MODE I FRACTURE ENERGY OF AUSTRALIAN NATIVE HARDWOOD SPOTTED GUM AT VARIOUS MOISTURE CONTENTS

Peiqing Lu[1], Benoit P. Gilbert[2], Chandan Kumar[3], Robbie L. McGavin[4], Hassan Karampour[5]

ABSTRACT: While there is an industry drive to use Australian hardwood spotted gum (*Corymbia citriodora*) boards in the manufacturing of glulam beams, such beams frequently fail the delamination requirements in the Australian and New-Zealand standard AS/NZS 1328.1 (1998). Delamination likely occurs due to (a) the difficulty in gluing this species and (b) the combination of large shrinkage coefficients and high moduli of elasticity of the material, resulting in large moisture-induced stresses developing in the gluelines during the wetting and drying cycles of the delamination test. The paper forms part of a research aiming at finding mechanical solutions to reduce the moisture-induced stresses in the gluelines, allowing spotted gum glulam beams to pass the delamination requirements and land on the market. Especially, this paper introduces the reader to the overall project and focuses on measuring the Mode I fracture energy of the spotted gum material in the tangential-longitudinal crack system and of the glueline between spotted gum boards at 8%, 12% and 16% moisture contents. The relationship between the Mode I fracture energies and moisture content are then discussed and analysed statistically to determine whether fracture energy is sensitive to the moisture content for the analysed range.

KEYWORDS: Australian hardwood glulam, fracture energy, moisture content

1 INTRODUCTION

With the current drive towards sustainable and green construction, the demand for high-performance engineered wood products is increasing. This brings opportunities and challenges to Australia's hardwood industry, such as for native forest grown spotted gum (SPG - *Corymbia citriodora*), a dense hardwood with superior mechanical properties and durability [1]. Spotted gum occupies about 70% of the annual hardwood logs supplied by Queensland (QLD) native forests [2]. There is a drive to manufacture glulam out of this species to be used as beams, columns or bridge elements. However, for SPG glulam to be commercialised, the bond between boards must satisfy the delamination requirements in the Australian and New Zealand Standard AS/NZS 1328.1 (1998) [3]. The delamination test consists of vacuum water impregnation followed by a drying process. The parameters of these two processes depend on the service class of the final product, i.e., its intended environmental application. However, despite best efforts to improve the gluability of SPG [4], SPG glulam products commonly do not pass the requirements in [3] for external applications, with outcomes from a typical delamination test shown in Figure 1. This phenomenon is thought to be attributed to (1) the difficulty in gluing the species from little adhesive penetration [5] and (2) the high moisture shrinkage coefficients combined with high elastic moduli of the material, resulting in large moisture-induced internal stresses developing in the gluelines during the delamination test.

As delamination develops from over-stressed gluelines [6], reducing the internal stresses could represent an effective mechanical solution to prevent delamination. Several approaches may potentially achieve this. First, as the shrinkage and swelling coefficients of SPG (and timber in general) are different along the radial and tangential directions [7], designing the glulam with boards stacked in a specific grain orientation combination could improve results from the delamination test. Second, cutting stress relief grooves in the boards, with specific shape and arrangement, could also reduce the internal stresses [8]. Finally, adjusting the board geometry (width

to thickness ratio) could also affect the internal stresses and thereby decrease the stresses imposed to the gluelines during the delamination test.

To study the delamination problem and find mechanical solutions to reduce the moisture-induced stresses in the gluelines, a numerical model that can reproduce (i) the heat-and-mass transfer in the timber during drying, (ii) the associated drying stresses and (iii) crack initiation and propagation in both the timber and gluelines, would represent an economical and efficient method to investigate potential solutions [8, 10]. The physical and mechanical properties of the SPG material and its associated gluelines need to be collected to establish such a model. The SPG physical properties, such as permeability, diffusion coefficient and desorption-isotherm, are already available in [7]. However, there is a lack of information regarding the mechanical properties, especially the fracture properties and their relationship with moisture content. This paper aims to determine the Mode I fracture energy of the SPG material and associated gluelines. As the mechanical properties of timber are moisture sensitive [9] and the SPG glulam moisture content varies during the delamination test in the AS/NZS 1328.1 (1998) [3], the fracture energies along the crack paths experienced during the delamination tests are determined in this paper at different moisture content, namely 8%, 12% and 16%. First, published fracture energy test methods for fracture Mode I are reviewed, and the most appropriate method for timber is selected. Second, the Mode I fracture energies of the timber with a Tangential (T)-Longitudinal (L) crack system, i.e., with the crack occurring in the RL plane and propagating along the longitudinal direction, and of the "glueline" crack system, i.e., with the crack normal to the glueline, at different moisture content are measured experimentally. Note that the timber orientation in the Tangential (T), Radial (R) and Longitudinal (L) directions is shown in Figure 2. The crack systems investigated are shown in Figure 3.

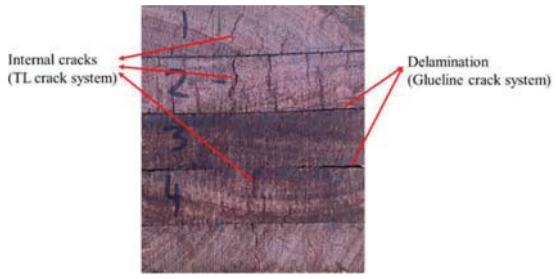

Figure 1: *Spotted gum glulam after delamination test*

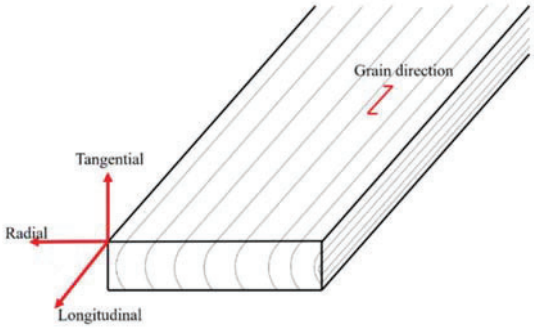

Figure 2: *Timber Tangential (T), Radial (R) and Longitudinal (L) directions*

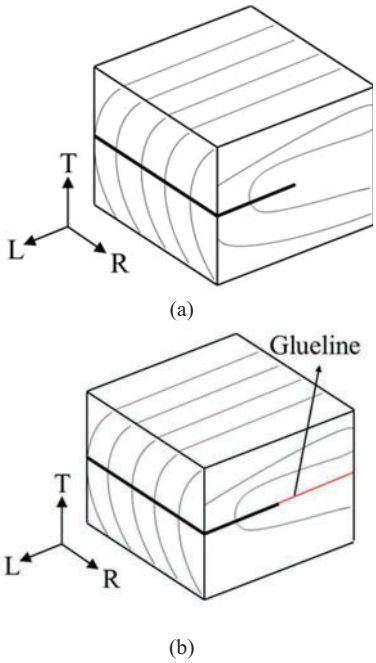

Figure 3*: Timber crack systems (a) TL and (b) glueline*

2 METHODOLOGY

The methodology to obtain the Mode I fracture energies consists of three main steps: (a) determining the test setup used for Mode I fracture energy experiment, (b) preparing the timber and glulam samples and (c) analysing the Mode I fracture energy results statistically by one-way ANOVA.

2.1 MATERIAL, GLUEING AND CONDITIONING

Australian's native forest SPG sawn boards, with the trees harvested in QLD, were used to investigate the Mode I fracture energy and its sensitivity to the moisture content. After the drying process of the delamination test [3], the cracks typically developed within the timber normal to the tangential direction and along the gluelines, as shown in

https://doi.org/10.52202/069179-0064

Figure 1. Therefore, in view of modelling, the fracture Mode I energies in the TL and glueline crack systems were investigated in this study.

When boards needed to be glued to manufacture the samples, as detailed in Section 0, boards were bonded following the results in [4, 10-12] to maximise adhesion, consisting of face milling the boards to a thickness of 22 mm to activate the surface and using commercial resorcinol–formaldehyde adhesive (RF) manufactured by Jowat Adhesive. The gluing process consisted of: (1) mixing the resorcinol with formaldehyde by 4:1 for 5 mins and letting it stand for 10 mins, (2) face milling the surfaces to be glued with a Rotoles 400 D-S manufactured by Ledinek [5], (3) manually applying the adhesive on the milled surfaces, immediately after milling, at a glue spread rate of 450 g/m^2, and (4) pressing the boards together under a pressure of 1.4 MPa for a period of 12 hours.

After the gluing process was finished, the samples were put into different conditioning chambers with targeted equilibrium moisture content of 8%, 12% and 16%, corresponding to the conditioning chambers set at 20℃/40% relatively humidity (RH), 20℃/65% RH and 60℃/90% RH, respectively [13]. The moisture content were selected based on measurements on the glulam samples during delamination tests which reached moisture content up to 16% after vacuum impregnation and down to 8% after kiln drying.

Immediately after testing (Section 2.2), the actual moisture content of each sample was determined following the oven-dry method in the Australian standard AS/NZS 1080.1 [14].

2.2 FRACTURE MODE I TEST SETUP

Different test methods have been adopted in the literature to measure the Mode I fracture energy of timber specimens. Ostapska and Malo [15] applied to timber the wedge splitting test method that was proposed by Brühwiler and Wittmann [16] for concrete. However, this test method is complex and laborious if only fracture energy is required [15]. Franke and Quenneville [17] applied the compact tension shear (CTS) test setup, which was proposed by Richard and Benitz [18], to Radiata Pine Laminated Veneer Lumber (LVL) and sawn timber. The advantage of the CTS is that either Mode I, Mode II or mixed Mode fracture energies can be measured with one test rig by changing the angle of the applied load. However, the CTS specimens must be carefully prepared with high accuracy to avoid that unsymmetrical loading occurs which would significantly affect the applied stress and resulting fracture energy [17]. In addition, De Moura et al. [19], applied the double cantilever beam (DCB) test for fracture Mode I to Pinus pinaster sawn timber and stable crack propagations were achieved.

The most adopted method to measure the Mode I fracture energy of timber samples was proposed by Gustafsson [20] and was used in [17, 21, 22]. It is referred to as single end notched beam specimen (SENB). A notched specimen is glued to two pieces of timber to form a beam. The specimen is loaded in three-point bending, forcing the crack to open and propagate. Due to the gluing involved in preparing the specimens, the manufacturing process is time-consuming if a large number of tests are required. Ardalany et al. [21] improved the setup and replaced the side timber pieces with steel sections to which the notched timber specimens can easily be connected to, significantly simplifying the manufacturing process. A counterbalance weight is placed on each steel section to offset the effect of the self-weight of the test rig into the calculations of the fracture energy. This method was used herein due to its simplicity and its common adoption for timber.

The Mode I tested samples are presented in Figure 4 (a) for the TL crack system and Figure 4 (b) for the glueline crack system. In Figure 4 (a), 100 mm deep × 90 mm wide × 44 mm thick samples were produced. To produce the 44 mm thick samples from the 22 mm thick boards, two SPG pieces, cut from the same board, were face glued together. All boards were selected for grain orientation so that the cracks developed in the chosen system, with the orientation shown in Figure 4 (a). For each sample, (1) a 5 mm thick × 60 mm deep notch was cut by a V-shaped blade in the middle of the sample from which the crack can initiate and (2) two 25 mm deep side notches were cut to connect the sample to the test rig shown in Figure 5 (photo) and Figure 6 (schematic).

In Figure 4 (b) for the glueline crack system samples, four 22 mm thick pieces were glued together to form an 88 mm thick glulam. The two middle pieces came from the same sawn board and were selected to have the grain orientation relative to the glueline making an angle of 1-4 degrees and converging towards the glueline. This configuration encourages the crack to propagate along the glueline as explained in [23, 24]. A thin adhesive tape was positioned over 60 mm on the two middle pieces before gluing to prevent adhesion and create a notch equivalent to the samples shown in Figure 4 (a) and from where the crack can propagate. The produced samples were 100 mm deep × 88 mm wide × 44 mm thick sample with the orientation shown in Figure 4 (b). Two 25 mm deep side notches were cut to connect the sample to the test rig as shown in the figure.

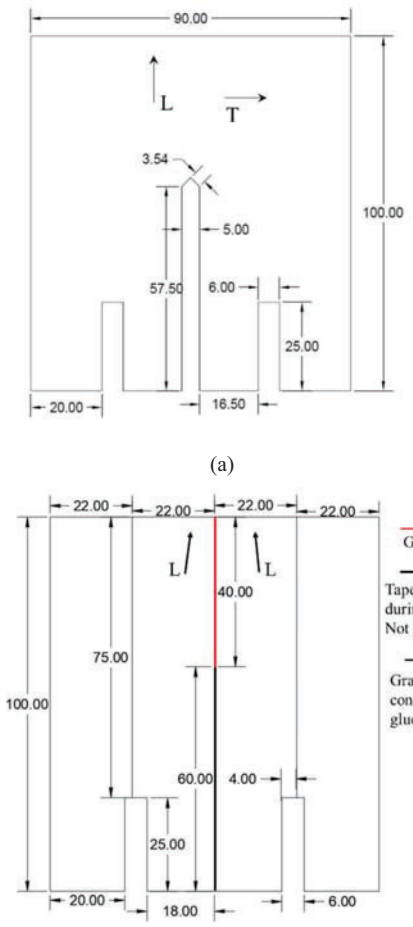

Figure 4: *Sample geometry for (a) TL and (b) glueline crack systems (unit in mm)*

The samples were then connected to two aluminium beams, as shown in Figure 5 (photo) and Figure 6 (schematic) to form a beam. The beam was positioned on two roller supports to be loaded in 3-point bending in a 100 kN capacity INSTRON universal testing machine fitted with a 2.5 kN load cell. A half-round was connected to the load cell to load the specimens at mid-span. Counterbalance weights were also used at the extremity of the aluminium beams to offset both the self-weight of the timber samples and the beams themselves.

