens are consistent.

Temperature profiles were developed for each slab and based on the thermal measurements it is confirmed that both TCC floor slabs are in good agreement with each other and very comparative in terms of rate and heat transfer through the slab cross-sections. The first five thermocouples are the most critical, with TC1 being 17.5 mm inward, TC2 being 35 mm, TC3 being 54 mm, TC4 being 71.5 mm, and TC5 being 89 mm, as they are first to experience the effects of fire. Also, the rate at which their temperatures are increased dictates the overall performance of the TCC floor assembly. Additionally, temperature measured by TC5 was used as the test critical temperature where the fire tests were to be terminated if its temperature reached the 300 ˚C (wood charring temperature) to protect the utmost major strength ply of the CLT panel.

4.1.1 Temperature Profiles

Figures 6 and 7 show the entire fire test duration and temperature profiles of data averaged for the thermocouples installed at the same depths at the different three sections along the length of each slab. This is to better examine the overall performance of the slabs and compare them against each other more simply. All presented time-temperature curves show relatively smooth profiles with a more gradual increase in temperature (e.g., no sudden jumps in increased temperature). This is attributed to the minimal delamination the CLT panels experienced during fire tests. As there are no sudden spikes in the thermal behaviour of the fire tested TCC floor slabs, no significant amount of charred timber fell during testing on the furnace floor. Delamination is a critical issue for CLT panels in fire conditions, and

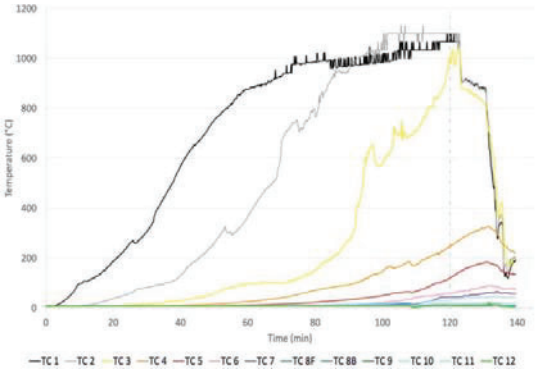

Figure 6: *Slab 1 average temperature readings*

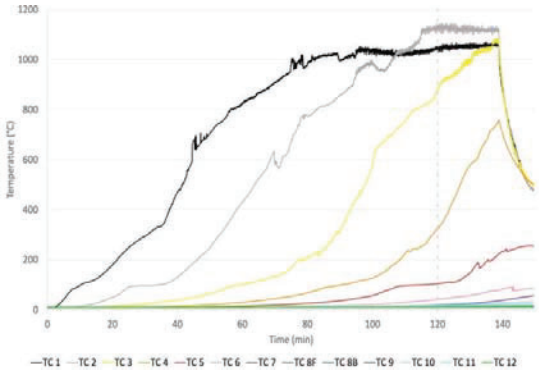

Figure 7: *Slab 2 average temperature readings*

4.1.2 Critical Thermocouple Comparison

The most critical thermocouple (TC5) was carefully monitored throughout fire tests. The measurements of that thermocouple were used to terminate the fire test. The said thermocouple (TC5) is located at the interface between the third and fourth ply of the CLT panel, thereby having this thermocouple not reaching the charring temperature allowed for this minor-strength direction ply to protect the utmost and final major-strength direction ply. Since the examined TCC floor specimens were one-way slabs, only the major-strength direction plys resisted the applied

https://doi.org/10.52202/069179-0241

loading and thus, were used to determine the strength and stiffness of the CLT panels under fire exposure.

After examining the developed time-temperature profiles at the targeted 2-hour fire resistance time mark, the measurements of TC5 reach approximately 100-150°C. Therefore, the location is undoubtedly experiencing the effects of the fire but not at the point where significant strength of the CLT panel was lost.

4.1.3 Heat Transfer Through TCC Sections

Monitoring the fire development and charring progression of the TCC sections throughout the fire testing comes down to evaluating how heat transfers through the floor slabs. Apart from the thermocouples that are exposed initially and others not until near the end of the fire test, it is essential to examine the temperatures measured by the thermocouples that are protected from previous layers of wood and those located in the concrete top layer.

Thus, examining the time-temperature profiles shows that very minimal temperature increase occurred above the temperatures measured by TC5. Meaning a lack of heat transfer to the top of the slab, although the bottom is experiencing a fire temperature of approximately 1000°C. Proving a lack of heat transfer through the slab as most of the installed thermocouples did not reach temperatures higher than 40°C after the 2-hour fire duration. It also should be noted that those thermocouples that measured increased temperatures are mostly TC6 and TC7, which are still located in the CLT panel. Comparatively, the thermocouples found in the concrete and at the interface between materials barely increased (approximately 10°C only) from the initial starting temperature before the fire test began.

4.2 CHARRING BEHAVIOUR

4.2.1 Charring Rates

A crucial aspect in studying the behaviour of timber materials when exposed to fire is the rate and development of the charred front. While compared to contemporary theories and reasons for the hesitation when increasing the construction of tall timber buildings, these combustible products perform very well in fire conditions. Heat transfer through the different plys that form a CLT panel takes a significant amount of time. Proving the insulation properties of the material, and while the temperature threshold of loss of strength is low, it takes an extended period while exposed to an elevated temperature to reach this point.

The nominal charring rate from the European Code is 0.65 mm/min. Additionally, this is the recommendation from the Canadian Wood Council in the Canadian *Engineering Design in Wood* Standards [3] for CLT. The charring rate is 0.65 mm/min when the char depth is within the first ply of a CLT panel and an increased rate of 0.80 mm/min is considered when the charred front progresses beyond the first glue line. The 0.80 mm/min charring rate is exceedingly higher than expected and previously recorded behaviour.

Results from charring rate calculation can be seen in Tables 1 and 2, showing each thermocouple location as well as the averaged results for the entire test specimen. The typical behaviour can be observed from the results where there is initially a lower charring rate as the fire is just beginning and, therefore, not at the hottest temperatures. Then increases while the fire continues as the CLT is ignited and charring starts to develop upward. However, notice that later locations continue to decrease again as although there is a developed char layer, it works as a layer of insulation to the unburned internal plys.

Table 1: *Slab 1 calculated charring rates based on thermal measurements*

Averaged temperature across the slab for TC No.	Charring rate (mm/min)
TC 1	0.59
TC 2	0.67
TC 3	0.59
TC 4	0.56

Table 2: *Slab 2 calculated charring rates based on thermal measurements*

Averaged temperature across the slab for TC No.	Charring rate (mm/min)
TC 1	0.57
TC 2	0.66
TC 3	0.61
TC 4	0.60

The overall average charring rate is approximately 0.60 mm/min with standard deviation of only 0.0396. It also shows the reliability of the European Standard charring rate of 0.65 mm/min and the good agreement with the experimental results of this study.

4.2.2 Residual CLT Thickness

Comparing Figures 8 and 9 shows the difference when the char layer is removed, thereby exposing the remaining wood to resist the applied loads. The apparent difference in appearance makes it easy to differentiate between charred and robust wood.

Only Slab 1 had the char removed as the test had a duration of 125 min where this fire test was terminated shortly after passing the 2-hour fire resistance time mark. Therefore, it was essential to know how much wood was remaining. At the same time, it is understood that more fire exposure for the other slab (Slab 2) would simultaneously lead to a more significant reduction in the residual wood section.

Figure 8: *Slab 1 right after fire testing and before the char layer was removed*

Figure 9: *Slab 1 after 2-hr standard fire exposure and the char layer removed*

It is relatively easy to distinguish between the major and minor plys from Figure 9, with the different ply orientations. However, it is more challenging to know the difference between the middle major ply and the top major ply from the figure alone. Thus, Table 3 presents the residual depth at the three different sections along the first fire tested floor slab. The residual section is more accurate following the centreline of the slab in the longitudinal direction rather than near the edges of the slab.

Table 3: *Residual CLT depths with 2-hr fire exposure in Slab 1*

Location	Residual depth
Left side	54.0
Centreline	68.9
Right side	64.6

It should be noted that the residual depth values greater than 54 mm would indicate that the charring progressed into the third (or middle) ply along the major strength direction. The residual section would be in the fourth ply based on the predicted values using an increased charring rate. While according to the experimental results of this study, with average charring rate calculated based on thermal measurements at 0.60 mm/min, which is very close to the European code nominal charring rate (0.65mm/min), the residual section would be in the third ply.

5 CONCLUSIONS

The new insurgence of structural design involving mass timber elements and increasing the buildings height restrictions under a prescriptive design methodology is tethered to the understanding of the structural fire performance of the main structural systems utilized in such tall timber buildings. Addressing these concerns requires extensive experimental programs to study such mass timber elements and verify their actual fire resistance ratings. Studying TCC sections offers valuable knowledge in expanding their use and design procedures and opening possibilities to further progress the mass timber construction. Both in terms of building taller in timber and having these elements exposed, thereby not limiting design options to EMTC.

Based on the results obtained from the experiments presented in this study to investigate the behaviour of TCC slab-type floor assemblies, the following conclusions can be drawn:

1. TCC floor assemblies can successfully be designed to meet the required 2-hour fire resistance rating. An essential requirement to create tall mass timber buildings and limiting factor in the Canadian *Engineering Design in Wood* standard.

2. The correct design and procedures can enhance the fire resistance of CLT panels by converting the floor systems to TCC sections with the addition of shear connectors and top concrete layer. This successfully takes a CLT panel rated for 1-hour fire resistance and achieve 2-hour fire resistance under the same loading. Thereby doubling the fire resistance time and proving the impact that TCC sections can have on the industry and design recommendations.

3. The thermal behaviour of the two TCC floor assemblies was comparable to each other, providing consistency in results and outcomes while studying time-temperature curves and charring behaviour. Furthermore, it agreed with the standardized charring rate of timber under the European Code nominal value of 0.65 mm/min, and test specimens did not globally delaminate.

4. Even though the exposed CLT was experiencing elevated temperatures of approximately 1000°C near the end of the 2-hr fire tests, there was still minimal heat transfer at the interface between the top concrete layer and the CLT panel or at any depth in the concrete. This demonstrates the benefits of the TCC slab-type floor assembly over the beam-type assembly as it is not needed to consider the thermal effects on the concrete component. Additionally, when the wood charred ply remains intact it acts as an excellent insulator to the inner and yet unexposed plys.

In conclusion, the unique results of the full-size experimental fire tests presented in this paper enhance the current understanding and assist in reducing the knowledge gap on the actual behaviour of TCC floor assemblies utilizing CLT panels when subjected to fire in Canada and globally, especially considering the rarity of large-size fire testing programs. Additionally, providing reliable experimental results for designers to validate the performance-based design and assign appropriate fire resistance times are very beneficial.

ACKNOWLEDGEMENT

This research project has been mainly funded using the Discovery Grant awarded to the second author by the Natural Sciences and Engineering Research Council of

https://doi.org/10.52202/069179-0241

Canada (NSERC). The authors would like to thank Nordic Structures for their support and generous in-kind contributions in form of providing all CLT panels used to fabricate the large-size TCC floor test assemblies examined in this project. Thanks are extended to Pioneer Construction Inc., Miller Precast Ltd., and Harris Rebar (Thunder Bay) for their in-kind contributions. Thanks are due to lab technologist, Mr. Cory Hubbard for his great assistance during the experimental investigation stage of this project.

IMPLICATIONS OF A DOWN-STAND BEAM ON THE CEILING FLAME EXTENSION CHARACTERISTICS IN A LARGE-SCALE CLT ENCLOSURE FIRE EXPERIMENT

Danny Hopkin[1], Michael Spearpoint[1], Renaud Blondeau[2], Tim Sleik[3], Harald Krenn[4], Gordian Stapf[5] & Wojciech Węgrzyński[6]

ABSTRACT: This paper provides further understanding of the fire performance of exposed cross-laminated timber (CLT) in large enclosures. An office-type configuration has been represented by a 3.75 by 7.6 by 2.4 m high enclosure constructed of non-combustible blockwork walls, with a large opening on one long face. Two experiments are described in which propane-fuelled burners created a line fire that impinged on CLT ceilings. The first experiment had a smooth CLT soffit, with the CLT formed from 160 mm thick panels (40-20-40-20-40 mm). The second experiment adopted the same CLT but included a 400 mm deep, 200 mm wide glulam beam half-way along the length of the enclosure. In both experiments, the lamella of each CLT were bonded using a standard polyurethane adhesive. The facing lamella of the CLT was not edge bonded. The results indicate the importance of consideration of the impact of ceiling protrusions, such as down-stand beams, with differences in both radiative heat flux to the ceiling and floor observed between the two cases. Considering large contemporary open plan office enclosures, this would likely translate to differences in spread rate within an enclosure and time to auto-extinction of flaming combustion which should be addressed by designers.

KEYWORDS: cross-laminated timber; auto-extinction; flame spread; glulam; ceiling protrusion

1 INTRODUCTION & MOTIVATION

When conceiving of a new office building in the UK, timber is increasingly considered as part of any potential framing solution. This is driven by a combination of embodied carbon, aesthetics, and constructability considerations. Commercial premises, such as offices, often have specific user/client demands, with emphasis placed on high floor-to-ceiling heights, long spans between column members and large areas of glazing. For this reason, the UK market is converging upon hybrid construction solutions where timber, in the form of cross-laminated-timber (CLT), is used in concert with other materials, such as steel and concrete.

Recent guidance has been published [1] which has clarified the design evidence that should be provided by engineers when demonstrating that an adequate level of structural fire performance will be achieved when adopting a combustible structural framing solution. In higher consequence of failure buildings, e.g., medium- to high-rise offices, the structure must be designed in a manner whereby it has a reasonable likelihood of surviving the full duration of a fire. This necessitates that if the structure becomes involved as a source of fuel, combustion must cease and the structure should remain capable of supporting the applied loads both during and beyond a fire. The cessation of combustion is generally taken to be that of flaming, with some expectation that fire service intervention is necessary to stop any subsequent smouldering combustion.

To design a structure to undergo auto-extinction of flaming combustion, there needs to be an understanding of: (a) the fire dynamics in the enclosure, in particular spread rates; and (b) the heat flux to the combustible structural elements. Both are likely to be impacted by the presence of ceiling protrusions, such as beams. To date, limited effort has been committed to understanding the importance of such protrusions, other than at reduced scale [2].

This paper, as part of a larger experimental campaign by the Structural Timber Association (STA) special interest group on CLT enclosure fire dynamics, reports on two large-scale experiments that compare fire behaviour of engineered timber ceilings (comprising CLT and glulam) both with and without a beam protrusion.

2 THE EXPERIMENTS

2.1 The fire enclosure

The geometry of the fire enclosure was chosen to: (a) ensure CLT spans were broadly aligned to that commonly

adopted in hybrid commercial (office) construction, with the CLT spanning 3.75 m from front to back, and (b) to be as large as feasible within the constraints of the laboratory, considering both footprint and anticipated maximum heat release rate (HRR). This led to an enclosure of internal dimensions of 3.75 m (depth) by 7.6 m (width) by 2.4 m (height). The enclosure of the rig was constructed from exposed lightweight concrete blockwork that was 240 mm thick. Given commercial construction is typically characterised by a large amount of perimeter glazing, one elevation of the rig featured a large permanent opening, measuring 7.6 m wide and 2.0 m high. To allow for the characterisation of potential external flames from the opening, a mock-up façade extension was included. This extended the full width of the enclosure, measuring 2.6 m in height, with a down-stand that extended 0.4 m below the CLT soffit.

Figure 1: *Image of the enclosure with the propane gas burners shown at the quarter point.*

2.2 The mass timber elements

In all cases, the CLT was 160 mm thick, with lay-up 40-20-40-20-40 mm lamellae. At the time of the experiments, the estimated moisture content of the CLT slabs was in the range of 12–14% by mass. Non-edge-bonded CLT was chosen in both experiments with the intent of realising a lower bound of fire performance, i.e., the lack of edge-bonding can permit the rapid development of gaps between CLT facing lamella upon heating and subsequent dehydration, followed by pyrolysis. In both experiments, lamellae were bonded with a standard polyurethane (PUR) adhesive (Henkel Loctite HB S).

The first experiment had a smooth exposed CLT ceiling, i.e., no ceiling protrusions. This is henceforth referred to as the "no beam" case. The second "with beam" experiment included glulam beam measuring 200 mm wide by 400 mm deep. This was fixed to slab 3, such that the beam edge aligned with the joint to slab 2. The glulam beam was fixed to the slab from below, using stirrups. These comprised a universal bracket commonly used for propping ventilation ducts from below, which were supported on threaded tension rods on each side.

Slabs are distinguished in the discussion of instrumentation and loading, see Figure 4.

2.3 Fire source

The ceiling was heated using propane gas burners, elevated to sit 1 m below the soffit. The burner array comprised of 6 burners, each measuring 150 × 300 mm on plan, configured to achieve a rectangle measuring 300 × 900 mm. The burners were located off-centre (at the quarter point), with the aim of inducing flame extension to 50% of the ceiling length in a reference experiment reported elsewhere [3] and a heat flux exceeding 120 kW/m^2 at the plume centreline. The HRR of the fire was controlled via mass flow switches, leading to a HRR that ramped to a maximum of 1250 kW (achieved over an 8 min period in 250 kW steps). The duration of steady heating (at 1250 kW) for the exposed CLT experiments was chosen to induce significant char fall-off in the smooth soffit experiment (above the burner), resulting in a steady phase duration of 80 min. After this phase, the burners ramped down in 250 kW increments every 5 min, before being switched off, see Figure 2. An imagine of the burner impinging on the ceiling is given in Figure 3.

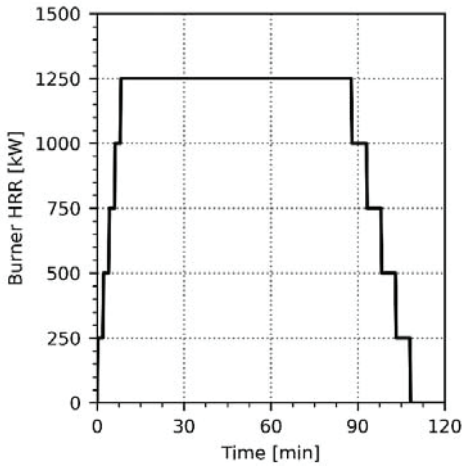

Figure 2: *Burner heat release rate with time.*

Figure 3: *Image of burner and ceiling jet, "no beam" experiment 1.*

2.4 Instrumentation and loading

The enclosures were instrumented using a combination of bead and plate thermocouples and water-cooled heat flux gauges. CLT slabs were loaded to achieve a nominally uniformly distributed load of 153 kg/m^2, or c. 4300 kg in total. Slab displacement was monitored, and CLT mass loss rate (MLR) estimated from load-cells. The experiments were identical, other than the inclusion of a glulam beam in the second experiment. Key dimensions and locations of instrumentation are shown in Figure 4.

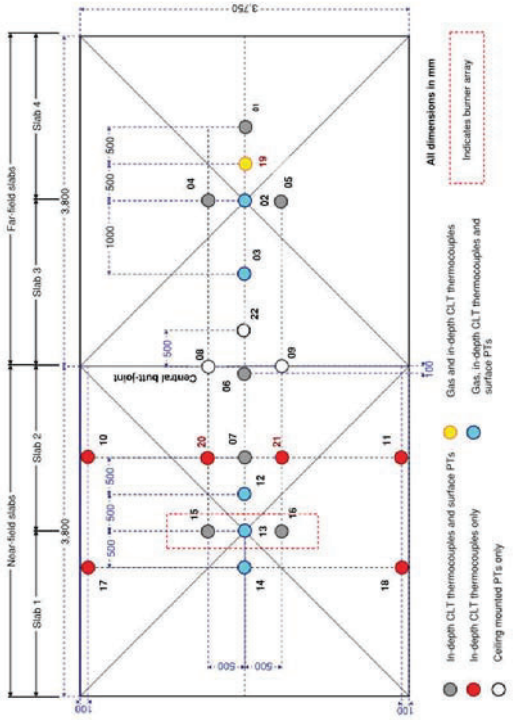

Figure 4: *Enclosure plan showing key enclosure dimensions, measurement locations and references, slab locations and burner array position.*

The CLT support structure comprised a perimeter steel frame, from which each pair of CLT slabs were suspended via tension rods. In line with these tension rods were a load cell to each corner, i.e., eight in total, recording the tensile load acting on the supports. The arrangement is as shown indicatively in Figure 5. The slabs sat within the perimeter of blockwork wall enclosure, ensuring the CLT and supporting structure were not propped by the perimeter wall. Minor gaps at the ceiling edges were fire stopped with mineral wool.

3 RESULTS

The emphasis of the results in this paper are on the fire development characteristics, i.e., no comment is made on the charring rates or mechanical performance associated with the engineered timber ceilings. To this end, results are presented in terms of the ceiling mass loss and heat release rate (HRR), gas temperatures below the ceiling, estimated radiative heat flux to the ceiling and floor, and the heat flux opposing the opening. Each are discussed in the sub-sections that follow.

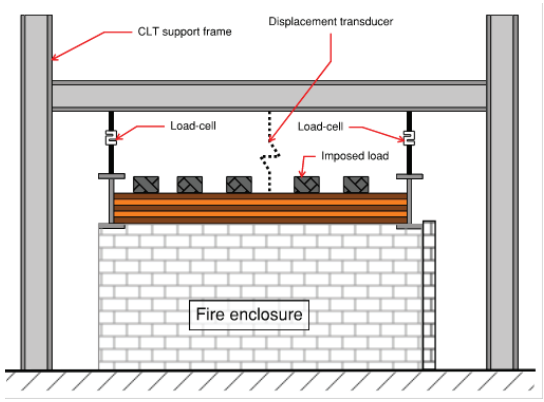

Figure 5: *Illustrative section through the rig showing CLT support mechanism, including load cells and displacement transducers.*

3.1 Timber mass loss and estimated HRR

The eight load-cells were summed and normalised relative to the starting mass on the system upon ignition of burners, with the resulting total mass lost with time for both experiments shown in Figure 6.

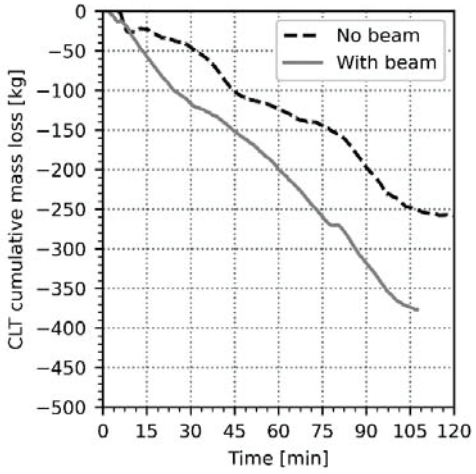

Figure 6: *Comparison of total slab mass lost with time.*

At the onset of the experiment, there was a c. 200 kg difference between the starting mass on the system for the "no beam" vs "with beam" case, which is largely attributable to the glulam beam mass, estimated at c. 40 kg/m.

Differentiating the mass lost with time and applying exponentially weighted smoothing over a 60 s period, gives the MLR, which has been presented per unit area in Figure 7. The MLR has been utilised alongside a net heat

https://doi.org/10.52202/069179-0242

of combustion of the timber of 17.5 +/- 2.5 MJ/kg to estimate the total heat release rate of the enclosure, when summed with the burner contribution given in Figure 2. The results are shown in Figure 8.

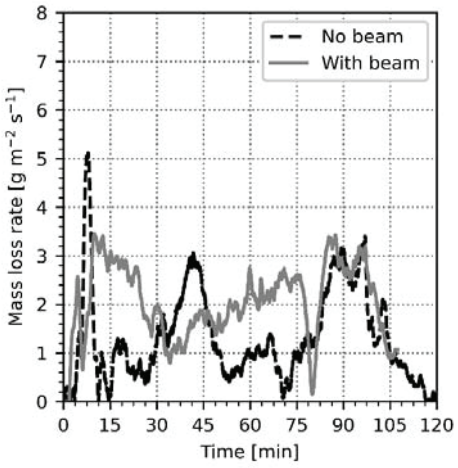

Figure 7: *Comparison of slab mass loss rate with time.*

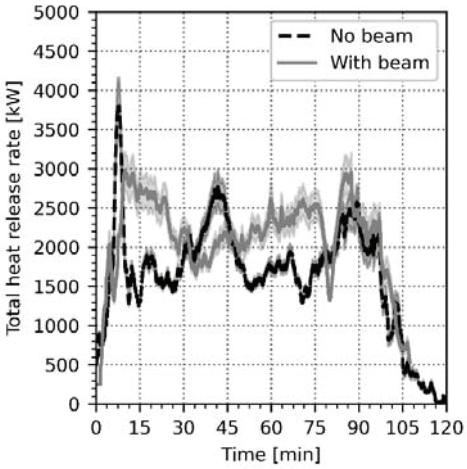

Figure 8: *Comparison of total heat release rate with time, based on mean heat of combustion of 17.5+/- 2.5 MJ/kg (shaded region)*

3.2 Heat flux to the floor and ceiling

Ceiling and floor mounted plate thermometers (PT) were utilised to estimate the radiative heat flux to the surfaces, adopting the correlations presented in Wickstrom et al. [4], as adopted by other researchers for similar applications, e.g., Su et al. [5]. Neglecting the heat storage term of the energy balance of the PT, as per Ingason and Wickstrom [6], the radiative heat flux was derived according to Equation (1) and Table 1.

$$\dot{q}''_{inc} = \frac{\varepsilon_{pt}\sigma T_{pt}^4 + (h + K_{cond})(T_{pt} - T_\infty)}{\varepsilon_{pt}} \quad (1)$$

Resulting profiles of radiative heat flux relative to distance from the burner are shown in Figure 9 and Figure 10.

Table 1: *Terms and constants adopted to estimate radiative heat flux to ceiling and floor, adopted from [7]*

Parameter	Description	Value	Unit
ε_{pt}	Emissivity of the PT	0.9	-
σ	Boltzmann constant	5.67×10^{-8}	$W \cdot m^{-2} \cdot K^{-4}$
h	PT convection coefficient	10	$W/m^2 \cdot K$
K_{cond}	Conduction correction factor	8	$W/m^2 \cdot K$
T_{pt}	PT temperature	Varies	K
T_∞	Ambient temperature	293	K

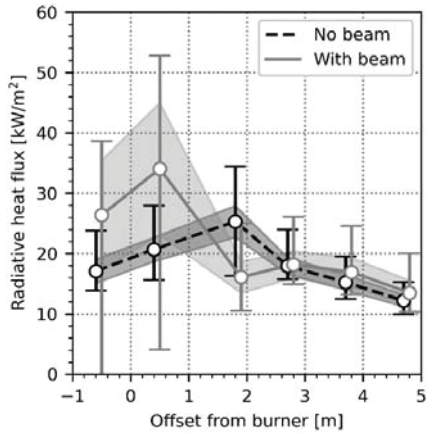

Figure 10: *Radiative heat flux to the floor at different burner offsets, comparison of no beam vs. with beam. Burner HRR = 1,250 kW. Shaded envelope shows +/- one standard deviation, error bars show range of values.*

3.3 Gas temperatures

Figure 11 and Figure 12 show the gas temperatures at ceiling level for the locations given in Figure 4.

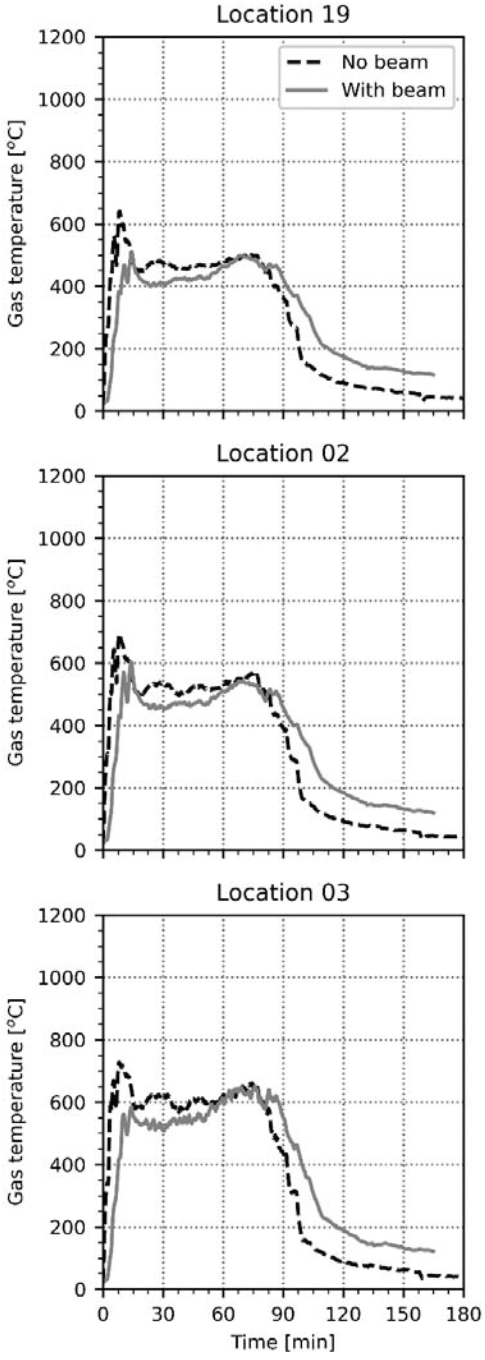

Figure 11: *Ceiling gas temperatures with time for locations 19, 02 and 03 (far field)*

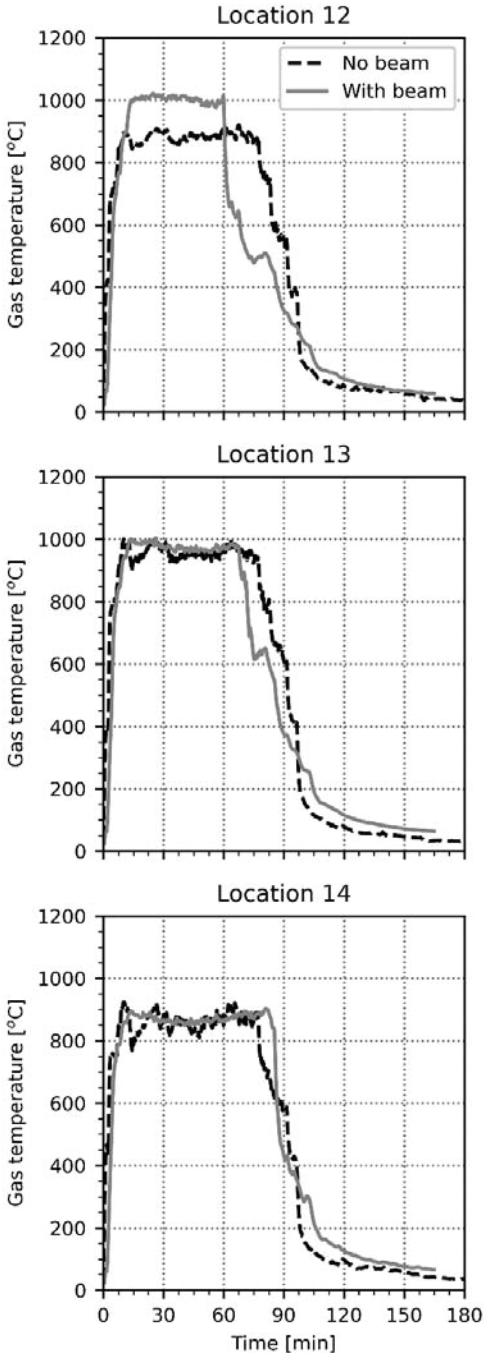

Figure 12: *Ceiling gas temperatures with time for locations 12, 13 and 14 (near field)*

https://doi.org/10.52202/069179-0242

4 DISCUSSION

4.1 Thermal exposure to the CLT soffit

Exposure to the CLT soffit can be distinguished by two zones, the near field and far field. The near field can broadly be taken as the ceiling area where burners impinged or resulted in a ceiling jet. This near field comprised slabs 1 and 2, with the far field slabs 3 and 4. In the case where a beam was included, this separated the near and far field.

In terms of the gas temperatures, Figure 11 showing results for the far field indicate no significant difference regardless of the inclusion of the glulam beam. Figure 12 for the near field shows increased gas temperatures in proximity to the glulam beam. This is likely a combination of (a) the flaming of the beam; and (b) a smoke reservoir effect, containing hot gases beneath slabs 1 and 2.

The increased gas temperatures correspond to increased heat fluxes to the ceiling in the near field, as evident in Figure 9 for the steady phase, where the burner HRR is 1250 kW. On the near field side of the beam, i.e., c. 1.8 m offset from the burner, the radiative heat flux (80 kW/m^2) is circa twice that observed for the flat ceiling case (40 kW/m^2).

Approximating the flame tip to coincide with a heat flux of c. 20 kW/m^2 indicates that the beam did not reduce the flame extension at ceiling level. During the steady phase where the burner HRR is 1250 kW, flames extended over the full length of the ceiling in both cases.

4.2 Thermal exposure to the floor

In the near field, the beam increased the heat flux to the floor. At locations either side of the burner, the heat flux at the floor for the case with a beam was c. 150% of that without a beam, during the steady phase (burner HRR of 1250 kW).

The format of the experiments undertaken, i.e., with a discrete heat source and otherwise fuel load free enclosure, did not permit any direct evaluation of what the combustible ceiling might mean for flame spread rates within a large enclosure. However, the radiative heat flux to the floor provides insight as to what might be expected through benchmarking against complementary studies, such as that by Gupta et al. [8]. In their studies on mechanisms of flame spread in large enclosures, Gupta et al. observe a correlation between the external heat flux to the fuel in advance of the flame front and the flame front velocity. In a proposed phenomenological model, Gupta et al. postulated that as the external heat flux to the fuel in advance of the flame front converges on a critical ignition criterion (taken as 10.5 kW/m^2 therein), the ratio of flame front to burn-out front velocity tends towards infinity, i.e., the flame spread rate is so fast so as to induce a "Mode 1" fire, which implies a fully developed post-flashover fire.

With reference to Figure 10, much of the floor in the far field receives a radiant heat flux significantly above 10.5 kW/m^2, implying that the combustion of the ceiling in either case would induce a change from a Mode 2 (growing fire) or Mode 3 fire (travelling fire) to Mode 1 (i.e., extremely rapid flame spread and transition to flashover). Such a rate of flame spread is supported by recent observations by Kotsovinos et al. [9] in their fire experiment in a 352 m^2 enclosure with exposed CLT ceiling. In Kotsovinos et al.'s "CodeRed #01" experiment, once ignition of the ceiling occurred, flame spread over the cribs covering the full length of the enclosure was observed in under 3 min. The beam had little utility in reducing the heat flux to the floor in the far field, with similar values observed to the case without a beam. It may even be the case that the presence of a protrusion, such as a beam, could lead to more rapid fire spread as heat flux to the floor in vicinity of the flame front (burner in this case) was substantially higher.

4.3 Implications for mass loss and HRR

Revisiting Figure 6, the overall mass lost was greater for the case with the beam versus without. This, in part, is likely a result of an overall greater system mass, including both more combustible material and combustible surface area arising from the glulam beam.

The involvement of the combustible ceiling in both cases can be considered by contrasting the HRR of the burner in isolation (Figure 2) and the estimated total HRR, adopting load-cell data for the engineered timber ceiling (Figure 8). Upon ignition of the timber ceiling, the total HRR is around three times that of the burner in isolation, regardless of the inclusion of a beam. Post-ignition, the HRR for the case with a beam remains higher than without. This corresponds with the observation of generally higher ceiling heat fluxes in the near field attributed to the constraining of the ceiling jet and a marginally deeper smoke layer.

During the steady phase of the burner assault, i.e., from 8 to 88 min, MLR and, correspondingly, HRR, were higher for the case with a beam versus without. With the beam, the HRR was c. twice that of the burner in isolation. Without the beam, the HRR was c. one and a half that of the burner in isolation.

In both experiments, the flaming of the CLT was observed to stop over most of the exposed surface. Owing to the method of fixing of the glulam, i.e., stirrups versus screwing from above, flaming continued in the vicinity of the glulam beam requiring intervention to finally extinguish the combustion. This is reflected in the residual in MLR and HRR towards the end of the experiment, see Figure 7 and Figure 8.

4.4 Bond-line failure

Bond-line failure (BLF) leading to premature char fall-off was observed in both the experiment with and without the

glulam beam. For the case without the beam, this is shown in Figure 13. With the beam, the detached charred lamella is seen on the floor and on top of the burner in Figure 14.

Figure 13: *Bond-line failure leading to premature char fall-off in experiment without beam.*

Figure 14: *Bond-line failure leading to premature char fall-off in experiment with beam. Detached char is apparent on floor and burner.*

Despite the BLF and resulting premature char fall-off, flaming of the CLT ceiling was observed to stop. Due to the limited exposed combustible surface area, i.e., only a ceiling, upon turning off the burners, the heat flux to the engineered timber ceiling quickly dropped below thresholds typically associated with auto-extinction, see Figure 15. This suggests that for hybridised construction formats, where little interaction between combustible surfaces exists and combustible surfaces are generally limited to ceilings, averting BLF through more heat resistant adhesives is not a prerequisite for adequate structural performance in the event of fire. However, it does require the designer to consider BLF in terms of the impact on structural capacity.

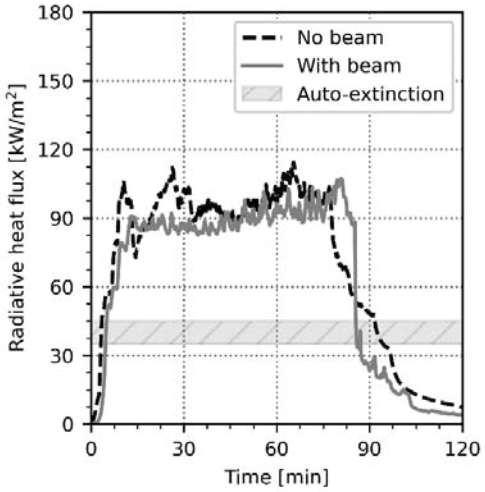

Figure 15: *Radiative heat flux with time to the ceiling at location 14.*

5 CONCLUSIONS

Two experiments are reported herein that are part of a larger body of research work. This paper has focused on the differences between exposed engineered timber ceilings that either include a beam (a glulam beam with CLT slabs) or feature a flat soffit (only CLT). In both experiments, the only variable is the beam which results in a ceiling protrusion. All other parameters, i.e., the CLT type, lay-up and adhesive, burner HRR and instrumentation remained the same. Considering the impact of the down-stand beam, it can be concluded that:

- The presence of the beam locally increased heat fluxes to the ceiling in the near field relative to the case without a beam. In proximity to the beam, this increase was around a factor of two and is attributed to a combination of the constraining of the ceiling jet and a deeper smoke layer.
- The increased heat flux to the ceiling translated to an increase in heat flux to the floor when considered relative to the case without a beam.
- The beam had little impact on reducing the flame lengths at ceiling level, with flaming observed over the full extent of the ceiling in both experiments once the burner HRR reached 1250 kW.
- The increased heat fluxes in the case with a beam present resulted in both a higher overall mass lost by the engineered timber ceiling and total heat release rate.

In more general terms, it is noteworthy that regardless of the presence of a beam, auto-extinction of flaming combustion of the CLT was observed to occur in both experiments. This was despite bond-line failures in both experiments, leading to premature char fall-off. In the

https://doi.org/10.52202/069179-0242

case with a beam, flaming continued in proximity to the glulam beam, which was attributed to the method of fixing, with the beam held in place from below via stirrups. This allowed a gap to develop between the top of the CLT and glulam beam, where flaming persisted, ultimately requiring intervention.

Based upon the findings of other studies conducted as part of the larger STA project, it is expected that the results of these experiments would be applicable to CLT manufactured by different suppliers, subject to consistency in moisture content, adhesive type, edge-bonding condition, CLT thickness and CLT lay-up. Studies reported in Hopkin et al. [10] noted there to be nominal differences in the fire behaviour characteristics of CLT from three different leading suppliers, subject to the same specification parameters. It is expected that such a small-scale testing format/regime could be utilised to inform whether the data developed from the large-scale experiments reported herein could be applicable to a given product/supplier.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the contributions of the wider STA project team, including the discussions and technical contributions made by the Structural Timber Association (STA), BK Structures and Eurban.

PERFORMANCE OF PASSIVE PROTECTION OF CROSS LAMINATED TIMBER DURING STANDARD FURNACE TESTS AND NATURAL FIRES

Siyimane Mohaine[1], Antonela Colic[2], David Morrisset[2], Jean-Christophe Mindeguia[3], Jean-Marc Franssen[4], Jochen Zehfuss[5], Robert McNamee[6], Luke Bisby[2], Fabienne Robert[1]

ABSTRACT: This paper presents the results of an experimental campaign designed to compare and understand the performance of passive protection under exposure to standard furnace tests and natural fires. As part of this campaign, five natural fire experiments were performed with partially protected cross-laminated timber (CLT) compartments under a range of ventilation conditions. In all the tests, only one side wall was left completely unprotected, and all other timber surfaces were protected with either two layers of 18 mm standard gypsum boards (GB) or two layers of 25 mm standard GBs. The structural CLT ceilings were subjected to a superimposed dead load of 1.35 kN/m² during the natural fire tests, and the fire load was (on average) 950 MJ/m²; chosen to represent the Eurocode 1991-1-2 characteristic value for dwellings. The performance of the passive protection was mainly evaluated with regards to the time to reach a protected timber surface temperature of 250°C. The testing confirms that the resulting fire protection performance of a given gypsum board layout depends on the ventilation conditions of the fire compartment, with more severe (and closest to ISO testing) outcomes when testing under ventilation-controlled scenarios. This paper provides data that sheds light on the co-dependency of the passive protection design and compartment fire dynamics and underlines the importance of considering the safety objectives of a building when defining the performance criteria of its structural elements.

KEYWORDS: Fire protection, Gypsum Plasterboard, Mass timber, Cross laminated timber, Natural fire

1 INTRODUCTION

"Too much fire protection is expensive, too little is dangerous" [1]. The use of structural passive fire protection (e.g. plasterboards) is often a key design approach – especially when designing for burnout of a compartment – to limit/prevent structural timber from contributing to a fire event and thus allow for successful compartmentation [2]. The thermal and physical properties of the plasterboards mitigate heat transfer to the structural timber elements in the event of a fire. For mass timber structures, the effectiveness of the protective plasterboards can be quantified in practice by tracking the temperatures at the interface of the plasterboard and the protected timber surfaces. This allows designers to compare the performance of such protective systems under various heating conditions.

Large scale compartment fire tests allow for the investigation of the fire protection instability depending on the natural fire dynamics combined with the application of structural load. Previous studies have demonstrated that flaming extinction in compartments can occur with limited amounts of exposed mass timber, and with the passive fire protection remaining in place. However, this has typically only been demonstrated for the designed fire duration (e.g. 4h [3]), after which experiments are usually terminated using manual suppression. In such prior test series, it has been shown that the total thickness of the necessary passive protection to prevent the contribution of timber to fire (for the constant fire load) varies depending on the ventilation conditions of the compartment. Since plasterboards are sensitive to the high incident heat fluxes (i.e., high heating rates may lead to accelerated deterioration), some natural fire scenarios may result in failure occurring earlier than in standard fire (i.e., furnace testing) conditions [4]. This was also noted by Hartl et al. [5] who tested small scale samples of gypsum plasterboards at heat fluxes of 50 and 100 kW/m².

The tests presented in the current paper are part of a larger research programme: the Épernon Fire Tests Programme – Phase 2. The project seeks to understand the links between normative fire resistance ratings and real fire performance in buildings for combustible and non-combustible structures [6] [7] [8] [9]. The objective of the second phase presented herein is to investigate the performance of different passive fire protection layouts under both standard furnace testing and compartment fire scenarios. The impacts of various parameters are considered, such as the ventilation conditions and the proportion of exposed mass timber surfaces. The performance of the implemented passive protection solutions is evaluated with regards to *(i)* the surface temperature between the fire protection boards and the timber during the entire duration of the fire (including the decay phase) and *(ii)* the time at which the protection fails (see later).

2 CHOICE OF THE PASSIVE FIRE PROTECTION LAYOUTS

The layouts investigated under standard furnace and natural fire conditions were chosen based on existing French guidelines for a layout associated with a fire resistance time of 60 min ([10] [11]). The proposed layout consisted of two Type A 18 mm thick gypsum boards (GBs). An additional layout with a presumed higher fire protection time was also considered, which consisted of two layers of 25 mm GBs. The same mechanical fixing rules – as presented in Table 1 – were used for both the standard furnace and compartment tests. The joints between the boards were staggered from one layer to the other. Distance of fasteners to edges and joints was 10 mm approximately.

Table 1: *Fixing rules for gypsum boards*

2*18 mm GBs			
GB layer		1st (inner) layer	2nd (outer) layer
Screws (length)		35 mm	55 mm
Spacing *(in both directions)*	Ceiling	300 mm	150 mm
	Walls	600 mm	300 mm
2*25 mm GBs			
GB layer		1st (inner) layer	2nd (outer) layer
Screws (length)		45 mm	70 mm
Spacing *(in both directions)*	Ceiling	300 mm	150 mm
	Walls	600 mm	300 mm

Throughout this work, the temperatures at the interface between the mass timber and the inner GB are identified as "surface temperatures" and the temperatures between two GB layers are identified as "interface temperatures".

3 STANDARD FURNACE TESTS

Intermediate scale furnace testing was performed to evaluate the performance of the chosen passive protection layouts under standard fire conditions. The performance has been assessed based on two parameters:
- the time at which the surface temperature reaches 250°C, and
- the time at which the inner GB layer starts to physically fall-off. This was evaluated through visual observation of the exposed face during the tests and the verification of the time at which the surface temperature differed by less than 50 K from the furnace temperatures.

For the performance of 2*18 mm GBs, three different sourcing of the gypsum boards were tested (S1, S2, S3). For the 25 mm GBs, only one sourcing of the boards was used. The tests were conducted under the ISO 834 standard fire exposure and were run until the GBs on all the timber surfaces started to detach from the timber. The GBs were fixed to horizontal CLT slabs (1,70 x 0,98 m²) and were exposed to fire over a surface of 1,30 x 0,98 m².

Table 2 summarizes the time at which the average surface temperatures reach 200°C (a temperature criterion suggested in the STA fire safety guidance to mitigate the onset of pyrolysis for the full duration of the relevant fire resistance period [12]), 250°C (a rise of 250 K is the temperature criterion according to EN 13501-2 and EN 14135 [13]) and 300°C (the temperature typically considered as representing the charring isotherm for timber [14]). In all cases, these temperatures were reached after 60 minutes, and only small deviations were observed between the three specimens. From the temperature criterion presented in Table 2, the difference between the 200°C and 300° criterion provides on average a difference of 12 minutes. For the remainder of the experimental programme presented in the current paper, all GBs correspond to S2.

Table 2. Inner interface temperature of the three 18mm GBs systems from different suppliers under ISO fire

	Interface temperature			Start of GB fall-off
	200°C	250°C	300°C	
S1	86 min *(±4 min)*	91 min *(±3 min)*	97 min *(±4 min)*	113 min
S2	81 min *(±2 min)*	87 min *(±3 min)*	93 min *(±4 min)*	118 min
S3	87 min *(±3min)*	93 min *(±3 min)*	99 min *(±4 min)*	132 min

An additional test has been performed to assess the performance of a thicker layer system, i.e. 2 x 25 mm GBs from supplier S2. The interface and surface temperatures of both layouts under the ISO exposure are shown in ***Figure 1***. Increasing the thickness of each individual GB layer by 7 mm postpones the time at which an average surface temperature of 250°C is reached by about 55 minutes.

https://doi.org/10.52202/069179-0243

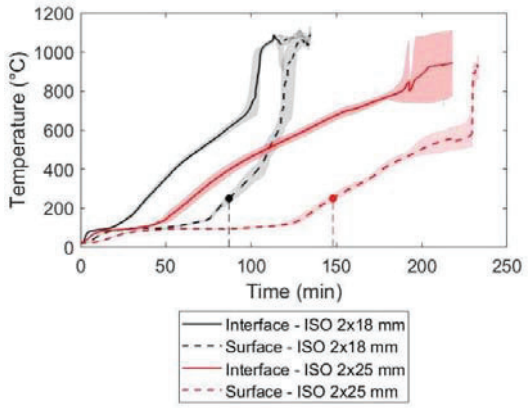

Figure 1. Comparison of ISO exposures with both 2x18 mm and 2x25 mm boards. The symbols indicate the time at which the surface reaches 250°C for each case.

4 NATURAL FIRE TESTS

The natural fire compartments were constructed with an internal area of approximately 21 m² enclosed by mass timber elements which are then surrounded by walls of aerated concrete blocks (Figure 2). Protected walls had two layers of GBs. The inner dimensions of the compartment after the installation of the timber elements and the GBs were 5.6 m (length) x 3.8 m (width) x 2.5 m (height), with small deviations when changing the arrangement of the protected walls (Table 3) or the thickness of the GBs.

The compartment was made of two lateral (i.e. side) loadbearing walls 180 mm thick CLT (40/30/40/30/40) supporting the timber ceiling, and two non-loadbearing longitudinal walls made of 60 mm thick (20/20/20) CLT.

In each test, only one timber surface was left initially exposed to fire. Figure 2 and Table 3 show the distribution of the protected and unprotected surfaces for each test, the passive protection layouts that were used, and the opening factors according to EN 1991-1-2 [15].

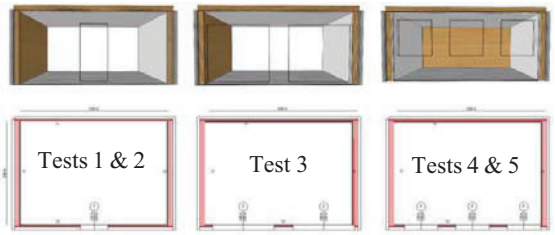

Figure 2: *Compartment plan with 3D view illustrating the opening configurations (W1: left wall, W2: right wall, W3: back wall, W4 : front wall with openings). Tests 1&2 (W1 exposed), Test3 (W1 exposed), and Test 4&5 (W3 exposed).*

The ceiling of the compartment used was a 180 mm thick CLT slab (40/30/40/30/40) for Tests 1 to 4 and a timber frame assembly (TFA) for Test 5 (Figure 3). The joists used in Test 5 were positioned on the spanning length of the ceiling and were spaced every 600 mm on centres. Noggins were also placed every 1,250 mm between the joists to allow additional fixing points for the GBs. The ceilings of the five tests were subjected to an imposed load composed of five dead weights for a total force of 29.5 kN, i.e., an average superimposed dead load of 1.35 kN/m².

Different ventilation openings were arranged in one of the long walls of the compartments to yield different ventilation conditions (i.e., fuel- or ventilation-controlled). Ventilation conditions ranged from an opening factor of 0.032 $m^{1/2}$ to 0.142 $m^{1/2}$.

A total moveable fire load of about 950 MJ/m² (related to the floor area), consisting of six wood cribs (and a combination of heptane and gasoline for ignition) was adopted to represent dwellings as per EN1991-1-2 Annex E [4].

Gas phase temperature measurements were made with plate thermometers (PTs) installed 100 mm from the boundary surfaces of the compartment (11 PTs in front of the ceiling and 9 PTs in front of each wall). Surface and interface temperatures were measured with 7 Type K thermocouples (diameter 1.5 mm) per surface.

In the following subsections, the gas phase compartment and surface/interface temperatures are illustrated for a duration of 130 minutes to interpret the growth and decay phases of the fires. Only the temperatures under the

https://doi.org/10.52202/069179-0243

ceiling are presented in this paper; the complementary data will be presented elsewhere.

4.1 VARIATION IN PASSIVE PROTECTION THICKNESS: 2x18 mm | 2x25 mm

Tests 1 and 2 were intended to represent ventilation-controlled fires (opening factor 0.032 $m^{1/2}$), with an exposed load bearing CLT wall positioned on the left from the opening. The two tests employed different thicknesses of the passive fire protection installed on all other surfaces: 2x18 mm for Test 1, and 2x25 mm GBs for Test 2.

Plasterboard Performance

Figure 4 presents the gas phase compartment temperatures at the ceiling for the two thicknesses of GBs tested. The results seen in ***Figure 4*** are also compared against the ISO 834 temperature-time curve. Performance is analysed in three representative stages for Test 1: <80min (growth), 80-100 min (decay) and >100min (re-growth); and two stages for Test 2: <80min (growth), >80min (decay). Visual representation of the stages is also presented in ***Figure 5*** and ***Figure 6***.

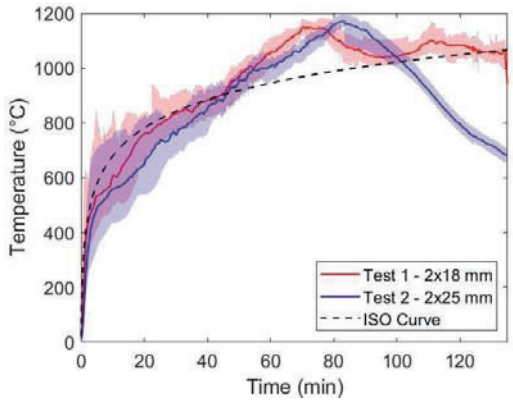

Figure 4: Compartment temperatures (from 11 PTs) under the ceiling for Test 1 (GB 2x18 mm) and Test 2 (GB 2x25 mm) compared to the ISO standard time-temperature curve (shaded areas show the extents of temperature variability).

As indicated in ***Figure 4***, after approximately 40-50 minutes the compartment temperatures in the natural tests 1 and 2 rise above the standardised test curve. The second stage marks the beginning of a decay phase at around 80 min for both natural fire scenarios. However, the onset of mechanical failure of the thinner (18 mm) layer of fire protection boards in Test 1 then led to the third stage, with fire regrowth at around 100 minutes. The temperatures inside the compartment remained approximately steady (at around 1000-1100°C). Conversely, in Test 2, the GBs remained in place for the full duration of the fire, and temperatures decreased in the compartment as a result.

In Test 1, the fire was manually suppressed after 135 minutes due to the severe fire regrowth and safety concerns. In Test 2, the temperatures continued to decay and the fire was manually suppressed after 225 minutes (when average temperatures were about 460°C). Moveable fuel was effectively consumed before the manual suppression in each case. Localised continuous flaming of the exposed load bearing wall was observed independently of the burn-out of the moveable fuel load, as shown in ***Figure 6***-3. This localized flaming continued up until the point of manual suppression (***Figure 6***-4). Continuous burning of the exposed CLT wall, as well as continuous smouldering in the other mass timber elements, were observed in both tests.

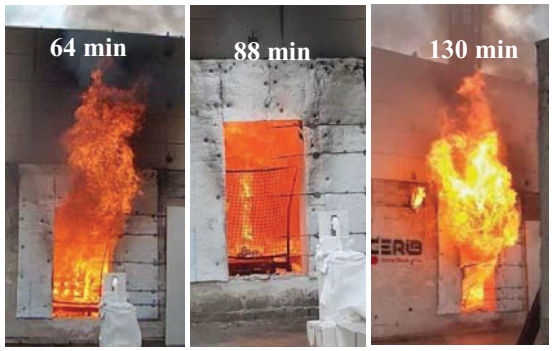

Figure 5. Test 1 stages: growth (l), decay (2), re-growth (3).

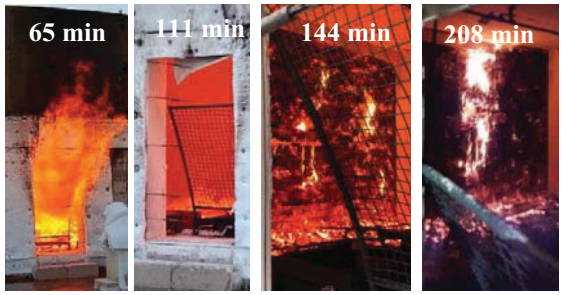

Figure 6. Test 2 stages: growth (l), decay (2); Continuous localised combustion of the exposed wall (3 & 4).

Interface and surface temperatures

Figure 7 shows the ceiling interface (i.e. between two layers of GBs) and surface (i.e. between timber and the inner GB) temperatures in Tests 1 and 2. During the first fire growth stage (<80min), the temperature plateau at 100°C is characteristic of the GB dehydration reaction in both tests, with a notably longer dehydration plateau seen in Test 2. The increased plateau duration was a result of the added thickness (i.e., increased volume of water in the GBs) from the 2*25 mm GBs compared to the 2*18 mm GBs.

https://doi.org/10.52202/069179-0243

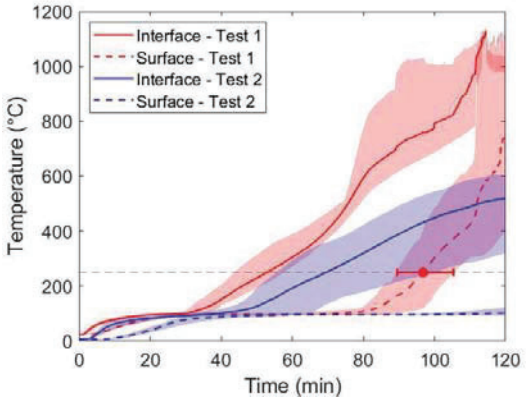

Figure 7. Test 1 and 2 – Ceiling interface and surface temperatures. The symbol indicates the time at which the surface of Test 1 reaches 250°C (error bars indicating the range of times observed).

In Test 1, thermally induced cracks lead to mechanical failure of the boards at about 100 minutes followed by rapid increases in interface temperatures. It should also be noted that after such mechanical failures these temperature measurements may be significantly influenced by gas phase temperatures and may no longer represent the interface temperatures. CLT surface temperatures reach 250°C as early as 90 minutes (an average time of 97 minutes). In Test 2, where thicker GBs are used, interface temperatures between the GBs enter a steady phase from 110 minutes onwards. The surface temperature of the CLT remains below 250°C for the full duration.

4.2 EFFECTS OF VENTILATION CONDITIONS

Tests 1 and 3 include compartments with the same boundary conditions (i.e. applied GBs and orientation of the exposed timber wall) and fuel loads, but a different size of the openings. Two ventilation conditions have been used, whereby an opening factor of 0.032 $m^{1/2}$ leads to ventilation-controlled conditions whereas 0.142 $m^{1/2}$ to fuel-controlled conditions.

Fire development is described in three stages for both experiments. Stages for Test 1 were explained in ***Figure 5***. Test 3's stages are: fire growth (<5minutes), steady state (<30min), and decay (>30minutes) as shown in ***Figure 8*** and ***Figure 9.*** The ventilation conditions resulted in faster fire growth in Test 3, reaching a maximum temperature of 1100°C within 10 minutes. The initial fire growth rate in Test 1 is lower, however it leads eventually to maximum temperatures of approximately 1100°C at 80 minutes.

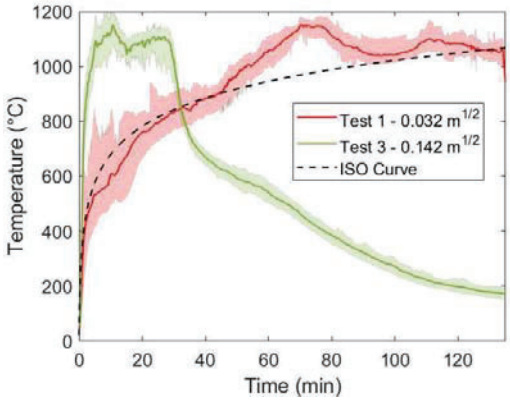

Figure 8: Compartment temperatures for Test 1 (opening factor 0.032 $m^{1/2}$) and Test 3 (opening factor 0.142 $m^{1/2}$) compared to the ISO 834 temperature-time curve.

Figure 9. Test 3 stages: growth (1-upper left), steady-state (2-upper right), decay (3-lower left); Continuous combustion of the exposed wall (4-lower right); Cracks after burnout of the moveable fuel load (5- last).

Rapid fire growth in Test 3 leads to a period of approximate steady temperature conditions where the temperature difference ranges between 200 to 600°C higher than compared to Test 1 or standardised furnace test during the first 30 minutes. The third stage of Test 3 is a decay phase where most of the moveable fuel is consumed; after which localised smouldering and flaming combustion of the combustible wall continues (***Figure 9-4***). All of the GBs remained fixed to the ceiling and walls

https://doi.org/10.52202/069179-0243

in Test 3, however many pronounced cracks were visible (***Figure 9-5***). Manual suppression was *not* performed, and eventually continuous smouldering combustion resulted in collapse of the unprotected wall at some unknown point during the following night.

Interface and surface temperatures

Figure 10 illustrates a more rapid increase in the interface temperatures early into Test 3 compared to Test 1. Test 3 also displays a shorter 100°C temperature plateau due to the more sever heating conditions. Interface temperatures continue to rise 30 minutes into Test 3, after which the compartment temperatures decay (see ***Figure 8***).

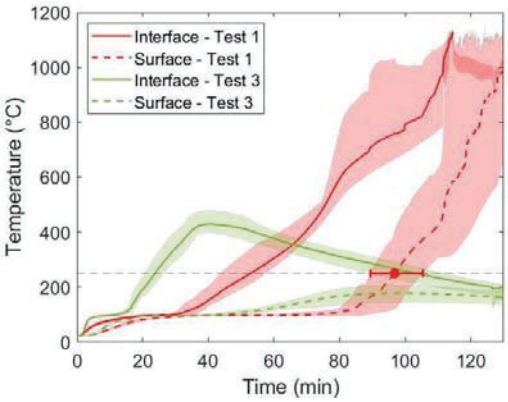

Figure 10. Test 1 and 3 – Ceiling interface and surface temperatures. The symbols indicate the time at which the surface reaches 250°C for each case.

The interface temperature data presented in ***Figure 10*** illustrates an earlier increase in the temperature at the interface compared to Test 1 but the surface temperatures for Test 3 were maintained below 200°C throughout the test. These results suggest that the rapid period of fire growth resulted in an earlier thermal wave through the first plasterboard, but the time scales of burning prevented the thermal penetration to significantly affect the second layer of plasterboard.

In Test 1 both surface and interface temperatures continued to rise at the similar rate once the GBs were dehydrated. Whilst the influence of the heating rate on the performance of the plasterboards was discussed previously [5], premature failure of the front exposed GBs was not observed for the fire conditions in Test 3. This result this confirms the importance of the exposure duration in addition to the heating rate [5].

Interface and surface temperatures: Test 1 and standard furnace fire test

The under-ventilated fire scenario (Test 1) and the ISO 834 furnace test show similar trends in the temperature developments. The average interface temperatures for the standard fire test and Test 1 follow similar heating rates up to 60 min. At about 75 minutes, a local rapid increase of temperatures was observed in Test 1, leading to local temperatures of 1000°C as early as 90 minutes (***Figure 11***).

Surface temperatures for Test 1 are comparable to the ISO 834 standard fire results. An average surface temperature of 250°C was reached at 87 minutes for the ISO 834 test and 97 minutes for Test 1, while this was never reached for Test 3.

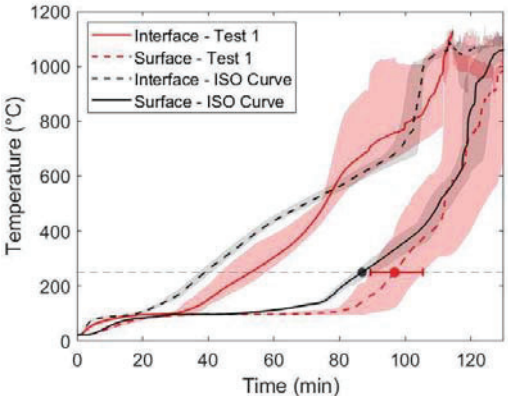

Figure 11. Surface and interface temperatures for Test 1 and furnace test (2*18 mm GBs). The symbols indicate the time at which the surface reaches 250°C for each case.

4.3 CLT VS. TIMBER FRAME CEILINGS

The last two tests of the series differ from Test 1 to Test 3 on two points:
- the use of an "intermediate" opening factor of 0.065 $m^{1/2}$ statistically representative of openings in many residential buildings (see e.g. [16]); and
- the modification of the exposed timber surface. In the first three tests, one lateral 180 mm CLT loadbearing wall was systematically exposed to fire, and continuous smouldering long after the end of the test led to eventual collapse. Thus, in the last two tests, it was decided to expose one long 60 mm CLT non-loadbearing wall (W3, in Figure 2).

Two additional tests were performed with intermediate ventilation conditions in order to compare a CLT and TFA ceiling in natural fire conditions. Test 4 and Test 5 are in all other respects identical except for the nature of the timber ceiling itself. Test 4 consisted of a CLT ceiling (identical to the one used for the previous tests) whilst the latter included a TFA ceiling. Whilst a detailed analysis of these two tests will be provided in a forthcoming paper, the main outcomes are presented here to illustrate differences that can be observed between the performance of mass timber and timber frame under natural fire conditions. Figure 12 shows the compartment temperatures for the two tests, with a reasonable similarity. Test 5 was, however, terminated at 250 minutes due to collapse of the TFA ceiling (see Figure 13).

https://doi.org/10.52202/069179-0243

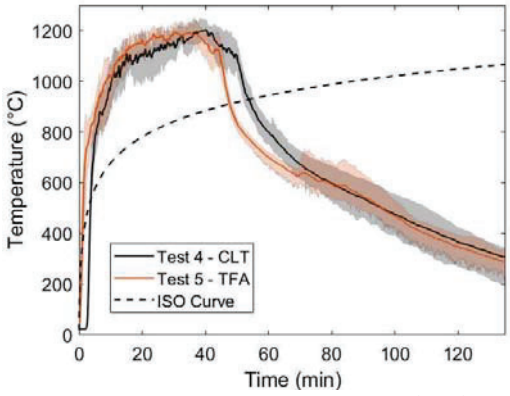

Figure 12. Compartment temperatures under the ceiling (measured with PTs) for tests 4 and 5.

Figure 13. Test 5 failure stages of the protected TFA ceiling.

5 DISCUSSION

Usually standardised pass/fail requirements for surface temperatures are representations of pyrolisis isotherms which indicate that timber is charring or has charred (i.e. 300°C in EN 13381-7 [17], or T_{amb}+250°C in EN 14315 [13] and as a threshold for K classification according to EN 13501-2 [18]). If one considers the *onset* of timber pyrolysis as a timber degradation criterion, this can be considered to occur from about 200°C [19]. The standard tests performed on three different sources of a 2x18 mm GBs layouts have shown that the difference in time to reach these different temperatures is about 10 minutes. Rather than discussing the temperature criteria themselves, an important question to answer is therefore the duration during which this temperature criterion should be delayed or prevented in a standard furnace test in order to limit the contribution of structural timber elements to a real fire – depending on the safety objectives and the fire safety strategy for any given building. If the temperature criterion is reached but the temperatures in the compartment remain high, the degradation of the GBs and the pyrolysis of the protected timber is likely to continue, which could then lead to fire regrowth and the prevention of burnout conditions [2] without fire service intervention. A single fire resistance rating (i.e., R60 or R90) could be associated with different safety objectives or fire safety strategies depending on the type of building (dwellings, offices ...). For some building categories (e.g. dwellings) a common strategy in some European jurisdictions is to limit the immediate evacuation to the floor (or even only the apartment) where the fire has started, while in other jurisdictions the strategy is instead that all people should leave the building alongside an assumption that the fire brigade *will* rapidly intervene. Such complexities warrant further investigation to observe the performance under a range of natural fire conditions.

Five natural fire tests have been performed in timber compartments of 21 m² with one exposed CLT wall and all other surfaces protected by either 2x18 or 2x25 mm GBs. It should be noted that different outcomes could result from exposing more timber surfaces or from changing the orientation of the exposed timber surfaces (e.g., ceiling instead of a wall). Three ventilation conditions were used, ranging from a ventilation-controlled fire (one opening, O=0.032 $m^{1/2}$) to a fuel-controlled fire (two openings, O=0.142 $m^{1/2}$). The variable of the ventilation factor in a realistic fire scenario assumes airflow through an available opening area (e.g., windows). However, toughened and fire rated glazing may not ultimately break, which could lead to a ventilation-limited fire even when large amounts of glazing are present. Hence, this paper analysed performance of the gypsum boards as a product and their influence on the compartment performance (i.e. fire dynamics) assuming all available openings allow for ventilation.

The compartment temperatures leading to manual fire suppression (Tests 1, 2 and 5) or without manual fire suppression (Tests 3 and 4) are given in Figure 14.

In the under-ventilated fire scenarios, the failure of the protection layouts in Test 1 (with 2x18 mm GBs) did not appear for the first 60-80 minutes, but the GBs failure ultimately led to fire regrowth and termination of the test by manual suppression (135 minutes). In Test 2, increasing the thickness of the two GBs by 7 mm each (25 mm layouts instead of 18 mm) significantly reduced the surface temperatures, keeping them below 250°C for the entire duration of the test up to manual suppression. Test 3 was more representative of a fuel-controlled fire and was characterised by a rapid growth and comparatively short fully developed phase. Thus, the interface temperatures in Test 3 were observed to decrease after approximately 40 min and the surface temperatures were found to remain below 250°C for the duration of the experiment. Results for tests 4 and 5, where three openings were used (O=0.065 $m^{1/2}$), are not part of this discussion but are noted to inform that the results obtained on CLT structures cannot strictly be applied to TFA structures. In the performed tests, an earlier failure of the TFA ceiling was observed compared to the CLT ceiling.

https://doi.org/10.52202/069179-0243

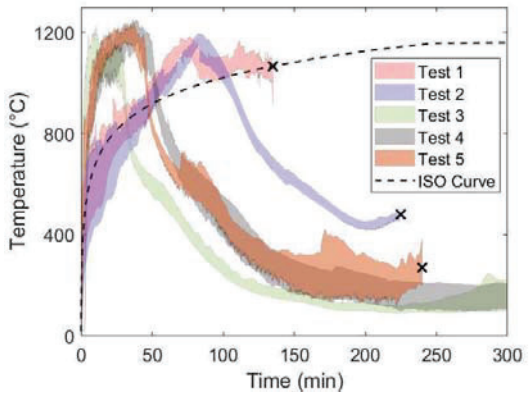

Figure 14. Overview of the compartment temperatures of the five natural fire tests up to 300 minutes with indication of manual suppression times (Tests 1, 2 and 5)

Each compartment was observed to collapse in the night following the experiment. Even the trials in which the CLT surface was measured to remain below the pyrolysis temperature were observed to ultimately fail (e.g., Test 3). In Test 1, following fire suppression at 135 min, the compartment temperatures were observed to steadily increase over a period of approximately 250-500 min. While the time of the structural failure is difficult to predict with certainty from temperature measurements alone, a collapse was observed approximately 6 hours following manual fire suppression. This underlines the importance of properly suppressing continued flaming and smoldering. In-depth heating of the timber may result in ongoing smouldering of mass timber structural elements, and potentially in re-ignition at a later stage. Understanding the mechanisms that may lead to delayed collapse, as observed in these experiments, requires further investigation.

6 CONCLUSIONS

A series of furnace and natural fire tests has been performed to study the performance of two passive fire protection schemes in various standard and natural compartment fire scenarios, and with the presence of one exposed CLT wall. It should be noted that different outcomes may result from exposing more timber surfaces or from changing the orientation of the exposed timber surfaces (e.g., ceiling instead of a wall). The experimental campaign confirmed that the performance of a given GB layout depends on the ventilation conditions of the fire compartment, with more severe outcomes when testing under ventilation-controlled scenarios for the given fuel loads used. This paper and the overall Épernon Fire Tests Programme Phase 2 suggest that GB passive protection applied to CLT appeared to perform about as well as it did in furnace tests (for the chosen performance criteria and the configurations tested). The data confirmed that ongoing smouldering and localised burning, if not fully supressed after the steady burning phase of a severe fire, have the potential to result in reignition and/or structural collapse at some time after the fire *appears* to have been extinguished. The conducted tests provide data that underline the importance of considering the safety objectives of the concerned building when defining performance criteria of a structural element.

NATURAL FIRE TESTS ON GLT COLUMNS INCLUDING THE COOLING DOWN PHASE

Fabienne Robert[1], Jean-Marc Franssen[2], Jochen Zehfuß[3], Sven Brunkhorst[4], Patrick Bamonte[5], Silvio Renard[6], Robert McNamee[7], Thomas Gernay[8]

ABSTRACT: This paper presents the data and the results of seven fire tests performed on glue laminated timber columns in a compartment built especially for the tests and in which timber wood cribs created a so-called natural fire. These tests are part of a research programme titled "burnout resistance" to establish a new methodology to better describe performance of structural elements during the whole duration of a fire. Comparisons with similar tests made in a fire resistance furnace allow comparing charring rates observed in standard conditions and in natural fires.

KEYWORDS: Fire, Column, GLT, timber, cooling

1 INTRODUCTION

The concept that has been used overwhelmingly for nearly one century to characterize and classify the ability of loadbearing members to withstand fire exposure is the concept of *fire resistance*. The element is loaded and then subjected to a standardised heating regime characterised by a time-temperature curve, for example the ISO 834 fire curve mentioned in Eurocode 1 [1] in Europe. If the fire resistance is determined by a test (as opposed to calculation), some prescriptions are also given about the pressure and the oxygen content in the furnace atmosphere [2]. The concept of fire resistance is a grading system. It is known that the duration which is the expression of the result must not be taken as the time during which the member, used in a real structure, would survive to a real fire that would develop in a real building. The underlying hypothesis of using the concept is that there is a monotonically increasing relationship between the fire resistance time and the performance level in a real fire; an element that has a higher fire resistance should perform better in a real fire, whatever the fire may be, than an element with a lower fire resistance. Similarly, if two different elements have the same fire resistance time, their performance in a real fire should be equivalent.

Although the concept of fire resistance has many shortcomings, there is some logic in that as long as the temperature of the fire is constantly increasing, as this will lead to constantly increasing temperatures in the elements and thus presumably to a constantly decreasing load bearing capacity.

Yet not all structures collapse during the heating phase of a fire. Some, if not most of them when the fire design was appropriate, are still standing when the fire temperatures start decreasing, either from firefighting intervention or from a lack of combustible material in the fire compartment. If the structure collapses during the cooling phase of the fire or even after the temperatures in the building compartment have gone back to ambient, this is a serious hazard for occupants that may not yet have evacuated the building but also for firefighters and rescue services who may still be fighting the fire or searching for occupants. There is a need for a new concept to allow evaluating the risk of collapse during or after the peak of the heating phase, as the current concept of fire resistance does not address this phase of the fire.

This paper first explains why the risk of collapse during the cooling phase of the fire may be particularly critical for timber elements, from theoretical considerations, then from some numerical examples and from experimental tests performed in a revised standardised environment. It then presents the results of seven tests performed in a room filled with a timber fuel load to generate a so-called natural fire with the first objective to check whether the observations and the conclusions derived from theoretical considerations, from numerical modelling and from standardised tests would remain valid when timber elements are subjected to a fire development more similar to a real fire. The final objective of the research is to provide appropriate tools to design non-protected timber elements which maintain stability during the whole duration of the fire including the cooling down phase.

2 THEORETICAL CONSIDERATIONS

Timber is a solid material in which heat transfer is predominantly by conduction when subjected to a

temperature gradient. This is the case in a solid timber wall or slab when building physics considerations are at stake, for thermal insulation of a house in the winter, for example. This is also the case in timber or in the charred layer of a timber element subjected to the fire, although many chemico-physical phenomena which are much more complex than conduction occur in this case, such as evaporation of moisture, movement of moisture, pyrolysis, combustion of the char, formation of cracks and shrinkage leading to a change of geometry [3]. The subsequent considerations are based on a simple conductive model, the simplicity of which allows deriving interesting qualitative conclusions.

Starting from an initial condition when a section is at a low quite uniform temperature distribution, the thermal gradient during a fire is from the outside to the inside of the section as long as the fire temperature increases and, in the beginning of the cooling phase, as long as the fire temperature is higher than the surface temperature of the section. The heat transfer is thus also from the outside to the inside of the section and the temperatures are rising everywhere in the section.

When the fire temperature becomes lower than the surface temperature of the section, the heat exchange at the surface is from the section to the environment and the peripheral zones of the section start cooling down. Yet, there is still a positive temperature difference between these peripheral zones and the centre of the section. As a consequence, part of the energy of the peripheral zones does not travel toward the environment, but toward the centre of the section where the temperatures keep on rising for a certain time, to finally decrease when the whole section goes back to ambient temperatures.

Figure 1, for example, shows the temperature profile along the centreline of a 280 x 280 mm² timber section subjected to the parametric fire of Eurocode 1 [1] with a Γ factor equal to 1 (and, thus, a temperature evolution during the heating phase very close to the ISO 834 fire curve) and a heating phase of 60 minutes; see Figure 4 for curves with a Γ factor equal to 1. The curves of Figure 1 result from numerical modelling, see section 3, and the temperatures are given after 1, 2, 3 and 4 hours.

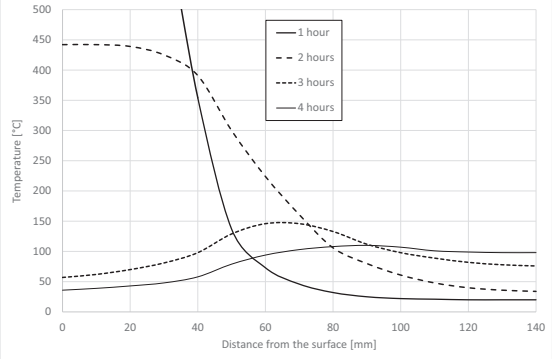

Figure 1: *Temperature evolution in a square timber section*

It can be observed that the temperature continues increasing in the zones of the sections long after the fire has reached its maximum temperature. A similar behaviour occurs in a human body member that has been severely burnt at the surface, hence the recommendation to keep the member under cold water for a long duration. What is specific to timber yet, is that the loss of mechanical properties with temperature is very fast, with all strength being lost at a temperature as low as 300°C according to Eurocode 5 [4]. Figure 2, for example, shows the evolution of the relative compressive strength of timber according to Eurocode 5 [4].

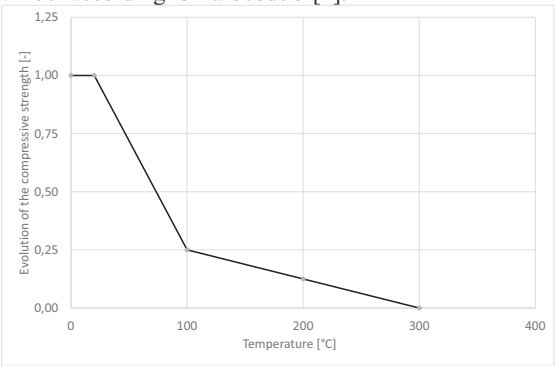

Figure 2: *Decrease of compressive strength according to EC5*

In addition to that, most of the phenomena that develop during heating, such as moisture evaporation, pyrolysis and combustion are irreversible (moisture may re-enter in the section in the long term, but not in the timeframe of a few hours) and it is thus unlikely that the mechanical strength can recover when char or heated timber cool down. Figure 3 shows, as a dotted line, the maximum temperature observed at any time along the centreline under the parametric fire discussed in Figure 1 and, as a full line, the residual compressive strength obtained from the curve of Figure 2 assuming that the residual strength is the same as the one determined at the maximum temperature.

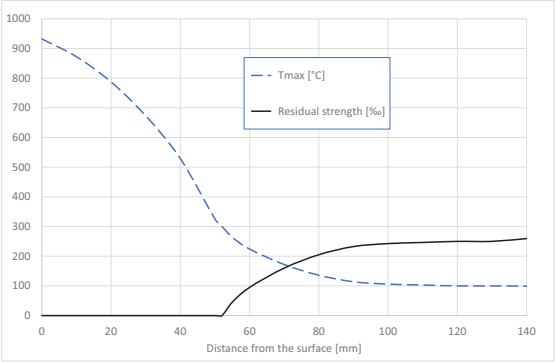

Figure 3: *Maximum temperature computed and corresponding residual compressive strength in a timber square section*

3 NUMERICAL SIMULATIONS

To quantify the theoretical considerations developed in section 2, Gernay made extensive numerical simulations

https://doi.org/10.52202/069179-0244

on timber columns [5], deriving their 'Duration of Heating Phase' (DHP [6]). The DHP quantifies the *longest* duration of exposure to heating according to the standard ISO 834 fire that will guarantee stability of a member throughout the entire fire duration. Figure 4 shows, in addition to the ISO curve on which the fire resistance time R has been noted, four parametric fire curves, each characterized by a different duration of the heating phase. Only one of these curves, the black one, corresponds to the DHP.

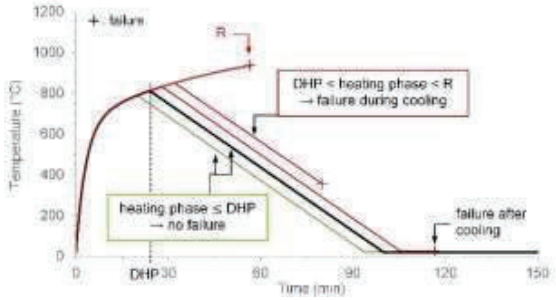

Figure 4: *Principle of the DHP*

In these simulations, the thermal and mechanical properties were taken as recommended by Eurocode 5 and it was assumed that all properties during the cooling phase keep the value they had at maximum temperature.
Gernay concluded that, depending on conditions, the DHP of timber columns varies between 20% and 50% of their standard fire resistance time. In other words, a column that is rated as R60 will collapse during or after the cooling phase if it is heated by the ISO curve for more than 30 minutes, followed by a linear cooling down phase of the fire temperature. In the worst situations, the heating phase of the fire cannot last for more than 12 minutes if stability after full burnout must be ensured.

4 EXPERIMENTAL TESTS IN MODIFIED STANDARD CONDITIONS

The numerical results mentioned in Section 3 are dependent on hypotheses on the material properties that, although they seem reasonable, have not been validated experimentally. The precise determination of all these properties in the cooling phase may be the topic of further fundamental research. In the meantime, researchers rely on experimental tests performed on timber elements to investigate the behaviour of these elements, such as the tests reported by Kinjo et al on GLT beams [7]. An experimental program was launched by CERIB with international partners to see whether the conclusions of the numerical simulations reported in [5] could be confirmed by tests on full scale timber columns.
A series of 8 tests were performed at the Technische Universität Braunschweig glued laminated timber columns with a section of 280 x 280 mm² [8]. The columns were pinned-pinned at the ends with a length between the support of 3,72 m and the load was applied with an eccentricity of 20 mm at each end. The columns were tested in a standard fire resistance furnace in which the heating according to the ISO 834 curve was applied for different durations, followed by a linear cooling down phase with a rate of -10.4°C/min.
The fire resistance of the columns was first determined as 55 and 58 minutes (two specimens). Two specimens were then subjected to a heating phase of 15 minutes and failed after 98 and 153 minutes. Two specimens heated for 10 minutes both survived the defined heating-cooling exposure. These furnace tests showed that timber columns can fail during the cooling phase when exposed to standard ISO 834 fire exposure for a duration significantly shorter than their standard fire resistance. In this particular case, the DHP between 10 and 15 minutes, is in the range of (18% ; 27%) of the average value of the fire resistance time (56.5 minutes), rather on the lower side of the range (20 % ; 50%) observed in the numerical analysis.
Thermocouples inside the columns also confirmed the sustained temperature increases for hours after the end of the heating phase, as shown by the numerical models.

5 EXPERIMENTAL TESTS UNDER NATURAL FIRE CONDITIONS

5.1 INTRODUCTION

Although the tests mentioned in section 4 confirmed the theoretical considerations and the numerical simulations, these tests have some features which are different from those of a real fire such as, for example, the nature of the fuel, the oxygen content, the shape of the cooling phase curve and the procedure that was followed in the tests to control the temperature in the cooling phase.
A series of tests was thus performed in a compartment specifically built at the Fire Testing Centre of CERIB, in France, in condition supposed to represent as closely as possible the conditions which could prevail in a real fire.
.

5.2 THE COMPARTMENT AND THE FIRE LOAD

The compartment was made of 300 mm walls of aerated concrete blocks and the roof was made of 200 mm thick slabs of aerated concrete. The concrete floor was insulated by a layer of mineral fibres, covered by a 20 mm thick layer of plasterboards. The ceiling was made of 200 mm thick slabs of aerated concrete, protected for the tests 11 to 15 by 55 mm of mineral wool.
The distance from the floor to the ceiling was 3.10 m for tests 9 and 10 and 3,05 m thereafter, and the internal dimensions in the plan view were 6.00 m by 4.00 m.
Different openings were made in one of the long walls to create the desired opening factor as mentioned in Table 1.
The fire loads was made of wood cribs of (0.75 m)³ made of 10 layers of 5 sticks with a section of 83 x 83 mm². The fire load was also varied from test to test to create the fire load density mentioned in Table 1. The wood cribs were ignited simultaneously to reach as quickly as possible a post-flashover fire.

https://doi.org/10.52202/069179-0244

The main characteristics of each tests are shown in Table 1, with the shaded cells showing the difference with respect to test 10 which could be seen as a reference from which variations have been made.

Table 1: *Conditions in the fire compartment*

Test	O ($m^{1/2}$)	q (MJ/m^2)	Section (mm^2)
9	0.144	780	280 x 280
10	0.065	780	280 x 280
11	0.065	950	280 x 280
12	0.065	780	340 x 340
13	0.065	780	360 x 360
14	0.065	420	280 x 280
15	0.032	780	280 x 280

5.3 THE COLUMNS

The tested columns were made of GLT with a section of 280 x 280 mm² for most of them, 340 x 340 mm² for test 12 and 360 x 360 mm² for test 13. The length of the timber columns was 3 680 mm. With the steel head plate and base plate, axes of the cylinders that formed the boundary conditions at both ends were at a distance of 3 740 mm.

5.4 THE LOAD

As for the tests made in Braunschweig, a load of 322 kN was applied with an eccentricity of 20 mm in one direction at both ends. The load was maintained for 15 minutes before the fire load was ignited and it was kept constant during the whole fire duration.

5.5 THE FIRE TEMPERATURES

The average temperature recorded in the compartment for all tests can been seen on Figure 5.

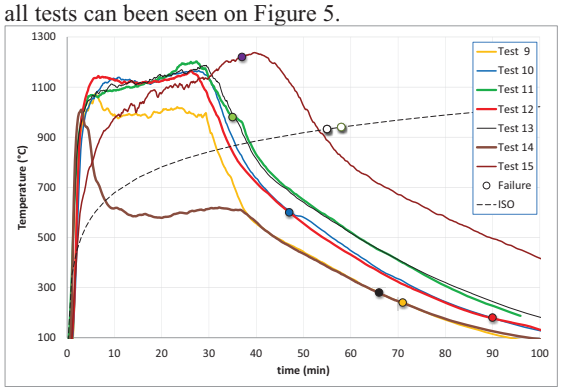

Figure 5: *Temperatures in the fire compartment*

Test 9 had a very large opening factor created by 3 openings of 1,30 x 2,50 m², see Figure 6, which led to the temperatures being limited to 1 000°C during only 30 minutes.

Figure 6: *Test 9 during the cooling phase*

The five subsequent tests were performed with an opening factor reduced by a factor of 2, with 3 openings of dimensions 1,30 x 1,50 m².

A similar situation developed in the compartment during tests 11, 12 and 13 although the fire load has been increased by 22% in test 11.

The fire load was reduced in Test 14 leading to a fuel-controlled fire with a lower power than the previous tests as soon as the heptane used as an ignition source was consumed. Oxygen concentration in the compartment indeed remained around 15% from minute 7 to minute 40 and increased in the cooling phase (oxygen concentration was around 2% for all other tests - except test 9 were it was around 5% - until the cooling phase started). This resulted in the peak temperature of around 1 000°C to be observed only from minute 2 to minute 5, after which a plateau of 600°C lasted for about 40 minutes.

The opening factor was again reduced by a factor of 2 for test 15 which was performed with a single opening of dimensions 0,95 x 2,40 m². The temperature development was more severe in this test with average temperatures reaching 100°C after 10 minutes, increasing steadily up to some 1 250°C after 45 minutes when the cooling down phase started.