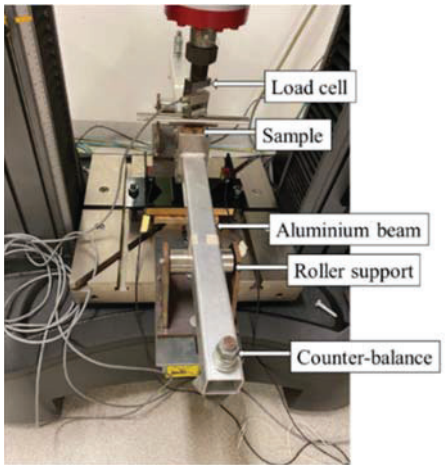

Figure 5: *Experimental setup for fracture Mode I*

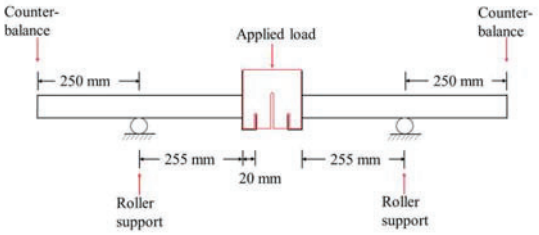

Figure 6: *Fracture Mode I test setup sketch*

A loading rate of 8 mm/min and 1.2 mm/min were selected for TL and glueline crack system samples, respectively, to target failure in 3-5 mins.

The Mode I fracture energy G_{If} was calculated as [22, 25], as.

$$G_{If} = \frac{Q}{h_c b} \quad (1.)$$

where Q is the work performed to fully fracture the sample and calculated from the load-displacement curve, h_c is the measured depth of the specimen above the crack tip and b is the measured specimen thickness. Note that despite the displacement provided by the testing machine may different to the actual displacement of the specimens, as outlined in [26], the testing machine behaves linearly and the work performed by the testing machine is equal to the work needed to fully fracture the samples.

2.3 STATISTICALLY ANALYSIS

After the fracture energy was obtained, a one-way ANOVA statistical analysis was conducted to determine whether there was a statistically significant difference between the mean of various moisture content groups.

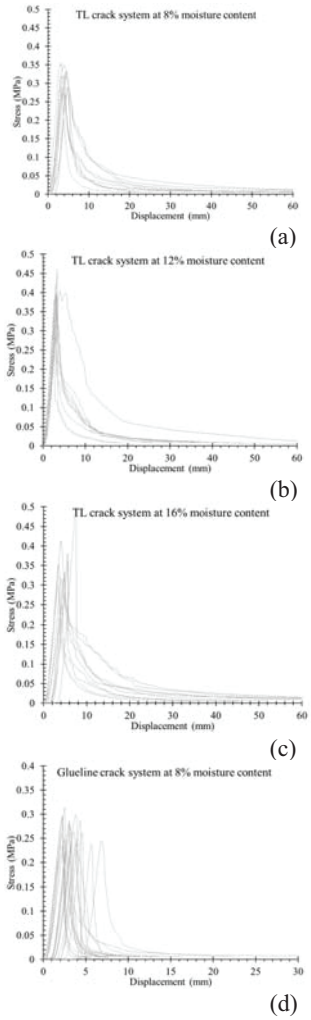
https://doi.org/10.52202/069179-0064

3 RESULTS AND DISCUSSION

3.1 FRACTURE MODE I TEST RESULTS

The stress-displacement curves for all the fracture Mode I tests relative to the different crack systems and moisture contents are presented in Figure 7. Nominal and actual moisture content, average measured fracture energies, with associated coefficient of variation (CoV), are summarised in Based on test results presented in Table 1, the Mode I fracture energy in the TL crack system is about four times higher than the fracture energy of the gluelines. This likely reflects the difficulty in gluing this species [5] and indicates that the fracture would propagate faster in the glueline than the timber.

Table 1



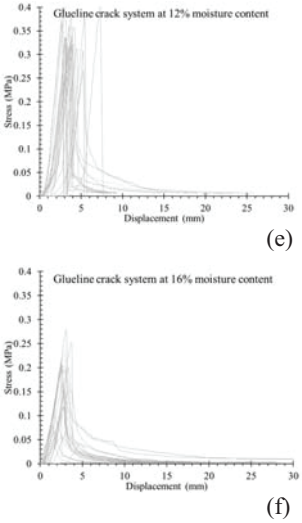


Figure 7: *Load-displacement curves for the Mode I fracture energy tests for TL crack system at (a) 8%, (b) 12% and (c) 16% moisture content, and glueline crack system at (d) 8%, (e) 12% and (f) 16% moisture content*

Based on test results presented in Table 1, the Mode I fracture energy in the TL crack system is about four times higher than the fracture energy of the gluelines. This likely reflects the difficulty in gluing this species [5] and indicates that the fracture would propagate faster in the glueline than the timber.

Table 1: *Fracture Mode I test results*

Crack system	Moisture content *(%)*			Fracture energy G_{If}		
	Nominal	Actual	CoV *(%)*	No. of tests	Mean *(N/mm)*	CoV *(%)*
TL	8	8.3	2.2	10	1.99	44.4
	12	12.5	2.3	10	2.02	55.5
	16	15.8	2.0	10	2.31	42.6
Glueline	8	8.2	3.5	20	0.46	38.1
	12	12.4	1.9	20	0.56	32.0
	16	16.1	1.6	20	0.42	49.6

The results from one-way ANOVA statistical analyses between the different moisture content groups show that for the fracture energies of (1) the TL crack system: $F(2,27) = 0.318$, $p = 0.7301$, and (2) the glueline crack system: $F(2,57) = 1.913$, $p = 0.157$. This implies that there was no statistically significant difference between group means for both TL and glueline crack systems, and therefore that the Mode I fracture energy is independent

of the range of moisture content analysed for both crack systems. This result also indicates that the fracture energy does not seem to follow the same trend as the "common" mechanical properties which vary with the moisture content. According to [27], the difference in mechanical properties between 8% and 16% would be of 27%.

Since it is found statistically that the Mode I fracture energy in both TL and glueline crack systems for SPG is not sensitive to moisture content, the average fracture energy of the three moisture content groups would be taken as future numerical model input.

Figure 8 shows the typical failure modes for the Mode I fracture tests. The cracks initiated either at the tip of notch or non-glued area, and propagated up straight or along the glueline for the TL and glueline system samples, respectively.

(a) (b)

Figure 8: *Fracture Mode I typical failure for (a) TL system and (b) Glueline system*

3.2 COMPARISON TO OTHER STUDIES

Table 2 compares the fracture test results to published studies.

Leka [28] applied the same test setup to the same material presented in this paper and found an average fracture energy 37.9% lower than the one in Table 1. Leka [28] tested both TL and RL crack systems, all together (i.e., with no distinction between the two systems), which could explain the above difference. Franke [17] measured the Mode I fracture energy of softwood Radiata Pine in the TL crack system, which resulted in a fracture energy 74.4% lower than this study. Ammann [24] conducted European beech hardwood glulam glueline fracture tests, with boards bounded with RF as in the present study. The fracture energy presented in Table 1 was only about half compared to Ammann's [24] tests, with 50% of the tests failing in timber rather than glueline in [24].

Table 2: *Mode I fracture energy from other studies*

Species/ type	Test setup	Crack system	Fracture energy (N/mm)	Reference
SPG sawn boards	Three-point-bending	TL	2.11	This study
SPG sawn boards	Three-point-bending	TL/RL	1.53	[28]
Radiata Pine LVL	CTS	TL	1.21	[17]
SPG Glulam	Three-point-bending	Glueline	0.48	This study
European beech Glulam	DCB	Glueline	1.00	[24]

4 CONCLUSIONS

The Mode I fracture energies of SPG sawn timber in the TL crack system and associated gluelines at various moisture contents were measured in this paper. The sensitivity of the fracture energy to the moisture content was analysed statistically. It was found that the average Mode I fracture energies were of 2.11 N/mm and 0.48 N/mm for the TL and glueline crack systems, respectively. The statistical analysis (one-way ANOVA) showed that the Mode I fracture energy of the analysed crack systems was not sensitive to moisture content variation. Therefore, a unique value can be considered for future numerical models which simulate crack initiation and propagation of SPG glulam during the delamination test.

ACKNOWLEDGEMENT

This research was supported by the Australian Centre for International Agricultural Research, project FST/2019/128. The authors would like to thank the technical team at the Salisbury Research Facility of the Queensland Department of Agriculture and Fisheries (DAF) for helping with the specimen preparation and the Griffith University technical team for manufacturing the testing jigs.

FLEXURAL REINFORCEMENT OF TIMBER ELEMENTS ON-SITE WITH PRF ADHESIVE AND WOOD-BASED PRODUCTS

Andreas Stenstad[1], Karl Christian Mahnert[2], Kristine Vik[3]

ABSTRACT: In this study, the potential application of a two-component phenol-resorcinol-formaldehyde adhesive for on-site reinforcement of glued laminated timber (GLT) and a recovered spruce beam was investigated. Different spread rates (500 – 2000 g/m^2), means of pressurization of the bond lines (clamps, screws and the reinforcements own mass) were applied to establish bond lines between the substrate to be reinforced and the reinforcements, GLT and plywood (PLW). The surface conditions (not planed, partly coated/ sanded, varying surface moisture content) were chosen to resemble situations that might be encountered during on-site reinforcement. The bond lines of two of the 11 different combinations fulfilled the required shear strength according to EN 14080. The investigations show that thicker bond lines and low pressure on the bond lines result in lower bond strength. Coating and partial removal of the coating by sanding are expected to have amplified the effect of the chemically weak boundary layer. Bond lines between materials with similar surfaces yield higher shear strength compared to bond lines between materials with differing surfaces.

1 INTRODUCTION

1.1 BACKGROUND

There are several different motivations to reinforce timber elements. The first one, reinforcement of glulam beams during production serves the purpose of increasing the span of that beam by replacing the outer lamellae with lamellae of hardwood or engineered wood products [1, 2], steel or aluminium [3, 4 5], natural fibres (hemp, flax, basalt, bamboo etc.) [6] or glass fibre reinforced polymers [7]

The second motivation might be to reinforce elements of load-bearing structures after mechanical or biological damage [8] as well as after boring of holes for ventilation and sewage pipes [9]. To avoid the reinforcement of regular glulam beams with holes, [10] propose the use of GLT-LVL composite beams which they proved to make reinforcement of one or multiple large rectangular multiple holes obsolete.

As the term circular economy finds its way into the building industry, the third scenario, reinforcing existing wooden structures to upgrade them for change of use or after changes in regulatory specifications for instance an increase in snow or wind loads as reaction to climate change, comes into play. To increase the lifetime of structural timber elements such as trusses or floor beams by on-site flexural reinforcement, the following approaches are described in the literature:

1) Application of self-tapping screws to avoid splitting of glulam along the grain [11, 12, 13].

2) Inserting of glued-in rods in the wooden element, a technique that has been successfully used for almost 40 years, a comprehensive state of the art report has been presented by [14]. The geometry of the timber, the adhesive area and the rod area, the size of the anchoring zone, the material stiffness and strength, fracture mechanical properties of timber and adhesive, variability of all properties and loading conditions as well as other parameters like wood species and manufacturing practices are defined as key parameters for the load bearing capacity of glued-in rod connections [15]. The rods must be fixed with an adhesive system that provides a continuous bond between the reinforcement and the timber, fills voids and cavities and is able to transfer and sustain loads. Epoxy resins are identified as specifically suitable as structural adhesives in repair [16], acrylic, polyurethane and phenol-resorcinol-formaldehyde adhesive types showed cohesive adhesive failures of adhesion failures [8]. However, the development of adhesive systems is ongoing, and it is obvious that these findings do not represent the state of the art within adhesive technology.

3) Addition of fibre reinforced polymers as described by [17] who tested intentionally damaged timber beams from a 32-year-old storage building reinforced by two types of carbon fibre reinforced polymer (CFRP). The reinforcement yielded an improvement in load-carrying by up to 184% compared to the controls without reinforcement. [18] studied the effect of combining basalt and carbon fibres as reinforcement of timber beams. They compared different grammages of basalt fibres and

unidirectional and bidirectional carbon composites. The results showed better effect of bidirectional fabrics compared to unidirectional fabrics and an increase of the beam stiffness with increasing grammage of basalt fibres. Besides grammage and orientation of the components of a CFRP, prestressing of the sheets was found to increase the bending strength of the reinforced beams significantly compared to those beams that were reinforced with non-prestressed CFRP was found [19].
4) Addition of wood-based panels [20].

1.2 FOCUS OF THIS STUDY

Generally, the reinforcing elements can be attached to the structural element by mechanical fixings, structural adhesives, or a combination of both to hold the reinforcing element in place and apply pressure during the curing phase of the adhesive.
When reinforcing on-site, engineers normally only consider load transfer due to mechanical fasteners. Adhesives are not considered due to uncertainty linked to the application process and whether the quality of the bond line is sufficient to enable the transfer of the load from the substrate to the reinforcement. There is a need for a better understanding on how on-site reinforcement using adhesives can be performed, and to identify the limitations. Currently only EN 17481 [21] covers adhesives explicitly for on-site repair of timber structures. Two-component epoxy and polyurethane adhesives which fulfil the requirements given in the standard are approved for the repair of cracked timber structures. However, two-component phenol-resorcinol-formaldehyde (PRF) adhesive systems which are widely used in the production of block glued glulam according to EN 14080 [22] might be suitable alternatives due to the ease of their application and the gap filling properties.
The aim of this study was to characterize the shear strength of the bond line between solid wood substrates of various qualities and selected wood based reinforcing elements.