5.6 RESULTS

In test 9, the column failed after 71 minutes when the temperatures in the compartment were down to the range from 200 to 300°C. Figure 7 shows the evolution of the temperature measured at different depth from the surface on the centreline of the section, each curve being the average of 6 measurements, 2 in the lower part of the column, 2 at mid height and 2 in the upper part. Although these temperatures have been obtained for a different fire curve and they are presented in a different form, these results confirm the trend presented in Figure 1, with temperatures decreasing very soon after the peak of the gas temperatures in peripheral zones of the section, while they keep on increasing during the cooling down phase in the central zones.

https://doi.org/10.52202/069179-0244

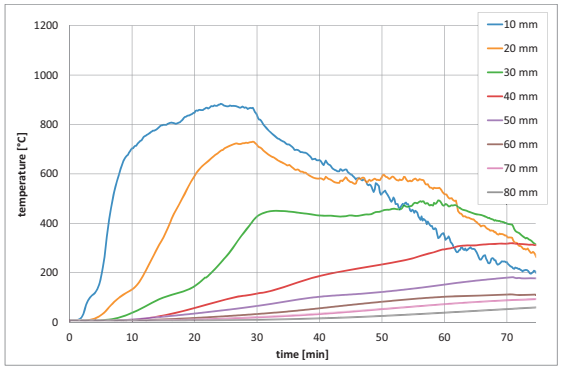

Figure 7: *Evolution of the temperature at different depth in the section for test 9*

At the time of failure, temperatures were at or above 300°C at 42 mm from the surface, 115°C at 60 mm and 55°C at a 80 mm. From the time it took to the 300°C isotherm to reach different depth, the average value of the charring rate can be calculated as 1.41 mm/min for the first 14 minutes, 0.83 mm/min from 14 to 26 minutes, and 0.28 mm/min from 26 to 61 min. These values can be compared to the quasi-constant value of 0.6 mm/min which was observed during tests 1 and 2 made under ISO curve in Braunschweig.

In test 10 where the opening factor had been reduced, the column failed after 47 minutes when the temperatures in the compartment were around 600°C. The temperatures in the peripheral zones increased faster, with average values of the charring rate varying from 1.78 mm/min during 11 min, 1.33 mm/min to 19 min and 1 mm/min up to 27 min. At the time of failure, a layer of 46 mm was at or above 300°C, the temperature was 115°C at 60 mm, but still at ambient at 80 mm.

In test 11 where the fire load had been increased but the compartment temperatures nevertheless followed the same evolution as in test 10, failure occurred after only 35 minutes, early in the cooling down phase with gas temperatures still around 980°C. This result, compared to the result of test 10, gives an idea of the variability inherent to the material.

Test 12 was made in the same conditions as test 10 but with a column that had a section of 340 x 340 mm². The objective was to see whether these additional 30 mm of "protection", together with an initial load level reduced to 68% of the one of test 10, would allow the column to survive to the fire until complete burnout and after. Collapse occurred after 90 minutes when the temperatures in the compartment were down to 180°C.

The section was increased again to 360 x 360 mm² for test 13 made in the same conditions as tests 10 and 12. The column was still supporting the load after 98 minutes, when an instability of the loading system developed at one of the supports due to an imperfect insulation of this support.

For test 14, the 280 x 280 mm² section was used again, but with a reduced fire load and hence, significantly lower temperatures in the compartment, exceeding 600°C for only 7 minutes. Collapse occurred after 66 minutes, with gas temperatures around 280°C.

Test 15 was also made with the 280 x 280 mm² section, with the same fire load as in test 9, 10, 12 and 13 but with a reduced opening factor leading to a longer duration of the heating phase and to higher temperatures in the cooling phase. Collapse occurred after 37 minutes, shortly before the end of the heating phase. It has yet to be mentioned that the temperatures measured differed significantly from one side of the section to the other side. Figure 8 showed that this was observed consistently for all three levels in the compartment where the measurements were made.

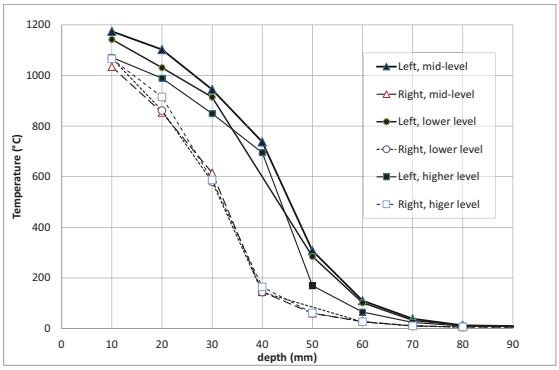

Figure 8: *Temperature distribution in the section at the time of collapse in test 15*

This may be due to the position of the unique opening which was not symmetrically located with respect to the column, as can be seen on Figure 9.

Figure 9: *Position of the opening in test 15*

This non symmetrical temperature development in the section developed although the temperatures measured in

https://doi.org/10.52202/069179-0244

the compartment did not display the same pattern, as can be seen on Figure 10. This may be due to a different oxygen content on the side of the column which was close to the opening compared to the other side.

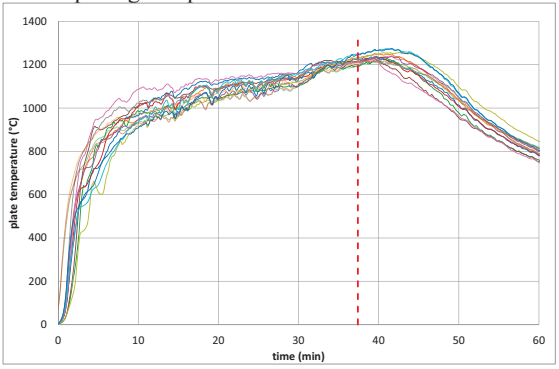

Figure 10: *Temperatures in the compartment in test 15*

Timber is indeed a material in which the physical phenomena that develop in case of fire are driven not only by the temperature but also by oxygen penetration.
This non symmetry in the section has created a structural imperfection that may have influenced the stability of the column. Although this makes it more difficult to compare the results of this test with those of the other tests in this scientific campaign, there is also a lesson to be learnt in the sense that nothing will guarantee a perfectly symmetrical development of the temperatures and of the char penetration in a real fire. Other materials would also be affected by differences in temperatures whereas timber may be the only material affected by differences in oxygen concentration.

5.7 CHARRING RATES

In was not possible, in these destructive tests, to measure the charring rate by direct visual observation. If charring is defined as reaching a temperature of 300°C, temperature measurements at different depth from the exposed surface allowed to observe the time at which each thermocouple reached this temperature and, hence, the average charring rate for the zone between two thermocouples.

Table 2: *Average charring rate for different zones along the depth.*

	0 - 10 mm	10 - 20 mm	20 - 30 mm	30 - 40 mm	40 - 50 mm
Test 1 (ISO)	0,67	0,63	0,55	0,51	
Test 2 (ISO)	0,67	0,70	0,63	0,50	
Test 9	1,71	1,20	0,83	0,28	
Test 10	1,82	1,74	1,33	1,13	
Test 11	1,69	1,82	1,17	0,92	
Test 12	1,74	1,69	1,05	0,78	
Test 13	2,00	2,14	1,05	1,29	1,24
Test 14	1,88	0,47	0,32		
Test 15	1,52	1,48	1,11	0,85	1,11

Table 2 shows the average value of the charring rate for different zones of 10 mm. Results from test 1 and 2 [8] show that the logarithmic increasing character of the ISO curve ensures a charring rate that is more constant than the one produced during the phase of the natural fire where the fire temperature was quasi constant. The charring rate in the natural fire tests decreases constantly during the period of quasi constant gas temperature, to finally drop down to 0 or very low values during the cooling phase.
Another difference is that, in natural fires, there is no zero strength layer of constant depth pushed ahead of the charring front, as assumed in the simple method of Eurocode 5. In the cooling phase of natural fires, the isotherms at 200°C and 100°C continue their progression long in the cooling phase.
This seems to indicate that a simple method to design timber elements under natural fire curves cannot result from a simple adaptation of the two values used for the constant charring rate and constant zero strength layer.

6 FUTURE TESTS AND FUTURE WORK

Two more tests should be performed by the time of the conference. Numerical simulations performed with the code SAFIR® [9] will also supplement the test results and will allow verifying whether the effective thermal properties of timber proposed in Eurocode 5 can be applied for computing temperatures in timber under nonstandard fires.
The last task will be to define a simple calculation method that ensures survival of timber columns during the whole duration of natural fire curves.

7 CONCLUSIONS

Seven tests have been performed under natural fire conditions on glue laminated timber columns for which the reference section of 280 x 280 mm² was shown to have a fire resistance of 55 and 58 minutes in standard testing conditions (two tests made).
In one test (test 15), collapse occurred after 37 minutes of the heating phase, but the temperatures in the compartment were higher than those of the ISO curve and a difference of temperature was observed between one side of the section and the other side, which induced a structural load eccentricity.
In one test made on a column with section increased by 65% (test 13), the columns had survived a heating phase of 30 minutes and was still supporting the load when a problem at one support of the loading system left to the premature termination of the test after 98 minutes, long into the cooling phase but not long enough to have all temperatures in the section back to ambient.
For the other 5 tests, failure occurred during the cooling down phase. For 3 of them with the same section (tests 9, 10 and 11), the temperature in the compartment had been higher than that of the ISO curve for the first 32 to 38 minutes and lower thereafter. For another one (test 12) the

https://doi.org/10.52202/069179-0244

temperature had been higher than that of the ISO curve during the first 35 minutes, but the fact that the section had been increased by 47% did not prevent it from collapsing after 90 minutes, when the temperatures in the compartment had significantly decreased. For one test (test 14) the section also collapsed in the cooling phase although the temperatures in the compartment had been significantly lower than those of the ISO curve for most of the test.

These tests confirm the conclusion of previous numerical and experimental studies that a timber column can fail in a fire long after the fire temperatures started to decrease, and the fact that the structural element displays some "self-extinction" does not mean that its stability is ensured.

Some of the results tend to confirm that the influence from a fire on a timber member is not as directly linked to temperature as could be the case for other inert materials. Oxygen content in the vicinity of the element and other complex exothermic phenomena may probably also play a role. Temperature development and oxygen repartition in the compartment can be influenced by wind velocity and direction and, although the tests were performed with a maximum wind velocity in the order of 2 m/s (maximum gusts at 3 m/s), the direction varied from test to test.

The quantitative results should, with the results of the additional tests planned and with the help of numerical modelling, allow deriving a simple model for computing the behaviour of timber members under real fires including the cooling down phase. Also, using the DHP as a simple metric indicating real fire behaviour including the cooling phase will be further investigated.

FULL SCALE VIBRATION TESTS ON A LONG SPAN TIMBER FLOOR

Patricia Hamm[1], Valentin Knöpfle, Johannes Ruf, Philipp Bacher[2], Tobias Götz

ABSTRACT: Since January 2021, Biberach University of Applied Sciences has been working in cooperation with PIRMIN JUNG Deutschland GmbH, Remagen, on the development of a lightweight, vibration-optimized timber floor system for large spans. There is already research that deals with the vibration behaviour of wooden floors. The new focus in this project is primarily on size. Structures such as schools, administrative and office buildings require floors with very large column spacings and therefore very large spans. Existing approaches to serviceability design of timber floors reach their limits for long-span timber floors with spans over 8 m. Therefore, a physical test bench with an aera of 12.5 by 12.5 m² and the inclusion of flexible bearings was built. Various floor systems with spans of up to 12 m were measured and evaluated. As a result, the cooperation partners have received important input for new design rules for very large timber floor systems.

KEYWORDS: Vibration, Timber Floor, full scale tests, long span,

1 INTRODUCTION

Since 2021, Biberach University of Applied Sciences has been working in cooperation with PIRMIN JUNG Deutschland GmbH, Remagen, on the development of a lightweight, vibration-optimized timber floor system for large spans. There is already research that deals with the vibration behaviour of wooden floors. The new focus in this project is primarily on size. Structures such as schools, administrative and office buildings require floors with very large column spacings and therefore very large spans. Existing approaches to serviceability design of timber floors reach their limits for long-span timber floors with spans over 8 m. Therefore, a physical test bench with an aera of 12.5 by 12.5 m² and the inclusion of flexible bearings was built. Various floor systems with spans of up to 12 m were measured and evaluated. The vibrations are measured when people walk on the test floor, to evaluate the conditions with the best vibration properties.

This research project "Development of a lightweight, vibration-optimized flooring system with beams for large spans over 8 m" includes theoretical and practical considerations on the vibration and damping behaviour of timber floors with large spans and beams.

2 EXISTING DESIGN RULES IN CODES AND LITERATURE

2.1 EUROCODE 5

Eurocode 5 [1] gives a suggestion, how to proof the vibrations of floors.
It is divided in the following **three verifications**:

1. The natural frequency of the floor should be at least 8 Hz, see equation (1).
2. The deflections due to a single force should be less than a varying value a, see equation (2), values for a are given in figure 1.
3. The velocity v due to an impulse of 1 Ns should be less than the value according equation (3) (for b see figure 1).

$$f_{e1} \geq 8\ Hz \tag{1}$$

$$\frac{w}{F} \leq a \quad [mm/kN] \tag{2}$$

$$v \leq b^{(fe1 \cdot D-1)} \quad [m/(Ns^2)] \tag{3}$$

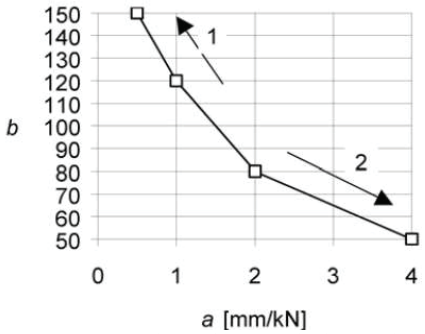

Figure 1: *Interrelation between the limit values a and b taken from Eurocode 5 [1]: Direction 1 means better behaviour, direction 2 means worse behaviour.*

[1] Patricia Hamm, Biberach University of Applied Sciences, Germany, hamm@hochschule-bc.de
[2] Philipp Bacher, Pirmin Jung Deutschland GmbH, Germany, philipp.bacher@pirminjung.de

https://doi.org/10.52202/069179-0245

If equation (1) is neglected and the natural frequency is less than 8 Hz, a more precise investigation should be conducted. However, Eurocode 5 [1] does not provide any further information on this more detailed verification.

2.2 FORMER RESEARCH

To close this gap, a research project was carried out at the Technical University of Munich from 2007 to 2009 and published in [2]. The research project showed that floors with natural frequencies less than the limit frequency work if two conditions are given: The frequency must be greater than the minimum frequency of 4.5 Hz and the acceleration due to walking in resonance with half or third the natural frequency is less than a limit acceleration.
The proof of acceleration is successful only in case of a heavy floor, such as timber-concrete composite systems or systems with wide spans.
The following flowchart (figure 2) shows the proof of vibrations according to [2].

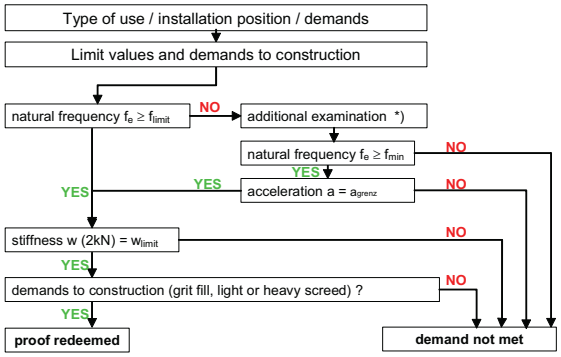

Figure 2: *Chart of rules for design and construction according to [2].*

2.3 DRAFT OF EUROCODE 5

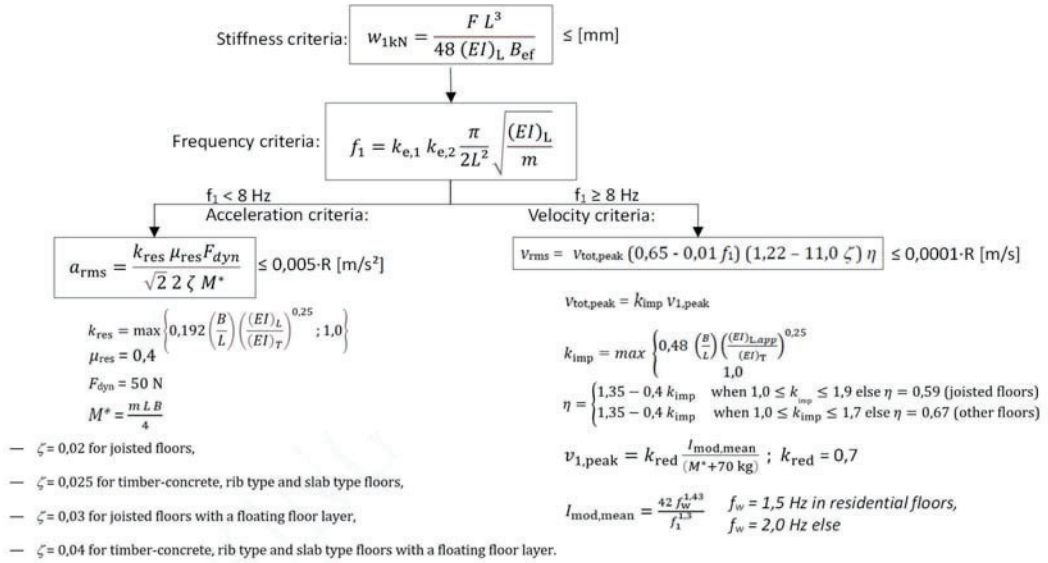

Figure 3. *Flowchart and equations according to [3].*

The basic idea of the new draft of Eurocode 5 [3] was to change the rules in a way, that the perception will be the most important value. Therefore, it was decided to introduce the response factor R. The perception depends on the first natural frequency, as shown below:

a_{rms} < Response factor × $a_{rms,base}$ when $f_1 < 8$ Hz
v_{rms} < Response factor × $v_{rms,base}$ when $f_1 \geq 8$ Hz

Figure 3 shows the principal way and the main equations of the proof, see also [4]. Table 1 contains the limit values of deflection due to point load and the response factors depending on the performance levels, taken from [3].

Table 1: *Limit values and response factor R according to performance level.*

	Floor performance levels					
Criteria	I	II	III	IV	V	VI
Response factor R	4	8	12	24	36	48
Stiffness criteria for all floors w_{1kN} [mm] ≤	0,25		0,5	1,0	1,5	2,0
Frequency criteria for all floors f_1 [Hz] ≥	4,5					
Acceleration criteria for resonant vibration ($f_1 < 8$ [Hz]) a_{rms} [m/s²] ≤	0,005 R					
Velocity criteria for transient vibration ($f_1 \geq 8$ [Hz]) v_{rms} [m/s] ≤	0,0001 R					

https://doi.org/10.52202/069179-0245

3 MOTIVATION

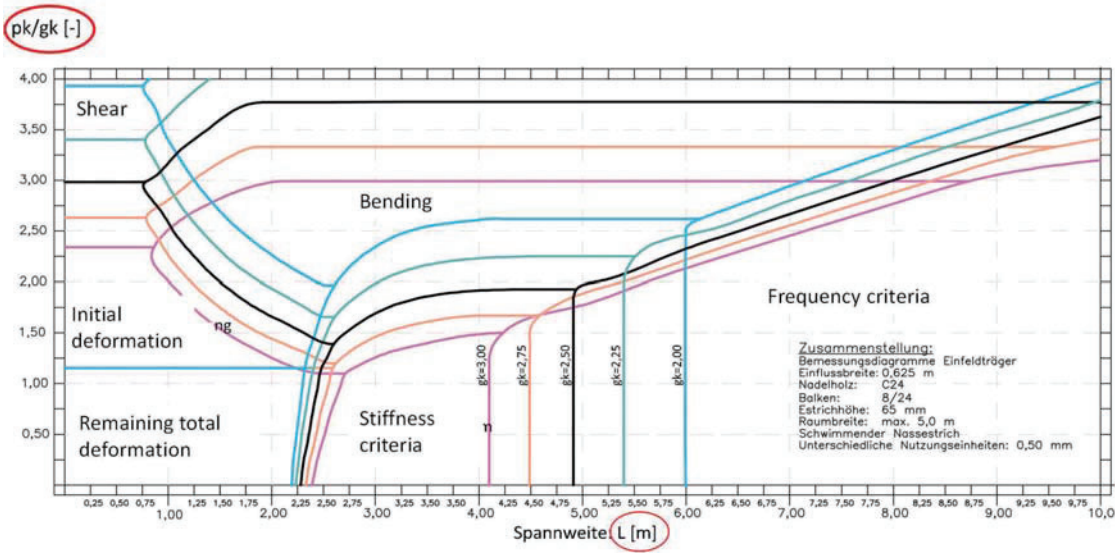

Figure 4. *Design relevant proof for a floor depending on span, based on [2], taken from [5].*

In [2] a possibility to handle low frequency floors is given. This "additional examination" has been adopted to [3] quite similar. Since this proof is based on mechanical laws, it works well.
The background is that low frequency floors are in resonance with one of the higher harmonics of the force that users exert to the floor when walking. Assuming resonance, the resulting acceleration can be calculated and compared to the limit value. To fulfil this proof, very heavy floors are needed.

On the other hand, resonance can be avoided. This means that the natural frequency of the floor must be greater than 8 Hz, see equation (1). In case of large spans, this proof would be relevant for designing the beams of the floor. Figure 4 shows the relevant proof depending on the span L (x-axes) and the relation of live load to steady load (y-axes). It can be seen that the proof of frequency criteria becomes relevant in case the spans are greater than 4-6 m.

For architectural reasons, long span floors are increasingly in demand. These floors would either be very heavy to fulfil the acceleration criteria or designed with very big dimensions to fulfil the frequency criteria.

In order to find out if this is really necessary or if the proofs can be modified and adapted for great spans, the research project mentioned above is carried out.

4 BUILDING UP THE TEST BENCH

The proof of vibration is a proof in the serviceability limit state. The most important thing is that the users of the floor feel safe and comfortable. To find out how people feel on the floor, the structure is built in scale 1:1.

The test bench is set up on a 1: 1 scale, so that all effects can be measured and felt. It has an area of 12.5 m x 12.5m and consists of box elements. The build-up of the test bench is shown in the figures 5 to 11. For detailed information regarding the planning and erection see [6].

5 MEASUREMENTS ON TEST BENCH

5.1 MODIFICATION IN CONSTRUCTION

Working with the test bench it was possible to build up different types of construction. The following different types were built and measured, see figures 13, 14 and 18:

1. raw floor. The main construction are box elements.
2. raw floor with mass. Mass realized by paving stones.
3. raw floor with mass, sound insulation layer and heavy screed. Screed is made by concrete elements.
4. raw floor, sound insulation layer and screed

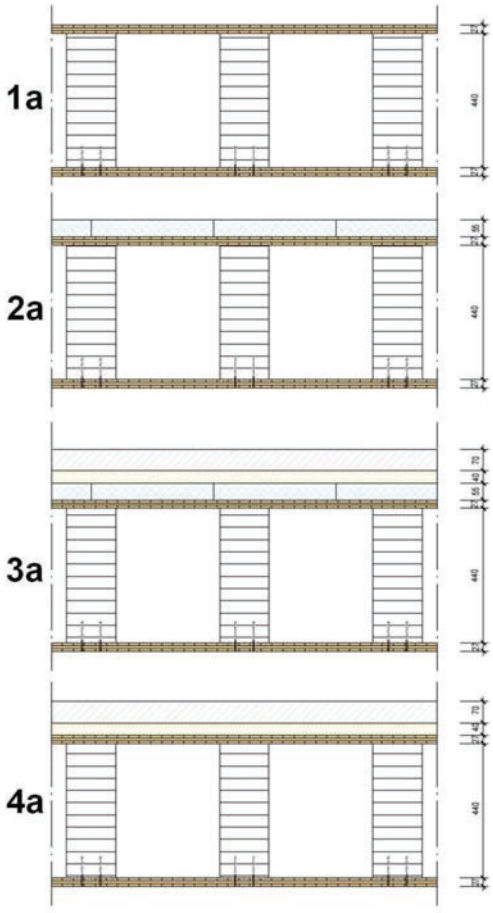

Figure 13: *Different constructions on the floor. Type 1a to 4a.*

https://doi.org/10.52202/069179-0245

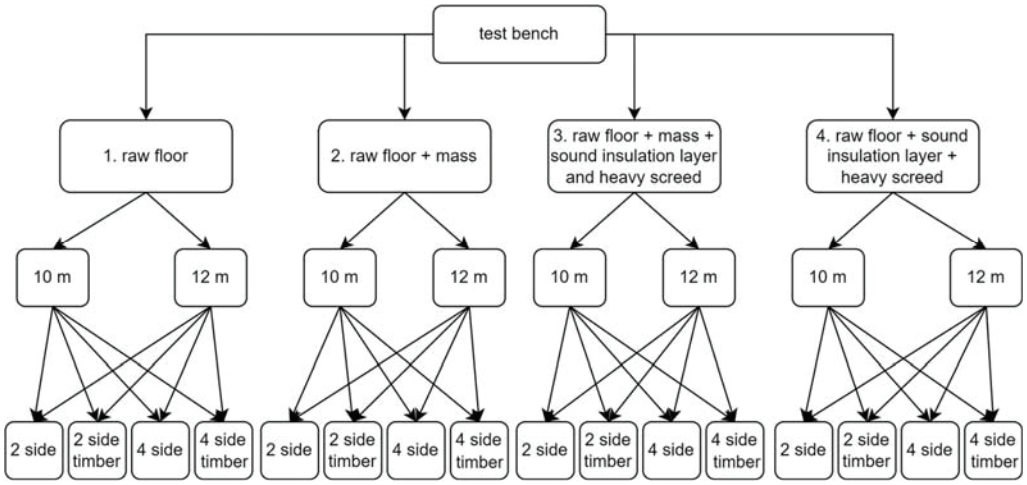

Figure 14: *Modifications in construction, spans and bearings.*

5.2 MODIFICATION IN SPAN AND BEARINGS

By using the test bench, the span could be varied. Spans from 8 m to 12 m were tested.
Another feature was to modify the bearing situation:

- stiff bearings (walls) on two sides
- stiff bearings (walls) on four sides
- elastic bearing (timber beam with two different widths) replacing one stiff bearing
- elastic bearing (steel beam)

Figure 14 shows the tested combinations.

5.3 EXCITATION

The following methods were used to excite the structure:

- heeldrop, to measure the natural frequencies, damping and velocity (see figure 15)
- a person walking around, to simulate the user and measure the velocity (v_rms)
- a group of people walking around
- walking or running in resonance in the centre of the structure, to measure the acceleration
- using a shaker, to have a defined excitation (see figure 16)

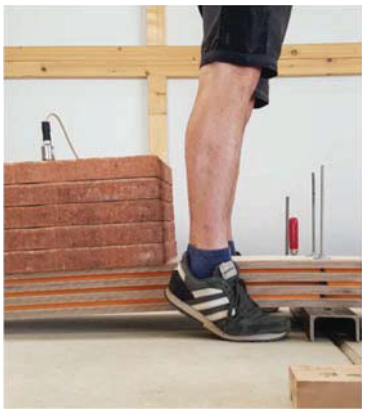

Figure 15: *Person doing a heeldrop.*

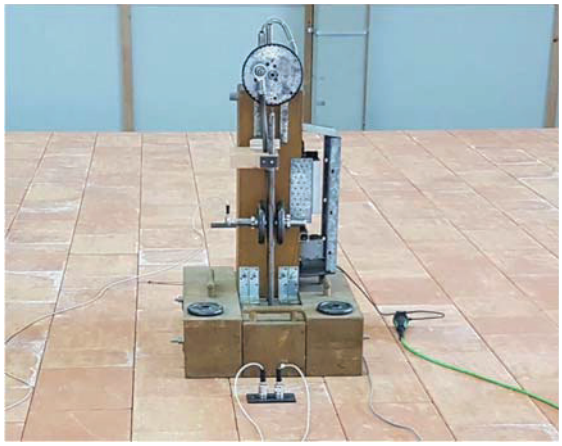

Figure 16: *Mechanical shaker placed on the floor, type 2b.*

5.4 MEASUREMENT DEVICE

The measuring equipment consists of

- 8 accelerometers (MMF Accelerometer KF48C)
- measuring amplifier (MMF Charge Amplifier M68D1 Ver. C)
- measurement card (Geitmann Siconn USB2-basic),

see figure 17.
The measurement, control and simulation tasks were carried out with the software DASYLab 2013.

Figure 17: *Measuring amplifier, accelerometers and measurement card.*

https://doi.org/10.52202/069179-0245

5.5 SUBJECTIVE EVALUATION

One of the most important points is the subjective evaluation of the floor vibration. The floor was evaluated by the test takers Johannes Ruf and Valentin Knöpfle, always in coordination with the other authors. Sometimes groups of students or other interested people visited the test bench. They were asked to evaluate the vibration behaviour, too. The used marks follow the research report [2] and Kreuzinger/Mohr [7]: Rate 1 (no vibration problem) to rate 4 (heavy vibration problem).

6 RESULTS OF MEASUREMENT

The combination of different types of construction and bearing conditions leads to many measurement situations.

Table 2: *Overview of combinations, frequency, damping ratio.*

construction	span [m]	bearings	elastic beam	measured frequency [Hz]	damping ratio incl. person [%]	v_rms [mm/s]
1a	9	2 side	steel	5,4	1,0	2,11
1a	10	4 side		9,3	1,7	1,00
1a	10	4 side	timber	7,5	1,3	1,24
1a	10	2 side		9,1	1,3	1,40
1a	10	2 side	timber	7,4	1,4	1,20
1a	12	4 side		7,2	1,4	1,48
1a	12	4 side	timber	6,1	1,6	1,21
1a	12	2 side	timber	6,0	2,4	1,38
2a	10	4 side		7,2	1,2	1,51
2a	10	4 side	timber	5,7	1,6	1,03
2a	10	2 side		7,0	1,1	2,33
2a	10	2 side	timber	5,5	1,3	1,18
2a	12	4 side		5,3	1,4	2,43
2a	12	2 side		5,1	1,1	2,13
2a	12	2 side	timber	4,4	1,3	1,20
2a	12	2 side	steel	4,0	1,0	1,35
3a	10	4 side		6,2	1,8	0,61
3a	10	4 side	timber	4,9	1,8	0,90
3a	10	2 side		5,8	1,7	0,49
3a	10	2 side	timber	4,8	1,7	0,60
3a	10	2 side	steel	4,1	1,3	0,64
3a	12	4 side		4,6	2,2	0,54
3a	12	4 side	timber	4,1	1,8	0,48
3a	12	2 side		4,4	1,7	0,51
3a	12	2 side	timber	3,9	1,6	0,50
4a	10	4 side		6,8	1,9	1,37
4a	10	4 side	timber	5,2	1,9	2,20
4a	10	2 side		6,6	1,6	1,03
4a	10	2 side	timber	5,2	1,7	2,01
4a	12	4 side		5,2	1,7	2,54
4a	12	4 side	timber	4,3	1,7	0,75
4a	12	2 side		4,9	1,4	1,15
4a	12	2 side	timber	4,2	1,5	0,61

6.1 FREQUENCY, DAMPING, VELOCITY

Table 2 shows some of the combinations, the natural frequency of the first vibration mode, the damping ratio and the velocity v_rms. This v_rms value is measured due to one walking person. It is the average of several steps.

The natural frequency is clearly influenced by the mass of the construction, the span and the elastic bearings.

The damping ratio is measured during the decay curve after excitation in resonance. The measured values are mostly smaller than 2%. Usually, damping ratios for timber floors are taken from [1], [2] or [3] as

- 2% for joisted floors
- 2,5% for rib type floors (type 1a or 1b)
- 3 % for joisted floors with a floating floor layer (type 3 or 4)

As a main result, it can be mentioned that the vibrations are perceptible and sometimes annoying, in spite of the great mass of the test bench (50 – 60 to). One of the reasons may be found in the small damping ratio. Therefore, the possibility to instal tuned mass dampers will be examined.

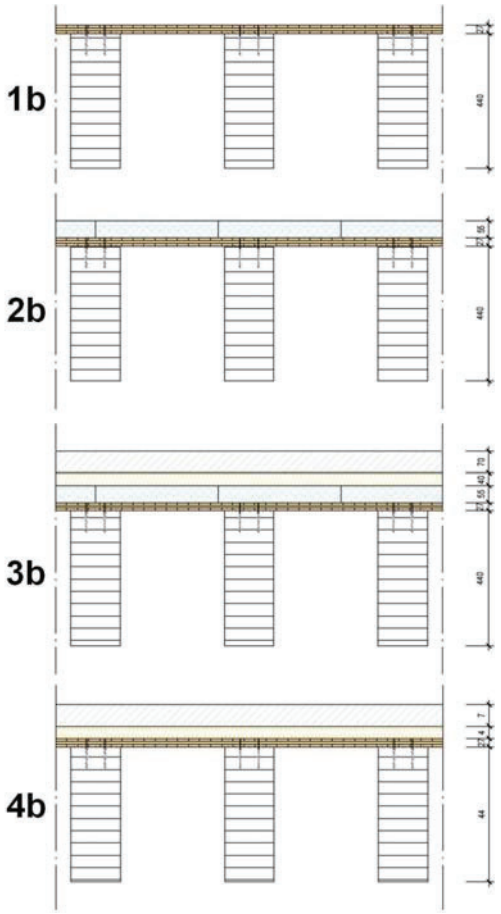

Figure 18: *Different constructions on the floor. Type 1b to 4b.*

https://doi.org/10.52202/069179-0245

6.2 MODIFIED CONSTRUCTION

In addition to the modifications in construction (type 1a to 4a) one of the three-layer panels was removed. This led to the following modifications type 1b to 4b shown in figure 18. Table 3 shows the results of the measurements and a comparison of the damping ratio including a person standing on the floor and no person on the floor. In this case the floor was excited by the shaker.

Comparing table 2 and table 3, one can see the influence of the second three-layer panel on the natural frequency. The construction with one three-layer panel only is less stiff. This results in reduced values of natural frequencies.

Table 3: *Overview of combinations, frequency and damping.*

construction	span [m]	bearings	elastic beam	frequency [Hz] measurement	damping ratio incl. person [%]	damping ratio without person [%]	v_rms [mm/s]
1b	12	2 side		6,20	1,9%		
2b	12	2 side		4,56	1,2%		2,62
3b	12	2 side		4,20	1,5%		0,73
3b	12	4 side		4,0	1,8%	1,3%	0,73
3b	12	4 side	timber	3,6	1,7%	1,2%	1,14
3b	12	2 side		4,0	1,6%	1,2%	0,69
3b	12	2 side	timber	3,6	1,6%	1,2%	1,48

From table 3 one can see the influence of the exciting person on the damping ratio: the damping ratio with one person standing on the floor is always higher.

7 CALCULATIONS WITH FINITE ELEMENT METHOD

To transfer the measurement results to calculations of future long span timber floors, it must be ensured that the measured values agree with the calculation. This was done with the help of a FE model (see figures 19 and 20). The model was built up step by step, analogue to the test bench. By this all the individual conditions like E-modulus, mass etc. could be taken into account.

The modelling was done with the program “Mechanical APDL” of the company “Ansys Inc.”. The advantage of this program is that data can be entered using the company’s own script language. This ensures that the parameters entered are used and not standardizes parameters from a database. At the same time, automation is possible without major effort. All parameters used are stored as variables and linked to each other. When a parameter is changed, most of the values adapt immediately.

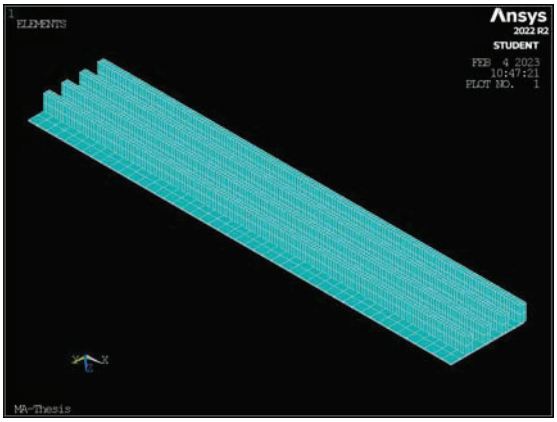

Figure 19: *One element for the step by step construction.*

In order to be able to transfer the subjective behaviour of people to other long span timber floors, the prevailing computational values must be known, at which the sensation of the persons was examined. By calibrating the model based on the measurement results, realistic predictions of new situation are possible through the model.

Table 4: *Comparison measured and calculated frequencies, first 3 modes.*

Construction	measured frequencies [Hz]			calculated frequencies [Hz]		
	mode 1	mode 2	mode 3	mode 1	mode 2	mode 3
one beam	7,32	-	-	7,32	-	-
one element	6,85	14,45	19,42	6,79	14,45	19,44
raw floor type 1b	6,20	7,43	8,62	6,24	7,43	8,65
type 2b	4,56	5,23	6,15	4,07	5,04	5,75
type 3b	4,20	4,95	5,09	4,35	4,64	5,20

It was shown that a simulation of the structural behaviour by using FE models, especially under special boundary conditions, can be carried out very accurately (see table 4). In the first step, the calibration was performed on the natural frequencies (see figure 19). However, to use this model for an assessment of the vibrations of timber floors, further investigations are necessary. For example, the velocities and accelerations due to walking and running persons will be considered, too.

Nevertheless, it is subsequently possible to determine the vibrations behaviour of the timber floor in the model without the need for costly on-site construction or modification of the floor and to subsequently investigate this behaviour by measurements. For detailed information on the FE model and the calibration see [8].

https://doi.org/10.52202/069179-0245

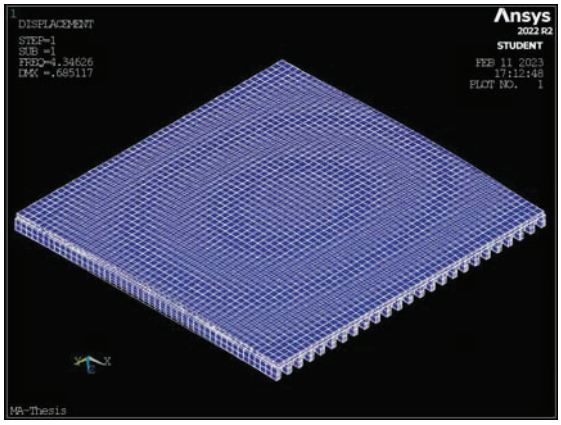

Figure 20: *Finite element model showing the first mode.*

8 RESULTS AND OUTLOOK

The result will be an extended design concept for long span timber floors. As the evaluation of measurement data and further measurements are going on, the concept will be presented during the oral presentation in Oslo.
As an outlook it can be stated that long span timber floors are likely to vibrate in spite of their great mass. The possibility to instal tuned mass dampers will be examined.

CONCLUSIONS: ZIM Research Project Pirmin Jung – Biberach University

A ZIM research project is being carried out in cooperation with Pirmin Jung Deutschland GmbH and the Institute for Timber Construction at Biberach University of Applied Sciences. It is precisely these wide-span floors that are being examined.
The aim of the research project is to develop a standardized and vibration-minimizing design system for wooden floors with beams and large spans of more than 8 m - based on theoretical and practical considerations.
For this purpose, a test stand for a timber floor with approx. 12.5 m x 12.5 m is set up, which is constantly being rebuilt. As a result, the cooperation partners have received important input for new design rules for very large timber floor systems.

ACKNOWLEDGEMENT

The research project has been carried out at Biberach University of Applied Sciences in cooperation with PIRMIN JUNG Deutschland GmbH, Remagen from 01.01.2021 to 30.06.2023. It was financed by ZIM. “ZIM” stands for “Zentrales Innovationsprogramm Mittelstand”, which means “Central Innovation Programme for small and medium-sized enterprises (SMEs)”. It is a funding programme of the Federal Ministry for Economic Affairs and Climate Action.

ACOUSTIC SENSITIVITY ANALYSIS AND MODELING OF SOUND INSULATION PERFORMANCE OF LIGHTWEIGHT WOODEN FAÇADE STRUCTURES

Mohamad Bader Eddin[1], Sylvain M*é*nard[2], Delphine Bard[3], Jean-Luc Kouyoumji[4].

ABSTRACT: A prediction model is developed based on neural networks approach to estimate the air-borne sound insulation performance of lightweight wooden façade walls. A hundred insulation curves are used to develop the model, and they are lab-based measurements performed on various façades in one-third-octave bands (50 Hz– 5 kHz). For each wall, geometric and physical information (material types, dimensions, thicknesses, densities, and more) are used as input structural parameters. The results are satisfactory, and the model can estimate air-borne sound reduction with acceptable variations. A better estimation is achieved at middle frequencies (250 Hz–1 kHz), while lower and higher frequency bands often depict higher deviations. The weighted air-borne sound reduction index (R_w) can be forecast with a maximum error of 3 dB. In certain cases, the model shows high deviations within fundamental and critical frequencies, which influence the predictive precision. A sensitivity analysis is implemented to investigate on which structural parameters the model relies. The results emphasize the importance of façade thickness and the total density of the clustered exterior layers.

KEYWORDS: Sound insulation, Façades, Artificial neural networks, Sensitivity analysis

1 INTRODUCTION

Wood has been widely used in structural engineering due to its availability in nature and ease of handling [1]. Additionally, it has a remarkably lower carbon footprint than concrete and offers significant thermal insulation. [2, 3]. In Scandinavia and Australia, wooden constructions have become widely popular due to their advantages [4, 5]. Moreover, In North America, wood frame systems were dominant in the building construction industry in the 20^{th} century [6].

Despite the fact that these types of structures reduce both cost and construction time, a disadvantage in these constructions is that the subjective sound isolation quality is considered lower than in concrete or heavy constructions, with the same insulation data [7]. This applies to different lightweight elements, such as floors, roofs, internal walls, and façades. Façade structures are vital to control the indoor acoustic environment by attenuating the outside noise. Inappropriate design may lead to undesirable impact on indoor acoustic comfort for occupants.

However, many façade structures are designed mostly for certain purposes, such as fire safety and thermal insulation, but acoustic aspects are often not considered or misunderstood [8]. The acoustic performance of such structures is derived from standardized measurements, such as

[1]Mohamad Bader Eddin, University of Quebec at Chicoutimi, Canada, Mohamad.Bader-Eddin1@uqac.ca
[2]Sylvain M*é*nard, University of Quebec at Chicoutimi, Canada, Sylvain_Menard@uqac.ca

https://doi.org/10.52202/069179-0246

ISO and ASTM, but it requires time and cost, and the results cannot be generalized to different structures.

A theory-based analytical expression uses stiffness, mass, and damping is utilized as a direct prediction tool known as the mass law [9]. This can be adapted for single-leaf partition, but it is not appropriate for lightweight multi-layered elements. Accurate estimation of the acoustic performance of multilayer structures remains a challenge [9]. Moreover, the standardized method in ISO 12354 Part 1 [10] is extracted using insulation data for heavy monolithic partitions, which is not applicable to lightweight multi-layered structures [11].

The applications of machine learning have paved the way for complex technological achievements in different fields that were considered challenging, such as image recognition, language translation, and building acoustics [12, 13, 14]. In this approach, large and diverse data is essential to enable the algorithm to learn and to improve its predictive power. Artificial neural networks (ANN) approach was used in building acoustics to predict air-borne sound insulation curves in $1/3$-octave bands for masonry walls [14]. 34 laboratory measurements were used to develop the model. Despite the concordance between the results, the study focused on a single monolithic partition.

To bridge this gap, 252 insulation curves of different lightweight wooden floors were used to develop an ANN model [15]. Structural parameters were used as inputs for the model, such as material thickness, density, depth and type of the joists, and more. The model can predict the weighted sound reduction index R_w and normalized impact sound pressure levels $Ln_{n,w}$ with maximum deviations of 2 and 5 dB, respectively.

The scope of this study is to develop an ANN model to estimate the air-borne sound insulation curves of façades structures. The data comprises lab-based measurements of lightweight wooden façades without considering the presence of windows, doors and small openings in the wall. Finally, sensitivity analysis was performed to shed light on the most important factors that influence the prediction of insulation curves.

2 MATERIALS AND METHODS

2.1 DEFINITION OF ARTIFICIAL NEURAL NETWORKS

The ANN model is a mathematical model which is inspired by the human neural system to simulate its behavior [16]. A simple model comprises layers: input, hidden, and output (see Figure 1). Each layer contains artificial neurons (computational units) and intermediate parameters, called weights, connect adjacent layers. The ANN model propagates information (input values) from the first layer (input layer) to the output layer, where prediction values are calculated [17]. The latter process is referred to as the training phase, in which weights and bias values (features of ANN) are tuned in order to reduce errors and achieve higher predictive accuracy. The output of an artificial neuron can be determined by,

$$y = f(\sum(w_i x_i + b)), \tag{1}$$

where y, w_i, x_i, and b are output, weight, input, and bias values, respectively. The computed output is called activation value, and it is utilized as an input value to the chosen activation function. The most common functions for ANN are tangent, sigmoid, and LeakyReLU [18].

In this study, a multilayer perceptron class of ANN is adapted. The network model comprises two hidden layers. The cross-validation technique is employed to validate the network model and to prevent overfitting issues. As an activation function, LeakyReLU (Leaky Rectified Linear Unit) is chosen for hidden layers [19]. Adam optimizer [20] is employed during the training phase.

Three subsets of measurements are used by splitting the entire curve measurements, namely: training, validation, and test set (Table 1). The root-mean-square error ($RMSE$) function is used as a cost function to evaluate the performance of the network,

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(\hat{y}_i - y_i)^2}, \tag{2}$$

where n presents the number of observations (measurements) that are used in the training

phase. Output (predicted) and input (measured) values are donated by $\hat{y}_i$ and y_i, respectively. In this study, the network model depicted an overall prediction accuracy of 4.44 dB between the predicted and measured curves. However, for a better evaluation of the results at different frequencies, each estimated curve is analyzed with comparison to the measured one using the *RMSE* function considering values in each one-third-octave band from 50 Hz to 5 kHz.

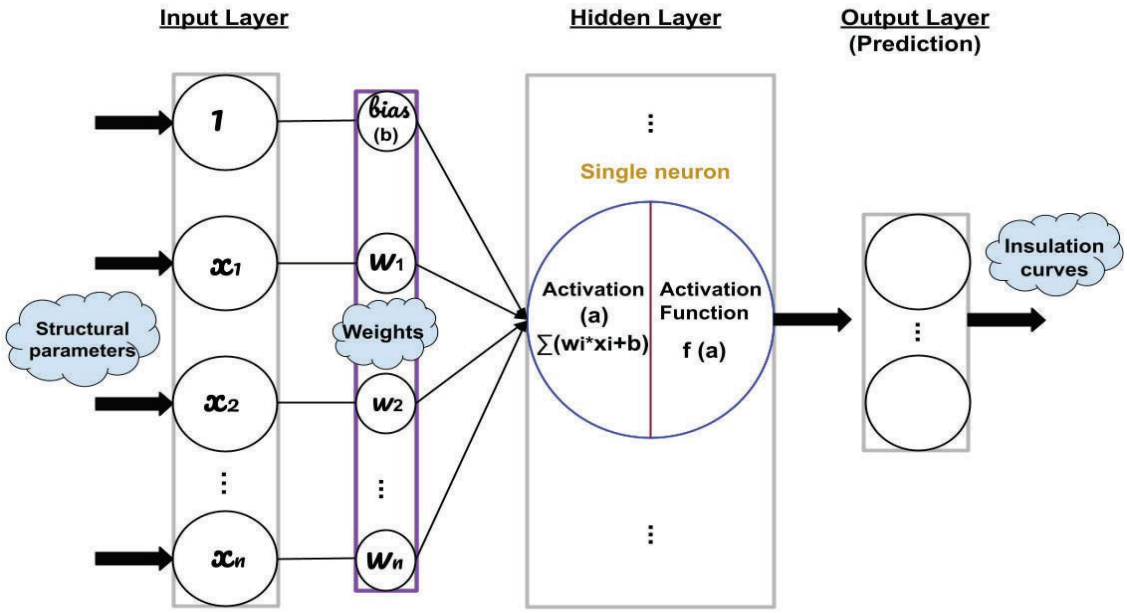

Figure 1: The architecture of an ANN model illustrating input, hidden, and output layers and how the structural parameters propagate through the network model.

2.2 ACOUSTIC DATA

A hundred lab-based measurements were collected from Lund University in Sweden and the National Research Council (NRC-CNRC) [21] in Canada. The data consists of air-borne sound insulation curves that concern various lightweight façade structures in one-third-octave bands (50 Hz to 5 kHz). The measurements were performed respecting ISO 10140-2 (2010) [22] and ASTM E90-09 (2016) [23]. All the insulation data that are performed in compliance with ASTM standards are converted to follow ISO 717-1 (2013) [24] descriptor (the weighted air-borne sound reduction index R_w). This conversion is essential to handle the data and to have a better agreement between them.

The database is organized using different structural parameters (Table 2) that are used as inputs to the network model. Despite the importance of some elastic properties, such as dynamic stiffeners and the modulus of elasticity, they are not considered in the study due to the lack of information provided by the acoustic reports. 10 measurements of different façade walls are used to initiate the features of the ANN model, known as validation set, and another set of 10 curves were selected (randomly from the total number of curves) to test the accuracy of the model (Figure A1 in the Appendix). Each façade configuration is clustered in three parts: interior, main and exterior parts, respecting the installation order of each façade component. The dominant component or material is represented by the main part. Therefore, the interior and exterior sections present components clustered and located alongside the main façade material (Figure 2).

2.3 SENSITIVITY ANALYSIS

Understanding the mechanism of ANN models is cumbersome, especially that they are known as black box prediction tools [25]. To recognize the parameters on which the ANN model relies on,

an axiomatic approach, called integrated gradients (IG) is adapted. The IG method is defined as $IG_i(x)$. Supposing a function $F : R^n \rightarrow [0,1]$ represents a network model. Using $x = (x^1, ..., x^n) \in R^n$ as an input and $z \in R^n$ as a baseline relative to x. Then a vector $A_F(x,z) = (a^1, ..., a^n) \in R^n$ is the attribution of the input x, where a^i is the attribution of x^i of function $F(x)$. IG values can be extracted by calculating the gradients across the straight path between the input x and the baseline z. Hence, IG for ith dimension is donated by [26],

$$IG_i(x) = (x_i - z_i) * \int_{\alpha=0}^{1} \frac{\partial F(z + \alpha * (x - z))}{\partial x_i} d\alpha. \quad (3)$$

3 RESULTS AND DISCUSSION

3.1 AIRBORNE SOUND INSULATION PREDICTIONS

Figure 3 depicts a comparison between predicted and measured curves. It shows that the estimations are close to the measurements with certain deviations in some cases at high or/and low frequencies. The smallest *RMSE* value is 2.19 *dB* for façade #3, and the highest is 5.73 *dB* for slightly complex wall #10.

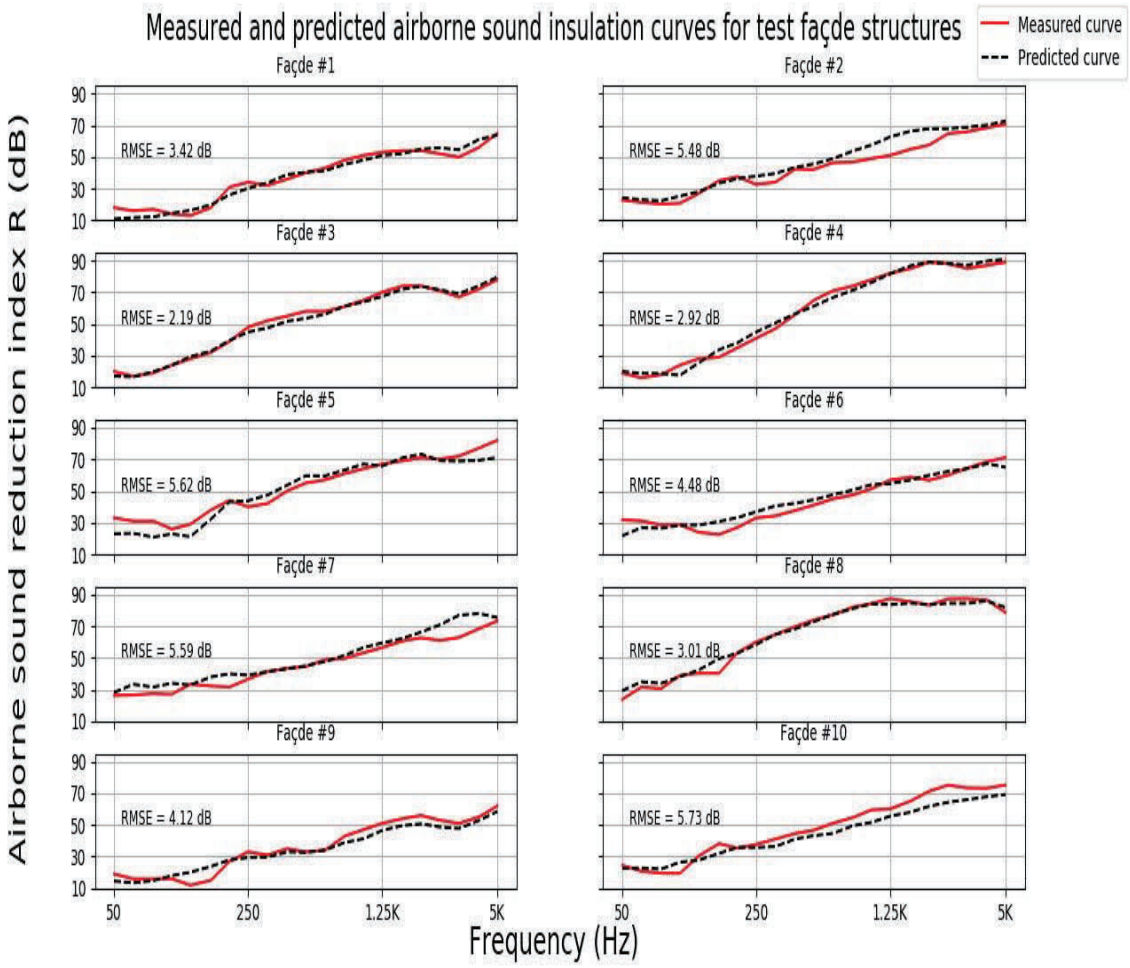

Figure 3: Predicted and measured air-borne reduction index curves for test façades.

https://doi.org/10.52202/069179-0246

In high frequency bands (1.25–3 kHz), a significant gap is notable between the curves. The later range usually includes the critical (coincidence) frequency for lightweight structures. At these frequencies, a match occurs between the incident wavelength that is projected onto the plate and the wavelength of the bending wave in the plate [9]. As a consequence of this matching, the structure will easily and efficiently radiate sound at and above this range [27].

Furthermore, similar deviations are observed at frequencies lower than 200 Hz, e.g. walls #1, #8 and #9. This can be explained due to the presence of fundamental resonances or first eigenfrequencies [9]. This reveals the limitation of the ANN model in the estimation around these frequencies. Similar challenges were also reported for ANN models [15, 14].

Table 3 presents the RMSE values in the prediction of air-borne sound insulation curves. It also shows the calculated single-number quantities (SNQ), R_w and $R_{wPredicted}$, for each curve. Façade #7 has the highest error with 3 dB, while the network model can estimate the same weighted reduction index values (walls #3 and #6). Additionally, the maximum difference in the calculation of correction terms ($C_{100–3150}$ and $C_{50–5000}$) is 4 dB in façade #5.

Table 4 summarizes the distribution of errors in estimation of insulation curves using *RMSE*, and taking three frequency ranges into account: low (50–200 Hz), middle (250 Hz–1 kHz) and high (1.25–5 kHz) frequency. The results showed that the model accuracy is the best in the middle frequency, while higher deviations are found in low and high frequency ranges. Again, this can probably be described due to the presence of resonance and critical frequencies.

3.2 SENSITIVITY ANALYSIS OF FAÇADES STRUCTURAL PARAMETERS

A sensitivity analysis is implemented to investigate the influence of the thickness and density of exterior, main and interior parts of each façade on the forecast. In those types of graphs, a user can find out the importance of each parameter considering the magnitude of $y-$ axis. Higher values indicate a larger size effect of the inputs. However,

values close to zero suggest a weaker relationship.

Plots in Figure 4 illustrate the contribution of the thickness and density of interior, main and exterior parts of walls to the prediction of insulation curves. It is noticeable that the density and thickness play a significant role at all frequencies. The density spectrum of the interior part illustrates fluctuation near the fundamental frequencies. In addition, the density of the exterior part is vital and the effects of fundamental and critical frequency are obvious on the attributions. A peak near 150 Hz and a dip near 1.25 kHz are obvious, which is probably due to effects of fundamental and critical frequencies, respectively. This is likely resulting due to coupling between resonant wall components that permits energy to transfer between them [27]. The latter happens when elements are physically connected, and they have sufficiently close natural or critical frequencies. This amplifies the radiations from components and affects the isolation negatively [9].

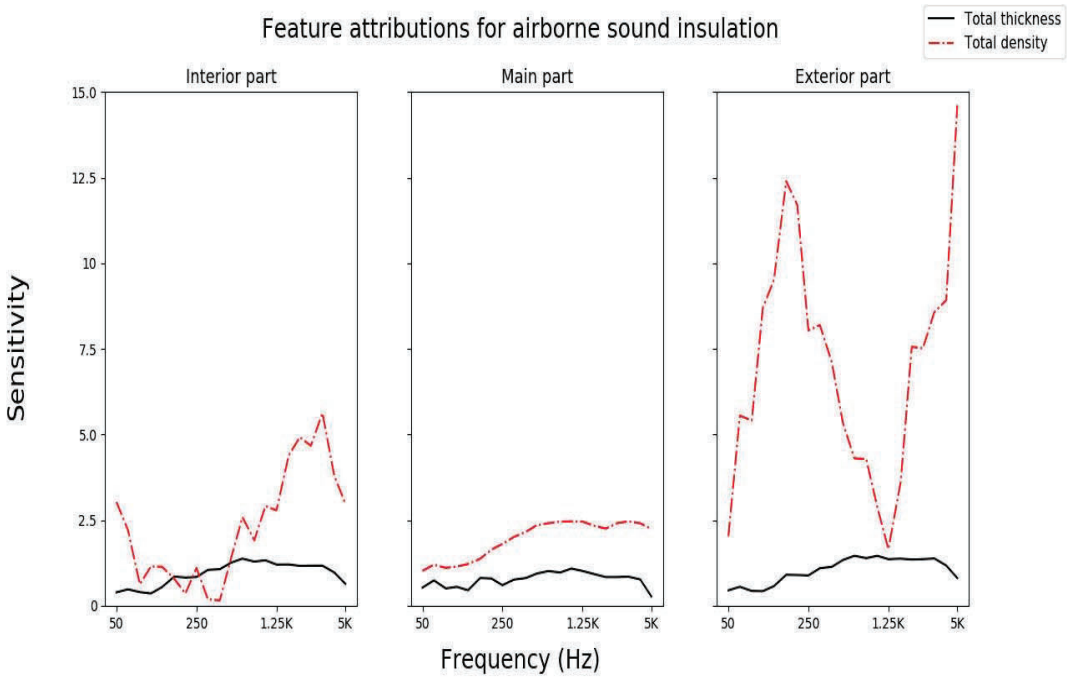

Figure 4: Feature attributions of interior, main and exterior parts façades to the predictions.

4 CONCLUSION

This study reveals the potential of ANN model to predict the air-borne sound insulation curves using 100 lab-based measurements of lightweight façade walls. The results are reasonable, and the model can forecast the sound weighted reduction index R_w with a maximum difference of 3 dB. These results encourage considering the network model in the early design phases, in particular the difference around 2 dB is lower than the noticeable noise differences. Regarding the whole frequency band. The best achieved accuracy is at the middle frequencies (250 Hz – 1 kHz). However, the prediction around fundamental and critical frequency is challenging for the network model and reveals some deviations.

A sensitivity analysis is carried out to explore the attribution of the input parameters to the predictions. The total thickness and total density of interior, main and exterior parts of façades have remarkable effects at all frequencies, and a higher attribution to the total density of the exterior part. The coupling between resonant façade components, resulting from fundamental and critical frequencies of each component, has a significant influence on the prediction.

https://doi.org/10.52202/069179-0246

Further research would be expected on enlarging the sensitivity analysis study to cover different structural parameters, and how these parameters can be optimized to enhance the sound insulation prediction. This would pave the way to explore the importance of certain structural parameters to achieve the desired isolation.

ACKNOWLEDGMENT

The authors are grateful to Natural Sciences and Engineering Research Council (NSERC) of Canada for the financial support through its IRC and CRD programs (IRCPJ 461745-18 and RDCPJ 524504-18), the Region Nouvelle Aquitaine for the financial support (ref. 2017-1R10223), and the industrial partners of the NSERC industrial chair on eco-responsible wood construction (CIRCERB). Special thanks for Lund university and CNRC for providing the acoustic measurement data of sound insulation.

DESIGN OF LONG-SPAN LIGHTWEIGHT TIMBER FLOORS SUBJECT TO WALKING EXCITATIONS: A CASE STUDY

Hassan Karampour[1], Farid Piran[2], Adam Faircloth[3], Chandan Kumar[4], David Zhang[5], Benoit. P. Gilbert[6], Hong Guan[7], Lin Hu[8], Ying Hei Chui[9] and Wen-Shao Chang[10]

ABSTRACT: Lightweight timber construction is popular in buildings with two or more storeys in Australia. The floors are made of a floorboard supported on joists or trusses. Recently, the sector is moving towards multi-storey construction of different building classes with different floor usages and shared tenancy. Thus, a need for high performing lightweight floor systems becomes urgent. The current vibration control criteria in the Australian standard recommends limiting static deflection, which is a coarse method and does not necessarily guarantee satisfactory performance. In the current study, vibration performance of a 6m×6m floor system with particleboard flange and truss webs is investigated under single walker excitations and at different walking frequencies. The vibration responses are compared to the predictions and performance criteria recommended in international standards and guidelines. The results show inconsistencies in the calculated levels of acceptance from different sources using simplified expressions and more rigorous methods of analysis. This highlights the significance of the need for further research to develop a harmonised method of analysis that can be used by manufacturers and engineers in Australia to confidently design floors for vibrations.

KEYWORDS: Floor dynamics, Footfall-induced vibration, Lightweight timber floors, Non-destructive testing.

1 INTRODUCTION

There is an increased global focus on using timber structures due to the availability of timber-based and engineered wood products (EWPs) as well as sustainability and lower carbon footprint of timber compared to other conventional construction materials [1]. In Australia, there is a growing trend in lightweight timber floors to enter the multi-storey market [2], mainly due to the increasing surge in land prices in capital cities. A major restriction in current buildings with timber floors is their close column spacing, while most developments require more open space. For spans longer than 6 meters, the design is governed by serviceability not strength; therefore, accurate assessment of the vibration performance of the floor is essential.

The current work aims to investigate the vibration performance of a 6m×6m lightweight timber floor system typically used in Australian buildings. The investigation is comprised of measurement of natural frequencies and accelerations due to walking of the examined floor as well as numerical modal analyses. The vibration responses are calculated and compared to recommendations in existing standards: CSA 086:2019 [3], EN 5:2004 [4], AS 1170.0:2002 [5] and guidelines of CCIP-016 [6], SCI-P354 [7], AISC DG11 [8], HIVOSS [9], and recommended performance criteria in ISO 10137 [10] and BS 6472.1 [11]. The paper is concluded by an analysis of the aforementioned comparison.

2 FLOOR VIBRATION DESIGN IN CURRENT STANDARDS AND GUIDELINES

Canadian standard CSA 086 [3] and Eurocode 5:2004 [4] provide simple methods for vibration design of timber floors. CSA-086 [3] uses simple T-beam equations and gives vibration-controlled span limit of joisted floors. The approach is based on the comprehensive experimental works of Hu and Chui [12, 13] and offers a limit based on the relation between fundamental frequency of the floor system and static deflection under 1 kN at its centre. More rigorous methods that categorise the floor based on the

fundamental frequency and calculate the response from modal analyses are outlined in [6-8]. However, these methods are developed for steel, concrete or steel-concrete composite floors and their appropriateness for timber floors is disputed.

Prediction of vibration in floor systems requires determination of vibration modes, associated frequencies and damping values. In order to assess the floor systems against serviceability criteria, the floors are categorised into (i) low-frequency floors and (ii) high frequency floors. Low frequency floors are associated with a steady-state resonant response under footfall-induced vibrations, whereas in high-frequency floors, the floor response is transient, and is damped out after each footstep. There is no clear quantitative measure that separates the two categories, and different guidelines [6-8] suggest cut-off frequencies ranging from 7 Hz to 10.5 Hz.

3 EXPERIMENTAL AND NUMERICAL RESULTS

3.1 PHYSICAL TESTS

In the present work footfall-induced vibration (FIV) of the 6 m×6 m lightweight timber floor system (shown in Figure 1) comprised of a floorboard (19 mm particleboard) resting on timber chords MGP12 (softwood), 90 mm × 35 mm in cross-section, and steel braced trusses and supported on 200 PFC steel bearer beams on two sides is studied.

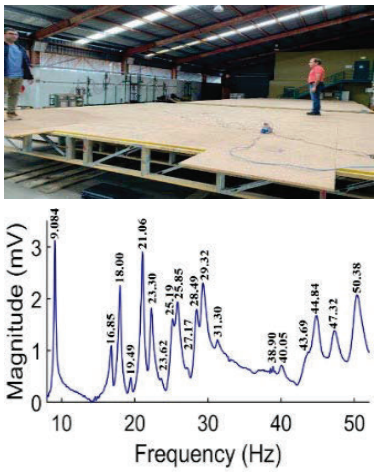

Figure 1: *The tested 6m×6m floor system and the frequency response function (FRF) showing frequency-domain response.*

The floor was excited using a digital hammer at a location close to the accelerometer 'A' shown in Figure 2. The impulsive excitation was repeated 10 times. Using Fast Fourier Transform (FFT) of the acceleration time-history, Frequency Response Functions (FRF) were developed and natural frequencies were calculated as shown in Figure 1. Natural frequencies, f_i measured at accelerometer A, and corresponding critical modal damping values ζ_i, showing average and CoVs are represented in Table 1. Damping values are calculated from the half-bandwidth method according to AS ISO 2631.2 [14]. The deflection of the floor under a static 1 kN load applied at the centre was found to be 1.54 mm.

Table 1: *Measured frequencies and critical damping.*

	Accelerometer A (centre of the floor)		Damping	
Mode, i	$f_{i\,(avg)}$ (Hz)	CoV	ζ	CoV
1	9.08	0.59%	0.90%	0.14%
2	17.05	3.77%	1.08%	0.66%
3	17.84	0.01%	1.03%	0.17%
4	19.41	0.01%	0.84%	0.55%
5	20.98	0.01%	0.91%	0.14%
6	22.01	0.26%	0.89%	0.14%
7	24.86	0.01%	0.95%	0.21%

Then, the floor was excited to dynamic walking forces, and accelerations were measured at three different locations (A, B, and C) on the slab.

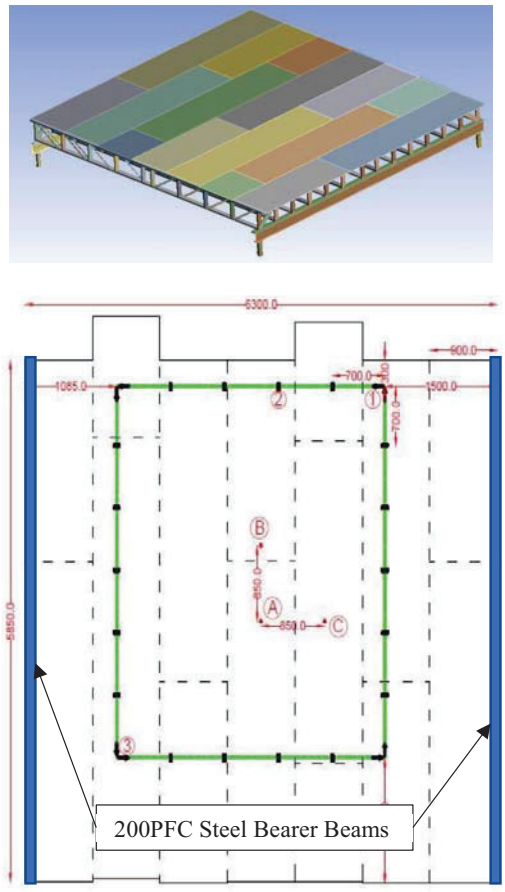

Figure 2: *The floor layout and walking path (in Green).*

Two walking scenarios, with single walker (80kg) in two different walking frequencies f_w of 1.80 Hz (brisk walking) and 2.25 Hz (fast walking), of W1 and W2, respectively, were selected to examine footfall-induced vibration of the floor. The 4th harmonics of walking

frequency of 2.25 Hz and the 5th harmonics of walking frequency of 1.80 Hz, correspond to the fundamental natural frequency (9.08 Hz) of the floor system.

The acceleration time-histories were calculated from each accelerometer and were filtered using the weighting factors outlined in AS 2670.1 (ISO 2631-1) [15]. The vibration responses of each walking scenario were calculated in terms of root-mean-square (rms) and Vibration Dose Value (VDV) defined in Equations (1 & 2):

$$a_w(t_0) = \sqrt{\frac{1}{\tau}\int_{t_0-\tau}^{t_0} [a_w(t)]^2\, dt} \quad (1)$$

$$VDV = \left\{\int_0^{\tau} [a_w(t)]^4\, dt\right\}^{\frac{1}{4}} \quad (2)$$

where τ is the time (integration variable) recommended to be equal to 1 second. The raw and ISO weighted acceleration time histories of W1 and W2 walking configuration tests are plotted in Figure 3. There were some differences between accelerometer results at A, B and C. However, for the sake of comparison against standards and guideline only results of accelerometer, A which is located at the centre of the floor are presented herein.

The acceleration time histories show a steady-state response much more significant than the transient response in both walking configurations, distinguished with a clear resonant excitation in W2.

The frequency content (FFT) of W2 walking test is also shown in Figure 3, and indicates that the fundamental frequency (9.08 Hz), as well as modes with frequencies of 21 Hz and 18 Hz are significantly excited. These frequencies were also shown to have the largest amplitude as displayed in the frequency domain results of Figure 1.

The measured vibration response parameters are represented in Table 2. Following recommendations of ISO 2631-1 [15], the running r.m.s. acceleration, a_w, is calculated using an integration time constant of 1 second. The maximum acceleration, $a_{w,max}$ corresponds to the peak in the time-history.

Table 2: *Measured vibration responses of the floor system.*

	a_w (m/s^2)	$a_{w,max}$ (m/s^2)	VDV (m/s$^{1.75}$)

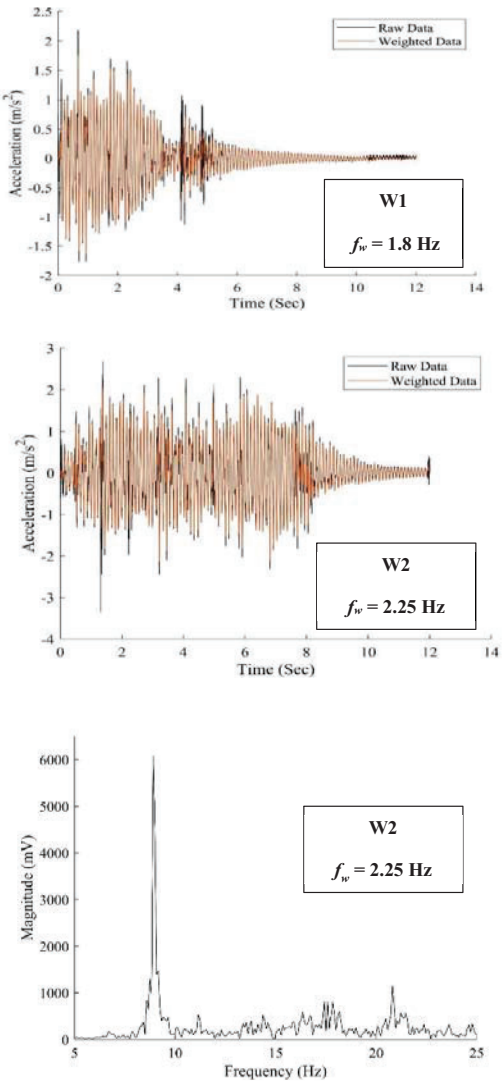

Figure 3: *The raw (black) and weighted (orange) acceleration time-histories of a single person walker, 80 kg at walking frequencies of 1.8 Hz (W1) and 2.25 Hz (W2). The frequency content of W2 is shown in the bottom of the figure.*

3.2 FINITE ELEMENT ANALYSIS (FEA)

Modal analysis of the floor system was carried out in the commercial package, Ansys [16]. Mechanical properties of sawn timber boards (orthotropic) and steel beams were taken from AS 1720.1:2010 [17] and AS 4100:2020 [18], respectively. Particleboard was assumed to be isotropic [19]. In the FEA model (see Figure 4) MGP boards, particleboard, PFCs and the supporting short columns were meshed using 8-noded Shell-181 elements with 5 integration points, and the metal webs were modelled with 2-noded beam elements [16]. The connection between the bearer beam and the PFC, and that between the PFC and the short column was defined a Mohr-Coulomb frictional contact with a coefficient of friction of 0.45 (calculated from a simple sliding test). From a mesh sensitivity analysis (not shown here for the sake of brevity), a mesh

https://doi.org/10.52202/069179-0247

with a total of 182,550 nodes was selected, which has mid-span deflection and fundamental frequency of less than 5% difference from an FEA model with 303,015 nodes. Mid-span deflection of the floor system from the FEA is 1.99 mm and the mode shapes and associated frequencies are shown in Figure 4.

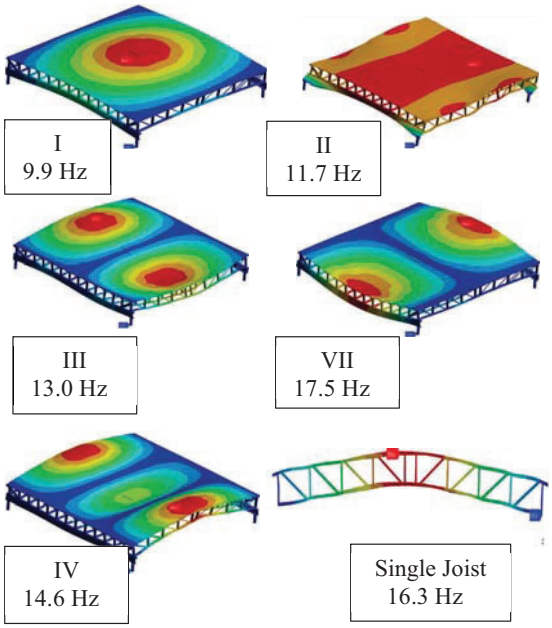

Figure 4: *Mode shapes and frequencies from the FEA ranked based on ascending frequencies.*

There is a relatively reasonable agreement between experimental and numerical frequencies. The fundamental FEA frequency of 9.9 Hz corresponds to a plate-type mode shape. The next frequency (11.7 Hz) is due to minor-axis bending of the PFC (steel) beams. Flexural modes along unsupported edges occur at frequencies below 15 Hz. Bending mode along the supported edge is at 17.5 Hz from FEA, and probably corresponds to the 18 Hz peak in the experimental FFT results of Figure 1.

The fundamental frequency of the floor system can be approximated from deflection under self-weight, δ:

$$f_1 = \frac{17.8}{\sqrt{\delta}} \tag{3}$$

Knowing δ is equal to 4.72 mm (from FEA), a fundamental frequency of 8.2 Hz is calculated using Equation 3, which is 10% lower than the measured frequency.

The other method normally used to calculate fundamental frequency of composite floor systems supported by primary beams and secondary beams of frequencies f_b, and f_j, respectively, is the Dunkerly's modal decomposition method [20] in Equation 4:

$$\frac{1}{f_1^2} = \frac{1}{f_b^2} + \frac{1}{f_j^2} \tag{4}$$

where the frequencies f_b, and f_j in Equation 4 shall be associated with the same mode shape as the fundamental mode shape of the floor system. The major axis flexural mode shape and frequency of the joist (16.3 Hz) is shown in Figure 4. Frequency of the PFC beam in the minor bending mode is 8 Hz (from FEA). Using Equation 4 and knowing the floor system has 2×PFC beams and 14×joists, a fundamental frequency of 15.9 Hz is calculated, which is 75% greater than the measured frequency. If the number of PFC beams and joists are reduced to one in Equation 4, a frequency 7.2 Hz is derived.

4 COMPARISON AGAINST EXISTING STANDARDS AND GUIDELINES

Several methods are available that provide insight into floor vibration. These methods vary from simple rules to more sophisticated methods. Simple methods require less design effort, modelling and analysis, whereas more complicated methods have more room for flexibility, engineering judgement and innovation. Vibration performance of the investigated floor system is discussed from a code-compliancy point of view, here forth.

4.1 AUSTRALIAN STANDARD

Most commonly accepted simple rule to minimise the annoying vibration is a limit on deflection based on the design live load. In the Australian standard AS 1170.1 [21] the design live load is 1.5 kPa for residential buildings and 3 kPa for commercial ones (excluding shopping areas, public assembly areas, dance halls, etc.). The ripple/sag serviceability limit state criterion in AS 1170.0 [5] is $L/300$ for dead load plus 40% live load combination. Moreover, for vibration serviceability, a static mid-span deflection under a 1 kN vertical load, (d_{1kN}) of less than 1 to 2 mm is recommended. The measured and FEA deflections of the floor system are both under 2 mm, which can be interpreted as satisfactory vibration performance according to the Australian standard. Under a self-weight plus 40% live load combination with 1.5 kPa (residential) and 3 kPa (commercial) distributed live loads, floor centre deflections are 13.9 mm and 23.1 mm (from FEA), respectively, compared to the 20 mm limit ($L/300$). Thus, in deflection serviceability, the floor is acceptable for residential usage, but misses the acceptance tolerance of commercial buildings by a margin of 15.5%.

4.2 ISO/TR 21136 [22]

The ISO/TR 21136 method [22] proposes a relation between fundamental frequency and static deflection of the floor as indicated in Equation (5), which is developed from a logistic regression on the database of field light

frame timber floors in across Canada occupants' survey and testing.

$$d_{1kN} \le \frac{f^{2.56}}{1090.31} \quad (5)$$

Knowing the fundamental frequency, *f*, is equal to 9.08 Hz, Equation 5 gives a deflection limit of 0.6 mm, which is 61% smaller than the measured deflection. The floor is "unacceptable" to ISO/TR 21136 [22].

4.3 Eurocode 5:2004 [4]

Eurocode 5:2004 [4] divides the floors into better performance and poorer performance using three criteria for controlling vibration in residential floors: (i) frequency limit, (ii) deflection limit, and (iii) impulse velocity control. These conditions are outlined in Equation 6.

$$(i) f > 8Hz \;;\; (ii)\frac{d}{F_s} \le a \;;\; (iii) v \le b^{(f\,\xi^{-1})} \quad (6)$$

where *v*, is the unit impulse velocity response, calculated as the maximum initial vertical velocity (m/s) caused by an ideal unit impulse (1 Ns) applied at a location on the floor that gives the maximum response. The first condition in Equation 6 is satisfied since the fundamental frequency is larger than 8 Hz. The force (F_s)-defection (a) criterion is also satisfied and places the floor within the better performance region of the curve in EN 5:2004 [4]. However, assuming 1% damping, the calculated unit impulse velocity response is v=23 mm/Ns^2, which is 42% larger than the recommended value of 16.2 mm/Ns^2 calculated using Equation 6.

4.4 CANADIAN STANDARD [3]

CSA 086:2019 [3] has a vibration-controlled span approach for single-span wood joisted floor systems with prefabricated wood I-joists and wood structural panel subfloor. The maximum recommended span l_v (m) is

$$l_v = \frac{0.122(EI_{eff})^{0.284}}{k_{tss}^{0.14} m_L} \quad (5)$$

$$k_{tss} = 0.0294 + 0.536k_1^2 + 0.516k_1^{0.5} + 0.31k_1^{0.75}$$

where EI_{eff} (Nm^2) is the effective flexural stiffness of the floor system in the span direction, k_{tss} is a factor that accounts for the flexural stiffness in the transverse direction, and m_L is the mass per unit length (kg/m) of the composite floor system. Using FEA and calculating k_1 and K_{tss} of 0.15, and 0.49, respectively, and EI_{eff} of 2.35×10^6 Nm^2, a maximum recommended span, l_v of 5.3 m is calculated, which suggests that the floor system is 13% longer than recommended.

4.5 CCIP-016 [6]

In floors with low-frequency (<10 Hz) the guideline [6] recommends prediction of vibration response based on the first four harmonics of the footfall forces for a range of walking frequencies. That requires calculation of the response in all modes to each of these harmonics and then combining them. The method in CCIP-16 [6] is valid for floors with natural frequencies less than 4.2 times the maximum footfall frequency (i.e. about 15 Hz). The calculation method is comprised of several steps to find mode shapes, frequencies, mode shape amplitudes at excitation and response locations, and eventually calculating the response factor by dividing calculated accelerations by the base accelerations in BS 6472-1 [11].

Response factors at the centre of the floor in a range of walking frequencies (1-2.8 Hz) based on CCIP-016 [6] are displayed in Figure 5. Response factors from the measurements are calculated by dividing a_w in Table 2 by the base acceleration of 0.05 m/s^2 recommended in ISO 2631.2 [14]. It should be noted that the CCIP-016 [6] response factors in Figure 5 are based on 3% damping (in all modes) recommended in the guideline, whereas the experimental response factors are based on the measured damping of 1% (see Table 1).

Using the CCIP-016 method, a maximum R of 479 is calculated at walking frequency of 2.48 Hz (the 4th harmonic of the FEA fundamental frequency), which is much greater than R=18.2, from walking measurements at walking frequency equal to the 4th harmonic of the measured fundamental frequency.

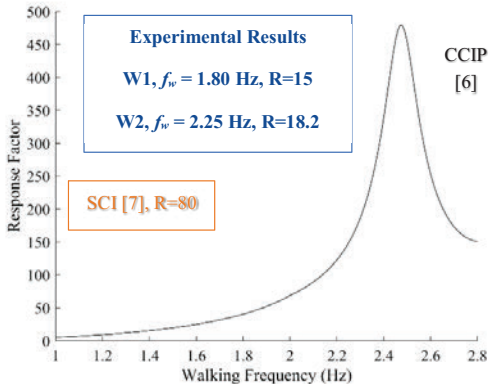

Figure 5: *Response factors from CCIP-016 [6] and SCI-P354 [7] modal approaches and those calculated from the experimental measurements.*

Acceptable response factors for residential and commercial floors are typically below 8. Therefore, assessment based on CCIP-016 [6] indicates that the floor is not acceptable.

4.6 SCI-P354 [7]

The method described in SCI P354 [7] is based on finding peak response (acceleration or VDV) from range of walking frequencies and floor frequencies. The cut-off

https://doi.org/10.52202/069179-0247

frequency (distinction between low- and high-frequency floors) for general floors is 10 Hz in SCI-P354 [7]. In low-frequency floors, both steady-state response and transient responses need to be checked. All modes of vibration with natural frequencies up to 2 Hz higher than the cut-off frequency shall be considered. Initially, the weighted root mean square (RMS) acceleration response of each force harmonic at every mode of the response at the centre of the floor from excitation at designated point on the floor is calculated. Then, the total acceleration response function is found by summing up RMS of each mode of vibration at each harmonic of the forcing function.

Using 1.1% damping for joisted timber floors suggested in [7], an r.m.s. acceleration of 0.4 m/s^2, and a response factor of 80 is calculated and is presented on Figure 5. The calculated response factor is larger than the recommended values (4-8) for residential and office floors, for continuous and intermittent vibrations in BS 6472-1 [11]. However, assuming impulsive vibration, response factors of 60-128 can be acceptable for office and school floors [11].

4.7 HIVOSS [9]

The method is developed by ArcelorMittal (Steel manufacturer) in their design for vibration of timber floors and is based on the statistical distribution of walking frequencies [9]. A design value $OS\text{-}RMS_{90}$ called the "*one step root mean square 90*", is developed which covers the response velocity of the floor filtered using the weighting functions for a significant step with the intensity of 90% of people's walking normally. In this method, the fundamental frequency and corresponding modal mass are calculated from FEA or simple equations. A critical damping value is chosen and from the provided design diagrams, a classification of the floor is derived.

Using a damping of 3% (recommended in [9] for joist timber floors) the floor is classified as 'E' in HIVOSS, which means it is critical for residential and office buildings. However, if used in industrial and sport facilities the floor will have vibration performance at an acceptable level.

5 CONCLUSIONS AND RECOMMENDATIONS

Dynamic properties and vibration response parameters of a lightweight timber floor was studied experimentally. The experimental results were compared to the predictions from simple methods and modal superposition methods, by implementing modal analysis in FEA.

Simplified methods of vibration design, provide a rigid "Yes" or "No" acceptance criterion. The acceptance criterion is based on frequency-deflection equations in which the frequency appears in powers of 2 and larger. Hence, finding the accurate frequency of the floor system is critical. It was understood that a modal analysis in FEA can provide a reasonable approximation of the measured fundamental frequency of the floor system. However, simplified equations fail to provide accurate predictions of natural frequencies. It should be noted that in future work, study of effects of edge supports (4-edge supported floors) on the floor dynamics and vibration performance will be implemented.

The other issue in using simplified methods is calculation of the deflection. The deflection of the floor system under a 1 kN concentrated load is normally smaller than 2 mm and its measurement is a delicate task.

An engineer may decide to use modal superposition methods. The vibration performance in these methods is based on the frequency cut-offs, modal mass, mode shapes and damping. This will provide the engineer more flexibility to make a judgement on the vibration performance of the floor. However, the current study shows that the response factors predicted by modal superposition methods considerably outweigh the experimental observations. The conservative design approach causes oversizing of the floor systems and their structural elements and may result in forsaking a timber design.

Based on the findings of the current study, the following future research directions may be pursued to promote implementation of timber floors in longer spans in buildings of different usages:

- Measure and formulate load functions of continuous and impulsive excitations as well as rhythmic activities, tailored for long-span timber floors.
- Characterise the dynamic properties (natural frequencies, modal mass, mode shape and damping) and response to vibration of floor slabs (i) in the laboratory environment, and (ii) floor systems in selected constructed or completed buildings. This will help understand the difference between a slab design analogy and the actual performance of the floor within the structural system.
- To develop experimentally validated analytical models that can reliably predict the dynamic properties and vibration response of the floor systems.
- To assess occupant comfort with different floor usage and identify acceptance criteria for the investigated floor systems.

In order to establish design criterion in Australia, subjective evaluation of occupants' perception of level of comfort needs to be conducted. There will be enormous benefit in gathering the data from field tests and occupant surveys to establish an international database for researchers and practitioners worldwide for vibration design of long-span floor systems.

EXPERIMENTAL STUDY ON THE VIBRATION CHARACTERISTICS OF A PREFABRICATED CROSS-LAMINATED TIMBER-STEEL COMPOSITE FLOOR

David Owolabi[1], Critiano Loss[2]

ABSTRACT:

Prefabricated mass timber-based floors are lightweight flooring alternatives gaining attention in building applications given their ease of erection, low carbon footprint and structural benefits in reducing the overall seismic mass and foundation requirements in buildings. However, in these floor archetypes, serviceability limit state requirements such as deflection and vibration performance often govern member sizing and layout design. In this paper, the vibration properties of one such flooring system – a prefabricated cross-laminated timber (CLT) -steel hybrid floor, are examined at full-scale via modal and walking tests, considering variations in material properties, geometric configurations, support conditions, walking paths and walking frequencies. The test results indicate that the composite floor is a high-frequency system with a transient response. The study also provides valuable insight into the potential vibration performance of CLT-steel composite floors for residential applications. A prediction of its vibration serviceability via the vibration dose value method indicates that it has a low probability of attracting adverse comments from users in residential applications when a continuous slab is created by connecting its fundamental units using self-tapping screws.

KEYWORDS: Floor vibration, CLT-steel composite floor, prefabricated construction; low-carbon structures

1 INTRODUCTION

1.1 DEVELOPMENT OF STEEL-TIMBER COMPOSITE FLOORS

The use of timber-steel composite decks dates back several decades. One of the earliest applications of this system is in bridge construction, notable among which are some bridge projects in Ontario, Canada. They featured prestressed wood and steel girders connected through shear studs welded to the girders and embedded in the timber via fibre-reinforced grout [1]. More recently, there has been a growing application of mass timber in the construction industry. This can be attributed to its low embodied carbon and constructional efficiency which provide a means of achieving sustainability targets in construction and fast-tracking project completion timelines.