2 MATERIALS AND METHODS

2.1 PREPARATION OF THE SHEAR SAMPLES

Pieces of recently produced commercial spruce glulam (GLT) and parts of a recovered spruce beam from an old barn were reinforced with GLT or plywood plates (PLW). A total of 18 sample blocks were prepared.

2.1.1 Materials to be reinforced

Two of the 11 GLT pieces (48 x 250 x 10400 mm) (b x h x l) were conditioned to 9-10 % (L) and 23 % (H) superficial moisture content. The remaining GLT samples were stored at 20 ˚C and 65 % relative humidity (M), one half of the surface of two of those samples was coated with a wall paint (C). The coated surface of one of the pieces was partly sanded (C+S).
Five pieces from a recovered spruce beam (RSB) (92 x180 x 152 mm) (b x h x l) were recovered from an old barn and stored at 20˚C and 65 % relative humidity prior to production of the sample blocks. Three of those pieces were sanded prior to the reinforcement.

2.1.2 Reinforcement

The GLT (36 x 250 x 10400 mm) and the pine plywood (PLW) (9 ply, 12 mm thickness) were stored at 20˚C and 65 % RH.

2.1.3 Assembly of sample blocks

The reinforcing element was bonded to the material to be reinforced with the PRF-adhesive Prefere 4094 and the hardener Prefere 5827, both supplied by Dynea AS. Adhesive and hardener were mixed at a ratio of 100:20, the application rate was varied between 500 g/m^2 to 2000 g/m^2. The adhesive was applied one-sided. Screws (5.0 x 50 mm) (SCR) (Figure 1), clamps tightened by hand (CLA) or the reinforcing elements` own weight (OW) provided pressure during curing of the adhesive.

Figure 1: *Sample blocks of two pieces of split GLT pressurized with screws.*

2.2 SHEAR TESTS OF BOND LINES

The samples were cut from the sample blocks at least 20 mm from the edges (Figure 2). Compressive shear strength (CSS) was tested according EN 14080 [2], Annex D (Figure 3). The shear area for the bond line was approximately 50 x 50 mm.
The Tukey-Kramer test and t-test in JMP 10 (JMP Statistical Discovery LLC) was used for respectively overall or pairwise statistical analysis of the data.

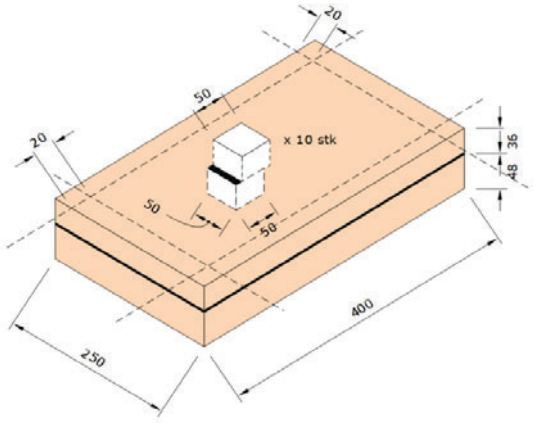

Figure 2: *Production of samples to test compressive shear strength.*

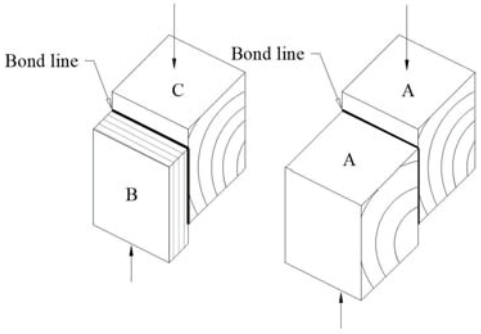

Figure 3: *Samples for compressive shear test of bond lines*

3 RESULTS AND DISCUSSION

3.1 REINFORCEMENT OF GLULAM

The average CSS of the bond lines between the material to be reinforced and the reinforcement was 7.1 N/mm^2 with significant difference between reinforcement GLT (7.6 N/mm^2) and PLY (5.5 N/mm^2), (Table 1). This can be explained by the combination of different surfaces in the samples reinforced with PLW compared to the similar surfaces of the reinforcement with GLT. Treatments 7 and 10 fulfilled the requirements for CSS in timber structures according to EN 14080. Detailed results are presented in Table 2.

Pressurizing the bond line with screws or clamps compared to the reinforcements` own weight increased the CSS of the bond lines significantly (Figure 4). The same applies for the wood failure percentage. This is most likely due to the higher pressure applied on the adhesive joint during curing by screws and clamps compared to the mass of the plywood panel. Thus, the latter results in lower penetration of the adhesive into the wood surface compared to the first, yielding a stronger bond and higher wood failure percentage.

Table 1: *Average compressive shear strength (CCS) of the bond lines between the recovered spruce beam and plywood (PLW) as reinforcement, S: sanded, OW: own weight.*

#	Treatment Name	Samples	CSS [N/mm^2] $\bar{x}$	σ_x
1	GLT(C)_GLT_1000_OW	10	4.3	2.2
2	GLT(C+S)_GLT_1000_OW	10	4.6	2.3
3	GLT(H)_GLT_1000_OW	10	4.3	1.1
4	GLT(H)_GLT_2000_OW	10	6.2	0.7
5	GLT(L)_GLT_1000_OW	9	6.3	1.1
6	GLT(L)_GLT_2000_OW	10	5.7	1.1
7	GLT_GLT_1000_CLA	10	7.4	0.6
8	GLT_GLT_1000_SCR	10	7.5	0.5
9	GLT_GLT_500_CLA	10	7.4	0.9
10	GLT_GLT_500_SCR	10	7.9	1.0
11	GLT_PLW_500_SCR	14	5.5	1.3

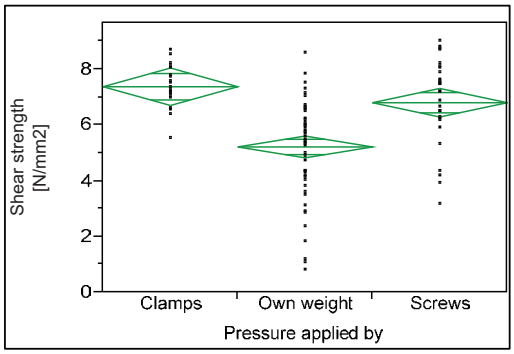

Figure 4: *Compressive shear strength of bond lines between GLT and reinforcement as result of pressurizing method*

A spread rate of 500 g/m^2 resulted in significantly higher CCS than a spread rate of 1000 g/m^2 (6.8 N/mm^2 versus 5.8 N/mm^2) (Figure 5), the same applies for the wood failure percentage. The reason for that is the supposedly thicker bond line resulting from the higher application rate. The lower shear strength of thicker bond lines compared to thinner bond lines is a known fact which is accounted for by the lower requirements for tensile shear strength of thick bond lines compared to close contact bond lines in EN 301 [23].

16	RSB(S)_PLW_2000_OW	4	5.6	1.9	98	90	3	0	1/4

An influence of the superficial moisture content of the GLT on the CSS was not found. High superficial moisture content, however, resulted in significantly lower wood failure percentage compared to medium and low surface moisture content. This might be due to water saturation of the fibres on the surface of the wetted sample hindering the penetration of the adhesive followed and the subsequent anchoring in the superficial fibres.

Coating of the GLT and sanding of the coated surface resulted in significantly lower CSS of the bond lines compared to the bond lines between untreated GLT and reinforcement (Figure 6). This result can be ascribed to the coating/ coating and sanding of the surface which intensifies the effect of the chemically weak boundary layer on the wooden surfaces that were not machined [24]. [25] did not find significant differences between the tensile shear strength of bond lines between substrates that were prepared by sanding on a professional sander and substrates prepared by planing. Sanding in the current study, however, was conducted manually, lacking the homogeneity of machine sanding.
Our findings underpin the importance of clean surfaces, often accomplished by machining of the material, as prerequisite for good bonding results. This is an issue especially when it comes to the reinforcement of aged wood structures with surfaces that are not accessible for machining.

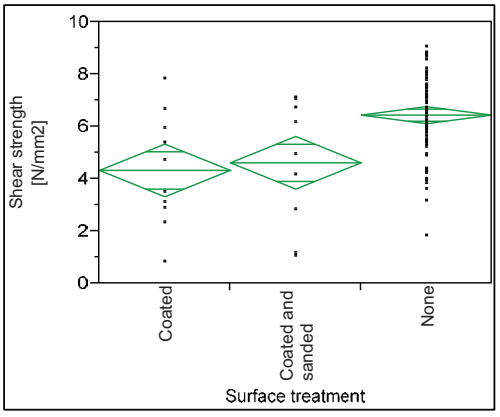

Figure 6: *Influence of surface treatment on the compressive shear strength of the bond lines between GLT and reinforcement*

3.2 REINFORCEMENT OF RECOVERED WOOD

The average CSS of the bond line between the recovered spruce beam and PLW was 3.0 N/mm², see Table 3 for average results per treatment. Neither spread rate nor sanding of the surface influenced the CSS or the wood failure percentage. None of the treatments fulfilled the requirements for CSS given in EN 14080. This is most likely due to the neglected machining of the recovered spruce beam with the resulting chemically weak boundary layer [25]. Ageing of the bulk wood material [26] may contribute, too.

https://doi.org/10.52202/069179-0065

3.3 COMPARISON OF REINFORCEMENTS

This comparison covers exclusively samples from blocks consisting of GLT reinforced with GLT or PLW with a spread rate of 500g/m² and bond lines pressurised by screws. Reinforcement with GLT resulted in bond lines with significantly higher CCS compared to reinforcement with PLW (Figure 7). This finding is in line with the significant difference between the CSS of the bond lines of all samples reinforced with GLT compared to PLW.

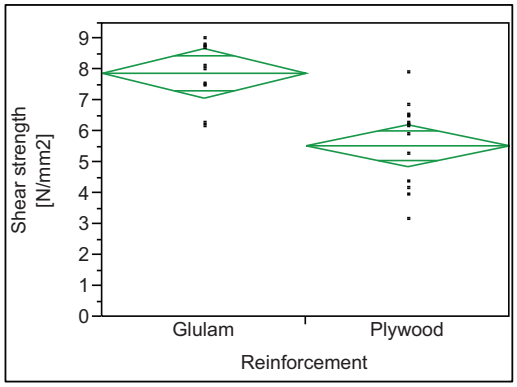

Figure 7: *Compressive shear strength of reinforcement with GLT compared to PLW*

4 CONCLUSIONS

The results suggest the potential of a combination of PRF adhesive and wood-based products as solution for on-site structural reinforcement of glued laminated timber and recovered wood. This application, however, implies neglecting generally accepted principles for wood bonding such as machining of surfaces and controlled application of pressure. These deficits were resembled by the design of the samples and explain the deficient bond strengths of most of the samples compared to the requirements defined in EN 14080. Further investigations should include higher numbers of replicates and reference samples prepared according to current practice of wood bonding.

Another aspect of reinforcing wooden structures on-site, especially in countries with extended periods of low air temperature, is the influence of these low temperatures on the curing of an adhesive and the definition of thresholds for reasonable use of the adhesives. This parameter should also be included in future research.

WEAR RESISTANT PROTECTION OF WOODEN POLES IN ADVERSE ENVIRONMENTS

Thomas Lindblad[1], Knut Magnar Sandland[2], Andreas Treu[2]

ABSTRACT: Wood protection is needed for wood products in outdoor applications due to biodeterioration of this natural material. While bulk treatments of wood have their disadvantages related to impregnation and costs, coatings can protect wood products to large extent. However, harsh environments such as outdoor use classes 3-5 can lead to unfavourable levels of wood moisture content because of the permeable character of most coatings. Water-tight coatings could be an alternative for certain areas of use. This treatment has been identified as a promising approach for prolonging service life in adverse environments. However, installation in larger scale may need connections and fasteners which perforate the coating material. This study shows various solutions of bolt connections including sealants which can be used for installations without significant penetration of water into the wood core. The study also makes reference to a full-scale installation survey covering the same time period, as well as an ageing test of the same coating.

KEYWORDS: coating, outdoor applications, poles, sealant, wood protection

1 INTRODUCTION

Wood protection in adverse climates is obtained by bulk treatments using biocides or wood modification agents. Both approaches require penetrability of the wood substrate and can be challenging with regards to environmental concerns or price. Being independent of the refractory behaviour of some wood species and avoiding any form of impregnation treatment is therefore an asset. However, exposure of unprotected wood products in harsh environments such as outside use, the use in ground contact and sea water contact are particularly demanding. Outside use areas are defined by the incidence of rain and changes in temperature and relative humidity, which can lead to deterioration of unprotected products by fungi and insects. Exposure of wood products in ground contact is dominated by bacteria and fungi due to the constant moist surroundings. Products, which combine both use classes, such as telegraph poles, need therefore not only wood protection for above ground (use class 3), but also in-ground contact (use class 4). In addition, the marine environment (use class 5) represents a different challenge which can only be prevented when the attachment of shipworm larvae on the wood surface and the boring through the wood substrate can be avoided. In addition, gribble can attack the wood surface area, which leads to extensive damage as well [1].

The use of coatings is beneficial for products in outdoor use areas (use class 3-4) and could even prevent marine borer attack (class 5). Coatings help to drastically reduce the uptake of water by the underlying wood substrate, and when airtight it also limits the access of oxygen. This is widely used on wooden facades of many private houses in the Northern European countries. However, coatings for cladding are usually not fully watertight, but allow an exchange with the surrounding relative humidity. Measurements of wood moisture content underneath a wood coating prove the permeable character of some coating types [2,3].