To further optimize the performance of mass timber flooring systems, composite solutions are being developed and mass timber-steel composites are one of the promising solutions. In these flooring systems, steel often provides ductility while mass timber's light weight and low-carbon qualities provide for an environmentally friendly, modular, and demountable system. In building applications, one of the foremost studies on mass timber-steel composite floors examined the feasibility of replacing the conventional composite steel-concrete floor with a CLT-steel solution, focusing on the floor performance under lateral loading action (seismic and wind loads) [2]. More investigations into mass timber-steel composite floors wherein mass timber panels such as CLT or LVL are connected to hot-rolled or cold-formed steel beams to achieve superior structural performance and efficiency have since been carried out [3-6]. These flooring systems have the potential as viable alternatives to mainstream steel-concrete composite floors.

1.2 VIBRATION DESIGN OF LIGHTWEIGHT FLOORS

The design of lightweight flooring systems is often governed by their serviceability limit state requirements – i.e., deflection and vibration, which control their allowable spans. Several guidelines on the vibration design of lightweight floors are available in the literature. These include the American Institute of Steel Construction Design Guide 11 [7], Steel Construction Institute Publication 354 [8], European Guideline on Human-Induced Vibration of Steel Structures [9] and Applied Technology Council Design Guide 1 [10]. Prominent vibration assessment methods contained in these guidelines include the baseline curve culled from ISO 10137 [11], the response factor method and peak acceleration criteria which are derivatives of the baseline

https://doi.org/10.52202/069179-0248

curve, and the vibration dose value (VDV) method detailed in ISO 10137 [11] and BS 6472 [12].

Many vibration control criteria have also been proposed for timber-joisted floors. These include deflection control requirements [13-15], fundamental frequency benchmarks [14-16], and thresholds on peak velocity and acceleration [14,15]. Recently, a span-limiting vibration control equation for CLT floors was adopted in CSA O86 [17] based on the Canadian CLT handbook [18] which also has a similar requirement for timber-concrete composite floors. However, the literature on the vibration behaviour of timber-steel composite floors and their specific vibration design guidelines is very limited [19,20].

1.3 STUDY OVERVIEW

This paper presents an investigation into the vibration characteristics of a prefabricated modular CLT-steel composite floor via modal tests and walking-induced acceleration measurements on full-scale specimens. The in- and out-of-plane static performance of analogous prototypes of the floor has been previously studied and found to be highly satisfactory [3, 21], but its vibration attributes have been hitherto untested. The study provides insights essential for the development of provisions for the vibration design of CLT-steel composite floors.

2 STUDIED FLOOR CONFIGURATION

The studied composite floor consists of fundamental modules, as shown in Figure 1, connected along their edges via self-tapping screws (STSs). Each fundamental module features a 3-layer CLT panel coupled to twin cold-formed steel beams having omega-shaped profiles. The beams are spaced such that the maximum transverse bending capacity of the CLT panel is not exceeded. Composite action is achieved by the transmission of shear stresses between the beams and panel via STSs.

In regions of high horizontal shear stresses (i.e., close to the beam ends), the STSs are driven in at 30°, guided by steel tubes welded over slots machined in the flange of the beams. In the middle regions of low shear, the STSs are inserted perpendicularly. The CLT panel, which enables two-way loading, is designed to be capacity protected, while the thin-profile steel beams (4.7mm thick) primarily take on plastic deformation. The dry assembly process enables easy production and decommissioning.

3 TESTING METHOD

3.1 PARAMETRIC CONSIDERATIONS

Roving hammer modal tests and walking-induced acceleration measurements were systematically carried out on the floor components, fundamental units, and pairs of connected units. The parametric changes considered during the tests are summarized in Figure 2. These include variations in the Canadian CLT panel grades – E and V grades; beam length – 5.7m and 6m; shear connection – full shear connection and partial connection wherein every other screw is omitted; and spacing of the beams – 1.2m and 1.6m. Regarding the beam spacing, 1.2m was adopted in the original design of the fundamental unit, while 1.6m is the maximum spacing for which a symmetric double T section can be maintained and the transverse bending stress in the CLT panels would remain below the permissible threshold. Also, the longitudinal edge conditions of combined modules were varied, considering free edges, and simply supported edges – to imitate panel continuity. At the supports, a simple support condition was maintained for all specimens throughout the testing.

https://doi.org/10.52202/069179-0248

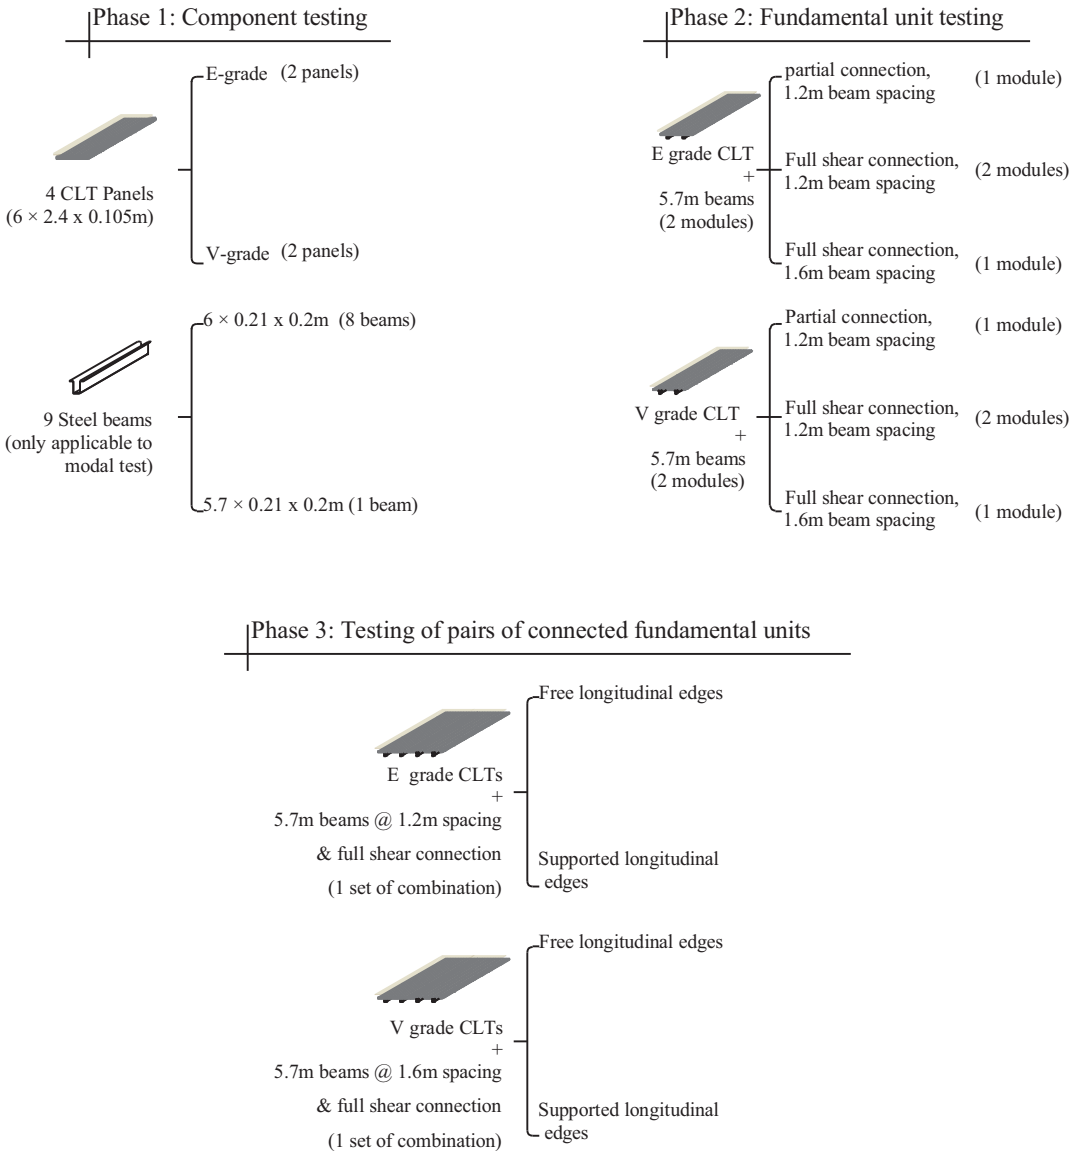

Figure 2: *Parametric variations considered during modal and acceleration measurements in the three testing phases*

3.2 MODAL TESTING AND ANALYSIS

Roving hammer modal tests were carried out in line with ISO 18324 [22] and BS EN 16929 [23]. The testing process and instrumentation are shown in Figure 3. In each tested CLT panel, fundamental unit and combined units, the experiment involved 49 impact locations and five accelerometers placed along the panel diagonal. In testing the beams, seven impact locations were set up along the base of each beam and three accelerometers were installed. The accelerometers employed in the modal test had an average sensitivity of 1mV/m/s^2. A six-channel data acquisition hardware with an input range of DC – 50kHz was used to record the data over eight seconds. Three averages were taken at each impact location of the beams, while two averages were taken for the CLT panels, fundamental units, and combined units, given their greater number of impact points compared to the beams.

Frequency response functions (FRFs) were generated from the excitation forces and frequency-domain accelerations obtained by fast Fourier transformation (FFT). The FRFs were used in the identification of modal parameters (i.e., mode shapes, natural frequencies, and damping ratios) via the rational fraction polynomial method.

Pertinent walking paths and accelerometer location for analysis of floor response:

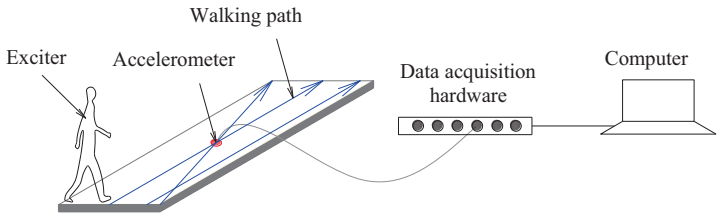

***Figure 4**: Walking-induced acceleration measurement*

3.3 WALKING-INDUCED ACCELERATION MEASUREMENT AND POST-PROCESSING

In this test, a 58kg human exciter aided by a metronome, walked over the specimens at different frequencies (1.2 Hz, 1.6 Hz, 2.0 Hz and 2.4 Hz) in line with ISO 10137-suggested range of forcing frequencies [11]. The acceleration data were obtained through the same set of accelerometers and data acquisition hardware used in the modal test. The pertinent walking events considered in analyzing the response of the specimens were those carried out along the longitudinal edge, diagonal and longitudinally along the middle of the specimens (Figure 4). Also, the acceleration data used in the analysis were those recorded at the centre of the specimens.

The root mean square values of the recorded vertical accelerations (A_{rms}) were computed, and the frequency-weighted acceleration data were obtained following guidance in ISO 2631-1 [24]. These were then used in calculating VDVs – see Equation (1), for predicting the probability of adverse comments by users based on BS 6472 [12].

$$VDV = \left(\sum_{n=1}^{N} \int_{0}^{T} a_n^4(t)dt \right)^{0.25} \quad (1)$$

where a_n is the frequency-weighted acceleration for vibration episode "n" and T is the total duration of the vibration event.

https://doi.org/10.52202/069179-0248

The VDV approach was chosen given its suitability for interpreting intermittent vibration events expected in residential settings. In obtaining the VDVs, a 16-hour day setting was adopted, with the assumption of a 10-minute interval between walking events. The worst value (highest value) of VDV obtained for each tested configuration was selected for drawing inferences about their vibration serviceability.

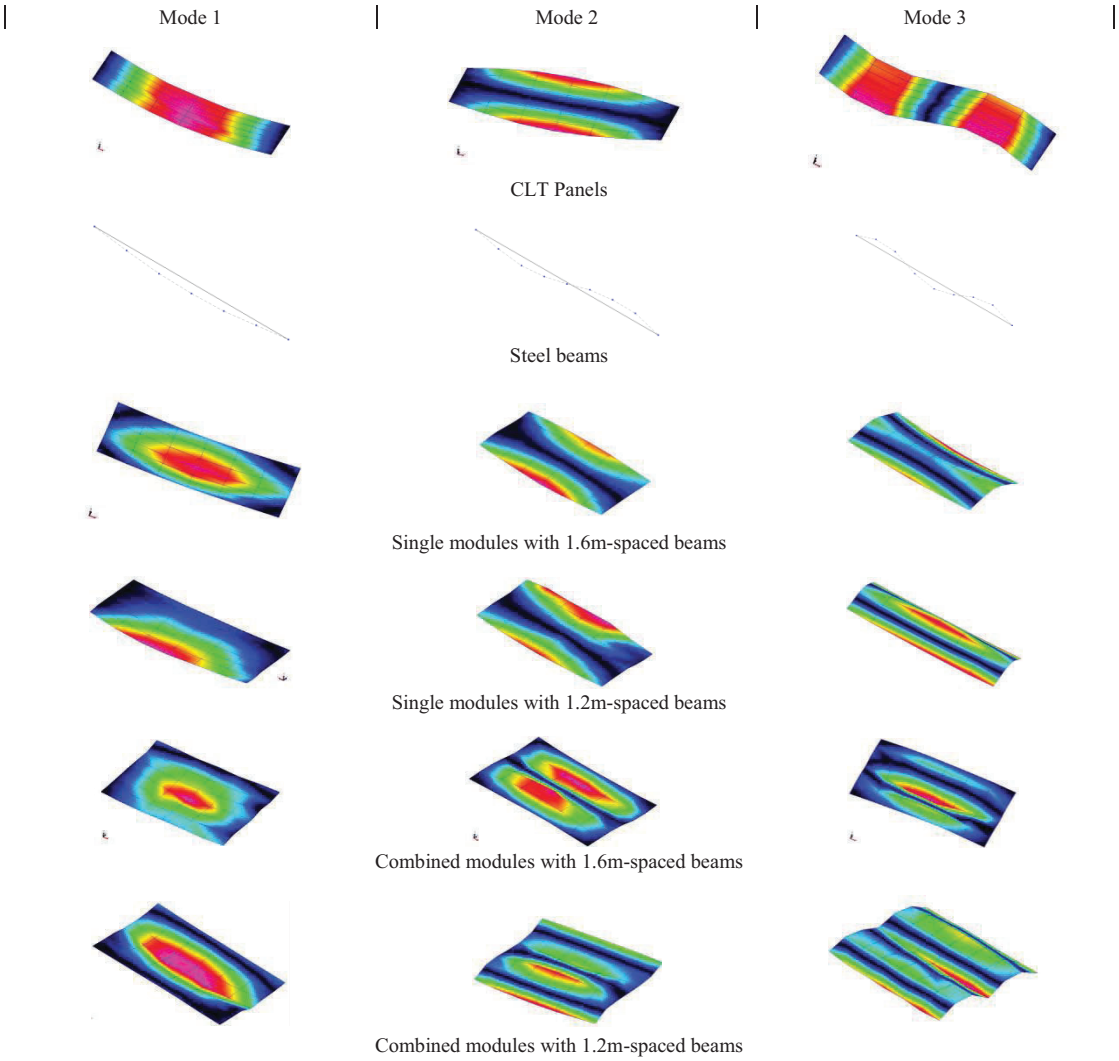

***Figure 5**: First three mode shapes of floor modules and their components*

4 RESULTS AND DISCUSSION

4.1 MODE SHAPES OF FLOOR MODULES AND THEIR COMPONENTS

Figure 5 shows the first three vibration modes of the tested specimens. The observed modes shapes of the steel beams were in conformity with the sinusoidal modes of an ideal simply supported beam. For the CLT panels, the first and third modes were bending modes while the second was torsional as anticipated. The spacing between beams was found to be the main influencer of mode shape discrepancies in the composite modules. As such, the vibration modes for composite modules in Figure 5 have been grouped based on beam spacing. In the fundamental modules, the first bending mode of specimens with 1.2m -spaced beams was partial longitudinal bending, while that of their counterparts with 1.6m-spaced beams was domed-shaped bending. However, their second (torsional) and third (transverse bending) vibration modes were similar. The combined modules had similar domed-shaped fundamental modes, but those with 1.2m-spaced beams experienced transverse bending in their second and third modes while the corresponding modes in specimens with 1.6m-spaced beams were akin to mirrored domes.

4.2 NATURAL FREQUENCIES AND DAMPING RATIOS OF FLOOR MODULES AND THEIR COMPONENTS

Table 1 summarizes the natural frequencies and damping ratios of the tested components and modules. Regardless of material grade, the CLT panels had similar natural frequencies and damping ratios (less than a 10% difference in the observed range of fundamental frequencies and damping values). The same is true of the steel beams where the discrepancy is less than 20%. The fundamental frequencies of the composite floors were heavily influenced by the beams, leading to high fundamental frequency values (greater than 15 Hz) which classified them as high-frequency floors. Other parametric changes did not significantly influence the fundamental frequencies. Also, their fundamental damping ratios (1.8% – 3.2%) were consistent with values suggested in ISO 10137 [11] for bare floors (1.3% – 2%).

The damping ratios of the combined modules were at least a fifth higher than those of the single modules. Also combined modules with supported longitudinal edges (introduced for simulating floor continuity) had about 21% higher damping values than their unsupported counterparts on average. This is suggestive of better vibration performance in on-site settings where there will be floor continuity.

Table 1: *Modal properties, A_{rms} and VDVs of floor modules and their components*

Component	$f_{1\ mean}$ (Hz)	$\xi_{1\ mean}$ (%)	$A_{rms,\ max}$ (m/s^2)	VDV_{max} (m/s$^{-1.75}$)	P (Adverse comment) [a]
Steel beam	18.1 (16.8 – 19.9)	1.5 (1.4 – 1.6)	-	-	-
CLT panels	6.6 (6.4 – 6.8)	4.4 (4.1 – 4.5)	1.3 (0.5 – 1.3)	4.3 (1.6 – 4.3)	Very likely
Single modules (1.2m-spaced beams)	17.9 (17.0 – 19.1)	1.9 (1.8 – 2.1)	0.4 (0.1 – 0.4)	2 (0.4 – 2.0)	Very likely
Single modules (1.6m-spaced beams)	16.8 (15.4 – 18.1)	1.9 (1.8 – 2.0)	0.6 (0.4 – 0.6)	2.8 (1.6 – 2.8)	Very likely

Combined modules (1.2m-spaced beams, supported edges)	16.9	3.2	0.1	0.4	Low
Combined modules (1.6m-spaced beams, free edges)	17.4	2.8	0.1	0.4	Low
Combined modules (1.6m-spaced beams, supported edges)	17.9	3.2	0.1	0.4	Low

Note: Values in parentheses are the range of values obtained for the specimens in each category. Entries without values in parentheses have the same values for all tested replicates.

[a] P (adverse comment): the probability of adverse comment. 0.2 to 0.4 – low probability of adverse comment, 0.4 to 0.8 – adverse comment possible, 0.8-1.6 – adverse comment probable, >1.6 – adverse comment very likely [12]

4.3 RESPONSE OF COMPOSITE MODULES AND CLT PANELS TO WALKING

The VDVs and A_{rms} values of the tested specimens are presented in Table 1. Specifically, the values obtained for the CLT panels and fundamental units varied significantly in each category and their VDVs were unsatisfactory for residential applications as implied by the predicted high probability of adverse comments. On the contrary, the results for the combined modules – the form in which the floor system will be installed in practice – were less varied and favourable. Their VDVs translated to a low likelihood of adverse comments by residential building occupants per BS 6472 [12] provisions. Further details on the vibration response of the floor system and its serviceability performance are presented in the paper titled: "Vibration properties and serviceability performance of a modular cross-laminated timber -steel composite floor system" which is currently under review.

5 CONCLUSIONS

The vibration characteristics of a modular CLT-steel composite flooring solution have been examined in this paper. The modal properties, acceleration responses and prediction of its vibration serviceability have been elucidated. The main deductions of the study are as follows:

https://doi.org/10.52202/069179-0248

- The studied composite flooring solution is a high-frequency floor largely due to its beam components
- The floor's damping ratios are in agreement with the provisions in ISO 10137 [11] for the precursory design of bare floors
- The modal properties and acceleration response of the floor were mainly influenced by beam spacing, module combination and edge condition while other parameters – CLT panel grades, and shear connection – were less significant
- The combined floor modules were found to have consistent A_{rms} and VDVs. The VDVs of the combined modules also indicated favourable vibration serviceability. Nonetheless, evaluations involving real humans are required to ascertain the veracity of the vibration serviceability prediction

ACKNOWLEDGEMENT

This research was funded by the Government of British Columbia through the FII Wood First Grant, "Investigating the structural performance of a modular prefabricated dry-assembly mass timber-steel hybrid floor element Phase II," and by the Natural Sciences and Engineering Research Council (NSERC) of Canada through the Discover Program grant number RGPIN-2019-04530, and Discovery Launch Supplement, grant number DGECR-2019-00265. Fruitful discussions with Dr. Jianhui Zhou on vibration testing are gratefully acknowledged. The authors appreciate the assistance rendered by James Andal and Michael Billups of the UNBC Wood Innovation Research Laboratory and the civil engineering students at the University of Northern British Columbia during the experiments. The authors are grateful to Rothoblaas Canada Construction Products Inc. for providing screws used in the floor assembly and for the CLT discount by Structurlam, BC. EXPERIMENTAL INVESTIGATIONS ON VIBRATION PERFORMANCE OF TIMBER-CONCRETE COMPOSITE BEAMS USING LIGHTWEIGHT AGGREGATE CONCRETE

Bo Wen[1], Benkai Shi[2], Haotian Tao[3], Huifeng Yang[4], Bowen Huang[5]

ABSTRACT: Better structural performances can be obtained by using concrete slabs instead of timber slabs in floor system of timber structures. The use of lightweight aggregate concrete (LWAC) in timber-concrete composite floors can reduce the self-weight of the slab. However, the vibration performance of timber-LWAC composite floors remains need to be studied. In view of this, an experimental programme was conducted to investigate the dynamic properties of the timber-LWAC composite beams. Three test specimens with different types of connections were designed and fabricated. The test results demonstrated that the timber-LWAC composite beams have good vibration performance with the fundamental natural frequency much higher than 8 Hz. Additionally, the vibration frequency of the composite beams with notch-screw connections or glued-steel plate connections is higher than that of the composite beams with crossed inclined screw connections.

KEYWORDS: Timber-concrete composite beams, Lightweight aggregate concrete, Vibration performance, Timber-concrete connections, Experimental investigations

1 INTRODUCTION

Floor system is the component with the closest contact between the human and building, which requires high structural performance both in ultimate limit state and serviceability limit state. The vibration performance is one of the crucial behaviours of floor systems, which significantly affects the comfort and safety of the structure. Due to the lightweight and low elastic modulus of timber, the traditional timber floor is prone to generate large vibration response. Excessive floor vibration will bring negative psychological effects to the occupants, and even affect the structural safety, which will restrict the development of modern timber structures [1].

Stiffness is the key factor affecting the vibration performance of floor system. Industry regulations control the vibration of timber floors by increasing the structural stiffness and limiting the deformation of timber members [2-4]. With the development of timber structures, the dynamic characteristic index is gradually used as an important parameter to evaluate the vibration performance of timber floors, such as the fundamental natural frequency $f_1 > 8$ Hz in the modal parameters of the floor, and the acceleration generated by human-induced load excitation [5-7]. In addition to the continuous development of vibration control methods, with the development of timber processing technology and structural construction, the types of timber floors are also changing. For the research work on the vibration performance of timber floors, the current main research object has changed from the traditional joist timber floor to the new types represented by cross-laminated timber (CLT) and timber-concrete composite (TCC) floor [1]. In recent years, some studies have proven that the timber-concrete composite (TCC) floors can significantly improve the vibration performance of the floor [8,9].

TCC structure has apparent advantages in stiffness, bearing capacity, sound insulation performance, and fire resistance when compared with traditional timber structures. Also, compared with concrete structures, TCC structure can effectively reduce the consumption of traditional building materials and promote the development of sustainable buildings [10,11]. Lightweight aggregate concrete (LWAC) has the characteristics of light self-weight, high stiffness, and good thermal insulation performance, which is more suitable for TCC structures than the traditional normal concrete [12].

However, few studies have been conducted on the vibration performance of timber-LWAC composite beams. In this study, the dynamic properties and vibration performance of the timber-LWAC composite beams were investigated, and the influences of different types of shear connectors on the vibration performances of the composite beams were evaluated.

2 TEST SPECIMENS AND METHODS

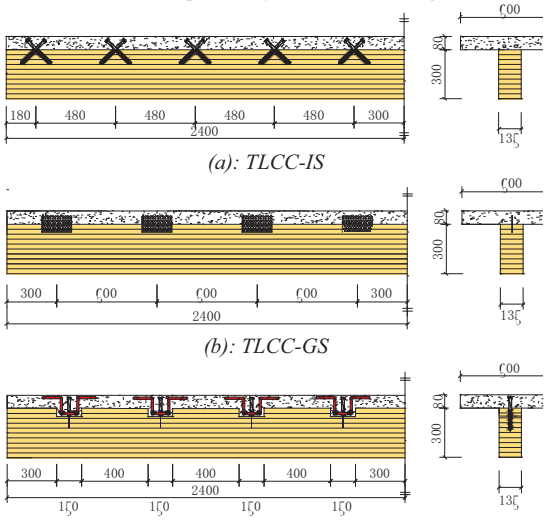
2.1 SPECIMENS

In this experimental programme, three timber-LWAC composite beams were designed, by considering different types of shear connectors. The connectors adopted in the composite beams include the crossed inclined screws, glued-in steel plates, and notched-screws. The specific component parameters were designed according to the Eurocode 5 [13], and the parameters of the specimens are shown in Table 1.

Table 1: *The parameters of the specimens*

Specimens	Connector		
	Types	Spacing (mm)	Quantity
TLCC-IS	crossed inclined screw	480	10
TLCC-GS	glued-in steel plate	600	8
TLCC-NS(R)	notch-screw (reinforcing bar)	550	8

The dimensions of the timber beam are 4800 mm × 135 mm × 300 mm (length × width × height), while the LWAC slab are 4800 mm × 600mm × 80 mm (length × width × height). The spacings of the crossed inclined screws connections are 480 mm, while those of the glued-in steel plate connections and notch-screw connections are 600 mm and 550mm, respectively, as shown in Fig. 1.



(a): TLCC-IS

(b): TLCC-GS

(c): TLCC-NS(R)

Figure 1: *Configurations of the specimens*

In order to obtain the basic mechanical properties of the connectors, the push-out tests on the connectors were carried out. The parameters of the push-out specimens are shown in Table2.

The push-out specimens adopted the symmetrical configuration, as shown in Fig. 2. For the specimens with crossed inclined screws, the inclination angle of the screw was 45°, and two screws with the diameter 16 mm and length 200 mm (M16L200) were adopted in each shear plane. For the specimens with glued-in steel plates, the length and width of the slots are 190 mm and 10 mm, respectively, and the glued-in depth is 50 mm. For the specimens with notch-screws, the length, width, and depth of the notch are 135 mm, 150 mm, and 50 mm, respectively.

Table 2: *The parameters of the push-out specimens*

Specimens	Connector	Metal Parts and Construction Methods
ISLC	crossed inclined screw	Two M16L200 screws, crossed and inclined at 45°
GSLC	glued-in steel plate	A 180mm×100mm×3.75mm steel plate was glued in the timber
NSLC(R)	notch-screw (reinforcing bar)	Reinforcing steel bars and M16L200 are set in the rectangular notch

2.2 MATERIALS

The glulam beams were made of North American Douglas Fir. The basic mechanical performances of the glulam are shown in Table 3.

Table 3: *The basic mechanical properties of timber*

Properties	Value (MPa)
Tension strength	69.7
Compressive strength	43.3
Shear strength	9.4
Modulus of elasticity	13100

The lightweight aggregate used in the LWAC slab is spherical shale ceramsite. The strength grade of lightweight aggregate concrete is LC30, and the mix design is shown in Table 4.

Table 4: *The mix design of LWAC*

Composition	Mass (kg/m^3)
Portland cement	490
Water	200
Coarse aggregate - shale ceramsite	485
Fine aggregate - sand	750

The standard cubic test blocks with a size of 150 × 150 × 150 mm^3 and standard cylindrical test blocks with a diameter of 150 mm and a height of 300 mm were tested. The test results show that the average compressive

https://doi.org/10.52202/069179-0249

strength of lightweight aggregate concrete is 28.15 MPa, and the elastic modulus is 18800 N/mm^2.

The screw connectors adopted in this experimental programme are galvanized hexagonal head self-tapping screws with a specification of M16L200, and the strength grade is Q235. Referring to ASTM F1575 [14], the yield bending moment of the screws was measured as 206430 N·mm. The strength class of the perforated steel plate in the glued-in steel plate connector is grade Q235, and the dimensions are 180 mm × 100 mm × 3.75 mm (length×width×thickness). The hole diameter is 10 mm, and the distance between the holes is 15 mm.

The adhesive used in the glued-in steel plate connector is a type of two-component epoxy resin, and the performance parameters are provided by the manufacturer, as shown in Table 5.

Table 5: *Basic mechanical properties of adhesive materials*

Properties	Value (MPa)
Tension strength	9.37
Bending strength	63.1
Compressive strength	110.1
Shear strength	16.7

The test specimens were fabricated in Nanjing Tech University. Fig. 3 and Fig. 4 show the fabrication processes of installing the connectors on the timber beam and pouring the concrete, respectively.

Figure 3: *Installed connectors on the timber beams*

Figure 4: *Poured concrete*

2.3 TEST DEVICE AND MEASUREMENT SCHEME

The test mainly attempts to extract the fundamental natural frequency f_i of the vertical bending mode of the specimen [13]. In the modal test, the simply supported boundary conditions were used for the beam specimens. One end of the beam was adopted as fixed hinge, while the other end was set as sliding hinge. The span between the supports is 4500 mm. The beams were stroked by a pulse hammer, and the vibration responses were captured using accelerometers mounted on the beam, as shown in Fig.5. Experimental Modal Analysis (EMA) software was used to identify the fundamental natural frequencies in the modal parameters of the timber-LWAC composite beams. Fourier transform was used to convert the acquired time-domain signals into a frequency-domain signals. The modal parameters of beam specimens were extracted from the frequency response using the post-processing module of the software. In this test, the dynamic signal test system with the model of TST3828E was used for collecting the response signals, and the software with model of DASP was used for analysing the dynamic performance modal. In order to improve the accuracy and reliability of the data, three repeated tests were carried out for each beam specimen, and the dynamic performance was determined according to the average value from the three tests.

Figure 5: *Dynamic test for timber-LWAC composite beam*

3 TEST RESULTS AND ANALYSIS

3.1 INTERFACE PROPERTIES OF COMPOSITE BEAM

The shear performances of interfacial connectors for timber-LWAC composite beams were determined by push-out tests. Based on EN 26891-1991 [15], the test device and loading procedure are shown in Fig. 6 and Fig. 7, respectively. The interfacial slip was recorded by the displacement meters. The slip stiffness value (K_s) of the connector at serviceability limit state can be obtained by Eq.1. The results are shown in Table 6.

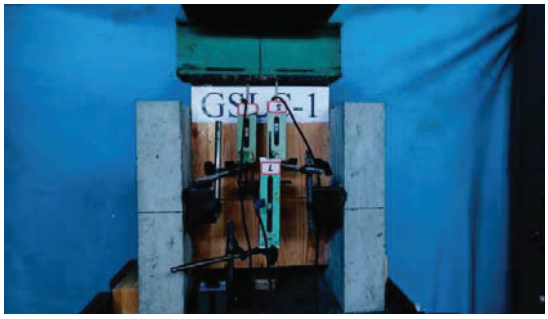

Figure 6: *Test set up of the push-out test*

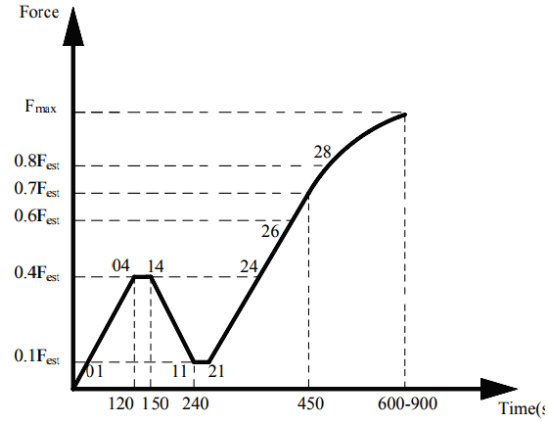

Figure 7: *Loading procedure*

$$K_s = \frac{0.4F_{est}}{4/3(\delta_{04} - \delta_{01})} \quad (1)$$

where F_{est} is the predicted value of the shear bearing capacity of the connector; δ_{01} is the corresponding slip value (mm) at $0.1F_{est}$; δ_{04} is the corresponding slip value (mm) at $0.4F_{est}$.

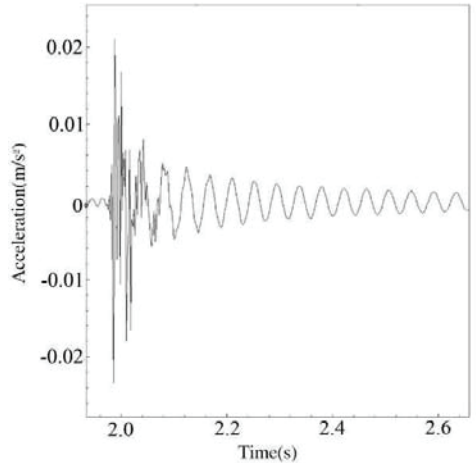
Table 6: *Push-out test results*

Specimen code	K_s (kN·mm^{-1})
ISLC	79.0
GSLC	220.5
NSLC(R)	264.5

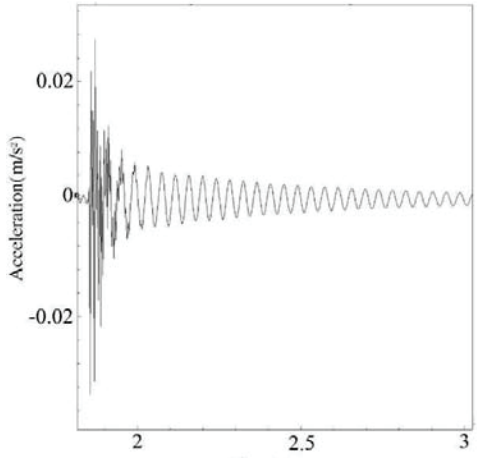
As shown in Table 6, the slip stiffness of the cross inclined screw, glued-in steel plate, and notched-screw connectors at the serviceability limit state are 79.0 kN/mm, 220.5 kN/mm, and 264.5 kN/mm, respectively.

3.2 DYNAMIC PROPERTIES OF THE TIMBER-LWAC COMPOSITE BEAMS

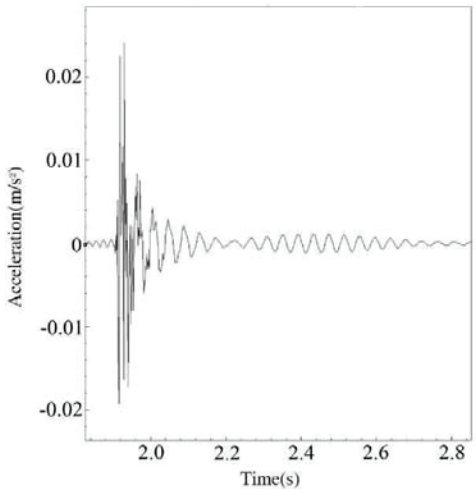
Fig. 8 shows the acceleration response time-domain signals of each timber-LWAC composite beam. The experimental value of the fundamental natural frequency $f_{1(exp)}$ of the timber-LWAC composite beams can be obtained by performing Fast Fourier Transform (FFT) on the time-domain signals through the analysis and processing software. The average values of $f_{1(exp)}$ obtained from 3 repeated excitation tests are listed in Table 7. At the same time, the damping ratios of the beams were calculated by the half-power method [16], and were listed in Table 7.



(a): TLCC-IS



(b): TLCC-GS



(c): TLCC-NS(R)

Figure 8:*Time-domain signals*

Table 7: *Dynamic properties of timber-LWAC composite beams*

https://doi.org/10.52202/069179-0249

Beam code	$f_{1(exp)}$(Hz)	$f_{1(cal)}$(Hz)	Damping ratio
TLCC-IS	23.68	23.69	3.9%
TLCC-GS	23.93	26.13	1.7%
TLCC-NS(R)	24.17	26.78	3.5%

The timber-LWAC composite beam was used as the one-way slab. Therefore, the fundamental natural frequency of the beam could be considered as that of the floor. The estimation of the fundamental natural frequency of the composite beam mainly refers to the Equation (2) according to Eurocode 5 [13].

$$f_1 = \frac{\pi}{2l^2}\sqrt{\frac{EI}{m}} \quad (2)$$

where l is the span of the floor (m), $(EI)_l$ is the effective bending stiffness of the floor (Nm^2/m), m is the mass per unit area of the floor (kg/m^2).

For timber-LWAC composite beams simply supported at both ends, the effective bending stiffness is calculated using Equation (3).

$$(EI)_{\text{eff}} = E_c I_c + E_t I_t + \gamma_c E_c A_c a_c^2 + \gamma_t E_t A_t a_t^2 \quad (3)$$

where E_cI_c and E_tI_t are the bending stiffness of the concrete slab and the timber beam of the composite beam, respectively; γ_c and γ_t are the reduction coefficients of the beam combination action, respectively; A_c and A_t are the cross-sectional areas of the concrete slab and the timber beam, respectively; a_c and a_t are respectively converts the distance from the section centroid to the concrete slab and timber beam centroid.

The subscripts c and t stand for concrete and timber, respectively. When calculating the value of the γ coefficient, the value of the slip stiffness K_s of the corresponding connectors determined by the push-out test was used.

The theoretically predicted fundamental natural frequency $f_{1(cal)}$ of each beam was calculated by Eq. 2, and were also listed in Table 7.

3.3 DISCUSSION

The theoretically predicted and the measured fundamental natural frequency are listed in the Table 7. It can be found that the fundamental natural frequency values estimated by Eurocode 5 method have a very small difference compared with the measured values, and the accuracy can meet the needs of engineering design.

It can be seen from the test data that if the timber-LWAC composite beams in this test are directly used as a one-way floor, the measured fundamental natural frequency values are all between 23 and 25 Hz, which can meet the general requirement of 8 Hz [13]. At the same time, the frequencies of the timber-LWAC composite beams are far away the frequencies range (1.0-4.0 Hz) of human-induced loads (such as walking, jumping, running, etc.) [17], which can effectively prevent the occurrence of resonance caused by people in the use of the floor.

The differences between the theoretically predicted values of the fundamental natural frequency and the experimentally measured values are 0.04%, 9.2%, and 10.8% for the timber-LWAC composite beams connected by crossed inclined screws, glued-in steel plate, and notch-screw connections, respectively. The calculation method in the Eurocode 5 showed the relatively high prediction results. This phenomenon may be caused by the overestimated values in effective bending stiffness for all beam specimens.

The fundamental natural frequencies of the beam specimens TLCC-NS(R) and TLCC-GS are bigger than that of TLCC-IS. This is because the glued-in steel plate (GSLC) and notched-screw (NSLC(R)) showed higher slip stiffness compared with cross inclined screw connection (ISLC). This result lead to the higher values in effective bending stiffness for beam specimens TLCC-NS(R) and TLCC-GS, compared with the beam specimen TLCC-IS. Investigating the reason, in the case of the same beam span and the same quality, it can be seen from the push-out test results that the slip stiffness value of the crossed inclined screws connector is smaller than that of the glued-in steel plate and notch-screw connector. On the other hand, there are also differences in the number of connectors. The number of crossed inclined screw connectors is 10 groups, while the number of glued-in steel plate and notch-screw connectors is 8 groups. The number of crossed inclined screw connectors is less than the other two, which further shows that the decisive factor is still the slip stiffness value of the connector. From this phenomenon, it can be deduced that the slip stiffness value of the connectors is a very important factor of the vibration performance for timber-LWAC composite beams.

In terms of damping ratio, the specimen TLCC-GS showed the value of 1.9%, which is much smaller than specimens TLCC-IS and TLCC-NS(R). There is no direct relationship between the connector stiffness and the damping ratio. The above results were only preliminary inferences obtained through sample tests, and the influence of sample size and test accuracy cannot be ruled out.

4 CONCLUSIONS

In this study, the dynamic tests were carried out on the timber-LWAC composite beams using three different connectors. The fundamental natural frequencies of beams were predicted by the calculation method suggested in Eurocode 5, and the predicted values were compared with the experimental values. By analyzing the modal parameters, such as the fundamental natural frequency and damping ratio, the basic vibration performances of the timber-LWAC composite beams were obtained. The main conclusions are summarized as follows:

The fundamental natural frequencies of the timber-LWAC composite beams in this study are in the range of 23.68 to 24.17 Hz, which meet the primary requirement in Eurocode 5. The fundamental natural frequency of the timber-LWAC composite beam is much higher than 8 Hz [13], which means the vibration performance meets with the preliminary comfort requirements.

From the test results, it can be preliminarily inferred that the number and slip stiffness of shear connectors can significantly affect the fundamental natural frequency of timber-LWAC composite beams.

The theoretical fundamental natural frequency of the specimens calculated according to Eurocode 5 show good agreement with the test results. However, there is still a certain difference between the predicted and experimental values, which might be caused by the overestimation of the bending stiffness of composite beams.

DEVELOPMENT OF A STAND-ALONE VIBRATION MEASUREMENT SYSTEM FOR BRIDGE MONITORING

Dio Lins[1], Steffen Franke[2], Roger Weber[3], Bettina Franke[4], Joel Karolin[5]

ABSTRACT: The quality assurance of timber bridges is currently ensured mainly manually by regular visual inspections over the entire life cycle. To reduce this (cost) effort, the possibility of continuously recording the condition of bridges through monitoring is being investigated. This would also increase the confidence in the long-term load-bearing capacity of timber bridges among planners and public. In addition to the permanent recording of the wood moisture content, conclusions can also be drawn about the condition and even possible damage by recording the natural frequencies which depends on the stiffness. For this purpose, a stand-alone vibration measurement and evaluation system was developed, which is easy to handle and suitable for long-term monitoring due to its energy efficiency. Beside a first application on a low-traffic timber bridge for several months, the system was validated with investigations on various types of artificial damages on the natural frequency of timber components.

KEYWORDS: Vibration measurement system, timber bridges, natural frequency, damage identification, quality assurance

1 INTRODUCTION

Every structure vibrates due to natural excitation or use in its natural frequency (see Figure 1), which depends on the mass and stiffness. If damage in individual structural members or the complete structural system occurs, the stiffness may change and so does the natural frequency [1]. By continuously recording the natural frequency, possible damage can therefore be detected at an early stage. However, the previous studies on this topic mostly refer to steel or reinforced concrete structures [2]. In timber construction, knowledge is available for the pure vibration assessment of timber ceilings or bridges, e.g. [3], [4]. The application to timber bridge structures for condition assessment is not yet established. Bridges are normally used daily and the slow traffic as well as heavy traffic causes the supporting structure to vibrate. The continuous recording of the changes of the natural frequency of timber bridges therefore not only serves to detect damage, but also to systematically gain knowledge.

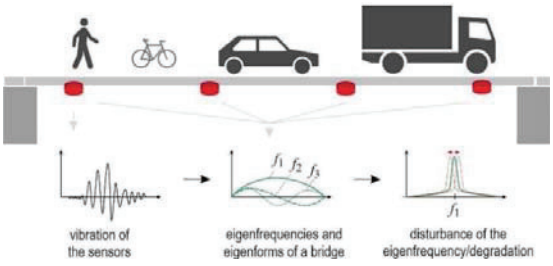

Figure 1: *Daily loading situations of a bridge*

Bridges are indispensable in the traffic area and are subject to regular quality inspections. In Germany for example, bridges must undergo a simple and a main inspection every three years alternately [5]. These are always carried out close to hand and therefore entail a great deal of effort, especially for timber bridges [6], [7], [8]. Efficient digital tools for monitoring purposes are missing in everyday life and are not specifically adapted to the material or purpose of timber bridges.