Water-tight coatings could be an alternative for certain areas of use. One example is the full coverage of wooden poles with polyethylene (PE) via an extrusion process [4]. The use of several millimetres of PE on the wood surface leads to high resistance against wear of the coating and to protection against deterioration of the wood core. Given the shore D hardness of 62, it also neutralises the risks of marine borer attacks. WOPAS uses such PE extrusion technology to wood which can be of different shape, square, cylindrical, or tapered. The wood is first dried to a target moisture content of 14%. WOPAS standard PE thickness for marine piles and pole building poles is 6 mm, and for power poles 9 mm. The thicker dimension for power poles stems from the frequent use of climbing shoes causing 2-3 mm recess. However, the installation of these poles often makes it necessary to perforate the protective PE layer if bolts and other mounting parts need to be connected. Sealing of the joints need to make sure that water and oxygen ingress is prevented. However, the type of technical solution for the fastening and the sealing material needs to be investigated.

The aim of the study was to analyse different fastening and sealing solutions in both a short-term submersion test and a long-term outdoor weathering and to select the solution where water ingress could be strongly reduced or prevented. Furthermore, the specific objectives were to include recommended solutions, non-recommended solutions, deliberately damaged coating, references without penetration and references for full scale

installations covering the same time period, as well as an ageing test of the PE.

2 MATERIAL AND METHODS

2.1 BOLTS AND FASTENERS

Starting in May 2019, different connection solutions (see table 1 and example in figure 1) were analysed using water submersion test at the NIBIO laboratory for 1600 hours. The samples were stored between submersion cycles in the freezer and in room climate. Thereafter, the test pieces were exposed to outdoor climate for 700 days (figure 3). Measurements were done twice per year. The weight change during submersion and exposure were measured gravimetrically using a 0.1 g readability scale. (Mettler ToledoPG5002-S DeltaRange), except for test series 21-25 where a 0.5 g readability scale was used (KERN DE 6K0,5N).

Table 1: *Connection material used for the test.*

Connection type	Name

Figure 3: *Exposure to outdoor climate.*

2.2 FULL-SCALE INSTALLATION

A 40 kV overhead line with 108 WOPAS poles was installed early 2019 and finalised in May the same year (see figure 4). The fitters used WOPAS recommended fasteners, i.e. pin bolts with curved washer and mastic, French bolts with mastic and building board screws with gasket. The installation was surveyed in June 2022 by a third-party wooden pole expert, representatives from the grid owner and WOPAS. The time frame between installation and survey equals the time frame for the accounted laboratory tests in 2.1.

Of the 108 poles a selection of eight poles was installed in different environments, such as arable land, forest, swamp, rocky ground and gravel. Several methods were used for the survey, such as classical hammer sound surveying, non-destructive electronical moisture meter by Tramex and drilling resistance measurement by use of an IML Resi F400-SX. Drilling was either made just above the ground or close to penetrating fittings, as shown in figure 5. The drilling resistance measurement method enabled recording and print outs, as shown in figure 11. Neither the drilling resistance measurements, nor the survey in general, showed sign of deterioration of the poles.

Figure 4: *Fitters from Linde Energi using French bolts with mastic to prevent sliding and rotation of cross arm fitting.*

Figure 5 *Drilling measurement using a resistograph, close to pin bolt with curved washer and mastic.*

2.3 AGING TEST

Critical to the sealing function is the integrity of the PE over time. Test laboratory CESI of Milan, Italy, on behalf of power grid owner Enel Grids has conducted a test programme of 8 repeating steps during 2022. In addition to mechanical tests like impact protection[5] (IK), bending fatigue and flame test, an ageing test was made to simulate outdoor daily cycle. The testing was made by placing a pole in an insulated steel tube filled with water, figure 7. The water temperature was controlled and varied between 20 and 80 °C (figure 6). The cycle consisted of 8 hours of heating and 16 hours of cooling. The thermal conditions of the cycle were described as consistent with climatic extremes to constitute an acceleration factor of the real stresses to which the pole is subject to in operation. The test was conducted for 1000 hours. The pole, sealed at the ends, is placed in a cylindrical chamber where water is circulated. The water was coloured to enable a subsequent verification of water ingress. At the end of 1000 hours the pole was extracted from the steel tube and inspected for cracks to the PE and welded end caps. The pole was then tested with a bending test to compare any deviation to other non-aged WOPAS poles. The PE layer was thereafter separated from the wood, and the moisture content of the wood was measured, as well as visual inspection tracing any coloured water penetration.

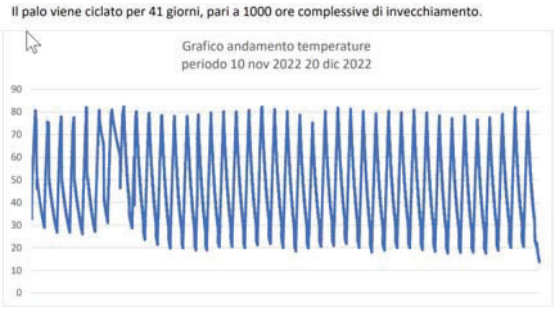

Figure 6: *Temperature variation during 1000 hours of water aging test.*

3 RESULTS

3.1 THE INFLUENCE OF BOLTS AND FASTENERS ON WATER UPTAKE

Minor weight changes during submersion and outside exposure were observed (figure 1 and figure 2). The water penetration through the used connections was therefore almost insignificant for all solutions except the use of bolts with insulation butty, which even showed mass loss during the exposure. This could have been caused by the different scale, which was used for these samples or by degradation of the washer. Reference poles with partly removed plastic coating showed higher water uptake during water submersion and outside exposure. The test proved the good performance of the sealants and underlines therefore the importance of the sealing material and the care during installation.

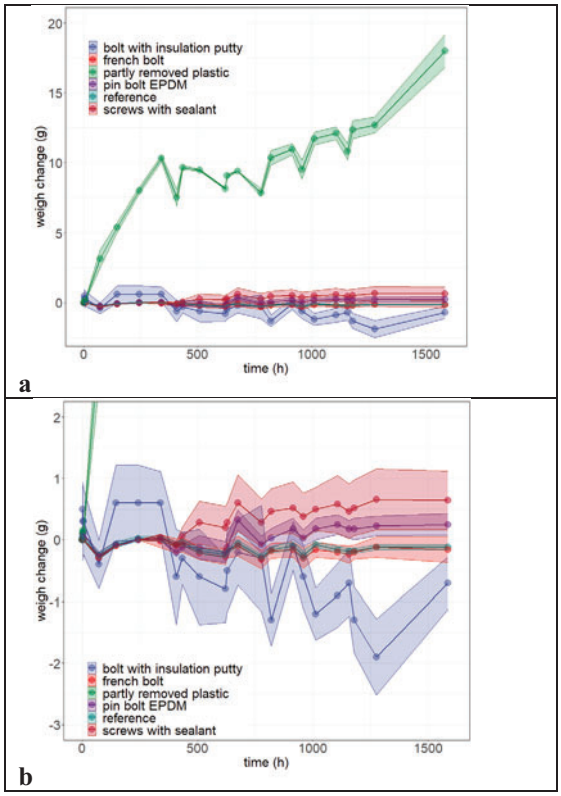

Figure 8: *Weight change due to water uptake during submersion test for more than 2 months. a) note the scale from 0-20, b) note the scale from -2 – 1. The colour-shaded areas show the standard deviation (N=5).*

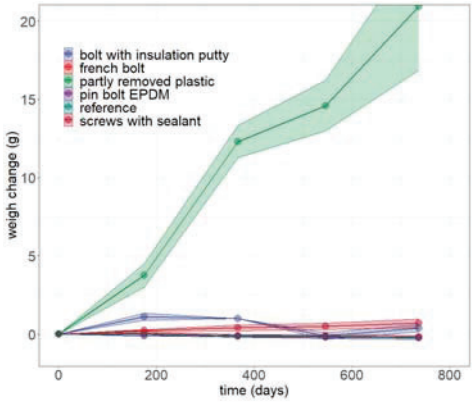

Figure 9 *Weight change due to water uptake during more than two years of outside exposure. The colour-shaded areas show the standard deviation (N=5).*

3.2 SURVEY OF FULL-SCALE INSTALLATION

The visual inspection showed no deviations. The construction was described as very well built by third party Vattenfall Eldistribution. The moisture measurements demonstrated no elevated values of wood moisture content. In addition, the resistograph showed no unusual values, which could indicate deterioration of wood components. See below the photograph of resistograph printouts, figure 11.

The hammer control noted two anomalous sounds, one behind a mark caused by the installation of the poles using excavator grab john (hydraulic pin grab on the back side of the bucket) and another at a random place. Both locations were examined with moisture measurement and resistograph, but without anomalous values. One hypothesis discussed was that the pressure from excavator grab john caused some kind of local sound change, and natural cracks that occur in the wood may have caused abnormal sounds as well.

Figure 10: *Anomalous sound from hammer was followed up using resistograph, in turn showing normal values.*

https://doi.org/10.52202/069179-0066

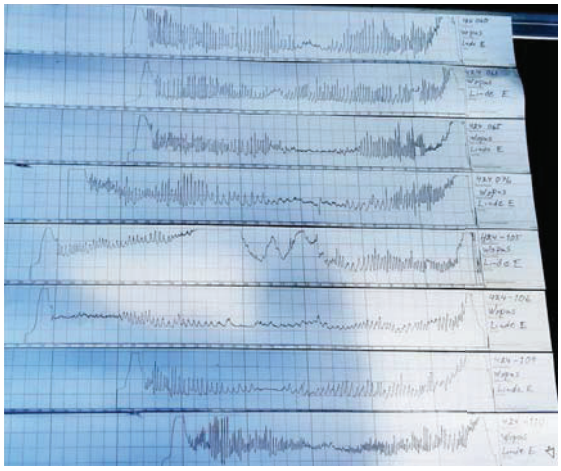

Figure 11: *Paper print-outs of drilling measurement using a resistograph*

3.3 THE RESISTANCE OF THE COATING TO HEAT AND WATER

After the aging test, the pole was tested for bending, impact (IK) and the PE was removed to measure the moisture level and for visual inspection of any coloured fluid. Even after the bending test, no damages were found on the PE, and no water ingress could be noted. The moisture level was observed at two positions, as shown in figure 12, and the moisture level was 10,5-10,7%.

It has been pointed out by CESI and Enel Grids that the specification and aging method have been defined by them for their test, and cannot be extrapolated.

Furthermore, it was described that the PE was well attached to the wood and is able to fill even the natural cracks. In this way the PE is not free to move, which was also verified during the torsion test.

The PE-welded end caps were considered the weakest point before the test. However, it demonstrated to be adequately robust for the intended use as power pole, both in terms of aging and impact. In fact, the impact protection rating corresponded to IK10 according to norm IEC 62262, or 20 Joule (weight of 5 kg from a height of 400 mm).

Figure 12: *Moisture content observation after the aging test*

4 CONCLUSIONS

Several connections through polyethylene coated poles were analysed during water submersion and long-term outdoor exposure. Sealant and careful installation play a crucial role for the long-term performance of installed poles in service. Various solutions of bolt connections including sealants can be used in large-scale installations. In addition, the performance in service as poles for electrical power lines shows promising results so far.

The characteristics and lifetime of polyethylene of PE100 quality is witnessed from water infrastructure, automotive, sea farming and other adverse environments. The combination with wood represents an interesting use, without the need for using biocides or wood modification agents.

ACKNOWLEDGEMENT

We are grateful for the support of the wooden pole experts Kenneth Stefansson and Arnold Solmar with Vattenfall Eldistribution, and the representatives from Linde Energi. Many thanks also to Enel Grids S.r.l. sharing data and Kema labs, CESI, S.p.A, Roberto Piccin performing tests with great dedication.

WOOD AND STEEL VISCOELASTIC DAMPERS: SHORT AND LONG-TERM PERFORMANCE

David W. Dinehart[1], Edward D. Bolte[2], David E. Lewicki[3]

ABSTRACT: The objective of this study is to characterize the performance and quantify the short-term and long-term differences between viscoelastic dampers constructed with steel and wood. Static and cyclic tests were conducted on steel and wood dampers utilizing 3M ISD-111 viscoelastic polymer. Initially, twelve specimens, six wood and six steel, were loaded statically to failure. Six dampers, three wood and three steel, were subjected to ten fully reversed cycles of sinusoidal displacement at various strains and frequencies. Twenty years later two of the dampers were retested under identical conditions to confirm material integrity and structural performance. For all dampers, the shear area of the VE was held constant, while the thickness varied. The initial static investigation demonstrated that the failure mode for all wood specimens was a shearing of the material at strains over 500%. There was no debonding of the VE material from the wood. After twenty years, the failure mode was delaminating from the wood at a strain of greater than 300%. The results of the cyclic tests showed good agreement between the stiffness and energy dissipations for the wood and steel dampers immediately after construction and twenty years later.

KEYWORDS: viscoelastic dampers, wood, energy dissipation, supplemental damping, polymer bond, time dependent

1 INTRODUCTION

Historically, viscoelastic (VE) dampers have been used exclusively in steel and reinforced concrete structures. Conventional VE dampers are constructed with the polymer bonded to steel plates which connect the dampers to the structure. With the recent increase in mid and high-rise structures constructed from wood, there exists a need to provide supplemental damping to wood structures.

2 BACKGROUND

When first implemented into the design of civil structures, viscoelastic dampers were aimed at decreasing the motion that the structure underwent because of wind. The original World Trade Center Towers in New York City, constructed in 1969, were the first applications of VE dampers in a tall building (Mahmoodi, 1969). The two towers used a combined 20,000 dampers made with VE material located between the lower chord of the floor system and the outside wall column at lateral bracing. VE dampers were utilized in the Columbia Center Building, located in Seattle, Washington, to reduce its acceleration levels (Keel and Mahmoodi, et. al. 1990; Samali and Kwok, 1995). The decision to use viscoelastic dampers in this structure was partially the result of how economic this material was for the overall cost.