For the development of a monitoring system of the natural frequencies, the constantly occurring measurement data (accelerations, vibrations) must be digitally recorded, filtered, and analysed so that differences in the vibration behaviour, in the natural frequency, can be recognised. In this way, e.g., as a traffic lights principle, authorities can obtain results about the condition of the timber bridge and at the same time engineers or researchers can obtain general data sets to improve vibration measurement or design. Here, the development of a measurement system of vibration sensors including online analysis for monitoring the vibration behaviour of timber bridges during daily use should support.

2 THE NEW VIBRATION MEASUREMENT SYSTEM

2.1 COMPOSITION OF THE MEASURING SYSTEM

For the development of a standalone, wireless, battery-operated, easy to use and to install vibration measurement system, the requirements for the specific application at timber bridges or timber floor systems were examined, such as the measurand (speed/acceleration), the required accuracy and whether 1- or 3-axis sensors can be used. Focus was also given to the lowest possible energy consumption for the acquisition and transmission of the measurement data (digitisation).

The developed system consists of several sensor nodes and a powered HUB, (see Figure 2). Each sensor node includes an accelerometer (+/- 6g) with a sampling rate of 2 kSamples/s and a bandwidth of 70 Hz, and subsequent downsampling to 100 Samples/s and allows the 3-axial acquisition of the accelerations. They are battery-operated (runtime 0.5 year) and communicate up to 100 m with the HUB via Bluetooth Low Energy 5.2. A nRF52840 from Nordic is used as CPU and BLE transceiver.

The HUB is based on a Linux board from Toradex (Apalis i.MX8), is powered by the network and is located within the 100 m range of the sensor nodes. Raw data is stored locally and sent via LTE to the database on the server (see Figure 3). The HUB controls and monitors the sensor nodes. Problems such as short disconnections to the sensor nodes are detected and handled so that long-term use is ensured.

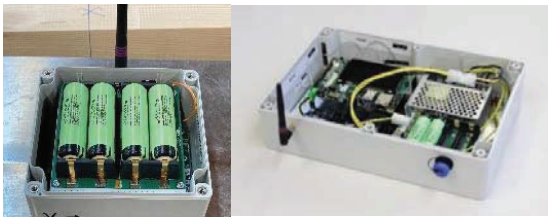

Figure 2: *Sensor node with 3-axis acceleration sensor below the battery pack (left) and HUB (right)*

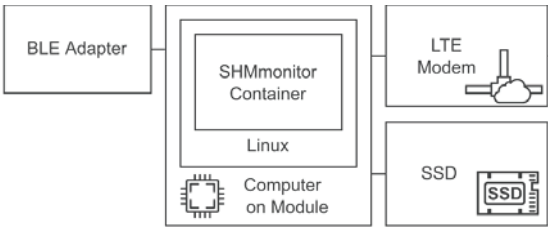

Figure 3: *Details of the HUB*

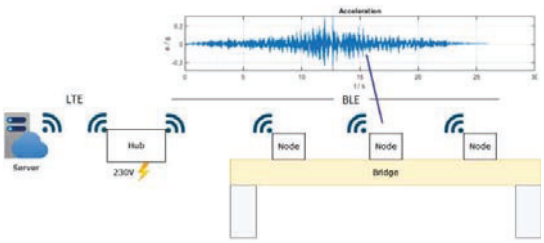

Figure 4: *Schematic diagram of the measuring system as cluster configuration*

2.2 SINGLE AND CLUSTER USE

In cluster use, several nodes can be integrated into one measuring system by the HUB to analyse several vibration frequencies at the same time or to determine the vibration form of the structure. All sensor nodes transmit the raw acceleration data to the HUB, which sends the data on to a server (see schematic diagram in Figure 4). Here, the data is evaluated and visualized offline by the SHMlive software developed in-house. Sensor data can be displayed in the time domain as well as in the frequency domain. Thus, it is possible to display the natural frequencies and to detect a shift/change of the frequencies.

As an alternative to the cluster use with the HUB, an adapter and notebook can be used to create a status recording or single use of one node. In this configuration, the sensor node directly transmits the raw acceleration data to a PC in real time where it can be further analysed. For this purpose, the SHMlive software is directly used to control the sensor nodes and visualise the acceleration data.

2.3 VALIDATION OF THE SYSTEM

The accuracy of the system was tested. To this end, status recordings were carried out on single span beams that were triggered by an impact (see Figure 5). The results of

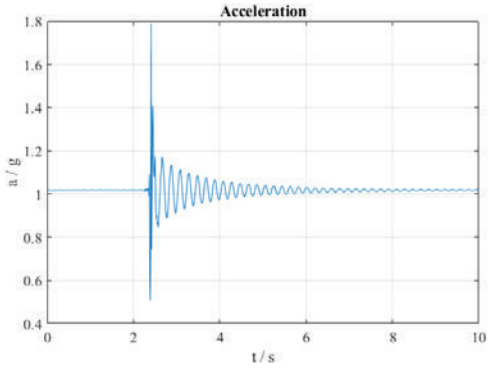

Figure 5: *Time domain: Acceleration over time*

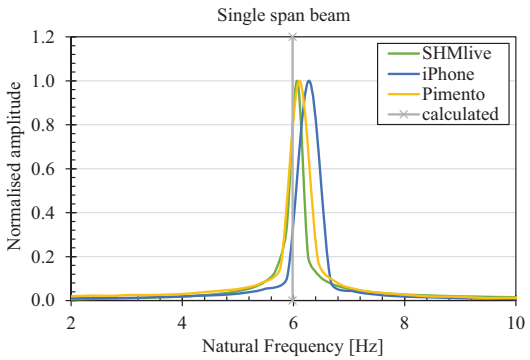

Figure 6: *Comparison of natural frequencies between different measurement systems*

https://doi.org/10.52202/069179-0250

the new system were then compared with existing measurement systems. Those were “Pimento” with one sensor and the application “phyphox” developed by RWTH Aachen University on the mobile phone (IPhone SE). As you can see in Figure 6, there is only a difference of 0.6 % compared to the “Pimento” system in this test. The deviations from “phyphox” are greater with 3.5 %, but this is also not a scientific measuring system as an application for the mobile phone. In addition, the repeatability of the new system was tested in various trials and found to be 0.05 Hz. In all these trials, it was also possible to ensure that the handling of the newly developed system is practicable and easy.

3 INVESTIGATION OF ARTIFICIAL DAMAGES

3.1 METHODOLOGY AND TEST SETUP

Tests were carried out to quantify what influence various types of artificial damage have on the natural frequency of timber components and to what extent these can be detected with the new system. For one of the experiments, a beam with a cross-section of 60 mm x 80 mm was used. This single span beam was separated at half span and a lap joint was created. To reconnect the two parts, side members with the same height and half thickness were screwed on both sides on the beams with 6 screws per connection and shear plane (Figure 7). By means of a 4-point bending test (see Figure 8) the lap joint was stepwise plastically deformed to analyse the influence on the natural frequency. It was loaded and unloaded in 8 cycles, increasing the maximum force for each of them, cp. Figure 9. After the individual cycles, the beam was retested for its natural frequency with an additional weight of 5 kg and 20 kg placed in the middle of the beam to analyse the influence within two different frequency ranges.

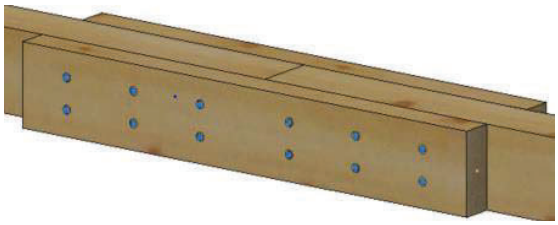

Figure 7: *Lap joint with screws (4.5 mm x 60 mm)*

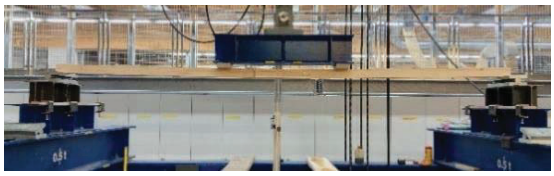

Figure 8: *Test setup*

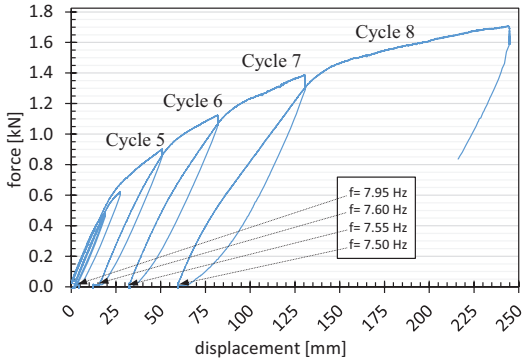

Figure 9: *Force-deformation diagram with associated natural frequencies*

3.2 RESULTS

Figure 10 shows the beam with lap joint at maximum deflection in the test setup (top) and a detail of the deformed joint (bottom). In the last loading cycle a maximum force of 1'684 N and a maximum deformation of 245 mm was achieved.

The force-deformation diagram in Figure 9 shows the load levels considered and the corresponding natural frequencies with an additional weight of 5 kg. The experimental investigation shows that frequencies can be measured with a resolution of 0.05 Hz using the developed system. This results from the FFT analysis and essentially depends on the analysed time duration, which was chosen to be about 15 s. As expected, the natural frequency of the beam tends to decrease with increasing artificial damage. However, the differences are very small, and the observation did not occur consistently across all measurements (see Table 1), so the results are still subject to some uncertainty.

Table 1 shows all the measured natural frequencies with the different additional weights. Even though it tends to decrease with increasing plastic deformation, for 5 kg an

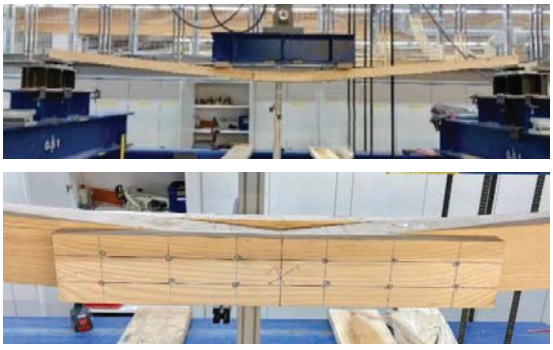

Figure 10: *Test setup (top) and deformed joint (bottom) at maximum displacement*

Table 1: *Natural frequencies [Hz]*

Load-cycle	1	2	3	4	5	6	7	8
5 kg	7.90	7.80	7.85	7.95	7.60	7.55	7.50	7.60
20 kg	5.20	5.20	5.20	5.15	5.10	5.10	5.15	5.10

https://doi.org/10.52202/069179-0250

increase of 0.05 Hz and 0.10 Hz is evident after cycles 3, 4 and 8. For an additional weight of 20 kg, an increase of 0.05 Hz can be observed after cycle 7. To validate these observations, further investigations need to be carried out with larger cross-sections and static systems.

4 MEASUREMENTS AT NEUMATT-BRIDGE AS APPLICATION

4.1 TEST SETUP

The developed vibration measurement system was installed on the Neumatt-Bridge near Burgdorf (Figure 11 and Figure 13). The Neumatt-Bridge is a covered truss system bridge made of soft- and hard wood products. With a span of 59 metres, it is the largest free-span timber truss bridge in Switzerland. It is used for slow traffic (mainly pedestrians and bicycles but also agricultural vehicles). With regard to be used at a Swiss Festival in 2013, four mass dampers adjusted to the natural frequency of the bridge were installed in order to limit the vibration accelerations. The new vibration measuring tool was installed at three positions, and each node measures the accelerations in x-, y-, and z-direction. The positions of the sensor nodes on the bridge were chosen to be at the points of maximum deflection of the first and second eigenform, i.e., two at the midpoint (at both trusses) and one at a quarter point of the bridge (see Figure 12). The sensor nodes were attached to the top chord of the trusses so that direct influences from the roadway planking did not falsify the results and the overall structural behaviour could be analysed.

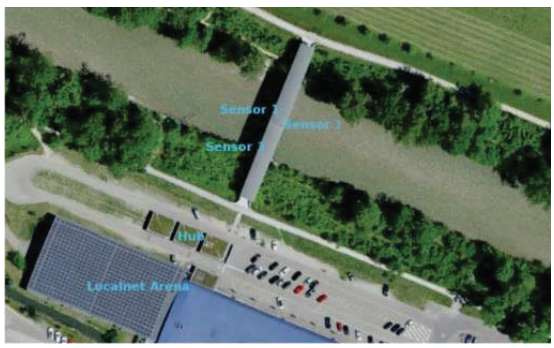

Figure 11: *Neumattbridge Burgdorf, side view of the timber bridge (top) and location of the measuring sensors and data logging station (bottom)*

During the monitoring period from March to June 2022, a data logging of the acceleration was started every 10 minutes for a period of 30 seconds with a sampling rate of 100 Hz. This corresponds to 144 measurements per day (Figure 14), whereby a PSD (Power Spectral Density) analysis was carried out for each measurement to determine the natural frequencies accordingly (Figure 15). The first natural frequency was averaged over one complete day. The data transmission and management are used as described before in chapter 2.1 and 2.2.

4.2 RESULTS

Figure 14 to Figure 16 show the results of the long-term vibration measurement in vertical direction of the timber bridge. Figure 14 shows in example the acceleration over time of one randomly selected single measurement. In Figure 15 the corresponding power spectral density analysis (PSD-analysis) is shown. The peak at a frequency of approx. 2.9 Hz represents the first natural frequency. Figure 16 summarizes the determined first natural frequencies averaged over one day for the complete measuring period. The results of all three sensors are shown for the first month. The results of sensor 3 are shown for all three months. In average, the fluctuations are between 2.5 Hz and 3.0 Hz. The sporadic higher readings are related to the daily analyses of the PSD rather than a change in the condition of the structure.

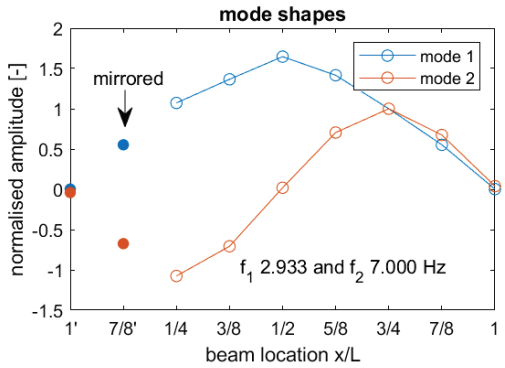

Figure 12: *First and second eigenform measured of the bridge*

Figure 13: *One of the sensor nodes of the new vibration tool*

https://doi.org/10.52202/069179-0250

A visual inspection of the Neumatt-Bridge was carried out before and after the measurement period. No visible defects were found in the supporting structure or in the connection details what is confirmed by the measurement results. Especially the measuring sensor 3 in Figure 16 does not show any trend development from the average level.

The vibration measurement handling and results are satisfying. The measurement sensitivity was sufficient for this first application and in relation to the built-in vibration dampers. Changes in the natural frequency could only be recorded through the daily stimulation by the random slow traffic. The measurement results achieved confirm the generally good condition of the Neumatt-Bridge.

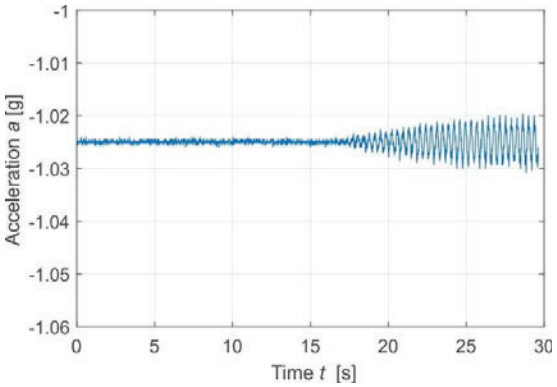

Figure 14: *Time domain: Acceleration over time*

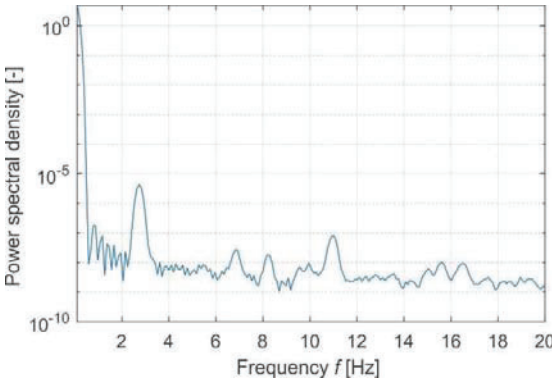

Figure 15: *Frequency domain*

5 CONCLUSIONS AND OUTLOOK

It was possible to develop a new type of vibration measurement system for simplified use, quick measurements, but also for monitoring. In a first step, the developed vibration measuring system was compared with other measuring systems. It shows a comparable accuracy to existing vibration measuring systems. However, the accuracy of the natural frequency measured is not only dependent on the hardware, but also on the evaluation period and the sampling rate of the recording.

The influence of different artificial damages on the natural frequency of timber components was investigated experimentally on a simple system (single span beam) at small scale. The artificial damages considered were investigated regarding their influence on the natural frequency. In general, artificial damage led to a decrease in the natural frequency. Damage to the structure usually leads to a loss of stiffness, which leads to a reduction in natural frequency. The first results reached are plausible but should be further verified on larger cross-sections, and long-term measurements. It was shown that the occurrence of artificial damage to beams can be detected by means of a natural frequency analysis. However, it was realised that a high measurement resolution is required to detect already smallest damages or anomalies.

The 3-month measurement at the Neumatt-Bridge in Burgdorf showed almost constant values of averaged natural frequencies. This confirms the overall good condition of the timber bridge by visually inspections. To be able to distinguish possible damages from seasonal fluctuations in the evaluation, measurements would have to be carried out for longer periods, at least one year. On consideration of the large fluctuations of the natural frequency on individual days it is noticeable that the frequencies are multiples of the most commonly measured frequency in the range of 2.5 Hz to 3.0 Hz and thus represent other natural frequencies of the bridge.

The vibration measurement system achieved is promising for the quality monitoring of timber structures and timber bridges. The wireless connection between the sensors and the HUB makes it possible to measure vibrations in buildings over several floors or rooms, for example. Due to the simple evaluation of the data, the required values

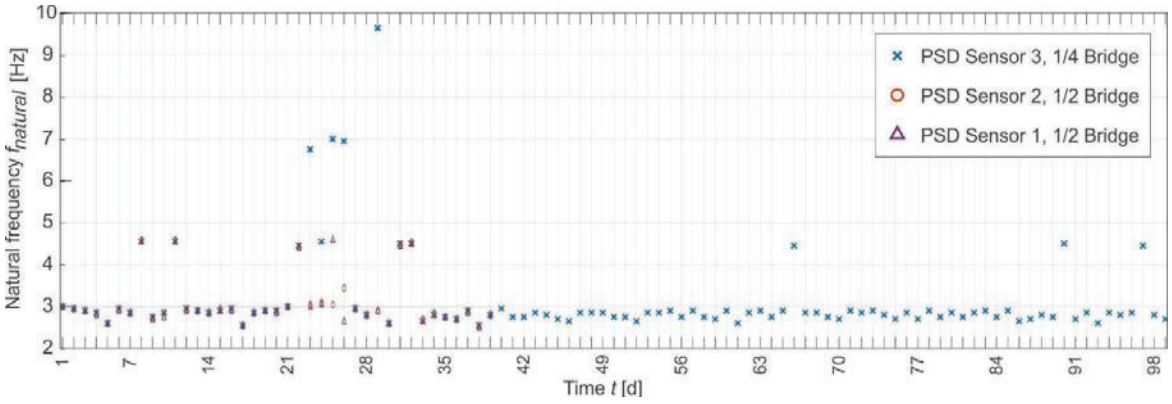

Figure 16: *First natural frequency vs time*

https://doi.org/10.52202/069179-0250

can be determined immediately. In addition, a live output of the intended values is possible by means of the supplied software.

In next steps, further areas of application in the monitoring of supporting structures or other materials could be examined. For long-term vibration monitoring of structures, it is also important to learn about damage-independent fluctuations of the natural frequency due to e.g., data analysing, averaging and climatic changes (temperature, humidity respectively wood moisture content) or seasonal changes. With this results, possible damage could be qualitatively reliably detected. The extent to which changes in load-bearing structures can be diagnosed at an early stage cannot yet be assessed with the experiments currently being carried out. Damages can only be detected so far, but neither localised nor determined in its extent.

The newly developed vibration measurement system can be requested for monitoring timber structures. With these continuing monitoring campaign, open questions can be answered, and possible market entry can be achieved.

ACKNOWLEDGEMENT

The project is a collaboration between the departments Architecture, Wood and Civil Engineering and Engineering and Computer Science of Bern University of Applied Sciences. Gratefully acknowledged by the authors is the intense cooperation among the partners of this project, especially Adrian Ivo Oesch, Stefan Lüthi and Sébastien Bonifacio as well as Bern University of Applied sciences, which made this interesting project possible.

ACTIVE MASS DAMPERS FOR TIMBER FLOORS

Thomas Hillberger[1], Thomas Furtmüller[2], Philipp Dietsch[3], Roland Maderebner[4]

ABSTRACT: Extensive modeling of timber slabs with active vibration elements has shown that, compared to passive vibration dampers, a significantly better effect is achieved with a fraction of the required mass. In this respect, it is obvious to intensify research in the field of active vibration control. These active damping systems are intended to positively affect the vibration properties of slender slab structures in particular. Fundamental for this research is that the requirements of the Eurocodes are met and the weight of the active elements is kept low. In the present work, the vibration properties, in particular the vibration response of cross laminated timber are addressed. The dynamic parameters determined for a simply line supported system define the following tests which are carried out with actively controlled damping elements. The tests with the cross laminated timber panel suggest that counteracting at certain times and with predefined levels of intensity causes a considerable reduction of the acceleration values. Based on controlling the acceleration response, tests are performed on a complex timber construction. Different excitation, including the random and dynamic motion of people moving on the slab, increase the difficulty to solve this task for slab systems using common control systems. Therefore, the purpose of this research is to verify the reduction of floor vibrations and to demonstrate its effectiveness in experiments with human-induced excitation. The results show a significant reduction in vibration acceleration for different types of excitation and highlight the possibilities of active vibration control.

KEYWORDS: Timber structures, cross laminated timber, active damper, vibrations, frequency

1 INTRODUCTION

A particular challenge in the design of timber floors are the requirements for the serviceability limit state (SLS). Fundamental research in the field of floor vibrations for different timber constructions was presented in [1]. Since then, the possible span of timber structures has evolved significantly due to improvements in timber products and fasteners.

If considering just the ultimate limit state (ULS), enormous advances in the realisation of slender floor elements are possible with currently executable constructions. However, this is accompanied by the fact that the SLS is becoming more and more relevant for the dimensioning of the components due to the large spans. In order to meet the noise reduction standards, appropriate masses are needed to ensure that the required sound insulations are achieved. This trade-off is solved with so-called heavy floor structures consisting of fillings, impact sound insulation boards and mineral floating screeds. These additional loads make it necessary to increase the structural heights and hence the material use of the timber slab to stay within the required limit value of the natural frequency.

The increasing number of publications regarding human-induced vibrations highlight the relevance of this topic for structural engineering [2,3]. Due to the dynamic properties of timber floors, experiments relating to the vibration behaviour are essential. The modal parameters such as natural frequencies and damping characteristics of floor elements depend on different design assumptions. The influence of support conditions of cross laminated timber (CLT) floors on the vibration properties has already been addressed in [4]. [5] deals with the effects of support conditions respectively plan aspect ratios on the natural frequencies and damping of the floor elements corresponding to the serviceability. By in-situ measurements but also in the laboratory, various research works have additionally examined the vibrational characteristics of the raw floor slab and furthermore differences between different floorings [4,6-8]. The tests presented in the current paper also provide measurement data for the human-induced excitation as well as additional experimental results for different floorings and support conditions. These experimental investigations are currently being performed as part of an ongoing research project at the Universität Innsbruck.

There are various approaches for improving the vibrational behaviour of floors. In [9] implementation examples of active vibration control with focus on seismic excitation are presented. Parallel-connected passive tuned mass dampers for slab elements have been examined [10]. The potential that active control systems can provide for floor constructions are discussed in [11]. Particularly active systems should enable to maintain the required serviceability limits despite the reduction in floor thickness. The effect of active vibration control (AVC) in a reinforced concrete slab is impressively shown in [12]

(acceleration feedback control) and [13] (velocity feedback control). The tests in these publications are based on recorded accelerations of the vibrating structures. The values are converted according to the used method and provide the actuator data for the counteraction. A significant reduction of the acceleration values can be achieved with these methods.
The aim of this research work is to demonstrate, the effect of adaptive, actively controlled vibration dampers on the acceleration values of CLT panels caused by human-induced vibrations. With the current state of research on active mass dampers and the use of this knowledge to reduce vibrations, the possibilities for timber construction are presented in the course of this work.

2 MATERIALS AND METHODS

2.1 GENERAL

Experimental tests are applied to verify the effectiveness of the active vibration elements. The vibration characteristics of the floor elements are essential. The experimental tests focus on CLT elements with different dimensions. The dimensions of the used plates can be found in Table 1. The excitation of the CLT panels is realized by different means, e.g. heel-drop or shaker. This is supplemented by experimental investigations of human-induced vibrations with the same test setup. In the experiments with active vibration control, the excitation is mainly imposed by a shaker, because initially reproducible vibration response is necessary.

Table 1: *Overview of CLT elements used in experimental investigations*

Type	Layer (mm)	Length (mm)	Width (mm)	Depth (mm)
CLT_01	5-Layer 40/20/40/20/40	7000	1222	160
CLT_02	3-Layer 30/30/30	4000	400	90
CLT_03	3-Layer 30/40/30	2000	970	100

2.2 EXPERIMENTS – VIBRATIONAL CHARACTERISTICS

For these tests, the element type CLT_01 from Table 1 is used. I-beams (HEB 300) with steel shaft ensure a hinged support (support distance of 5.80 m). In Figure 1 the test setup is visualized in addition to the two excitation modes (walking person and shaker). To determine the modal parameters, the plate is excited by an impulse hammer. The first natural frequency identified by these tests is 10.33 Hz. Furthermore, response data are recorded, which result from the excitation according to a heel-drop. Figure 2 and Figure 3 show the dynamic behaviour of the centrally placed sensors ACC-Sensor3 and ACC-Sensor4. These two sensors highlight the dominance of the first eigenfrequency. The acceleration values of a walking person are presented in Figure 2. Figure 3 shows the mid-section acceleration values according to the excitation mode heel-drop. All obtained experimental data are compared to results from fundamental literature [4-6] and used as basis to validate the computational models.

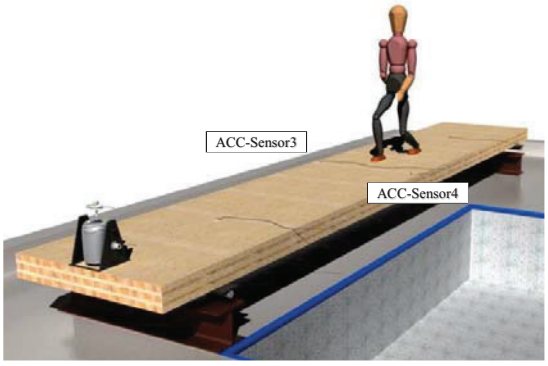

Figure 1: *Test setup for identifying vibrational characteristics with two different excitation (shaker and walking person) [14]*

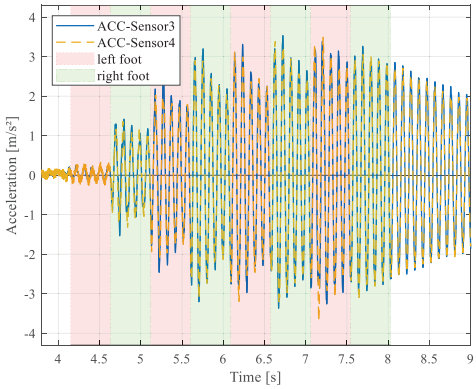

Figure 2: *Recorded response from walking tests*

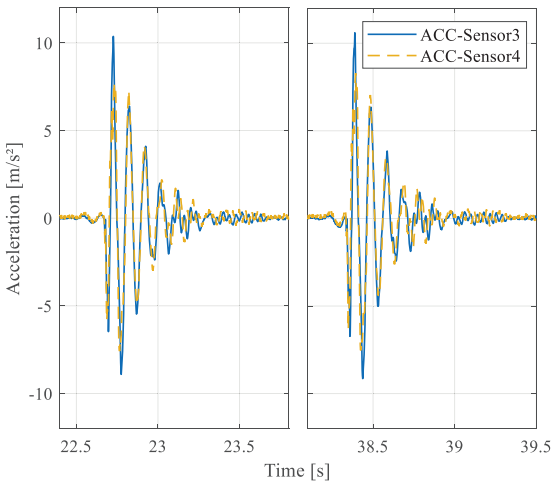

Figure 3: *Recorded response from heel-drop tests*

https://doi.org/10.52202/069179-0251

2.3 EXPERIMENTS – ACTIVE MASS DAMPER

The model of active vibration dampers in combination with slab elements corresponds to vibratory systems with two parts of force excitation. In Equation (1) M, C and K denote the mass, damping and stiffness matrices. The force excitation is on the one hand related to the excitation by a person $F_P(t)$ and on the other hand to the reaction of the active vibration elements $F_{AD}(t)$.

$$M \cdot \ddot{x}(t) + C \cdot \dot{x}(t) + K \cdot x(t) = F_P(t) + F_{AD}(t) \qquad (1)$$

The vibration response of the slab elements is reduced by defined force excitation in opposite direction to the load imposed by a walking person. Figure 4 depicts a possible reaction function of the active vibration elements. In fact, the diagram is an excerpt of an experimental test. It should clarify when the counteracting impulses of the vibration elements are needed and how the principle reaction of the active mass dampers (AMD) looks like.

The first tests for active damping are carried out with the test setup as displayed in Figure 5. The support conditions are defined in the same way as described for the preceding section. Figure 6 is intended to provide a better explanation of the measuring equipment and the entire experimental setup. Included are the input channels from the accelerometers (ACC-Sensor1 - ACC-Sensor6) to the measurement and control unit (MCU) and the output channel from the MCU to the shaker (LDS Shaker V400 Series with amplifier LPA 600). The CLT_02 is used in these test series.

With the previously determined eigenfrequencies, the structure can be excited at its first natural frequency (17.78 Hz). Such a reproducible excitation can be seen in Figure 7. In this diagram, the response recorded with the accelerometers (ACC-Sensor1 to ACC-Sensor4) and the output function for the exciter are displayed. After six periods, the shaker is switched off and the system can freely vibrate. The aim of these experiments is to demonstrate the effects on the vibration behaviour when the acceleration is counteracted by an active element at predefined times and with specified intensities. Figure 8 shows how the active counteraction can be realized in the experiments.

https://doi.org/10.52202/069179-0251

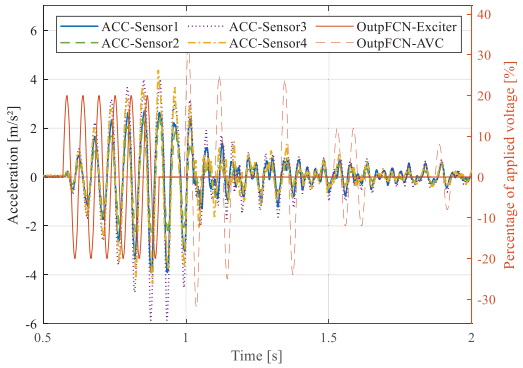

Figure 8: *Measured acceleration values for the active damping – counteracting damper after excitation by shaker*

2.4 EXPERIMENTS – ACCELERATION FEEDBACK

For the tests with active vibration control (AVC), the measured acceleration is used as measure for the intensity during counteraction (according to [12]). The experimental investigations are carried out with the test type CLT_03. A complex setup (see Figure 9 and Figure 10) is planned for this test series. In the lower left area, the CLT element has a fixed support. Due to the defined placement of additional masses (seen upper left and lower right), the first two eigenfrequencies of the system are close to each other (15.5 Hz respectively 18.2 Hz). The used shakers of type APS 400 (Shaker I and Shaker II) act on the system at the corner points. In addition, 800VA amplifiers of type APS 145 are used. Shaker I acts as exciter and Shaker II as active element for vibration control. Accelerometers ACC-Sensor1 and ACC-Sensor2 are placed next to the connection between the shakers and the CLT element. The records from ACC-Sensor2 are used for acceleration feedback.

Three different excitation modes are examined in these tests. On the one hand, as mentioned before, Shaker I serves as exciter (sweep and impulse) and on the other hand, a human-induced excitation by fist drop is performed. The voltage values for the two excitation by Shaker I can be seen in Figure 11. The linear sweep is performed between 5.0 Hz and 35.0 Hz over a duration of 30.0 s. The voltage amplitude is kept constant at a value of 3.7 V. The pulse is generated by a sine half-wave. The voltage amplitude is approx. 13.7 V and the periodicity is 0.5 s. In this test the data are recorded over a period of 10.0 s. The used equipment is from National Instruments. Data is collected and delivered by CompactDAQ and with Field Programmable Gate Array (FPGA) Target from CompactRIO the control of Shaker II is carried out. A Siglent SDG1032X function generator produces the sweep and pulse excitation.

During the tests, the measured acceleration of the plate at ACC-Sensor2 is transferred to the ComactRIO of the Control Unit (CU). Shaker II can also be switched on through this CU. The acceleration value is multiplied by a gain factor and the resulting voltage is sent to the Shaker II via the amplifier.

2.5 COMPUTATIONAL MODELS

First preliminary calculations are performed with the program *RFEM Release 5.24.01* [15]. The load functions of a moving person on a slab are based on the research work of Bachmann and Baumann [16]. The computational model and the loading method are illustrated in Figure 12. For realistic outcomes different walking paths are simulated.

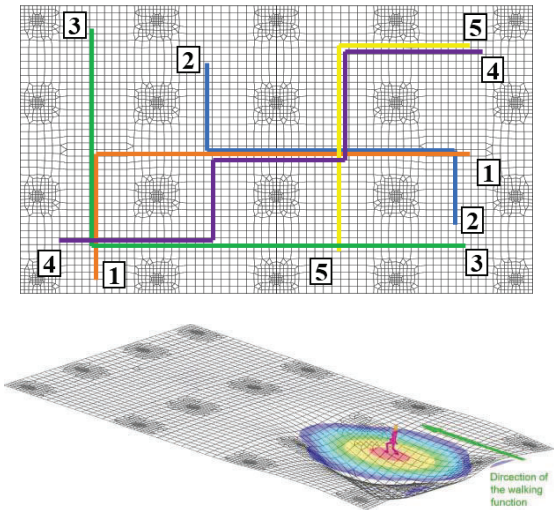

Figure 12: *Computational model of a point supported flat slab with the walking person*

3 RESULTS AND DISCUSSION

3.1 GENERAL

The following section focusses on the results of active damping with counteraction at specific times and control with acceleration feedback. There is always a comparison between reference system and the actively controlled tests. The so-called root-mean-square acceleration (a_{RMS}, see Equation (2)) is used as a reference value for the measurements. a_{RMS} is calculated with the acceleration $a(t)$ over the period T from an initial time T_1 to the end of duration T_2 ($T = T_2 - T_1$). For comparability, these values are shown in the diagrams as constant lines over the calculated period.

$$a_{RMS} = \sqrt{\frac{1}{T} \cdot \left(\int_{T_1}^{T_2} (a(t)^2 \cdot dt) \right)} \tag{2}$$

3.2 ACTIVE MASS DAMPER

In the first tests defined intensities at specific times are used to counteract the vibrating structure. For this purpose, those times are determined at which the lowest value for a_{RMS} is reached over the period T of 1.0 s (Equation (2)) after the excitation phase by means of a given counterimpulse. Due to the programming it is possible to run these tests several times with different time steps t_1 to t_n and the corresponding time increment Δt between the impacts (see Equation (3)). The aim is to identify the extremal values with respect to the minimum of a_{RMS}. In the current experiments, values between 2 and 30 milliseconds are used for Δt (depending on the sampling frequency f_{sample} = 2560 Hz and vibration behaviour of the plate).

$$\begin{aligned} t_1 &= t_0 + \Delta t \\ t_2 &= t_1 + \Delta t \\ &\dots \\ t_n &= t_{n-1} + \Delta t \end{aligned} \tag{3}$$

For each pulse this procedure is performed repeatedly. In the present case, this results in a process with six impacts at different times. Figure 13 shows the acceleration values of the reference measurement and the test with the active element switched on. The data refer to the sensors ACC-Sensor3 and ACC-Sensor4. For ACC-Sensor3, there is a reduction of the a_{RMS} of approx. 58 % and for ACC-Sensor4, the reduction is 62 %.

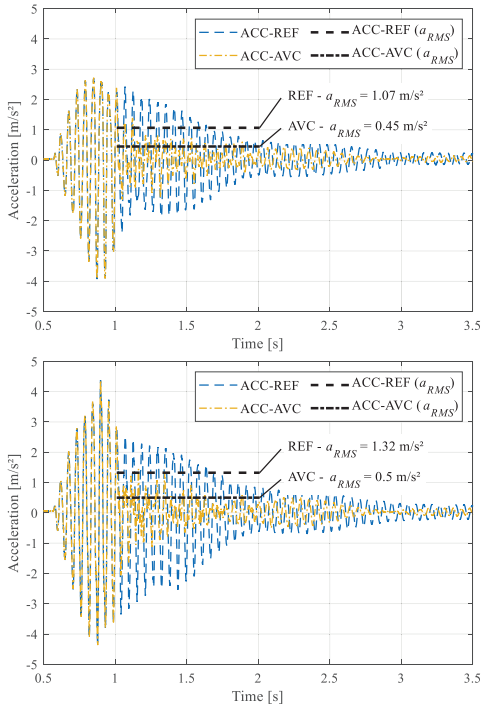

Figure 13: *Acceleration values of sensors ACC-Sensor3 (top) and ACC-Sensor4 (bottom) – reference test ACC-REF and test with active vibration control ACC-AVC*

3.3 ACCELERATION FEEDBACK CONTROL

Figure 14 to Figure 16 display the tests with a linear sweep over a defined frequency band of 30 Hz. Figure 14 shows the reference values (ACC-REF) and the test with active counteraction respectively active vibration control (ACC-AVC). At the local maxima in the area of 15.5 Hz and 18.2 Hz, the first two eigenfrequencies of the system are excited. Especially the response related to the first natural frequency can be controlled very well which is shown in Figure 14.

In the tests which are affected by switching on Shaker II, these two distinct maximum values are no longer visible.

A single peak at about 12.4 s is now clearly apparent. For clarification of this effect and the possible reduction of the vibration acceleration in this section, see also Figure 15 and Figure 16. Displayed are also the measured values of the applied voltages of Shaker I and Shaker II. In the period between 10.0 s (15.0 Hz) and 11.0 s (16.0 Hz), the reduction of a_{RMS} is 77.5 % and between 11.9 s (16.9 Hz) and 12.9 s (17.9 Hz) it is 48.9 %.

The tests excited by the pulses can be seen in Figure 17. With a periodicity of 0.5 s, a pulse with a vibrating duration of the sine half-wave T_{SHW} = 0.1 s is generated. The resulting accelerations are again measured by the reference test and the actively controlled system. The calculation is made with the duration T of 1.0 s (Equation (2)) to get comparative values of acceleration. For the reference system a_{RMS} = 0.39 m/s², with the active vibration control a_{RMS} = 0.26 m/s². This corresponds to a reduction of 33.1 %.

Of great interest, however, are the human-induced excitation. In the tests presented, the interaction between a person and the CLT element always takes place in the same way by a fist drop, but important is the possibility to generate comparable values. Care is taken to ensure that in both the reference system and the actively controlled system, two impacts are compared which have the same maximum value in the first 30 milliseconds. Although it must be considered that this peak is already damped to a certain extent (controlling in real-time). Therefore, the given comparison values are conservative. Figure 18 shows the raw data of both test series. The values from the reference system are compared with the values from actively controlled system. a_{RMS} is calculated over the time span T of 0.5 s (Equation (2)). For clarification, these tests are shown in detail in Figure 19. The time axis is taken from the reference system. The a_{RMS} is reduced by 53.2 % when comparing fist drop 1 (FD1) with fist drop 2 (FD2), and a reduction of 52.4 % is obtained when comparing the tests fist drop 3 (FD3) and fist drop 4 (FD4).

3.4 RESULTS OF CALCULATION MODELS

Research on point supported flat slabs [17] and solutions for edge connections [18] at the Universität Innsbruck highlight the importance of the floor's vibrational characteristics. In the course of these studies, the relevance of investigations in active counteraction, to control the vibrations of such slabs, increased. By using active vibration dampers and intelligent control systems, a considerable improvement of the vibration behaviour based on the slab structure can be achieved. Figure 20 shows the results of the calculation models. Despite the low natural frequency, values in the range of higher demands for floor structures can be achieved. The example of a point supported flat slab in Figure 20 shows that two active mass dampers are sufficient to achieve the vibration verification of the calculated floor construction even for higher demands according to EN 1995-1-1.

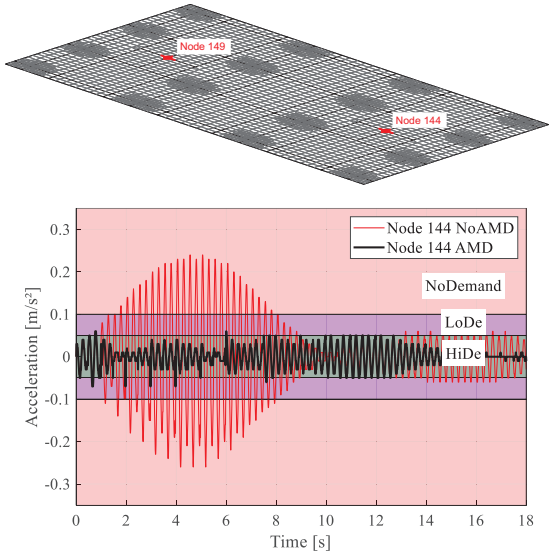

Figure 20: *Results of the calculation models; AMD ... active mass damper, LoDe ... low demands and HiDe ... high demands*

4 CONCLUSION AND OUTLOOK

The results for damping by active elements demonstrate an enormous improvement compared to the reference measurements in terms of the recorded vibration accelerations. Challenges like generating reproducible measurements as well as reacting in real-time could be solved with the available equipment. The reproducibility can be realized by means of shakers. The use of the CompactRIO enables the reaction to accelerations in real-time. Due to the encouraging results by active vibration control both in the area of impulsive counteraction and acceleration feedback control, further tests with the active elements are planned. For this purpose, the measurement and control equipment will be integrated into the experimental setup presented in Section 2.2. Human-induced vibrations, such as those caused by walking occupants, should also be significantly damped despite different setups, support distances and hence varying natural frequencies.

For the determination of modal parameters, further tests are scheduled in addition to the presented ones. The focus is on different support conditions and the variation of flooring. The comparison with existing literature and the possible validation of future calculation models will deliver an important input to the serviceability of timber floors. The calculations show promising results in terms of a better behaviour with regard to the vibrational characteristics and the possibilities in the reduction of construction materials. However, the calculations have to

https://doi.org/10.52202/069179-0251

be confirmed by laboratory tests and parameter studies. Another important issue is the optimization (dimensions, control, etc.) of the active damping systems. Experimental investigations with the AMD's complement the modeling and calculations.

In addition, the possibilities of machine learning to control the AMD's will be tested. Large-scale field experiments are then used to train the AMD's and make them able to react on numerous movement sequences.