The success of viscoelastic dampers in response to wind loading has led to the investigation of this material with respect to seismic activity. Research has shown that steel and reinforced concrete structures have seen improved performance through use of viscoelastic dampers. While wood structures are currently designed such that structural collapse is not a concern, they still experience considerable damage, both structural and nonstructural. A study conducted by Dinehart et. al. (1999a, 1999b) analyzed the performance of conventional shear walls to those constructed with viscoelastic dampers. This research concluded that there was significantly higher stiffness and energy dissipation ability displayed from the tests with viscoelastic dampers than the conventional shear walls.

The research previously conducted into the performance of viscoelastic material in wood structures has been promising, but not enough to fully justify implementation in wood structures. This paper discusses the performance of wood dampers made with viscoelastic material in both the short term and long term, as well as compares its performance to that of a similarly designed steel damper. The utilization of viscoelastic material in the design of wood dampers is an effective way to provide sufficient stiffness and energy dissipation capacity, while maintaining structural integrity. This VE design proves to

be successful in improving the performance of wood dampers not only in the short term, but it maintains its performance when investigated twenty years later. Furthermore, the evaluation of the steel damper confirms the durability of the viscoelastic material over time and its ability to withstand variable dynamic loading. Structures designed with viscoelastic dampers will not only have improved performance, but also decreased economic cost associated with maintaining these structures following seismic events.

3 TEST SPECIMENS

3.1 Polymer

This study utilized two specimens that were constructed and tested in 2000 and then tested again in 2021. The VE material used to construct these dampers was an ISD-111 VE polymer which was manufactured by 3M Corporation. It is important to note that this material is self-adhering. One damper, which will be referred to as "the wood damper", was constructed by adhering the VE material to a wood surface. The second damper, "the steel damper", had the VE material adhered to a steel surface. A double-lap configuration was used to create these dampers so they could resist load in pure shear when loaded axially.

3.2 Wood Damper

The wood damper was constructed by utilizing four-ply American Plywood Associated (APA) rated, 11.9 mm (15/32 in.) thick, plywood and Standard Spruce-Pine Fir (SPF) 50.8 mm by 101.6 mm (2 in. by 4 in.), to model the sheathing to stud connection. ISD-111 VE polymer with a thickness of 15.2 mm (0.6 in.) and a width of 50.8 mm (2 in.) was used to manufacture the wood damper and Grade 8 hex bolts were used opposite the VE material to fasten the damper to an A36 steel plate. Elevation and plan views of the wood damper can be seen in **Figure 1**.

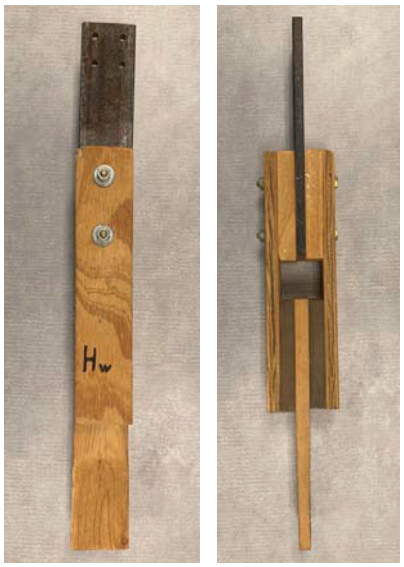

Figure 1: *Wood Damper*

3.3 Steel Damper

The steel damper was created in a manner consistent to that of the wood damper. The specimen utilized 9.5 mm (0.375 in.) thick, A36 steel and ISD-111 VE polymer with a thickness of 5.08 mm (0.2 in.) and a width of 50.8 mm (2 in.). Adjacent to the viscoelastic material, this damper was also fastened using four Grade 8 hex bolts. An example of a steel damper in the testing machine is presented in **Figure 2**. For both specimens, after the VE material was self-adhered, it was compressed to 20% of its initial thickness for 24 hours to ensure complete bonding, as instructed by the manufacturer.

Figure 2: *Steel Damper in test machine.*

3.4 Specimen Modifications

The wood damper was modified, as described in the following section, to allow for attachment to the test apparatus as. Two 6.35 mm (0.25 in.) thick A36 steel plates were added to the SPF Stud and then a third A36 steel plate was placed in between to allow for the damper to be gripped by the test apparatus. The same modifications were made on the opposite side of the damper to the existing 9.5 mm (0.375 in.) A36 Steel Plate. These modifications did not impact the integrity of the specimen, nor alter the results in a way that would make them incomparable to the results collected in 2000.

https://doi.org/10.52202/069179-0067

4 EXPERIMENTAL SETUP AND PROCEDURE

4.1 Testing Apparatus

All the tests conducted on the two dampers were done by an MTS TestStar Materials Testing Workstation. This apparatus has two hydraulic wedge grips that can handle a maximum load of 24.9 tons. The bottom grip functions as the actuator, which is controlled by both the load unit control panel and a multi-tasked TestWare SX program. It is powered by the hydraulic power supply, which provides pressure to the servovalves that then regulate the flow of fluid between the hydraulic power supply and the actuator in a closed loop control mode. An image of the test apparatus that was used in 2000 can be seen in **Figure 3**. A similar test apparatus was utilized again in 2021 for testing consistency.

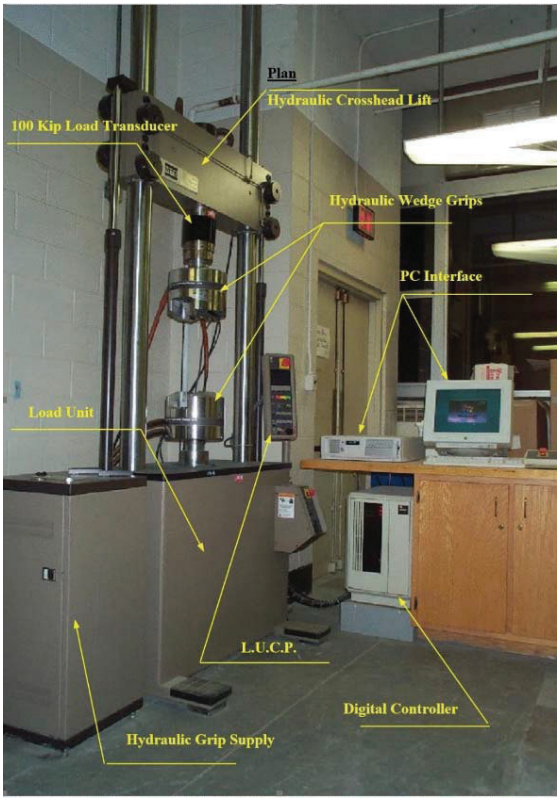

Figure 3: *MTS Workstation*

4.2 Displacement Protocol

The two dampers were subjected to 10 cycles under various frequencies and strains in 2000 and then retested in 2021 under similar frequencies and strains to evaluate their behavior and response. Temperature conditions for 2021 were chosen to ensure that the data would be comparable to the results obtained in 2000.

The wood damper was tested under the following conditions in both 2000 and 2021: 1.0 Hz at 10% strain, 0.5 Hz and 1.0 Hz at 20% strain, and 0.5 Hz at 80% strain. This produced four sets of data to be compared over time. The steel damper was tested at 1.0 Hz at 10% strain and 0.5 Hz at 80% strain in 2000 and then tested at the same strains and frequencies as the wood damper was in 2021. **Figure 4** shows the displacement protocol for the wood damper tested at 1.0Hz and 10% strain.

The tests were originally conducted at a temperature of 26.7°C, a condition that was recreated in 2021 to ensure testing consistency since the VE material is temperature dependent. Both specimens were removed from the testing apparatus between tests and allowed to rest for a predetermined time of thirty minutes to allow the damper to set before undergoing more testing, thus maintaining the integrity of each test's individual results.

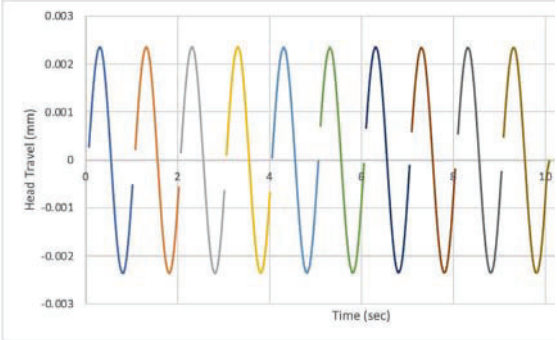

Figure 4: *Displacement versus time test input.*

5 EXPERIMENTAL RESULTS

The data collected from the tests were used to generate hysteresis loops, which display the cyclic response of the damper. **Figure 5** shows a hysteresis loop obtained for a single cycle.

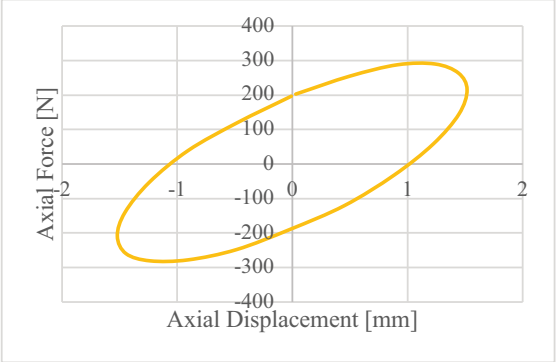

Figure 5: *Example hysteresis loop*

Hysteresis loops were created for each of the tests that were run on the dampers. The hysteresis loops produced from tests conducted at a frequency of 1.0Hz and 10%

https://doi.org/10.52202/069179-0067

strain are shown for the wood and steel dampers in **Figures 6 and 7**, respectively.

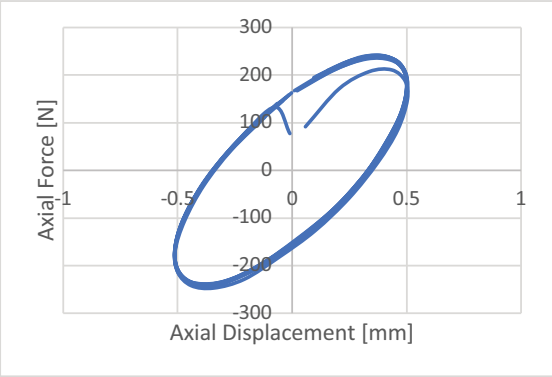

Figure 6: *Wood damper results from tests at a frequency of 1.0Hz and 10% strain*

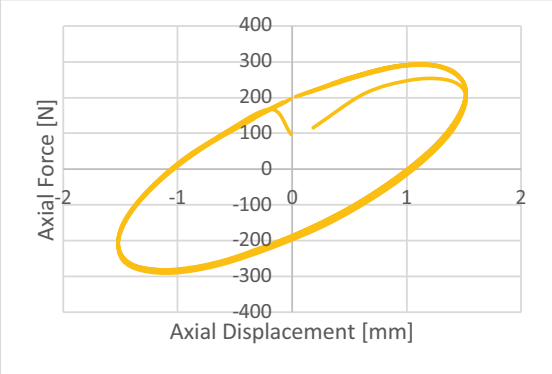

Figure 7: *Steel damper results from tests at a frequency of 1.0Hz and 10% strain*

The slope of the diagonal of the hysteresis loop is equal to the effective stiffness of that cycle. This was calculated using Equation (1):

$$K_{effective} = \frac{P_{x_o} - \bar{} P_{x_o}}{x_o - \bar{} x_o} \quad (1)$$

where P_{xo} = load correlating to the maximum displacement, $\bar{P}_{xo}$ = load correlating to the minimum displacement, x_o = maximum displacement, and $\bar{x}_o$ = minimum displacement.

The area bound by each of the hysteresis loops determines the energy dissipation of that cycle. This was determined utilizing Equation (2):

$$E_D = \pi \gamma_o^2 G'' A h \quad (2)$$

where γ_o = peak shear strain amplitude, G" = the loss modulus, A = shear area, and h = thickness of the VE material.

The hysteresis loops shown for the first cycle of the tests have lower values initially than the rest of the cycles which is the result of this being the initiation cycle for the test. At the completion of the final cycle, the hysteresis loop can be seen decreasing away from the other cycles', which is a result of the test ending and is not necessarily representative of a decrease in material performance. These trends were observed for all the tests conducted on the two dampers.

Average effective stiffness values were obtained for each of the tests conducted in 2000 and 2021 for the two dampers. The average effective stiffness was determined by calculating the mean effective stiffness over all ten cycles of a given test. The values obtained for the wood and steel dampers are shown in **Table 1** and **2**, respectively. A positive percent change value denotes an increase in the effective stiffness between the results obtained in 2000 and 2021.

Table 1: *Average Effective Stiffness (N/mm) for the Wood Damper*

Frequency	Strain	2000	2021	Percent Change
1.0 Hz	10%	115	141	22%
0.5 Hz	20%	93	105	13%
1.0 Hz	20%	119	133	12%
0.5 Hz	80%	81	92	14%

Table 2: *Average Effective Stiffness (N/mm) for the Steel Damper*

Frequency	Strain	2000	2021	Percent Change
1.0 Hz	10%	417	356	-15%
0.5 Hz	80%	283	240	-15%

The wood damper (**Table 1**) shows a relatively consistent increase in average effective stiffness from the tests conducted in 2000 to those conducted in 2021. The steel damper (**Table 2**) saw a 15% decrease in average effective stiffness for the two tests being compared.

The average energy dissipation capacity of the dampers was determined by calculating the area bound by the load-displacement ellipse using Equation (2) for each cycle and taking the mean over the ten cycles of each test. Average energy dissipation values for the wood and steel dampers from each of the tests conducted in 2000 and 2021 can be seen in **Table 3** and **4**, respectively.

https://doi.org/10.52202/069179-0067

Table 3: *Average Energy Dissipation (N-mm) for the Wood Damper*

Frequency	Strain	2000	2021	Percent Change
1.0 Hz	10%	746	786	5%
0.5 Hz	20%	2203	1919	-13%
1.0 Hz	20%	3141	2826	-10%
0.5 Hz	80%	30054	25137	-16%

Table 4: *Average Energy Dissipation (N-mm) for the Steel Damper*

Frequency	Strain	2000	2021	Percent Change
1.0 Hz	10%	316	114	-64%
0.5 Hz	80%	12685	10247	-19%

All the tests, with one exception, experienced a decrease in average energy dissipation from the results obtained in 2000 when retested in 2021. The exception to this trend was the wood damper when tested at a frequency of 1.0Hz and 10% strain, which saw a minor increase of 5%. The steel damper saw a decrease of 64% between 2000 and 2021 when tested at a frequency of 1.0Hz and 10% strain. This appreciable difference in performance is a byproduct of the low energy dissipation capacity of the steel damper under these testing conditions.

6 CONCLUSIONS

From these tests, the following conclusions can be drawn:
1. There was minimal change in the average effective stiffness of the two dampers over twenty years. The wood damper saw an average increase of approximately 15%, while the steel damper saw an average decrease of 15%.
2. The wood damper displayed consistent energy dissipation over time, only experiencing a decrease of about 10%, on average, when tested in 2021. Comparatively, the steel damper had minimal energy dissipation abilities when originally tested, which held true when the tests were conducted again in 2021.
3. The structural integrity of the two dampers held up well between tests and over time, with minimal damage observed between the two dampers.

The results from this research display the promise of using viscoelastic polymers more prominently in structural design of wood structures. These results show that there was no appreciable difference in performance between the steel and wood specimens. Based on this study, engineers can now investigate innovative applications of VE material in mid and high-rise wood frame structures without concern for the long-term effects of connecting VE material directly to wood. The next step in evaluating the performance of this material is to test it on a larger scale within a shear wall and compare the data to traditional shear walls.

ACKNOWLEDGEMENT

The authors greatly appreciate the support of Villanova University in providing and maintaining the equipment used in this study. Technical training of undergraduate researchers by Jeff Cook, Director, Structural Engineering Teaching and Research Laboratory, is also appreciated.

DURATION OF LOAD UNDER LONG-TERM BENDING LOAD OF LAMINATED VENEER LUMBER AND WOODEN I-BEAM

Ryuya Takanashi[1], Takahiro Tsuchimoto[2], Yoshinori Ohashi[3], Wataru Ishihara[4]

ABSTRACT: A wide range of wooden materials have been developed and used in construction. Although wood-based composites are important structural materials, few studies focusing on their creep rupture properties have been reported. We conducted long-term bending tests and investigated long-term allowable loading levels of laminated veneer lumber (LVL) and wooden I-beams made of LVL flanges and oriented-strand-board (OSB) web. Creep rupture of wooden I-beam specimens occurred in their LVL flanges. At the same time, LVL and I-beam specimens showed similar estimated long-term (50 years) allowable stress levels, which were equal or higher values than that of lumber. Survival analysis of the obtained data indicated no effect of the specimen type (LVL or I-beam) on survival distribution. The duration of load of wood-based composite materials could be estimated based on that of its component members.

KEYWORDS: Creep rupture, Bending, LVL, Constant environment

1 INTRODUCTION

Wood and wooden materials are important building materials. In recent years, timber construction has attracted increasing interest globally for use in many fields [1]. A wide range of wooden materials has been developed and used in construction to make various construction design. Wooden I-beams, which are often called I-joists, are I-shaped engineered wood structural members. They consist of top and bottom flanges, typically of laminated veneer lumber (LVL) or solid sawn lumber, and the web made of plywood or oriented-strand-board (OSB). I-beams possess multiple advantageous properties, such as stiffness, strength, and light weight, and are well-suited for long-span joist and rafter applications [2].

Wood materials demonstrate characteristic behaviors under constant load. When the stress is sufficiently high, failure eventually occurs under constant load. This type of failure is called creep rupture [3]. Creep rupture is an important factor in timber construction, it must be considered to ensure the long-term safety of wooden structures. Several studies have investigated the creep rupture properties of solid lumber [4, 5, 6], wood-based structural panels [7], and cross-laminated timber [8, 9]. However, few studies have been conducted on the duration of load of wood-based composite materials such as wooden I-beams. At the same time, the bending performance [10, 11, 12], shear performance [10], and creep performance [11, 13, 14] of wooden I-beams have been comprehensively investigated. To the best of our knowledge, there have been no reports on the duration of load of wooden I-beams. In addition, wood-based composite materials often have large dimensions, then it is difficult to conduct long-term loading tests because it requires special equipment for long-term loading and takes a long time for the test. If the relationship between the creep rupture properties of a composite and those of its element is elucidated, the creep rupture properties of wood-based composites could be estimated based on tests of their elements with small dimensions. In the present study, we conducted long-term bending tests on LVL and wooden I-beams composed of LVL flanges and OSB web to investigate and compare their long-term bending properties.

2 MATERIALS AND METHODS

2.1 SPECIMENS

2.1.1 LVL

LVL specimens were comprised of eleven-ply veneer of Japanese Larch (*Larix kaempferi*) glued with phenol resin adhesive. Specimens were 53 mm in width (veneer face), 35 mm in thickness (lamination direction), and 700 mm in length. The criterion for stress grading was 120E of Japanese Agricultural Standard for LVL (12.0 kN/mm^2 in mean and 10.5 kN/mm^2 in lower limit for bending modulus of elasticity). LVL specimens were collected from nine LVL motherboards with 1200 mm width. Figure 1 shows the cutting pattern of LVL specimens. Nine specimens were cut from each LVL motherboard: five side-matched specimens for a short-term loading test and four specimens for a long-term loading test. Thus, the total numbers of LVL specimens were 45 and 36 for short-term and long-term loading tests, respectively.

https://doi.org/10.52202/069179-0068

2.1.2 Wooden I-beam

Wooden I-beam specimens were composed of LVL flanges and OSB web glued together by resorcinol resin adhesive. LVL flanges had the same dimensions as LVL specimens and were end-matched with them. Thus, the number of I-beam specimens with side-matched flanges was 81: 45 for short-term and 36 for long-term loading tests. Figure 1 shows the cutting pattern of flanges of I-beam specimens. LVL flanges were 53 mm in width and 35 mm in thickness. The thickness of the OSB web was 9.5 mm. I-beam specimens were 235 mm in height and 4700 mm in length.

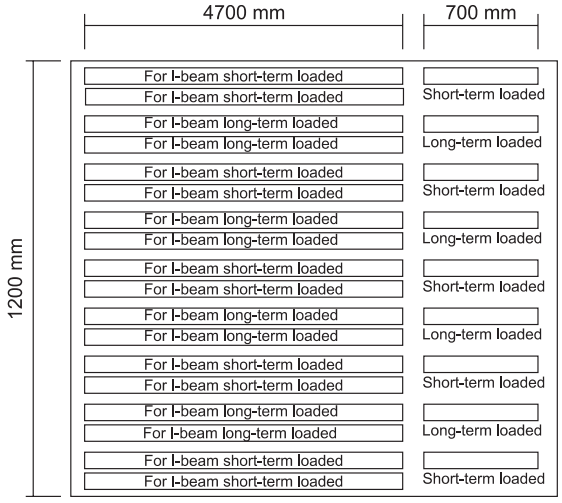

Figure 1: *Cutting pattern of LVL specimens from LVL motherboard*

2.2 SHORT-TERM LOADING TEST

2.2.1 LVL

LVL specimens were conditioned at 20°C and 65% relative humidity (RH) prior to the four-point bending test conducted using a testing machine (ORIENTEC Co. LTD; maximum loading capacity of 100 kN) in an unconditioned room. The specimens were loaded in the vertical direction to lamination at their third-point across a 630 mm supported span at a cross-head moving speed of 2 mm/min. Both the load (P) and displacement at the span center of a specimen from the ground (δ) were measured. Then, the bending modulus of elasticity (E_m) and the bending strength (σ_b) were, respectively, calculated as follows:

$$E_m = \frac{23\Delta P L_1^3}{108\Delta\delta b h^3} \quad (1)$$

$$\sigma_b = \frac{P_{max} L_1}{b h^2} \quad (2)$$

where P_{max} is the maximum load, ΔP is the load increase in an elastic range ($0.4P_{max} - 0.1P_{max}$ for this study), $\Delta\delta$ is an increase in δ with ΔP, L_1 is the length of the support span (630 mm), b is the specimen width, and h is the specimen thickness.

The moisture content of the specimens was measured after the tests based on the oven-dried weight of specimen pieces.

2.2.2 Wooden I-beam

I-beam specimens were conditioned at 20°C and 65%RH prior to the four-point bending test conducted using a testing machine (TOKYO KOKI TESTING MACHINE Co. LTD; maximum bending load capacity of 200 kN) in an unconditioned room. The specimens were loaded at their third-point across a 4410 mm supported span. The tests were conducted with lateral supports on a specimen to prevent horizontal buckling. Cross-head movement speed was 12 mm/min. The load (P) was measured and the maximum bending moment (M_{max}) was calculated as follows:

$$M_{max} = \frac{P_{max} L_2}{6} \quad (3)$$

where P_{max} is the maximum load, and L_2 is the length of the support span (4410 mm).

The moisture content of the specimens was measured after the tests based on the oven-dried weight of specimen pieces.

2.3 LONG-TERM LOADING TEST

Figures 2 and 3 show the experimental setup for the long-term loading tests for LVL and I-beam specimens, respectively. The testing instruments were capable of loading approximately 14 and 17 times the weight suspended at the end of the moment arm to specimens, respectively. The tests were conducted at a constant temperature (20°C) and relative humidity (65%RH). A four-point bending setup was used, which is equivalent to the short-term loading test. In the tests of I-beam specimens, lateral supports on the specimens were used to prevent horizontal buckling of the specimens. The mean maximum load of two both-side-matched short-term loading specimens to a long-term loading specimen was assumed to be the standard (100%) load of a long-term loading. The applied constant load (stress level: SL) was 90, 80, and 75% of the standard load. Thirty-six LVL and I-beam specimens were tested: 12 specimens for each stress level. The displacement was measured at a span center for LVL specimens and the moment arm for I-beam specimens at the measurement interval of 1 min. The measurements were proceeded until specimen failure. The duration of load (time to failure) was calculated as the duration between the completion of loading and specimen failure.

Figure 3: *Experimental setup for the long-term loading tests of I-beam specimens*

3 RESULTS AND DISCUSSIONS

3.1 SHORT-TERM LOADING TEST

Tables 1 and 2 show the results of the short-term loading tests. All specimens demonstrated bending failure. Most LVL specimens broke at a scarf joint on the tensile surface, and most I-beam specimens broke in the bottom LVL flange (tensile surface). Test duration from the beginning of loading to specimen failure was less than 10 min for most specimens.

Table 1: *Results of the short-term loading test for LVL*

	Density (kg/m^3)	MOE (kN/mm^2)	MOR (N/mm^2)	MC (%)	Test duration (minute)
Mean	621	12.60	57.0	10.2	6.4
SD	23	0.90	8.2	0.7	2.3
Max	667	14.46	75.4	11.6	13.6
Min	580	10.73	38.5	9.1	3.4

MOE: Modulus of elasticity (see Eq. (1)), MOR: Modulus of rupture (see Eq. (2)), MC: Moisture content, SD: Standard Deviation.

Table 2: *Results of the short-term loading tests for I-beams*

	M_{max} (kNm)	MC (%)	Test duration (minute)
Mean	14.9	9.6	4.9
SD	1.7	0.3	0.5
Max	18.1	10.5	6.4
Min	10.9	8.9	3.7

M_{max}: Maximum bending moment (see Eq. (3)), MC: Moisture content, SD: Standard Deviation.

3.2 LONG-TERM LOADING TEST

Tables 3 and 4 show the duration of load in the long-term loading tests. One I-beam specimen loaded at 80% stress level showed horizontal buckling before the completion of loading and this data was not used for analysis. In addition, specimens with blank data in Tables 3 and 4 experienced failure before the completion of loading. Two LVL specimens loaded at 75% stress level that did not fail and two I-beam specimens loaded at 90% stress level that showed horizontal buckling were censored (marked with an asterisk in Tables 3 and 4). Most LVL specimens broke at a scarf joint on the tensile surface and most I-beam specimens broke in the bottom LVL flange, similar to the short-term loading tests. Figures 4 and 5 show the relationship between the duration of load and stress level. Figures 6 and 7 show this relationship with the stress level converted to the ratio of practical stress to the overall mean value for short-term loading specimens. The black solid line in Figures 4–7 represents an empirical hyperbolic curve based on clear and small specimens [4]. This curve is called the Madison Curve, which is expressed as follows:

$$SL = 108.4t^{-0.04635} + 18.3 \quad (4)$$

where SL is stress level and t is time in seconds.

Most specimens show almost equal or longer duration of load than Madison Curve. These specimens exhibit equivalent long-term bending properties to clear solid lumber. The red and blue dashed lines are regression lines fitted by the following models:

$$SL = a_1 \ln(t) + b_1 \quad (5)$$

$$\ln(t) = a_2 SL + b_2 \quad (6)$$

where SL is stress level, t is time in seconds, and a_1, a_2, b_1, and b_2 are coefficients.

Table 5 shows regression coefficients, coefficients of determination, and extrapolation values of SL in 50 years (SL_{50y}) as a long-term performance of the specimens. Duration of load of specimens that showed failure before the completion of loading were assumed to be 1 s in the calculations. Those of censored specimens were assumed to be durations until censoring. First, I-beam specimens show better coefficients of determination of the stress level relative to the overall mean of short-term loading (SL_2). Second, SL_{50y} values for LVL and I-beam

https://doi.org/10.52202/069179-0068

specimens are similar for the same stress level methodology. Finally, specimens in this study show equal or better long-term bending properties than lumber. Long-term strength of lumber is assumed to be 60% of short-term strength [3], and the Japanese building code assumes 55%. The Japanese building code assumes "long-term" as 50 years. Most SL_{50y} for all models in this study exceeds this value. I-beams with the composition and dimensions used in this study are widely employed in practice. Therefore, general I-beams may show equal or higher long-term bending strength than conventional wood members. Furthermore, long-term bending properties of I-beams could be estimated based on those of LVL members in which creep rupture of I-beams occurred. The reasoning behind these claims is discussed further in the next section.