FIELD MEASUREMENT OF VIBRATION LEVEL DIFFERENCE ACROSS VERTICAL JUNCTIONS IN A TIMBER FRAME BUILDING

Simone Conta[1], Anders Homb[2]

ABSTRACT: Reliable vibration level difference $D_{v,ij}$ data are necessary to accurately predict flanking transmission. In this paper we present the measurement of $D_{v,ij}$ we performed on two timber frame buildings and a selection of the obtained results. The measurements were performed according to ISO10848 with different excitation sources. The analysis focuses on both methodological aspects and constructive solutions. Methodological aspects comprise the comparison of the different excitation sources used (shaker, impact hammer, loudspeaker) and the discussion of the challenges related to mixed wall constructions in field situation. Constructive solutions include the assessment of a party wall compared to an outer wall and the possible mounting options for the inner plasterboard leaves, i.e., directly on the timber frame, on timber laths, on metal Z-profile and on metal resilient bars. Results show that hammer and shaker provide comparable and reliable excitation. The loudspeaker did not provide sufficient excitation. Mixed wall construction will lead to different values of $D_{v,ij}$. Sensor placement can help reducing the mixed effect, but the introduced uncertainty could not be evaluated in the field. Finally, the different mounting options of the inner plasterboard showed a potential improvement of more than 20 dB over a broad frequency range by replacing the direct installation on the timber frame with resilient bars, the other options performing in between.

KEYWORDS: flanking sound transmission, vibration velocity level difference, field measurements, experimental setup.

1 INTRODUCTION

Vibration level differences across a junction are required to predict flanking sound transmission [1, 2]. Several papers present laboratory measurements and the corresponding results, often highlighting the related challenges [3-6]. Measuring vibration level differences in the field is necessary to increase the knowledge and the amount of data set available for reference [7, 8]. However, field measurements must tackle uncertainties in the vibration transmission path. Suitable excitation is also needed, but not straightforward due to practical limitations and the risk of airborne excitation of other transmission paths. In the context of a research project aimed at developing a building system for 8 stories timber frame building, we performed several field measurements of vibration level difference. In this paper, we present a preliminary selection of the obtained results discussing methodological aspects and constructive solutions. We look i) at different excitation sources, ii) at the challenge in the field due to mixed wall assemblies and iii) measured vibration level differences with different solutions for the mounting of the inner plasterboard wall leaf. The paper is structured as follow; in chapter 2, we give a description of the measurement objects with the corresponding constructive details. In chapter 3, we give a brief overview of the measurement setup. In chapter 4, we present and discuss the results; 4.1 is about the comparison of the excitation sources, 4.2 is about the comparison of party wall and outer wall and the effect of mixed construction, 4.3 looks at the effect of resilient bars and metal Z-profiles, 4.4 compare the collected results with data from the literature. In chapter 5, we present our conclusions.

2 MEASUREMENT OBJECTS

We performed measurements at two apartment buildings under construction at two different locations, which we will refer to as location 1 (L1) and location 2 (L2). Figure 1 shows an outer view of location 1. Both buildings are erected using prefabricated timber frame modules. The two buildings have comparable load bearing structure but different wall and floor assemblies.

Figure 1: Outer view of one of the two buildings used for the measurements.

[2] Anders Homb, SINTEF Community, Norway, anders.homb@sintef.no

https://doi.org/10.52202/069179-0252

At each location, we performed the measurements between two apartments with identical floor plan located above each other and including a party wall (W1) and an outer wall (W2). In this paper, we restrict the analysis to the vertical wall-wall transmission. The floor plans and the considered walls are shown in Figure 2 and Figure 3.

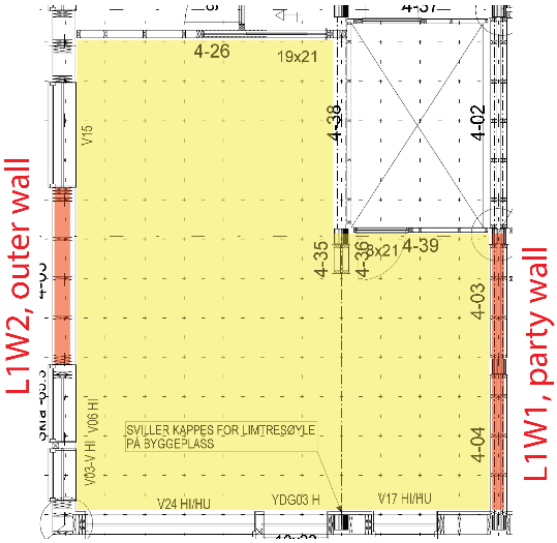

Figure 2: Floor plan of the apartment used for the measurements at location 1. The investigated walls L1W1 and L1W2 are highlighted.

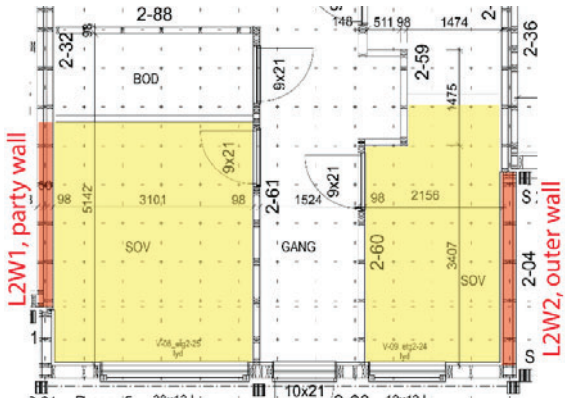

Figure 3: Floor plan of the apartment used for the measurements at location 2. The investigated walls L2W1 and L2W2 are highlighted.

The two locations used the same type of elements but with different solutions for the interior wall cladding and for the floor assembly. The wall assemblies are given in Table 1. The respective cross sections are shown in Figure 4 and Figure 5. The main difference between the two locations is the mounting method chosen for the inner plasterboard. At location 1, metal resilient bars (L1W1) or metal Z-profiles (L1W2) were used. At location 2, the plasterboard was screwed on the timber laths installed on the main wall frame. Figure 6 shows a horizontal section for location 1, where both the party wall and the outer wall are visible and a picture of the party wall with the resilient bars.

3 MEASUREMENT SETUP

We designed the measurements with two main objectives; the first was to test and gain experience with the measurement method itself. The second was to collect data for further reference and further development of the constructive solutions. We performed the measurements according to the standard ISO10848 [1]. We defined measurement positions on both wall and floors. We measured the acceleration simultaneously on the sending and receiving side by means of several accelerometers that were moved at different locations. We used at least 9 measurement positions and two excitation positions, totalling at least 18 measurement positions per surface. Excitation and measurement positions were chosen both on wall studs and in between. The velocity was calculated by integration of the acceleration signal. We used different type of excitation; instrumented hammer, electrodynamic shaker driven with white noise, loudspeaker, and standardized tapping machine. The latter will not be discussed further here. Figure 7 gives an overview of the expected transmission paths and the sensor placement and the assignment of the codes D, d, F, f to the building elements. Figure 8 shows the shaker installed in front of the wall at location 1 and the accelerometers distributed on the surface. The yellow circles are excitation positions (5) while the blue circles, solid and dashed are the two groups of measurement positions used (2 x 6), totalling in this case to 60 measurement positions. $D_{v,Ff}$ was calculated from the average over all source and receiver positions according to the procedure described in the standard. In all figures presenting the results, the plotted line represents the vibration level difference and the area above and below the line represent the standard deviation.

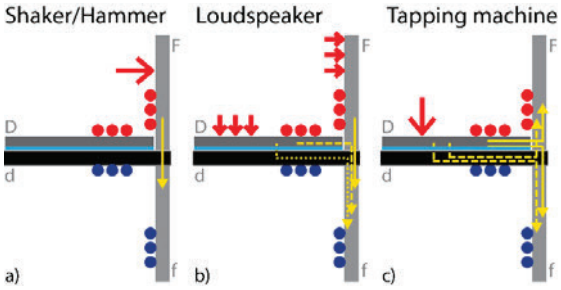

Figure 7: Excitation and expected main transmission paths.

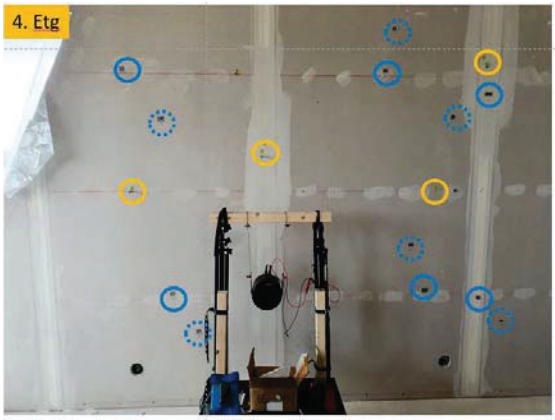

Figure 8: Shaker and accelerometers on the sending side.

4 RESULTS AND DISCUSSION

4.1 EXCITATION SOURCES

Figure 9 shows a comparison of the $D_{v,Ff}$ measured on the same partition with excitation from three different sound sources: hammer, shaker and loudspeaker.

The data show that hammer and shaker excitation provide comparable results, well within the standard deviation range. The measured $D_{v,Ff}$ with loudspeaker excitation clearly deviates from the other two sources. The loudspeaker was driven with typical levels for building acoustics measurements ($L_{A,eq}$ in the order of 95 dB). A closer look at the vibration velocity data on the receiving side revealed that the loudspeaker did not provide sufficient excitation; the generated vibration levels did not exceed the background level on the receiving side. The measured $D_{v,Ff}$ is therefore erroneous and too low. Also not shown, but important to note the measurement in the opposite direction, delivered comparable data for each source type. The results from the measurements performed at location 2, show the same trend: the loudspeaker did not deliver enough energy and the measured $D_{v,Ff}$ is lower than it should as shown in Figure 10.

We can draw two main conclusions; first, suitable excitations are hammer or shaker excitation. Loudspeaker it is not a suitable source. Secondly, a maybe natural remark on the quality check of the data: it is important to measure the background noise levels and plot them along with the excited vibration levels to verify that sufficient excitation was provided. A simple check that the measured values in the two directions are comparable might lead to a wrong assessment.

https://doi.org/10.52202/069179-0252

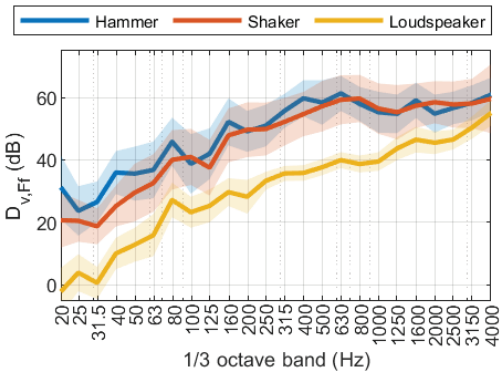

Figure 9: Vibration level difference measured on the L1W1 wall (path Ff) with hammer, shaker and loudspeaker excitation.

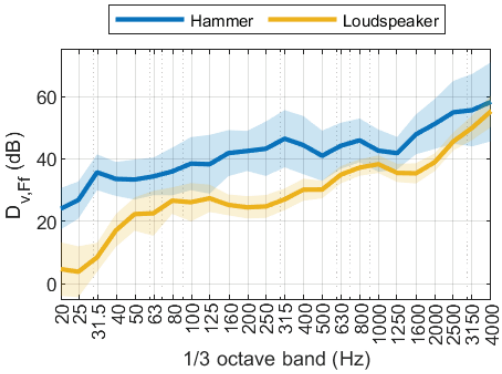

Figure 10: Vibration level difference measured on the L2W1 wall (path Ff) with hammer and loudspeaker excitation.

4.2 DIFFERENT WALL TYPES AND MIXED WALL ASSEMBLIES

When measuring in the field, it rarely happens that conditions are ideal. A challenging example was the situation at location 2. Both the party wall and the outer wall which were available to perform measurements presented mixed constructions as shown in Figure 3. Both walls had a portion that was party wall and a portion that was outer wall, although in different ratios. L2W1 was primarily a party wall and L2W2 was primarily an outer wall. The visible plasterboard layer covered over the two different portions at both walls. We chose to place several measurement positions on the larger portion and have one measurement position on the minor portion as a control point. We excited the wall within the major portion. In Figure 11 and Figure 12, we show the obtained results for L2W1 and L2W2 respectively. The continuous line is obtained from the measurement position on the larger portion and the dashed line from those on the minor portion.

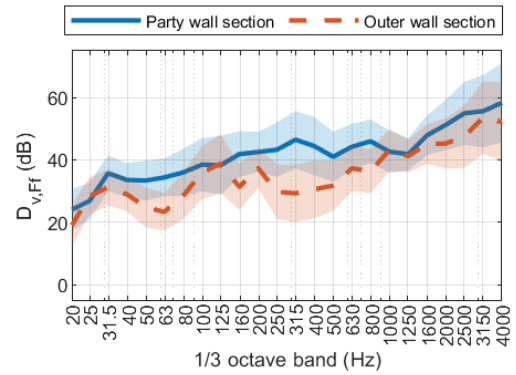

Figure 11: Vibration level difference measured at L2W1. The larger portion of this wall is a party wall.

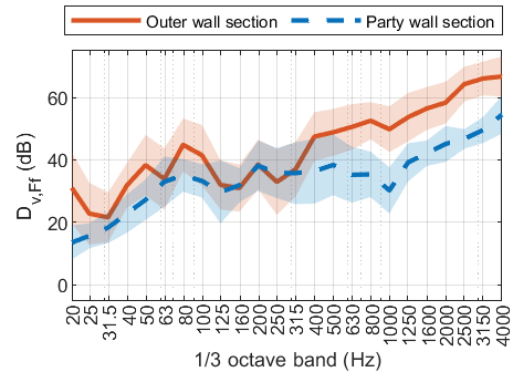

Figure 12: Vibration level difference measured at L2W2. The larger portion of this wall is an outer wall.

The results in Figure 12 show that there are clear differences between the two different portions of the wall. The measured $D_{v,Ff}$ for the outer wall portion above 500 Hz exceeds by more than 20 dB the $D_{v,Ff}$ measured for the party wall portion. Differences between the two portions of the wall are also observed in Figure 11 but the trend is not as clear as on Figure 12; the $D_{v,Ff}$ measured for the two portions fall within the standard deviation range in large part of the frequency range. We observe the larger deviations in the frequency range 200 – 800 Hz.

In Figure 13, we compare $D_{v,Ff}$ for the party wall (main portion of L2W1) and the outer wall (main portion of L2W2). We observe the same trend as in Figure 12: the vibration transmission along the party wall seems to be stronger (lower $D_{v,Ff}$) than along the outer wall. However, the difference is not as strong as observed in Figure 12. An exception is the range 100-350 Hz where the transmission appears to be stronger along the outer wall.

https://doi.org/10.52202/069179-0252

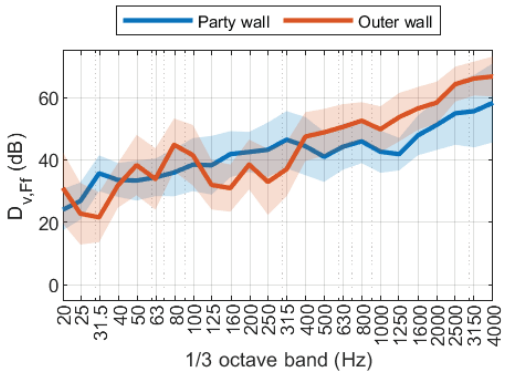

Figure 13: Vibration level difference measured at location 2 for the party wall (L2W1) and the outer wall (L2W2).

In this section, we looked at measurement performed on walls that had different construction on different portions. The results showed that it is possible to observe the differences between the different portions by placing the accelerometers well within the corresponding area. However, with the available data we cannot assess the measurement uncertainty that it is introduced in this kind of situation.

4.3 EFFECT OF RESILIENT BARS AND Z-PROFILES.

We performed the measurements at two locations (L1, L2) on two wall types: party wall (W1) and outer wall (W2). The respective basic wall structure was comparable at the two locations while the installation of the inner plasterboard was different. At location 1, the plasterboard was installed by means of resilient bars on the party wall (L1W1) and Z-profiles on the outer wall (L1W2). At location 2, the plasterboard was screwed directly on the timber framing both on the party wall (L2W1) and the outer wall (L2W2).

Figure 14 shows the comparison between the measured $D_{v,Ff}$ for L1W1 and L2W1, showing the effect of the resilient bars. The results show clearly that the resilient bars increasing effectively $D_{v,Ff}$ in the frequency range 125-2500 Hz by 10 to 20 dB. The resilient bars seem to have no effect at lower and higher frequencies. At frequencies close to 40 Hz, the $D_{v,Ff}$ measured on the wall with resilient bars is lower than that for direct installation; this might have to do with the resonance frequency of the system.

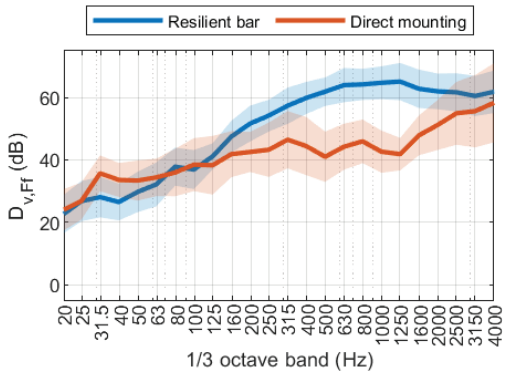

Figure 14: Vibration level difference measured on the party wall the two locations with hammer excitation. With resilient bar: L1W1. Direct installation: L2W1.

Figure 15 shows the comparison between $D_{v,Ff}$ for the outer walls at location 1 and 2 (L1W2, L2W2) and the effect of the Z-profiles. The $D_{v,Ff}$ below 100 Hz are comparable. Between 100 Hz and 1250 Hz, $D_{v,Ff}$ for L1W2 is up to 5 to 20 dB higher than for L2W2. This result shows that the Z-profiles effectively dampen the vibration transmission from the inner plasterboard to the wall structure, but on a reduced frequency range compared with the resilient bars.

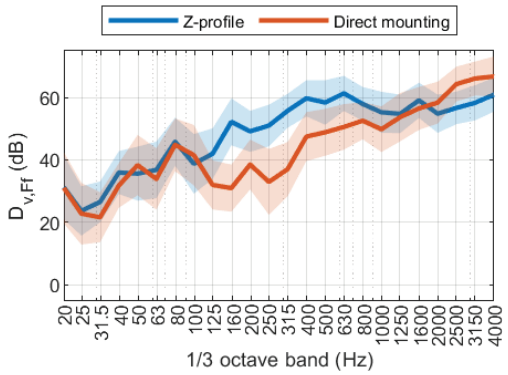

Figure 15: Vibration level difference measured on the party wall the two locations with hammer excitation. With Z-profile: L1W2. Direct installation: L2W2.

https://doi.org/10.52202/069179-0252

4.4 COMPARISON WITH DATA IN THE LITERATURE

Homb in [8] published $D_{v,Ff,n}$ values from an experimental setup and compared with several other published data. In Figure 16 we compare the measurements results from our measurements with a relevant one from the datasets in [8].

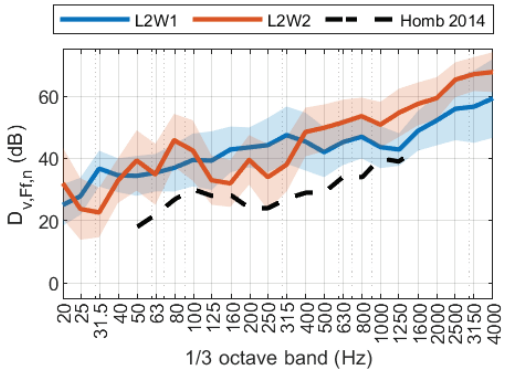

Figure 16: Comparison of the results for L2 with data from the literature [8].

The comparison shows that the measured values at location 2 are 10 – 15 dB higher than those from the referenced paper. The main difference between the measurement objects was the installation of the plasterboard: at location 2 the plasterboard is screwed to horizontal laths which are screwed to the load bearing timber frame. In the reference the plasterboard was screwed directly to the timber frame. This leads to at least two relevant differences; i) the horizontal laths influence the vibration field in the plate and ii) there is an additional vibration transmission reduction at the interface between the laths and the beam of the timber frame due to the connection loss. The combination of the two effects justifies the observed difference in the $D_{v,Ff,n}$ values.

5 CONCLUSIONS

We performed $D_{v,Ff}$ measurements at two different buildings erected as timber frame. The collect data and experiences allow to draw conclusions at two levels; at a methodological level and in terms of reference data for practitioners.

The methodological conclusions we can draw are:

- Hammer or shaker are convenient excitation sources. They deliver comparable results.
- Loudspeaker excitation with typical sound pressure level was not sufficient to measure vibration level differences in the field situation.
- Background noise on the receiving side must be monitored during measurements and included in the analysis to ensure reliable data.
- Mixed wall assemblies in field situation are a challenge that might limit measurement reliability. By choosing appropriate measurements positions, it is possible to observe significant differences. With our measurement setup, we could not quantify the uncertainty that this situation introduces.

The collected data can be used as reference in further projects. The collected data and the comparison with data from the literature showed that, assuming the same wall assembly in the sending and receiving room:

- Installation of plasterboard on horizontal timber laths, gives a broadband vibration transmission reduction in the order of 10 to 15 dB compared to direct installation on the frame.
- Installation of plasterboard using metal Z-profiles, gives a vibration transmission reduction in the range between 100 Hz and 1250 Hz in the order of 5 to 20 dB compared to the installation on the laths.
- Installation of plasterboard using metal resilient bars, gives a vibration transmission reduction in the range between 100 Hz and 2500 Hz in the order of 10 to 20 dB compared to the installation on the laths.

ACKNOWLEDGEMENT

The measurements have been performed within the project BV2020. BV2020 is a project of Støren Treindustri, supported by the Research Council of Norway. SINTEF Community is the research partner.

CHARACTERISATION OF RESILIENT INTERLAYERS

Paola Brugnara[1], Alice Speranza[1], Luca Barbaresi[2], Luca Sestigiani[1]

ABSTRACT: In buildings the sound transmission between rooms is characterized not only by direct transmission but also by flanking transmission through the structure. Timber structures, like all lightweight structures, do not have high acoustic performance if they are designed like heavy structures. It is important to take in account the effect of sound propagation through the wall/ceiling structure junctions, because it can significantly reduce the acoustic performance of these elements. Elastic separating layers between rigid junction can prevent the propagation of sound vibrations in the building structure and reduce the contribution of flanking transmission.

This paper provides the guideline to codify the characteristics of flexible interlayer made by a homogeneous viscoelastic material for the reduction of flanking sound transmission for airborne, impact and building service equipment.

To select a correct resilient strips, it is important to consider that acoustic interlayers are working at the level of the structure and the material needs to be extremely stable in long term to guarantee the stability of the building and avoid later deformation that will affect linings and static.

KEYWORDS: Building acoustic, interlayers, flanking transmission, static-acoustic interaction, standardisation

1 INTRODUCTION

The wooden structures are statically assembled with different types of connections. Mainly we talk about screws, angular and hold-down. These connection systems have the task of precisely coupling the different structural elements to form a single large junction structure. While in parallel to overcome the problem of transmission of vibrations, in recent years resilient profiles in polyurethane or EPDM are very often being used which have the task of decoupling and reducing the transmission of vibrations between the different elements.
To date, there are no common standards that describe in detail how to characterize the product and which performance shall be determined to guarantee a proper static and acoustic performance.
Aim of this paper is to analyse the intended use of resilient interlayers and define the values that allow to design a joint with them. Defining a common test procedure allow also to compare products from different manufactures and chose the best product depending on project requirements.

2 EUROPEAN ASSESMENT DOCUMENT (EAD)

Resilient interlayers are used between structural elements, typically between floor and wall, and they become part of the structure. For this reason, not only acoustic performance, but also static stability and durability over the time shall be investigated.
For materials used as elastic interlayers, there are no standards which characterize the mechanical properties in accordance with the use for reducing noise transmission in buildings.
From an acoustic point of view, it is not enough to define dynamic elastic modulus and damping factor. K_{ij} value must be determined for the calculation of airborne sound insulation between rooms according to ISO 12354-1 [1] and impact sound insulation between rooms according to ISO 12354-2 [2].
From a static point of view, it is important to test the compressive behaviour of the material through the determination of elastic modulus, compressive creep, compressive stress and deformation and compression set.
In recent years, resilient interlayers are increasing their presence in buildings for the reduction of flanking transmission and consequently the demand to characterize and compare the different types of products placed on the market has increased.
In order to find a common criterion for the assessment of product's performance, a specific EAD was developed. The EAD is developed by the EOTA network consisting of some 45 highly qualified Technical Assessment Bodies (TABs) mandated by their states to issue ETAs. EOTA also co-operates with external experts and stakeholders to

develop state-of -the-art technical specifications for the construction sector.
EAD provides manufacturers with a way to CE marking for construction products that are not or not fully covered by a harmonised European standard (hEN) under the Construction Products Regulation (EU) 305/2011.
It contains, at least, a general description of the construction product and its intended use, the list of essential characteristics relevant for the intended use, methods and criteria for assessing the performance of the product and principles for the implementation of the system for assessment and verification of constancy of performance.

2.1 DESCRIPTION AND INTENDED USE

The EAD covers flexible interlayers made of a homogeneous viscoelastic layer of monolithic polyurethane or EPDM (ethylene propylene diene monomer rubber) or similar material.
The product is used as flexible interlayer for the reduction of flanking transmission for airborne, impact and building service equipment sound between adjacent rooms and/or vibration transmission. The product is installed between at least two elements (i.e., floor and wall).
Methods and criteria for assessing reaction to fire, compressive creep, compression set, compressive stress and deformation, dynamic elastic modulus, damping factor, flanking transmission for airborne, impact and building service equipment sound between adjacent rooms and compressive modulus are described in the EAD.

2.2 COMPRESSIVE CREEP AND COMPRESSION SET

Resilient interlayers are subjected to constant load during their working life.
It is important to estimate the long-term behaviour for static reasons (to avoid differential failure in the structure) and for acoustic reasons (a crushed interlayer does not have the same elastic response and consequently the acoustic performance decays).
For the same reason it is important to define the ending thickness of the product after compression for a given time and after a given recovery time.
For the determination of the compressive creep ISO 8013 [7] can be used, for the determination of compression set it is recommended ISO 1856 [8].

2.3 COMPRESSIVE STRESS AND DEFORMATION AND COMPRESSIVE MODULUS

Resilient interlayers have been tested with very high compression stress, demonstrating a linear behaviour even with high loads. Despite this behaviour, from a static point of view it is important to provide the compressive stress as a function of the strain (e.g.: 1mm, 2mm and 3mm compression) in order to limit the maximum deformation and possible structural failure.
Compressive stress and compressive modulus have been tested according to EN ISO 844 [9] under different conditions of friction.
Tests show that friction could affect the result and for this reason it is necessary to perform always the measurements with appropriate lubricant to make the effects of surface friction negligible. This ensures the repeatability of the result and without any treatment to have the in situ operating value of elastic modulus and compressive strength [10].

2.4 FLANKING TRANSMISSION

In previous investigations it has been shown that K_{ij} depends on the test setup. Due to the lack of a common standard, each manufacturer provides K_{ij} values tested in a different configuration (choosing the type of joint, the number of fastening system, etc). Many variables can affect the K_{ij} and it is important to make clear the test setup [3, 4, 12].
Considering the variety of possible joints, materials and fastening systems, it was not possible to define a single configuration useful to define the performance of the resilient profile.
Although there is a detailed standard to determine the vibration reduction index (ISO 10848 [5]), there is a need to improve the way results are expressed in order to avoid ambiguities on fastening systems.

3 EUROPEAN TECHNICAL ASSESMENT (ETA)

The European Technical Assessment (ETA) provides an independent Europe-wide procedure for assessing the essential performance characteristics of non-standard construction products.
The ETA offers manufacturers a voluntary route to CE marking, when the product is not or not fully covered by a harmonised standard (hEN) under the Construction Products Regulation (EU) 305/2011.
CE marking based on the ETA allows manufacturers to freely market their product on the entire European internal market and introduce innovative products and new product features with short lead times.
Only independent Technical Assessment Bodies (TABs) may issue ETAs. The independent assessment strengthens the credibility of the product performance information, enhances market transparency and builds customer trust.
ETAs provide reliable product performance information that is comparable across Europe based on harmonised technical specifications, the European Assessment Document (EAD).

3.1 MEASUREMENT OF COMPRESSION CREEP

The samples provided are in the form of cylinder of 13 mm diameter and 6 mm of nominal thickness (tolerance class M4 according to the ISO 3302-1). The test is carried out on 3 specimens of each material.

https://doi.org/10.52202/069179-0253

The method for the determination of the compression creep consists in subjecting the samples to a compression of 10% strain for 6000 seconds.

$$\frac{\Delta\varepsilon}{\varepsilon_1} = \frac{\delta_1 - \delta_2}{\delta_0 - \delta_1} \quad (1)$$

Where:

- δ_0 [mm]: initial thickness of the test piece
- δ_1 [mm]: thickness of the test piece under constant force 10 min after application of the force
- δ_2 [mm]: thickness of the test piece under constant force 6000 s after the application of the force

The test is done at ambient temperature. The compression is made with a hydraulic machine for tensile/compression INSTRON 8032. by mounting a load cell of 1 kN for the transduction of the pressing load. After the compression of 10% strain. the force obtained is held constant and the acquisition of the deformation starts for 6000 s.

Table 1: *Compressive creep*

Product	$\frac{\Delta\varepsilon}{\varepsilon_1}$
XYLOFON 35	0,54
XYLOFON 50	0,53
XYLOFON 70	2,9
XYLOFON 80	10,3
XYLOFON 90	0,28

3.2 COMPRESSION SET

The samples provided are in the form of squares of 50x50mm with 6 mm of nominal thickness (tolerance class M4 according to the ISO 3302-1).
Four samples are overlapped to obtain the minimum thickness of 25 mm. The assembly shall work as a single layer of equivalent thickness.
The method for the determination of the compression set consists in subjecting the samples to a thermal conditioning at ambient temperature and then to a mechanical conditioning. imposing a deformation of 50% for a 22h time interval. At the end of the application of the static load, after a recovery time of 30 minutes, the residual deformation is measured and the compression set (c.s.) is calculated as a percentage variation in the thickness of the sample compared to the pre-test measured thickness.
The compression set $c.s._i$ is defined as:

$$c.s._i = \frac{d_0 - d_r}{d_0} \times 100 \quad [\%] \quad (2)$$

The absolute value of the product after compression and recovery. $t_{c.s.}$. is defined as:

$$t_{c.s.} = t - (c.s. \times t) \quad [mm] \quad (3)$$

Where:

- d_0 [mm]: original thickness of test piece
- d_r [mm]: thickness of the test piece after recovery
- t [mm]: nominal thickness of the product

The thermal conditioning of the specimens is made at ambient temperature, according to EN ISO 1856 [8]. The mechanical conditioning of the specimens runs on a hydraulic machine for tensile/compression INSTRON 1275 (±100 mm stroke) by mounting a load cell of 500 kN for the transduction of the pressing load.
After the mechanical conditioning and the subsequent relaxation time, the thickness of the sample is measured again on 5 points using the bench thickness gauge.

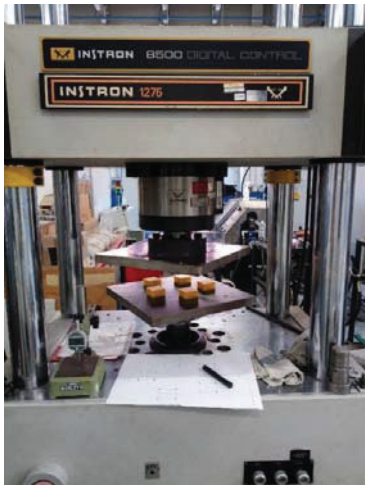

Figure 1: *Measurement equipment mounted on the hydraulic machine INSTRON*

Table 2: *Compression set*

Product	c.s.	t [mm]	$t_{c.s.}$ [mm]
XYLOFON 35	0.72 %	6	5,96
XYLOFON 50	1,25 %	6	5,93
XYLOFON 70	0,71 %	6	5,96
XYLOFON 80	1,31 %	6	5,92
XYLOFON 90	2,02 %	6	5,88

Results of the test show that the tested materials have very good elastic behaviour and the residual deformation is negligible.

https://doi.org/10.52202/069179-0253

3.3 COMPRESSIVE STESS AND DEFORMATION

The samples provided are in the form of squares of 50x50mm with 6 mm of nominal thickness (tolerance class M4 according to the ISO 3302-1).
The test is carried out on 5 specimen and 5 lubricated specimens of each material.
The method for the determination of the compressive stress σ at 1mm, 2mm and 3mm is to correlate the pressure required to obtain the different deformations.
The thermal conditioning of the specimens is made at ambient temperature, according to EN ISO 1856. Also the test is done at ambient temperature. The compression is made with a hydraulic machine for tensile/compression INSTRON 8032 by mounting a load cell of 10 kN for the transduction of the pressing load.

Table 3: *Compressive stress and deformation*

Product	σ_{1mm} [MPa] $\sigma_{1mm,\ lubricant}$ [MPa]	σ_{2mm} [MPa] $\sigma_{2mm,\ lubricant}$ [MPa]	σ_{3mm} [MPa] $\sigma_{3mm,\ lubricant}$ [MPa]

XYLOFON 90	5,8 3,4	14,4 8,0	29,0 14,9

Where:
- σ_{1mm} [MPa]: mean value of compressive stress at 1 mm strain (surfaces not treated with lubricant)
- $\sigma_{1mm,lubricant}$ [MPa]: mean value of compressive stress at 1 mm strain (surfaces treated with appropriate lubricant)
- σ_{2mm} [MPa]: mean value of compressive stress at 2 mm strain (surfaces not treated with lubricant)
- $\sigma_{2mm,lubricant}$ [MPa]: mean value of compressive stress at 2 mm strain (surfaces treated with appropriate lubricant)
- σ_{3mm} [MPa]: mean value of compressive stress at 3 mm strain (surfaces not treated with lubricant)
- $\sigma_{3mm,lubricant}$ [MPa]: mean value of compressive stress at 3 mm strain (surfaces treated with appropriate lubricant)

3.4 COMPRESSIVE MODULUS

The samples provided are in the form of squares of 50x50mm with a 6 mm of nominal thickness (tolerance class M4 according to the ISO 3302-1).
The test is carried out on 5 specimen and 5 lubricated specimens of each material.
The compressive modulus is calculated as following:

$$E_{C.i} = \frac{\boldsymbol{\sigma}_{\mathbf{15.i}} - \boldsymbol{\sigma}_{\mathbf{5.i}}}{\varepsilon_{15} - \varepsilon_{5}} \quad (4)$$

Where:
- $\sigma_{15.i}$ [MPa]: compressive stress at 15% strain (ε_{15})
- $\sigma_{5.i}$ [MPa]: compressive stress at 5% strain (ε_{5})

The thermal conditioning of the specimens is made at ambient temperature according to EN ISO 1856. Also the test is done at ambient temperature. The compression is made with a hydraulic machine for tensile/compression INSTRON 8032 by mounting a load cell of 10 kN for the transduction of the pressing load.

XYLOFON 90	36,6	21,9

3.5 DYNAMIC ELASTIC MODULUS AND DAMPING FACTOR

The samples provided are in the form of a cylinder of 9 mm diameter and a nominal thickness (class M4 according to the ISO 3302-1) of 6 mm. The form factor is h(height) : d(diameter) = 1:1.5.
The test is carried out on 3 specimens of each material.
The thermal conditioning of the specimens is made at ambient temperature, according to EN ISO 1856.
The measurement equipment is made of DMA 242E Artemis NETZSCH.

- $\tan\delta_{50Hz}$: mean value of tangent of the loss angle at 50 Hz

3.6 FLANKING TRANSMISSION

The samples provided are in the form of rolled stripes of 6 mm of nominal thickness (tolerance class M4 according to the ISO 3302-1).

The vibration reduction index K_{ij} is a quantity related characterises the transmission of vibrations through the structural elements of a junction. It is calculated according to ISO 10848 [5]:

$$K_{ij} = \frac{D_{v,ij} + D_{v,ji}}{2} + 10\,log\frac{l_{ij}}{\sqrt{a_i \cdot a_j}} \quad dB \tag{5}$$

Where:

- $D_{v.ij}$ [dB]: velocity level difference between element i and j when element i is excited
- $D_{v,ji}$ [dB]: velocity level difference between element j and i when element j is excited
- l_{ij} [m]: common junction length between elements i and j
- a_i [m]: equivalent absorption length of element i
- a_j [m]: equivalent absorption length of element j

The values stated in the ETA refers to transmission path characterized by the presence of the resilient interlayer. For each path shall be defined the vibration reduction index with resilient interlayer in frequency (K_{ij}) and correction of the $\overline{K_{ij}}$ in presence of elastic interlayers in junction (Δ_l).
Δ_l for a specific path is calculated as difference between $\overline{K_{ij}}$ of the same path with and without resilient interlayer. $\overline{K_{ij}}$ is the arithmetic average of K_{ij} within the frequency range 200 Hz to 1 250 Hz (one-third octave bands) according to point 10 of the EN ISO 10848-1 [5].

$$\Delta_l = \overline{K_{ij,with}} - \overline{K_{ij,without}}$$

For the acquisition of the velocity levels the panels were excited using piezoelettrics shaker screwed to panels. Velocity levels were acquired using 4 accelerometers at a time.
Structural reverberation times T_{15} have been extracted from MLS measurements, which were measured in the number of six positions on each panel.
The excitation and measurement points were chosen according to the EN ISO 10848 [5] standard. For each element a minimum of 3 source positions are required and for each excitation position three pairs of measurement positions must be considered randomly over the test element. In the measurement session 6 receivers and 3 source were used.
Two types of junctions were constructed: "T vertical junction" and "X vertical junction".

Tested build up of "T vertical junction" (Figure 1):
- (4) Top wall: 5-ply CLT, 100 mm, (2,4 m x 3 m)
- (1) Floor: 5-ply CLT 100 mm (2,4 m x 3,5 m)
- (2) Bottom wall: 5-ply CLT, 100mm, (2,4 m x 3 m)

Fastening system:
- 6 Partially threaded screws HBS 8x240mm; step 440mm
- 2 Angle brackets NINO15080 (CLT pattern with 31 screws 5x50 mm) + XYLOFON 35 (55x150x6 mm); step 1760mm

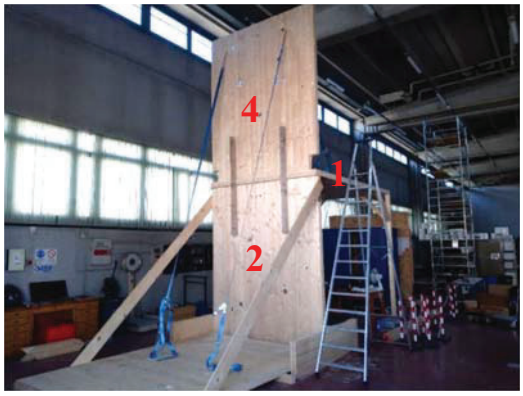

Figure 3: *"T vertical junction" build up*

Tests on this configuration were conducted changing the type of resilient interlayer and the load applied. An example with results follows.

Product: XYLOFON 50
Position: between top wall and floor and between floor and bottom wall.

Other junction types we assessed following the same principles, changing the type od profile and the load applied.

4 CONCLUSIONS

The aim of this work is to demonstrate how a harmonized standard can be produced to uniquely characterize resilient profiles used in flanking transmission, to assess in a harmonized manner the effects of including these profiles in building joints from an acoustic, mechanical and structural point of view.
The project led to the definition of a European Assessment Document (EAD) and to the issue of a European Technical Assessment (ETA), that allows manufacturer to introduce innovative products and new features to the entire European market.

VIBRATION SERVICEABILITY PERFORMANCE OF MASS TIMBER FLOORS UNDER VARIOUS SUPPORT CONDITIONS

Chenyue Guo[1], Jianhui Zhou[2*]

ABSTRACT: Mass timber floors are prone to human-induced vibration due to their light weight. Vibration serviceability limit design often governs the maximum allowable span of mass timber floors. The current design methods including the vibration-controlled span equation in CSA O86-19 and the design method in EC5 usually assume the mass timber floors are simply supported on rigid walls, which can't be directly applied to floors being supported by beams. In this study, the vibration performance of mass timber floors including nailed laminated timber, dowel laminated timber, and cross-laminated timber floor panels was investigated experimentally. The effect of various support conditions on the dynamic properties of mass timber floors was studied through modal testing, and the vibration acceptability of these floors under normal human walking was assessed by subjective evaluations. The test results indicated that the stiffness of the support significantly impacts the dynamic properties and vibration performance of the entire floor slab. The performance criterion specified in CSA O86 demonstrated potential for accurately predicting the vibration performance of beam-supported mass timber floors. However, both the vibration-controlled span equation and the beam stiffness equation were found to be insufficient for designing such floors. The vibration response-based design methods that utilize the ISO 10137 baseline curve showed inconsistencies across all groups. Dunkerley's system frequency prediction equations yielded overestimated results, while Kollar's method exhibited an average error within 5%, demonstrating promising potential for practical use. Further research is required to develop a reliable design approach for beam-supported mass timber floors.

KEYWORDS: Mass timber floors, vibration performance, support conditions

1 INTRODUCTION

Mass timber panels (MTPs) are a category of large-dimension panelized wood products, including cross-laminated timber (CLT), nailed laminated timber (NLT), dowel laminated timber (DLT), or glued-laminated timber (GLT) panels [1]. They are used mainly as load-bearing floors, walls, and roofs in mid-rise or high-rise wood buildings. In comparison to alternative materials, such as concrete and steel, MTP-constructed floors possess a relatively lighter weight and lower damping ratio, thereby making them susceptible to human-induced vibrations [2].

The vibration performance of mass timber floor is significantly dependent their edge support conditions [3-4]. Beside the rigid wall supports often found in platform CLT buildings, there are a large portion of mass timber building projects that uses post-and-beam combined with mass timber panel floors. It should be noted that the structural design of supporting beams is to meet ultimate limit state (ULS) including moment compacity and shear resistance strength as well as serviceability limit state (SLS) including deflection limits of the beams only. The effect of the beam flexibility on the floor vibration performance is not considered.

Current design methods including the vibration-controlled span equation in Canadian standard CSA O86 [5] and the vibration design method in Eurocode5 [6] are based on the assumption that the mass timber floors are simply supported on rigid walls. Due to the flexibility of beams that support the floor panels, these design equations cannot be applied to such beam-supported floors. Thus, FPInnovation [7] proposed a beam stiffness equation to limit the beam's stiffness to ensure the supporting beams are sufficiently rigid, which enables the applicability of the vibration design method in CSA O86 to beam-supported CLT floors. However, this beam stiffness equation was developed based on the subjective evaluations of a few beams under heel drop excitations in a laboratory condition, without experimental verifications on beam-supported CLT floors.

The current engineering practice also adopts vibration response-based design methods using the ISO 10137 [8] baseline curve and multiplying factors for mass timber floor vibration design [9]. To conduct a response-based vibration serviceability design, it is inevitable to calculate the system's natural frequencies of floors with flexible supports, with the fundamental natural frequency being a key parameter. Dunkerley's method is widely used and adopted in American Institute of Steel Construction (AISC) DG-11 [10] for the prediction of system natural

frequency, which are being used for mass timber floors with beam supports. However, the validity of such criteria as well as the frequency prediction equations for mass timber floors remains unverified to date. In addition, Kollar [11-13] proposed a model and equations for the calculation of the fundamental natural frequency of plates which considered the deflection of the supporting beams. However, these equations have yet to be verified through experimental studies.

The aim of this study is to examine the dynamic properties of mass timber floors under varying support conditions and evaluate their vibration serviceability performance through both physical parameter measurements and subjective evaluations. Additionally, the study will assess the validity of commonly-used vibration design criteria for mass timber floors with supporting beams, and assess the accuracy of prediction equations for system frequency.

2 THEORETICAL BACKGROUND

2.1 COMMONLY-USED MASS TIMBER FLOOR VIBRATION DESIGN CRITERIA

In an effort to establish standards for acceptable vibrational behavior in mass timber floors, numerous approaches have been proposed. In Canada, Hu [14] first proposed a performance criterion which used the combination of fundamental natural frequency and the deflection under 1 kN point load. This performance criterion was derived through a comprehensive analysis of field floor data and the results of occupant perception surveys, utilizing logistic regression analysis, as shown:

$$\frac{f_1}{d^{0.39}} \geq 15.3 \quad (1)$$

where d is the measured static deflection under 1 kN concentrated load at the center of the floor, and f_1 is the measured fundamental natural frequency of the floor.