3.3 SURVIVAL ANALYSIS

Survival analysis is a collection of statistical procedures for data analysis in which the variable of interest is time until an event occurs [15]. It is a popular data analysis approach in epidemiologic and reliability engineering, which can be used for censored data. In the present study, survival analysis was conducted for the duration of load, which is time until failure. Figures 8–10 show survival curves derived from survival analysis using the Kaplan–Meier method (a non-parametric method). This analysis was performed using the statistical software R version 4.2.2 [16]. One second was used as the duration of load for specimens that failed before the completion of loading. Survival function shows no significant differences ($p > 0.05$) between LVL and I-beam specimens at all stress levels using the log–rank test. In addition, Cox proportional hazard model [17] was applied to data in this study as follows:

$$h(t|x) = h_0(t)\exp(\beta_1 SL_1 + \beta_2 x) \quad (7)$$

where $h(t|x)$ is the hazard function with covariance, $h_0(t)$ is baseline hazard, β_1 and β_2 are coefficients, SL_1 is the stress level relative to that of side-matched specimens, and x is specimen type (LVL: $x = 0$, I-beam: $x = 1$). The hazard function represents the instantaneous failure rate. This model assumes that the hazard ratio depends only on covariance, not on t. Table 6 shows the estimated values of the coefficients. The coefficient of specimen type (β_2) shows no significant differences. In this case, the hazard ratio of the I-beam specimen to the LVL specimen is exp (β_2). This value includes 1.0 in the confidence interval. Therefore, survival functions also show no significant differences between the LVL and I-beam specimens. Considering the discussion in this and former sections, the duration of load of I-beams could be evaluated from that of LVL, which is an element of I-beam in this study.

4 CONCLUSIONS

Long-term bending tests were conducted on LVL and wooden I-beam specimens composed of LVL flanges and OSB web to investigate and compare their long-term bending properties. The results of this study are as follows.

1. Creep rupture of I-beam specimens occurred in the bottom LVL flange, in which the tensile stress occurred.
2. LVL and I-beam specimens showed similar estimated long-term (50 years) allowable stress levels in all fitted models.
3. Specimens in this study show equal or better long-term bending properties than lumber.
4. Survival analysis of the data in this study indicates no significant differences between survival distributions for the LVL and I-beam specimens. Additionally, the duration of load of I-beam specimens could be estimated from that of LVL flange members.
5. Thus, the duration of load of wooden composite materials may be estimated from that of element members that contribute to the failure mode of the composites.

DERIVATION FROM EN927 METHOD FOR EVALUATING THE OUTDOOR DURABILITY OF COATED FIRE-RETARDANT-TREATED WOOD

Ryo Takase [1], Atsuko Ishikawa[2], Daisuke Kamikawa[3]

ABSTRACT: Conducting an artificial weathering test using UV lamps and water spraying is necessary to predict the outdoor durability of coated fire-retardant–treated wood. This paper describes the results of prototypes derived from the EN927-6 methods, which are artificial weathering methods for coated wood. Modified tests using QUV demonstrated that testing conditions such as the duration of each spray or temperature have different effects on coatings. Thus, low-build coatings tend to be evaluated poorly under the standard cycle. Moreover, maintaining a high moisture content by raising the initial moisture content or lowering the testing temperature speeds up leaching from high-build coatings.

KEYWORDS: Fire retardant, Exterior claddings, Durability, Artificial weathering

1 INTRODUCTION

Fire-retardant chemicals (FRC) effectively reduce the flame spread and heat release in wooden claddings when exposed to fire. The chemical content near the surface is an especially important factor in suppressing the flame spread along fire-retardant–treated (FRT) materials. Under repeated drying–wetting environment, the impregnated chemicals move toward the wood surface [1] because most chemicals are water soluble. If used outdoors, then these accumulated chemicals are easily lost to condensed water or rain. Thus, protection with coatings is important not only from an aesthetic point of view but also to reduce fire risks.

Conducting an artificial weathering test using UV lamps and water spraying is necessary to speed up the development of new coating materials to evaluate how long coated FRT wood maintains the desired amount of FRC. This paper describes the results of modified versions of EN-927 standards [2], which are known as the methods for coated untreated wood.

The degradation of FRT wood is possibly caused by wetting, exposure to the sunlight, and drying. In some existing studies, degradation of coated untreated wood during exterior use is considered [3-5], and in some studies, accelerated tests using a xenon arc lamp method or UV fluorescent lamp method by QUV reproduced aesthetical deteriorations to some extent. Surface cracks and changes in gloss were reproduced using QUV, and changes in colors were correlated using QUV and a Xenon arc lamp [3]. However, attempts to predict FRC retention based on accelerated tests are rarely reported other than in study such as literature [6], while there are some reports related to the outdoor durability such as [7, 8] and fire testing methods for FRT wood after accelerated weathering test [9].

In the evaluation of the durability of FRT wood, moisture absorption should be considered. Figure 1 shows a diagram of the typical deterioration in coated FRT wood. After long-term outdoor exposure, coating cracks and efflorescence followed by leaching of chemicals are common, and many of them originate owing to moisture absorption or desorption.

(a) FRT absorbs more water than untreated wood [10], which means less dimensional stability and more stress on coatings.
(b) Efflorescence occurs at the wood coating boundary [11], which could break the wood coating bonding (only in the case of high-build types of coating).
(c) Water leaches FRC out of wood.

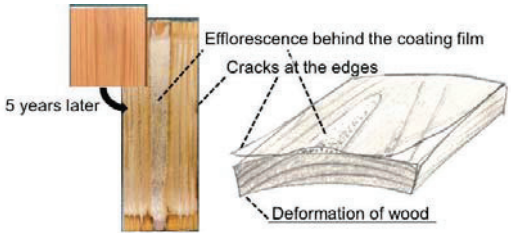

Figure 1: *Typical degradation of FRT wood coated with film-forming type material*

In this study, most of the testing conditions in EN927-6 were applied, and only conditions related to water absorption and desorption were modified to allow the leaching speeds of FRC to catch up with the degradation (i.e., changes in color) speed of coating materials.

There is also a fire testing method called NT Fire 053 [9, 12] that targets the outdoor usages of FRT wood products. The materials eventually undergo the fire spreading test after being repeatedly exposed to spray and drying (UV

https://doi.org/10.52202/069179-0069

light is also added in Method 2). Except for the absence of the condensation function in NT Fire 053, this method has similar functions as QUV. Thus, some findings from this study provide implications for a better correlation between NT Fire testing and outdoor exposure.

2 EXPERIMENTAL SECTION

Pieces of *Sugi* (*Cryptomeria japonica*) FRT wood with several types of coatings (Figure 2) underwent each test, as shown in Figure 3. In this study, QUV accelerated tests, one year of outdoor exposure test, and steady sorption test were carried out.

In the one year of outdoor exposure test, the moisture content of each coated FRT and untreated wood was measured to grasp the extent of absorption and desorption in actual conditions.

QUV tests that have different testing conditions were conducted, and chemical retention after each accelerated test was compared with the four-year-outdoor exposure reported elsewhere [8].

Alongside these unsteady tests, the diffusion coefficient (ID) of each material was measured to discuss how the moisture absorption speeds are affected by testing conditions, as the temperature in the present QUV equipment is often higher than it is outdoors.

2.1 SPECIMENS

As shown in Table 1, three groups of specimens of different sizes were prepared. For outdoor exposure, specimens with a size of 300 mm (longitudinal, L), 18 mm (radial, R), and 70 or 105 mm (tangential, T) were prepared. For artificial weathering, specimens with a size of 300 mm (L), 18 mm (R), and 70 mm (T) were prepared. They were treated with 25 wt% of FRC aqueous under a pressure of 0.95 MPa and dried. The FRC used herein was a guanidine phosphate based FRC.

After impregnation, each front face and both edge grains were coated with one of the five types of coatings as shown in Figure 2. For the remaining faces, the procedures are the same among the coating types. The back face of the specimens were coated with film-forming alkyd (same one as coating D), and both end-grain faces were sealed with epoxy resin and foil tapes. The above procedures are the same as in previous studies [6, 8].

For ID measurement, wood blocks with a size of 30 mm (L), 18 mm (R), and 30 mm (T) were prepared. Sheets of aluminum foil were directly glued to the remaining five faces with epoxy resin to achieve strict one-dimensional absorption.

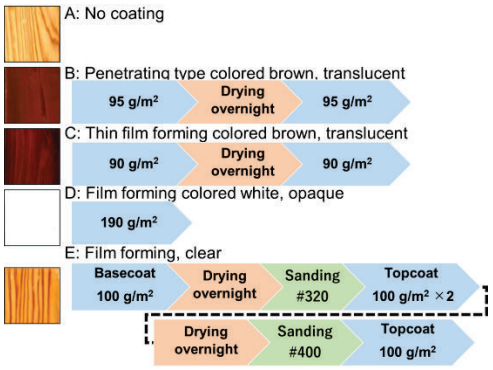

Figure 2: *Coating procedures for weathering tests*

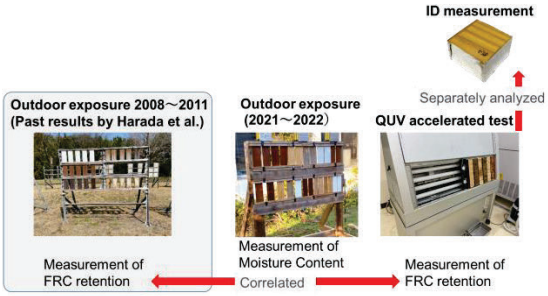

Figure 3: *Experiment schemes*

2.2 MEASUREMENT OF MOISTURE CONTENT DURING OUTDOOR EXPOSURE

On the basis of the outdoor exposure testing method described in Japanese Industrial Standards [13], each specimen in Table 1 underwent outdoor exposure. The site is located in Tsukuba, Japan. Specimens were fixed vertically facing due south. During the exposure, the moisture content was monitored by weighing each specimen almost three times a week. Measurements of moisture content are often performed using electrodes [14-16], but this approach is unsuitable for FRT wood because chemicals are electrically conductive.

Table 1: *List of specimens*

Testing	Number of repetitions (for each coating)	Fire retardant treatment	Specifications of specimens				
			Lengtial [mm]	Radial [mm]	Tangential [mm]	Coating procedures	
Outdoor exposure (2021-2022)	2	None	300	18	105		Face ① to ③ : Either coating system A to E Face ④ : Coating system D Face ⑤ and ⑥ : Epoxy resin covered with foil tapes
	2	Phosphate guanidine based	300	18	70		
QUV	1 or 2	Phosphate guanidine based	300	18	70		
ID measurement	1 or 2	None	30	18	30		Face ① : Either coating system A to E Face ② to ⑥: Aluminum foil glued with epoxy resin
		Phosphate guanidine based					

The experiment for untreated wood was conducted from May 2021 to Sep. 2022. For FRT wood, the experiment was conducted from July 2021 to Sep. 2022. The rainy season in Japan is typically between June to the end of July. Thus, the exposure of FRT wood started later to minimize the interference of weight changes due to the loss of FRC.

Values of moisture content were calculated as demonstrated in Figure 4 and Equation (1), which defines the weight of each untreated wood piece as 100%.

$$M = \frac{W_g - W_{FRC} - W_w}{W_w} \times 100 \qquad (1),$$

where M is the moisture content [%], W_g is the gross weight [g], W_{FRC} is the weight of FRC approximated with exponential function [g], and W_w is the wood weight [g].

To correct the baseline for the FRC loss during exposure, one specimen for each coating system was separately prepared, exposed to the same environment, and oven dried every 4 or 6 months to be weighed. From the weights measured above, FRC retentions over time were approximated using the exponential function.

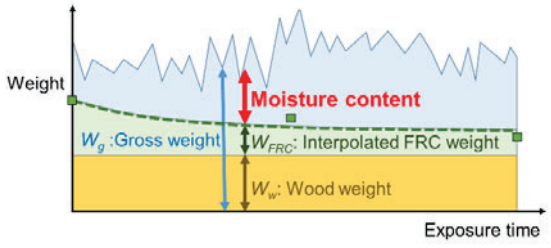

Figure 4: *Estimation scheme of moisture content within FRT wood*

2.3 MODIFICATION OF QUV CONDITIONS

Six conditions that differ in cycles and preconditioning environments were considered as shown in Table 2. The functions named "Condensation", "UV exposure" and "Spray" in Table 2 come standard with Q-LAB QUV/spray equipment. Condensation is typical for QUV equipment and is achieved by condensing hot vapor from a water pan at the specimen surface cooled by ambient air. Among these conditions, cycle S-25% is the closest condition to the EN927-6 standard. The tests were conducted over 504 h of testing time (three repetitions of 168 h cycles) as a unit. All specimens were conditioned beforehand until they reached equivalent moisture content (abbreviated as EMC in Table 2 and later figures), and oven-dried weights were measured subsequently. FRC retentions were calculated using Equation (2). Oven drying took place for three weeks for interim weighing (504, 1008, and 1512 h) and six weeks for the initial and final weights.

$$R_T = \frac{W_t - W_w - W_c}{W_0 - W_w - W_c} \times 100 \qquad (2),$$

where W_0 is the gross initial weight [g], W_t is the gross weight after t hours of QUV test [g], W_w is the wood weight [g], and W_c is the weight of coating materials [g].