The accuracy of the criterion was confirmed through a comparative analysis of 58 lightweight flooring systems, using subjective evaluation ratings as a reference. The results indicated that when the ratio calculated through the equation exceeded 15.3, the flooring system was highly likely to meet the vibrational performance requirements and be deemed acceptable to occupants.

This approach was adopted for the development of the vibration-controlled span equation for CLT floors in accordance with CSA O86-19 [5]. The same form of design criterion which used the calculated parameters is shown in equation (2), the equations to calculate the parameters are also shown as follows:

$$\frac{f_1}{d^{0.7}} \geq 13.0 \quad (2)$$

$$f = \frac{\pi}{2l^2}\sqrt{\frac{EI}{m}} \quad (3)$$

$$d = \frac{1000Pl^3}{48EI} \quad (4)$$

where m is the mass per unit area, kg/m^2; l is the floor span, m; EI is the bending stiffness of the 1-meter-wide floor, N·m^2; P= 1000 N.

The performance criterion equation takes into account the measured results to assess the vibration serviceability performance of a built timber floor. However, the vibration design of CLT flooring systems is achieved through the second equation, referred to as the "design criterion", which was developed based on the lab tests of CLT floors with three different thickness. Both the performance and design criteria will be used to analyze the test data obtained in this study.

The direct method for evaluating floor vibration serviceability takes into account human perception of whole-body vibration and requires appropriate response measurements. According to ISO 10137 "Bases for design of structures—Serviceability of buildings and walkways against vibrations" [8], the baseline curve representing the acceleration in the z-axis provides a limit for human perception of vibration. Within the frequency range of 4 to 8 Hz, vibrations at a level of 0.005 m/s^2 are considered to be negligible. ISO 10137 also provides multiplying factors for different occupancies, suggesting a factor of 2 to 4 for continuous or intermittent vibrations in the case of residential buildings during daytime hours. The AISC DG 11 [10] uses peak acceleration based on the principles outlined in ISO 10137. Although this guide was initially developed for steel-framed floors, it has been widely adopted in the timber engineering community [9] for the design of mass timber flooring systems.

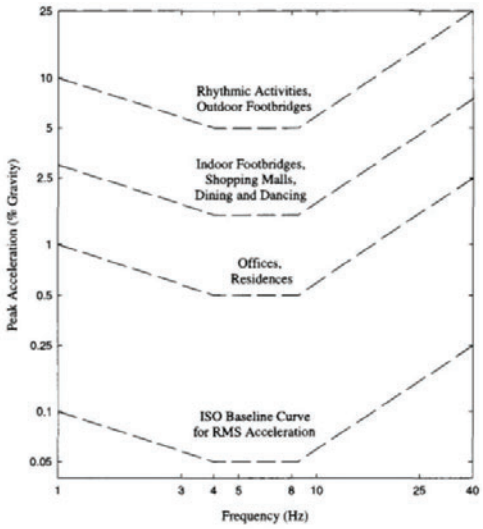

Figure 1: *Recommendation of acceleration for human comfort in AISC 2016*

2.2 SUPPORTING BEAM STIFFNESS LIMITATION

Since Eq. 2 was developed with CLT floors with rigid supporting walls, FPInnovation [7] proposed a beam stiffness equation so that Eq. 2 can be used for beam-supported CLT floors. This equation limits the beam's

https://doi.org/10.52202/069179-0254

stiffness to ensure the supporting beams are sufficiently rigid to avoid negative effect on floor vibration performance.

$$EI \geq F_{span} 132.17 l^{6.55} \quad (5)$$

where EI=the supporting beam apparent stiffness (N/m^2), l=the clear span of supporting beam (m), F_{span} is taken as 1 for simple span beam and 0.7 for multi-span continuous beam.

The evaluation of the rigidity of the beams was conducted by doing a heel drop test on the center of the beam, the specimen can be treated as rigid if the evaluator does not feel any movement after the heel drop. It should be noted that the beam stiffness requirement is not dependent on the mass timber floor thickness and span according to Eq. 5.

2.3 SYSTEM FREQUENCY PREDICTION

In the AISC DG 11 [10] for the vibrations of steel framed structural systems and the revised version of EC5 [15], Dunkerley's method was suggested for the estimation of system frequency:

$$\frac{1}{{f_n}^2} = \frac{1}{{f_j}^2} + \frac{1}{{f_g}^2} \quad (6)$$

where $f_j$is the beam or joist panel mode frequency, f_g is the girder panel mode frequency.

Kollar [11-13] proposed a model and equations using Dunkerley's method and Southwell's method for the calculation of the fundamental natural frequency of orthotropic plates which considered the flexibility of the supporting beams. The equations considered different configurations when the floor was supported by one to four beams on edge, and the equations were applied to timber and timber-concrete floors and verified by numerical models. The equations for floors with two opposite beams are simplified as shown, more details can be found in [13].

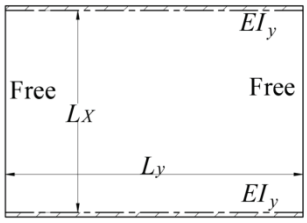

Figure 2: *Floor supported on two opposite beams*

$$D_{11} = \frac{E_x h^3}{12(1-\gamma^2)} \quad (7)$$

$$D_{22} = \frac{E_y h^3}{12(1-\gamma^2)} \quad (8)$$

$$f_x^2 = \frac{\pi^2 D_{11}}{4mL_x^4} \quad (9)$$

$$f_y^2 = \frac{\pi^2 D_{22}}{4mL_y^4} \quad (10)$$

$$f_{EIy}^2 = \frac{\pi^2 EI_y}{2mL_x L_y^4} \quad (11)$$

$$\delta_y = \frac{1}{1 + {f_y}^2/{f_x}^2} \quad (12)$$

$$f^2 = \left(\frac{1}{f_x^2} + \frac{1}{f_{EIy}^2 + \delta_y f_y^2}\right)^{-1} \quad (13)$$

where E_x and E_y is the Young 's modulus, m is the mass over unit area, h is the thickness, γ is the Poisson's ratio, L_x and L_y are the dimensions of the plate in the x and y direction,EI_y is the supporting beams' stiffness.

3 MATERIALS AND METHODS

3.1 MATERIALS

The dowel laminated timber (DLT) panels, nail laminated timber (NLT) panels and cross laminated timber (CLT) panels were investigated. The DLT and NLT panels were assembled with one 11-mm oriented strand board (OSB) panel as the sheathing, in accordance with construction practices.

Three floors with varying dimensions and layouts were constructed in the laboratory at the University of Northern British Columbia for testing purposes. DLT floor and NLT floor were both made by three 4.3 m × 1.8 m panels, CLT floor was made by three 4.0 m × 1.8 m panels. The panels were spanned in the major strength direction at 4.1 m o.c and 3.9 m o.c respectively. The non-destructive test developed by Zhou [16] was used to simultaneously measure the elastic constants of each panel including modulus of elasticity in major and minor strength directions (E_x and E_y) as well as in-plane shear modulus G_{xy}. These parameters are required if the floor plate is modeled as a two-dimensional orthotropic thin plate. The floor dimensions and measured elastic constants are shown in Table 1 and 2. It is important to note that the CLT panels were obtained from prior testing and contained some internal cracks, which led to a lower E_x value than its design value. However, this did not impact the floor's vibration performance with the tested span.

Table 1: *Information of the constructed mass timber floors*

Floor Material	Length (m)	Width (m)	Thickness (m)	Density (kg/m^3)
DLT	4.3	5.4	0.151	448

https://doi.org/10.52202/069179-0254

In this study, the rigid wall and glulam beams were both selected as floor supports. The design and construction of two beams with varying cross-sectional configurations were carried out to meet both ULS and SLS requirements first with a structural grid of 6×6 meters according to NBCC 2020 [17]. The 20f-E sprue-pine glulam beams with a span of 6 meters and a density of 435 kg/m^3 were selected. In this study, the 175*494 mm supporting glulam beams B1 were designed based on Eq.5 which is expected to has the adequate stiffness to avoid negative effect on floor vibration performance. The 175*608 mm beam B2 was then selected which has a stiffness two times higher than B1. The elastic constants of the two groups of beams were obtained through the methodology established by Chui [18] and are presented in Table 3.

Table 3: *Information of the supporting beams*

Beam	Width (mm)	Thickness (mm)	E (MPa)	G (MPa)
B1	175	494	11705	693
B2	175	608	12090	629

3.2 FLOOR CONSTRUCTION

The floors were sitting on wood walls resting on the ground along the major span direction, which can be treated as rigid supports (Figure 3). Panel-to-panel connections were achieved by installing full-thread self-tapping screws at 45˚ (Holz CLC, 8 mm diameter and 160 mm length,), with a spacing of 400 mm. Panel-to-support connections were also installed by using half-thread self-tapping screws at 90˚ (HBS, 8 mm diameter and 220 mm length,), with a spacing of 450 mm.

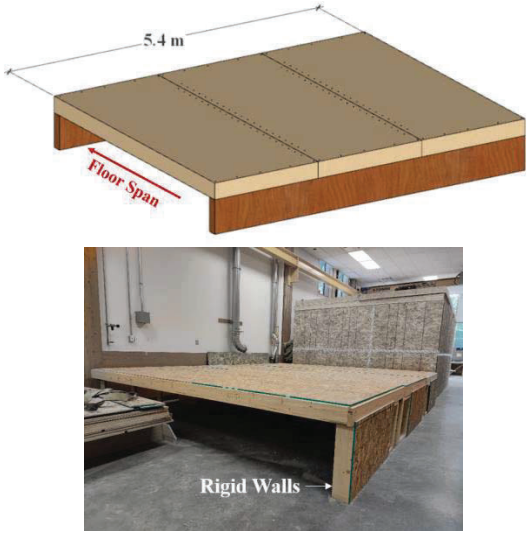

Figure 3: *Floor with rigid supports*

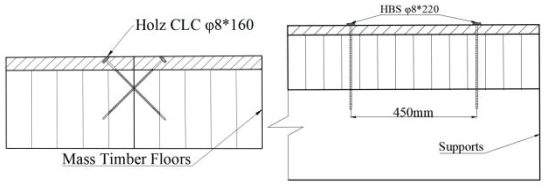

Figure 4: *Panel-to-panel connection and panel-to-support connection*

The floors were then supported on two groups of beams respectively, the beam-to-column connections were achieved by PITZL-HVP connectors with a dimension of 80*220 mm, the screws used are φ 5 mm*100 mm. When the beams were connected with columns on both sides, the floor panels were placed on the two beams along the longitudinal direction with the same panel-to-panel and panel-to-support connections.

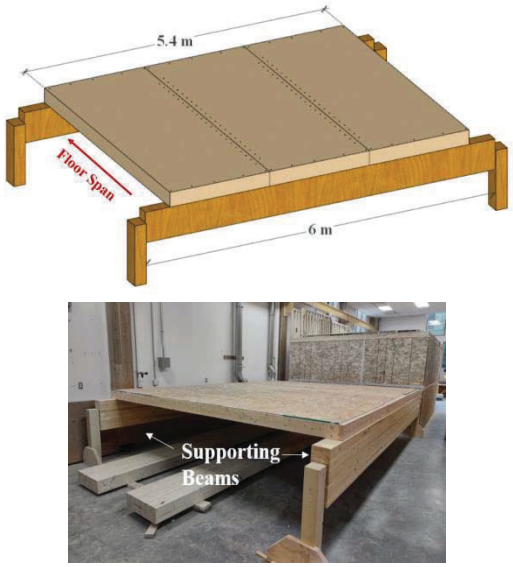

Figure 5: *Floors with supporting beams*

Figure 6: *Beam-column connectors*

3.3 METHODS

3.3.1 Modal tests

Experimental modal test was performed to obtain the dynamic properties including natural frequencies, damping ratios and mode shapes. To accurately capture the corresponding mode shapes, a 7×7 grid was divided on the floor, and each point is impacted by an instrumented impact hammer [PCB Model 086D05] for

three times to obtain an averaged frequency response function (FRF) curve. Five accelerometers [PCB Model 352C04, nominal sensitivity 1.02 mV/(m/s^2)] were installed on the floor with hot melt glue, and the signals from the impact hammer and accelerometers were recorded by a dynamic data analyzer (Brüel & Kjær, LAN-XI 3050) within the frequency range of 100 Hz. BK Connect (Brüel & Kjær) vibration engineering software was used to conduct the modal analysis. The location of accelerometers and test setup is illustrated in Figure 7.

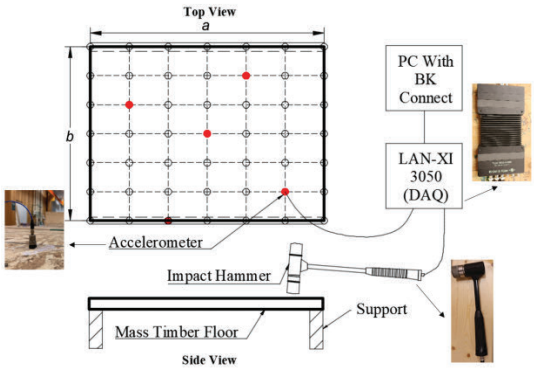

Figure 7: *Schematic drawing of modal test setup with selected accelerometer locations*

3.3.2 Vibration performance tests

After the modal test, a floor vibration performance test was conducted in each group for their acceleration levels under normal human walking. The walking test was performed by a 75 kg evaluator following several walking paths with a gait around 2 Hz. For each floor, four accelerometers were mounted on the left and right midspan (Am-1 and Am-2), and on top and bottom of the floor center (Ac-1 and Ac-2) respectively. The acceleration responses were recorded at various locations that were believed to exhibit the highest possible vibration magnitude and recorded by BK Connect Software. The time-domain acceleration data of the whole walking path was post-processed based on ISO 2631 [19].

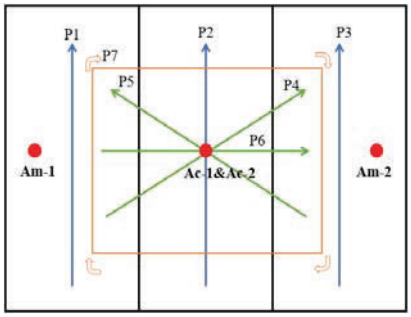

Figure 8: *Human walking paths on the tested floors*

Deflection test was conducted according to ISO 18324 [20] by applying a 1kN point load (a 100 kg concrete block) at the center of the floor, the deflection of the floor was measured by one dial indicator with an accuracy of 0.01 mm at the midspan under the loading point.

Figure 9: *Deflection test (Left: Applied 1 kN concentrated load on the floor, Right: Data collection)*

Subjective evaluations were conducted for the acceptance level of the floors according to ISO 21136 [21], categorizing the floors into levels 1 to 5, i.e. 1 = definitely unacceptable, 2 = unacceptable; 3 = marginal, 4 = acceptable, 5 = definitely acceptable. A survey with 20 evaluators was conducted on each floor. The evaluator first walked on the floor, then stood and sat stationary at the center while a 75kg walker walked on the floor, as shown in Figure 10. Each evaluator completed a questionnaire provided in ISO 21136 to report his/her perception and acceptance regarding vibration levels, all the ratings for each floor were averaged and reported as its final rating.

Figure 10: *Subjective evaluation of tested floors*

4 RESULTS AND DISCUSSION

4.1 DYNAMIC PROPERTIES

Modal tests were performed on the floor panels with different supports. The first three natural frequencies as well as the damping ratios were obtained and presented in Table 4, the corresponding mode shapes with rigid supports and beam supports of NLT and CLT are shown in Figure 11 and 12.

Table 4: *Measured dynamic properties of the floor specimens*

Floor	Supports	f_1 (Hz)	f_2 (Hz)	f_3 (Hz)	Damping (%)
DLT	Rigid	14.88	15.88	19.50	3.6
	B1	11.13	16.25	17.64	3.5
	B2	12.05	16.05	17.97	2.8
NLT	Rigid	14.38	14.88	18.13	4.8

	B1	10.63	17.00	21.00	3.7
	B2	12.15	19.75	21.00	3.4

https://doi.org/10.52202/069179-0254

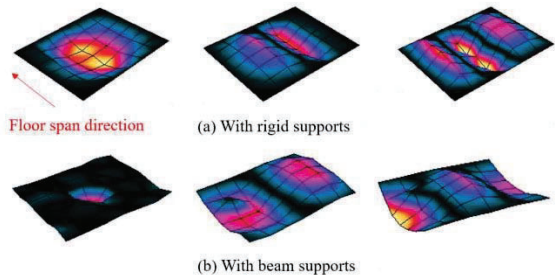

Figure 11: *Corresponding first three mode shapes of NLT floors*

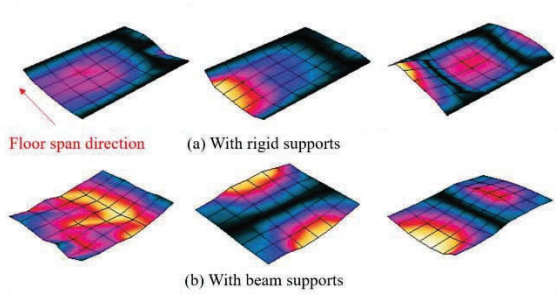

Figure 12: *Corresponding first three mode shapes of CLT floors*

The dynamic properties of the supporting beams were measured prior to their connection with the floor panels. The fundamental natural frequency of beams B1 and B2 was found to be 28.32 Hz and 32.57 Hz respectively, when connected with columns. Table 4 showed that the fundamental natural frequency (f_1) of DLT, NLT, and CLT floor systems decreased over 20% as they were supported from rigid supports to glulam beams, while f_1 increased as the beam stiffness was increased. The damping ratios of each floor system remained relatively unchanged as the support conditions changed, with an average value of 3% to 4%.

Since the composition and material properties of DLT and NLT plates are relatively similar, they had the same mode shapes in the modal test. The corresponding mode shapes of NLT floors are the same under different support conditions, which are the first three bending mode along the longitudinal direction. The CLT also had the first three bending mode shape with rigid supports. Due to the flexibility of supporting beams, the first mode shape of CLT floor is governed by the supporting beams which is the bending mode along the beam direction.

4.2 VIBRATION SERVICEABILITY PERFORMANCE ACCESSMENT

The vibration performance parameters were determined by the experimental tests, subjective evaluations for each floor were also conducted, the results for each floor systems are shown in Table 5-7.

Table 5: *Summary of DLT Floor's vibration performance parameters*

Support	Supporting beams' span (m)	f_1 (Hz)	d_{1kN} (mm)	Rating
Rigid	/	14.88	0.72	3.5

	3	13.73	0.71	3.5
	2	14.25	0.73	3.5

Table 7: *Summary of CLT Floor's vibration performance parameters*

Support	Supporting beams' span (m)	f_1 (Hz)	d_{1kN} (mm)	Rating
Rigid	/	17.25	0.15	5.0
B1	6	10.63	0.17	2.9
	3	14.50	0.12	3.5
	2	16.13	0.11	4.0
B2	6	12.15	0.16	4.0
	3	14.92	0.13	4.5
	2	15.67	0.10	5.0

Changing the supports from rigid to supporting beams has a significant influence on the floor's fundamental natural frequencies, while the static deflection increased slightly due to the flexibility of beams. From the occupants' perspective, the NLT and DLT were acceptable for most of them when using the rigid wall supports, but they performed worse with the supporting beam 1 with an average rating lower than 3, which means not acceptable. Even the beam thickness was largely increased from 494 mm to 608 mm, the occupants still gave a marginal rating towards the floor vibration performance. CLT floors with the rigid simple supports can achieve a rating of 5, which is totally acceptable for the evaluators, while the performance changed significantly to not acceptable when connected with B1, and improved slightly with B2.

https://doi.org/10.52202/069179-0254

To address the influence of supporting beams' stiffness to the vibration performance of the whole floor, the multi-supports were installed under the supporting beams to shorten their effective span. The test results showed that the installation of multi-supports under the beams reduced the floor deflection slightly, and increased the fundamental natural frequencies gradually close to the floors with rigid supports, leading to improved floor vibration performance for the occupants.

The results of this study were compared to the performance and design criterion outlined in CSA 086-19, as shown in Figure 13 and 14. When evaluating the results using the performance criterion, a good correlation was observed between the data points and the subjective evaluation results, with a value greater than 15.3 indicating an acceptable level of floor vibration performance. However, the CLT floors in the study had a greater thickness, leading to smaller deflections compared to the DLT and NLT floor systems, but with similar fundamental natural frequencies. This resulted in an $f/d^{0.39}$ value that exceeded the limit, despite subjective evaluations that did not always align with the predictions.

The design criterion was developed using data from three CLT floors with rigid supports, the calculated design parameters (calculated using equation (4) and (13)) and the subjective evaluation results in this study did not correlate well with the curve provided in the design criterion. This suggests that the vibration-controlled span equation may not be suitable for real-world design applications for mass timber floors supported by beams.

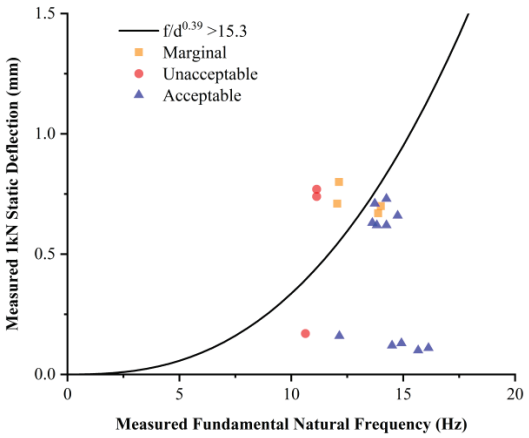

Figure 13: *Comparison between measured result and their subjective rating by performance criterion*

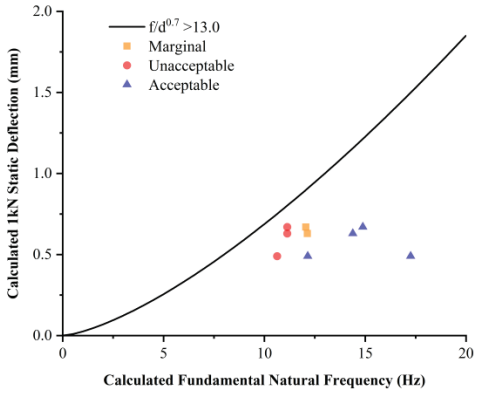

Figure 14: *Comparison between calculated result and their subjective rating by design criterion*

The peak and root-mean-square acceleration under human walking on floors were collected and the maximum value from all the walking paths is shown in Table 8. An example of captured acceleration waveform of CLT floor with B2 under human walking is shown in Figure 15, each peak represents a step on the floor. A transient response of the floor under human walking excitations can be observed, the frequency weighted data is also shown.
The peak acceleration can be greatly affected by the walker, walking path, boundary conditions, and any random disturbance from a single foot pulse excitation, which also showed great differentiation among each group in this study. Despite utilizing the same walking paths and excitation source in every test, the results still showed variation among the groups and all values were found to be higher than the tolerance value as specified by ISO 10137 even after the application of the multiplying factors. The results obtained from the RMS measurement do not align well with the subjective ratings obtained from the evaluators. This highlights the need for further investigation if RMS acceleration levels are to be used as an indicator of floor vibration performance.

Table 8: *Measured maximum frequency-weighted accelerations (m/s^2)*

Floor	Supports	$a_{w,rms}$	$a_{w,peak}$
DLT	Rigid	0.323	5.720
	B1	0.255	2.320
	B2	0.181	0.800
NLT	Rigid	0.375	5.330
	B1	0.077	0.670
	B2	0.111	0.510
CLT	Rigid	0.038	0.259
	B1	0.025	0.119
	B2	0.190	0.639

https://doi.org/10.52202/069179-0254

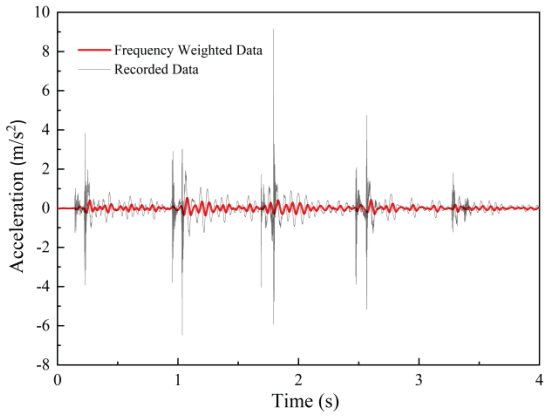

Figure 15: *Time history acceleration data of CLT floor under human walking excitation*

The beam B1 was designed by FPInnovation's beam stiffness equation, however, though the beams' bending stiffness meet the requirement, from the vibration performance tests and the subjective evaluations, all three mass timber floors performed much worse when they were constructed with B1 supporting beams, where the fundamental natural frequencies decreased significantly and the static deflection increased, and the ratings reduced from acceptable to not acceptable. Even with the supporting beam B2, which has twice the stiffness of B1, the floor's vibration performance was still impacted. Since this equation was developed by a few beam test data in the laboratory, further investigation is needed to verify and complete this method.

4.3 VERIFICATION OF SYSTEM FREQUENCY PREDICTION EQUATIONS

Dunkerley's method and Kollar's method were used to calculate the system frequency with the given material properties. The results were compared with the test result, shown in Figure 16:

Table 9: *Calculated f_1 of simple-supported floors and beams*

	Calculated f1(Hz)
DLT	14.87
NLT	15.31
CLT	17.25
B1	32.24
B2	40.42

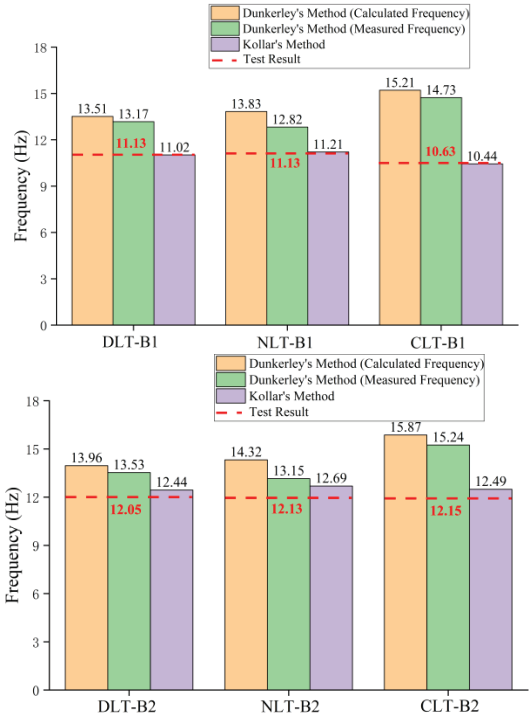

Figure 16: *Comparison of Dunkerley's method and Kollar's method to experimental test result of floor fundamental frequency*

It can be observed from the two figures that the estimated fundamental natural frequencies by Dunkerley's method are overestimate the floor system frequency. Even using the measured value from floors and beams under simple-supported conditions, the estimated value is still higher than the test result with an error of over 10% to 40%. However, the Kollar's method can predict the system' frequency precisely with an average error within 5% in each group.

5 CONCLUSIONS

In this study, modal test, vibration response test and subjective evaluation were conducted on three types of mass timber floors (NLT, DLT and CLT) under various support conditions. The measured dynamic properties of those floor systems were compared among each group and evaluated by the current commonly-used design criteria. The accuracy of prediction equations for beam-supported floor's frequency was also examined. From the study these conclusions can be drawn:

1. The stiffness of the support has a significant effect on the dynamic properties and vibration performance of the mass timber slab floors. When the rigid wall support is replaced with beam supports, the system's fundamental natural frequency is reduced and the subjective feeling becomes much worse. By increasing the thickness of the beam or adding multiple supports under the supporting beams, the frequency gradually returns to a level similar to that of the rigid support and the subjective perception improves.

https://doi.org/10.52202/069179-0254

2. The performance criterion outlined in CSA O86 generally exhibit a high level of correlation with experimental results, demonstrated potential for accurately predicting the vibration performance of beam-supported mass timber floors. However, for the design of such floors, the vibration-controlled span equation and the beam stiffness equation proposed by FPInnovation are both insufficient. The acceleration criterion outlined in ISO 10137 reveals notable discrepancies across all groups, with results consistently surpassing established limits.
3. The Dunkerley's equation overestimate the fundamental frequency of mass timber floor system by up to 40%. While the method proposed by Kollar had an average error within 5%, which demonstrates remarkable potential for practical use.

Future studies aim to extensively explore the feasibility of accurately predicting the dynamic parameters of beam-supported slabs through numerical modeling. The research also seeks to synthesize and develop a practical vibration design method for beam-supported mass timber slabs, based on a comprehensive analysis of current laboratory data and data collected from multiple on-site buildings.

DYNAMIC CHARACTERISTICS AND DYNAMIC RESPONSE OF TIMBER FOOTBRIDGES TO DYNAMIC HUMAN ACTIVITIES

Marek Pantak[1], Whokko Schirén[2], Carl Larsson[3], Michael Dorn[4]

ABSTRACT: The dynamic action of footbridge users in different forms of activity (especially during walking and running) may cause an excessive vibration of the footbridge deck and may disturb the comfort of use of the structure. The dynamic susceptibility of the footbridges varies depending on the construction material used to build the footbridge and the typical construction solutions (construction details) resulting from the construction material used. The paper presents the basic dynamic characteristics of timber footbridges of various structural solutions, collected during dynamic field tests of these structures. The obtained results indicate relatively high dynamic resistance of timber footbridges to the dynamic loads generated by users under normal conditions of use. In addition, the results show that in the case of timber footbridges, it is possible to consider changing the requirements of international standards defining the range of natural frequencies sensitive to the dynamic impact of users. In the case of timber footbridges, characterized by a relatively high self-weight (compared to steel footbridges), high stiffness and high damping, it is possible to consider changing the requirements for performing forced vibration analyses only for structures with fundamental vertical vibration frequency $f_v \leq 3.0$ Hz instead of the currently defined $f_v \leq 5.0$ Hz.

KEYWORDS: Timber Footbridges, Vibration, Dynamics, Damping, Walking, Running, Comfort of Use.

1 INTRODUCTION

Footbridges are perceived as lightweight structures. The main features observed in the design of footbridges, i.e., the scale of the structure adapted to the human scale, a relatively small deck width, often a high slenderness of the structure, and the application of new (lightweight and/or high-strength) materials, can lead to a reduction in the stiffness of the structures and an increase in their dynamic susceptibility.

In a situation of dynamic impact of pedestrians on footbridges, in a large number of cases, steel and composite steel and concrete footbridges with a span length $L \geq 25.0$ m exhibit high dynamic susceptibility. For lengths $L \approx 25.0 \div 45.0$ m, the fundamental natural vibration frequency of steel footbridges is often in the range of the steep frequency f_s of a running person $f_s \geq 2.40$ Hz (Figure 1). The vibration acceleration caused by a single running person can significantly exceed the allowable vibration acceleration value for vertical vibrations $a_{max} \approx 0.50 \div 1.0$ m/s^2 (respectively: maximum and minimum comfort level; 1.0 m/s^2 permitted for rarely occurring vibration) [1-4]. For span lengths $L \geq 35.0$ m, these footbridges also become susceptible to dynamic action of walking users.

The high dynamic susceptibility of the footbridge under the influence of people walking or running may contribute to excitation of its vibrations by vandals jumping or doing squats with a frequency equal to the natural vibration frequency of the structure.

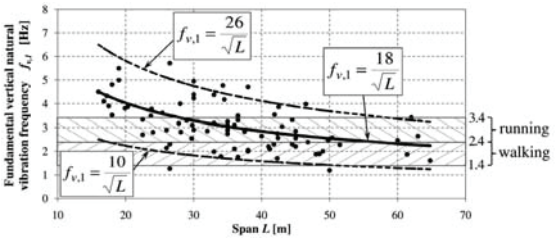

Figure 1: *Fundamental natural vibration frequency $f_{v,1}$ of steel and composite steel and concrete footbridges (own research results).*

As indicated by numerous dynamic field tests of timber footbridges, the dynamic susceptibility of these structures is much lower than steel and composite steel and concrete structures.

The lower dynamic susceptibility of timber footbridges to dynamic impacts of users results from their relatively high stiffness and, thanks to this, high value of their natural vibration frequencies as well as their ability to quickly dissipate energy (high value of the vibration damping coefficient).

It is worth remembering that in the case of resonant vibrations, the vibration amplitude is inversely proportional to the vibration damping coefficient. In other words, a large value of the vibration damping coefficient

leads to a decrease in the vibration amplitudes of the structure.
The paper presents the results of numerous dynamic field tests of timber footbridges of various structural solutions. Basic dynamic characteristics of timber footbridges are presented, i.e., basic vibration frequency, damping, and the maximum dynamic response of the structure (maximum vibration acceleration) for various operating conditions.

2 DYNAMIC FIELD TESTS

Dynamic field tests of 25 footbridges were carried out for normal and exceptional operating conditions of the structure. Under normal operating conditions, the vibrations of the tested structure were induced by people walking or running with the step frequency f_s defined as normal for a given type of activity. Normal step frequency for walking was assumed to be f_s = 1.75 Hz [5]. Normal step frequency for running was assumed to be f_s = 2.65 Hz [5].
In exceptional operating conditions, the vibrations of the tested structure were induced by squatting. The frequency of human activity in exceptional operating conditions was assumed to be equal to the natural frequency of the tested structure in order to induce resonant vibrations of the structure.
In the first stage of the research, in order to determine the fundamental vertical natural vibration frequency of the structure, a person positioned in the middle of the footbridge span and in the middle of the footbridge deck made a series of unrestrained (unsynchronized) jumps.
In order to identify the frequency of torsional vibrations, the person jumping was positioned near the edge of the footbridge deck. Identification of the frequency of transverse vibrations was carried out by affecting the structure of the transverse force generated by the lateral displacement of the body by the person inducing the vibrations with the simultaneous impact of the foot on the footbridge deck.
The pre-identified natural frequencies of the structure were then confirmed by subsequent tests involving the excitation of resonant vibrations of the structure through dynamic actions in the form of jumps, running and transverse body swaying. The correct value of the frequency of activity was indicated by an electronic metronome.
The vibrations of the structure (vibration acceleration) were collected using portable data loggers (portable accelerometers) with a sampling frequency of 200 ÷ 1000 Hz.
Based on the collected vibrations of the footbridge deck induced by a person running along the entire length of the footbridge with resonant frequency of steps, the identification of the number of vibration extremes of the footbridge was carried out, and thus the mode shape of the footbridge was identified.

3 CHARACTERISTIC OF TESTED FOOTBRIDGES

Dynamic field tests were carried out on slab, beam, truss, arch, cable-stayed and suspension timber footbridges with a span length of 12.0 ÷ 50.0 m. General views and parameters of the tested footbridges are shown in Figure 2.

Figure 2: *General views and parameters of 25 tested footbridges (L – span length, f_v – vertical vibration frequency, f_h – horizontal vibration frequency, δ – mean value of the logarithmic decrement of damping)*

4 TESTS RESULTS

For all tested footbridges, the basic natural frequencies, the maximum vibration accelerations for normal and exceptional conditions of use and the values of the logarithmic decrement of vibration damping were determined.

In Figure 2, the basic natural frequencies and the values of the logarithmic decrement of vibration damping are presented. In most of the tested footbridges, the basic form of vibration was vertical vibration. In the case of four footbridges, the basic form of vibrations was horizontal vibrations transverse to the longitudinal axis of the structure (Figure 2 f, i, j, y).

The value of the logarithmic decrement δ was determined using the free vibration decay method.

a) 
b) 
Figure 3: *Variation of the logarithmic decrement of damping δ for vertical vibrations (mean values) with the corresponding regression lines and equations: a) δ as a function of span length L, b) δ as a function of vibration frequency f_v.*

The δ values were determined on the basis of vibration acceleration signals, recorded during excitation of

vibrations by one person running (the person inducing the vibration was leaving the structure, the vibrating structure was loaded only by its self-weight). Parts of the recorded vibration accelerations representing free vibrations of the structure were used to determine δ. Filtered vibration acceleration signals were used in the analyses. The Butterworth low-pass filter of order 4 and a cut-off frequency of 10 Hz was used. The final value of δ was determined as the average of 5 ÷ 8 measurements at each bridge. Figure 3 shows the variability of the logarithmic decrement of damping for vertical vibrations as a function of the span length and vibration frequency for the 25 bridges.

The dynamic responses of all footbridges were tested in normal and exceptional operating conditions.

Figure 4 shows examples of vibrations accelerations of footbridges decks recorded under normal operating conditions, i.e., vibrations induced by people walking with a step frequency f_s = 1.75 Hz and people running with a step frequency of f_s = 2.65 Hz.

Figure 5 shows examples of vibration accelerations of footbridge decks recorded under exceptional operating conditions, i.e., vibrations induced by people doing squats in place with a frequency corresponding to the natural vibration frequency of the structure (resonance).

Figures 4 and 5 show the vibrations of the footbridges presented in Figure 2c and n.

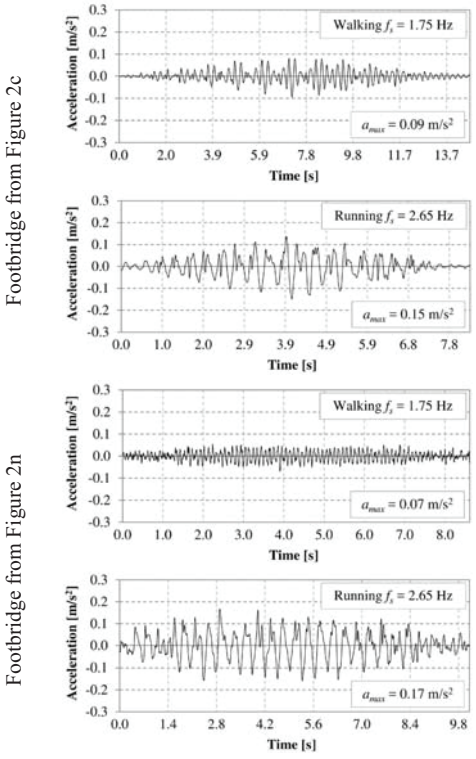

Figure 4: *Examples of vibration acceleration induced by a person walking and running with step frequencies f_s = 1.75 Hz and f_s = 2.65 Hz.*

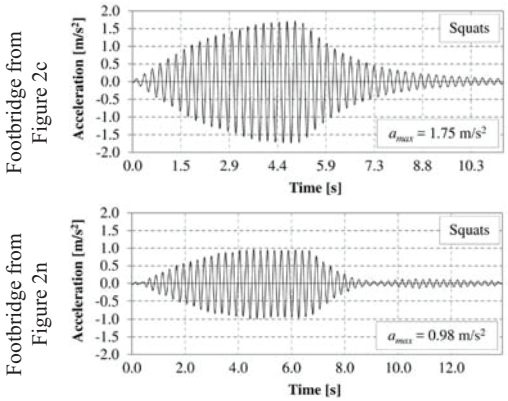

Figure 5: *Examples of vibration accelerations induced by a person doing squats with a frequency corresponding to the natural vibration frequency of the structure.*

Table 1 presents the values of the maximum vibration acceleration obtained on each of the examined footbridges. The given values were read from the filtered vibration acceleration signal.

Figure 6 presents the results from Table 1 in relation to various comfort levels for vertical vibrations [4, 6, 7]:

- $a_{max} \leq 0.5$ m/s^2: maximum comfort –vibrations are imperceptible to users, dotted line in Figure 6;
- $0.5 < a_{max} \leq 1.0$ m/s^2: average (medium) comfort – vibrations are slightly felt by users, dashed line in Figure 6;
- $a_{max} > 1.0$ m/s^2: minimum comfort – vibrations are clearly felt by users, vibrations disturbing walking, acceptable only in case of the occasional occurrence, area above dashed line in Figure 6;
- $a_{max} < 5.0$ m/s^2: structure safety level – maximum acceptable vibration level defined for exceptional events such as acts of vandalism (jumps, squats), vibrations are clearly felt by users, comfort of using the structure is strongly disturbed, free walking is impossible, standing or running is difficult and strongly disturbed, dash-dotted line in Figure 6b.

5 SUMMARY AND CONCLUSIONS

The tested timber footbridges are characterised by relatively high damping. The logarithmic decrement of damping δ for 70% of the tested footbridges is in the range of 5 ÷ 15%. The obtained results are in accordance with the recommendations of [8] according to which the δ value for wooden bridges is in the range of 6 ÷ 12%.

Regression lines presenting the variability of δ for vertical vibrations, in relation to the footbridge span length as well as vibration frequency (Figure 3), seem to be appropriate to determine the value of logarithmic decrement of damping of timber footbridges. These results can be used in dynamic analyses of timber footbridges.

Two of the tested SLT footbridges showed exceptionally high damping of 30 ÷ 40%. This result is interesting and worth confirming by further research of SLT structures. In the light of the results of field tests, the SLT technology seems to be beneficial from the point of view of the dynamic resistance of footbridges to dynamic impacts of users. The high value of vibration damping ($\delta \approx 30 \div 40\%$) has a positive effect on reducing the vibration amplitudes of the structure. The achieved effect probably results from the presence of many planes of cooperation of elements in the SLT structure that allow for effective energy dissipation. The presented result was obtained for a structure with a short span length. It will be interesting to perform vibration damping analyses in SLT structures with larger spans. However, high self-weight of the SLT structure may lead to a significant reduction in their natural vibration frequency and an increase in their dynamic susceptibility. This subject requires further research and analyses.

The natural frequencies of the presented glulam beam, truss and arch footbridges reached values of $f > 3.0$ Hz and relatively high values of the logarithmic decrement of vibration damping δ = 7% ÷ 20% (about 4 ÷ 10 times higher than δ for welded steel structures $\delta \approx 2.0\%$). This effectively reduces the risk of excitation of their vibrations by users.

In the case of the presented cable-stayed and suspension footbridges, the values of frequency and vibration damping are lower than in other tested objects. Comparison of the results achieved for cable-stayed and suspension footbridges with the results achieved for other tested structures indicates the presence of an increased risk of their dynamic excitation by users. However, the data set is too small to draw clear conclusions about structures of this type. Vibration accelerations induced on the cable-stayed and suspension structures by walking people were within the range of maximum comfort. Vibration accelerations induced on these structures by runners were in the range of average comfort. Also, intentional excitations of vibrations by squats did not cause significant vibrations of the structure. The vibrations induced during squats remained in the range of minimal comfort. In the case of a rare occurrence, they can be considered acceptable. The analysed cable-stayed and suspension structures are either characterised by relatively high frequency and low damping or low frequency and high damping. The high frequency of natural vibrations or the relatively high vibration damping value ensured the appropriate dynamic resistance of these structures.

The obtained results of the dynamic tests indicate relatively high dynamic resistance of timber footbridges to the dynamic loads generated by users under normal

conditions of use. The induced acceleration of vibrations only in rare cases lightly exceed the level of maximum comfort specified for the moving people for vertical vibrations. If the maximum comfort level is exceeded, the structure's vibrations remain in the medium comfort area. This means that under normal conditions of use of the analysed structures, their vibrations are not felt by users.
The amplitudes of vibrations intentionally induced by people doing squats (resonant action) exceed the level of minimum comfort. However, these vibrations do not reach the limit value due to the safety of use of the structure. Compared to the results obtained for steel footbridges (vibration acceleration induced by one squatting person in the range of 3.0 ÷ 8.0 m/s^2), the obtained results prove the relatively high resistance of timber footbridges to intentional excitation of vibrations. The explanation of this situation can be found in two factors: in the high value of the ratio of self-weight of the structure to the value of moving loads (G/Q = self-weigh/pedestrians' weight) and in the relatively high value of structural damping.
In addition, on the basis of the obtained results, in the case of timber footbridges, it seems appropriate to verify the requirements of international standards [1] defining the range of natural frequencies sensitive to the dynamic impact of users. In the case of timber footbridges characterized with relatively high self-weight, stiffness and damping, it seems reasonable that the dynamic analyses should be required for structures with a fundamental vertical vibration frequency $f_v \leq 3.0$ Hz instead of the currently defined $f_v \leq 5.0$ Hz.

ACKNOWLEDGEMENTS

The paper is the result of a PhD seminar on vibration of footbridges held by Marek Pantak in May 2022 at Linnaeus University and his cooperation with the employees of the LNU. The presented research results have been collected by the main author since 2017 during numerous field tests of footbridges with various structural systems.