Changes in colors are estimated to be approximately 17.4 times faster than that under vertical exposure outdoors under QUV standard condition [5]. The amount of water sprayed in QUV is at least 30 times greater than wall precipitation outdoors; 5.76 L/cm^2 of water is sprayed within 2016 hours in QUV, whereas the wall precipitation at the testing site is estimated to be less than 0.83 L/cm^2 per year, according to Equation (3) [17].

$$R_w = aR_hU\cos\delta \qquad (3),$$

where R_w is the wall precipitation [mm], a is a constant value determined by building size, R_h is the horizontal precipitation [mm], U is the wind speed [m/s], and δ is the horizontal attack angle between a wall and raindrops.

2.3.1 Initial Moisture Content

For some coating materials, conditioning moisture content is practically difficult because of the low permeability of the coating. Conditioning times could be even longer than the testing time. To figure out how much attention should be paid to controlling the initial moisture content, specimens with initial moisture content near 0% and 25% were compared.

Table 2: *Conditions of QUV tests*

Cycle	Testing shedule as a unit: Pre-conditioning → QUV exposure 168h × 3 → Oven dry 60°C, 3 weeks → weighing		QUV details		
	Preconditioning	QUV exposure cycle as a 1/3 unit	Condensation	Spray	UV Exposure

2.3.2 Duration of Each Cycle

Condensation and spray were alternately repeated for eight hours in cycle M1 to enhance water absorption in one wetting cycle. The total durations of each function (condensation, spray, and UV exposure) are the same between cycles S and M1.

2.3.3 Temperature During UV Cycles

To evaluate the effect of temperature on the leaching speed, cycle M2 that differs from cycle M1 only in the ambient temperature during UV exposure was considered. Cycle M2 is the combination of the lowest temperature available in Q-LAB QUV/spray equipment in each function. High temperatures are available (up to 60°C for condensation and UV exposure) but not considered in this study.

2.4 MEASUREMENT OF DIFFUSION COEFFICIENTS

The diffusion coefficient of each material in Table 1 was calculated from weight change under constant temperature (23°C, 45°C, and 63°C) and humidity (65% RH). These environments were achieved using containers with saturated salt (sherbet-like aqueous of NaCl) placed in incubators. Tests under a high humidity (95% RH) were also attempted, but they provided unstable results due to deliquescence, swelling, and seal failure.

3 RESULTS AND DISCUSSION

3.1 MOISTURE CONTENT DURING OUTDOOR EXPOSURE

Figure 5 shows the yearly transitions of moisture content and the weather record. The weather record from the nearest observatory was retrieved from the database of the Japan Meteorological Agency [18]. The actual peak values of the moisture content are expected to be a little high because the measurement did not necessarily take place right after rainfall. Also, the data earlier than day 40 should be excluded because of its unsteadiness. During the testing period at the site (Tsukuba), the equivalent moisture content estimated by relative humidity and temperature [19] is between 12% to 27%. The results for the coated untreated wood generally agreed with this estimation. The FRT wood had considerably high and unsteady values. The eventual moisture content exceeded 30%, allowing the presence of free water even after a short rainfall.

3.2 EFFECTS OF QUV CONDITIONS

Figure 6 shows the amount of FRC lost after 2016 hours of each test. The following sections show comparisons from some aspects.

3.2.1 Initial Moisture Content

Cycle S-25% is the closest condition to the EN927-6 standard. For specimens C, D, and E (considerably high-build types of coatings), more FRC leached under the cycle S-25% than under S-0%. The influence of initial moisture content becomes unclear for cycles M1 and M2. Initial moisture content seems more important for high-build coatings exposed to short-term spray, due to the low permeability of the coatings.

3.2.2 Duration of Each Cycle

Cycle M1 is the rearranged version of a standard cycle (cycle S). Judging from the fact that most of the specimens leached more under the cycle S than M1, combining condensation and spray as one wetting cycle seems insufficient to enhance the sorption of the coated wood.

3.2.3 Temperature during UV Cycles

Cycle M2 was designed to combine the lowest temperatures available in the present QUV equipment. However, it differs from M1 only in the ambient temperatures during UV exposure. Regardless of the initial moisture content, more FRC tended to leach under cycle M2 than under M1 in the case of specimens A (no coating), D, and E (high-build types of coating).

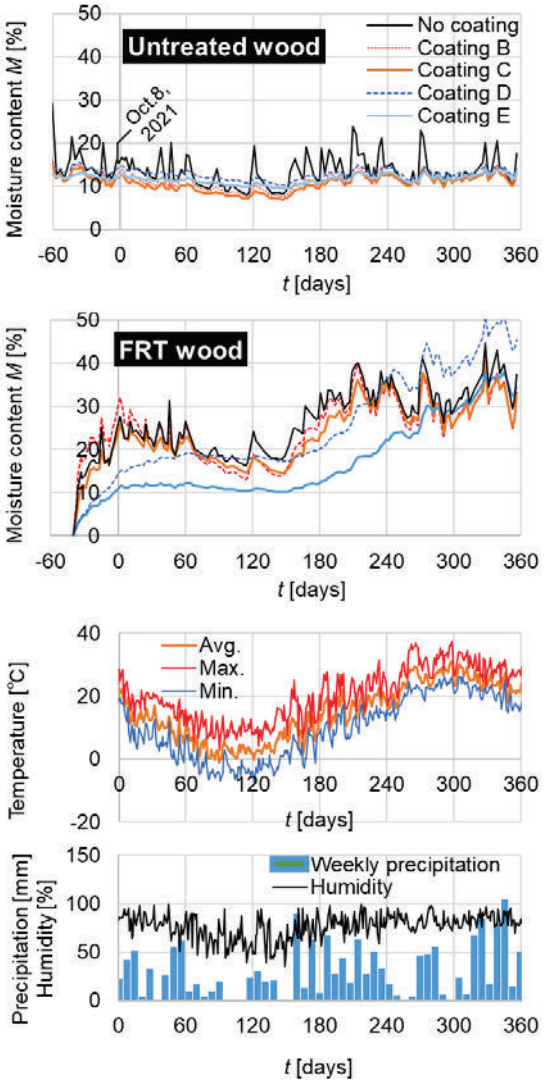

Figure 5: Moisture content and the weather at the site

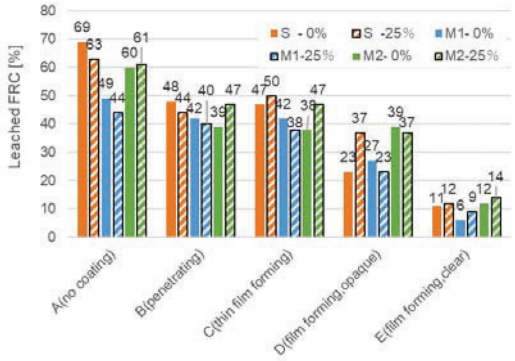

Figure 6: *Leached FRC during 2016h of accelerated tests*

3.3 RELATIONS BETWEEN LEACHING SPEEDS AND DIFFUSION COEFFICIENTS

Table 3 shows the gross (moisture excluding effectiveness of the coating is included) diffusion coefficients according to the method in reports such as [20]. With E defined as shown in Equation (4), its value against the square root of time increases linearly if the sorption follows Fick's law. Figure 7 shows an example of the sorption curves plotted against the square root of time.

$$E = M_t / M_\infty \qquad (4),$$

where E is the dimensionless moisture, $M_t$is the moisture content over time, and $M_\infty$is the equivalent moisture content in the ambient air.

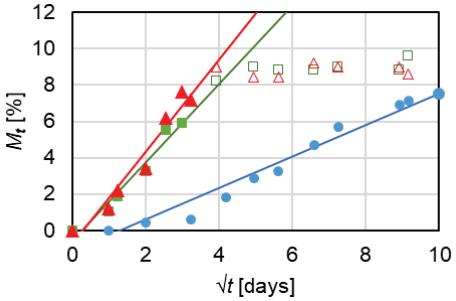

Figure 7: *Examples of sorption under steady environments*

With the use of the slope up to E = 0.8, the diffusion coefficients were calculated using Equation (5)

$$\mathrm{ID} = \frac{l^2}{5.1}\left(\frac{dE}{d\sqrt{t}}\right)^2 \qquad (5),$$

where ID is the diffusion coefficient [m^2/s], l is the length equal to twice of the sample thickness [m], and t is the time [s].

As shown in Table 3, the ratios of ID among the coatings are not maintained as long as the testing temperature is higher than that outdoors. The temperature dependence of IDs differs according to the base material (FR treated or not) and the coating materials, and tends to be highly temperature dependent in the cases of specimens D and E (relatively high-build coatings are applied).

3.4 COMPARISON WITH OUTDOOR RESULTS

In deducting the test method for new coating materials, the degree of acceleration is preferably uniform among the types of coatings. With this degree defined as the acceleration coefficient (Figure 8g), their ratio among specimens A to E is presented in Figure 8. For instance, figure 8d shows that the testing under standard condition (cycle S-25%) for specimens A (no coating), D and E (high-build type of coating) is not as efficient as that for specimens B and C.

In all conditions, the acceleration coefficients for the first 504 h are scattered and larger than the values afterwards. The gradual decrease of acceleration coefficients typical for specimen B and C (considerably low-build types of coatings) agrees with Table 3 in that the ID difference between untreated and FRT wood becomes large at high temperatures.

3.4.1 Effects of Testing Cycles

Regardless of the initial moisture content, the acceleration coefficient is reduced especially in specimens A (untreated), D, and E (high-build type of coating) by modifying the cycle from S to M1. As mentioned in 3.2.2,

Table 3: *Temperature dependence of diffusion coefficients*

	Temperature [°C]		No coating N=2	Coating B N=1	Coating C N=1	Coating D N=1	Coating E N=1
Control	23	ID* [×10^{-11}]	13.75	8.88	9.76	2.78	2.98
	45	ID* [×10^{-11}]	40.68	38.34	46.49	16.15	27.94
		(Ratio to 23°C)	(3)	(4.3)	(4.8)	(5.8)	(9.4)
	60	ID* [×10^{-11}]	57.5	49.0	46.5	35.7	38.5
		(Ratio to 23°C)	(4.2)	(5.52)	(4.8)	(12.8)	(12.9)
FRT wood	23	ID* [×10^{-11}]	22.0	13.1	10.3	0.8	2.6
	45	ID* [×10^{-11}]	91.1	58.8	77.5	21.8	28.6
		(Ratio to 23°C)	(4.1)	(4.5)	(7.5)	(27.1)	(11)
	60	ID* [×10^{-11}]	232.9	121.7	141.3	68.7	71.4
		(Ratio to 23°C)	(10.6)	(9.31)	(13.7)	(85.4)	(27.5)

https://doi.org/10.52202/069179-0069

combining condensation and spray as one wetting cycle seems insufficient to enhance the sorption of coated wood. In addition, no specimen reached an acceleration coefficient of ~30 just because 30 times more water is sprayed in QUV. These findings imply that most of the water sprayed in QUV simply runs down to wash out FRC on the surface of the specimens. Thus, the amount of water in QUV is greater than that absorbed by the wood.

3.4.2 Effects of Testing Temperature

The variation in acceleration coefficient evaluated from RSD is smaller in M2 than M1.

In spite of the ID tendencies shown in Table 3, the acceleration coefficients for specimen D and E shown in figure 8 do not decrease when the testing temperature is lowered from M1 to M2. This finding indicates that, due to the increase of equivalent moisture content by lowering the temperature during UV cycles, the absorbed water was able to remain as free water and enhance the leaching of FRC.

4 CONCLUSIONS

The preferable conditions of artificial weathering tests for FRT wood are narrowed down through the following findings:

1. FRT wood exposed outdoors in Tsukuba could exceed 30% of moisture content, regardless of their coating type.
2. The temperature dependence of the diffusion coefficient differs among the coating materials and base materials, resulting in various acceleration coefficients during QUV tests.
3. Keeping moisture content high by raising the initial moisture content or lowering the testing temperature speeds up the leaching from FRT wood coated with high-build coatings. In other words, the durability of FRT wood combined with these coatings tends to be overestimated under the QUV standard condition if the initial moisture content is low. This finding suggests that tests merely following EN 927-6 could also overestimate durability of these materials because it could take more than a year for these materials to reach equilibrium if the specimens are conditioned at 20°C, designated temperature in the EN 927-6.

A single type of fire-retardant chemical and five types of coatings demonstrated the difficulty of accelerating their degradation to the same degree, especially at high temperature. Acceleration coefficients can be more stabilized not by speeding up unsteady sorption during spray but by keeping testing chamber more humid throughout the testing time. Reducing the thickness of the specimens might be another effective way of speeding up moisture absorption without raising the temperature. Further experiments are being conducted.

DIMENSIONAL VARIATIONS MONITORING OF RADIATA PINE CLT PANELS: A CASE STUDY IN CONCEPCIÓN, CHILE

Víctor Rosales[1], Fernanda Pascal[2], Franco Benedetti[3], Pedro Rebolledo[4], Alan Jara-Cisterna[5], Mauricio Vargas[6]

ABSTRACT: Variations in wood moisture content lead to changes in virtually all physical and mechanical properties of timber. Besides, the damage to building elements is usually associated with unfavorable changes in material properties, support conditions, geometry, or load variations that can influence the structure's performance or durability. This research is oriented to monitoring the behavior of a CLT module prototype under the action of humidity, simulating the possible changes resulting from its use as a habitable space. With these field measurements, we study the dimensional variation of wall elements and moisture content in the structural panels in order to explore the possible behavior of the PymeLAB experimental building PymeLAB, a 5-story living laboratory that was installed on campus from the University of Bío-Bío during 2022. In this study, a prototype has been manufactured with conditioned 3-layer Radiata pine CLT panels with an initial moisture content of 11.6%. Dimensional changes caused by different humidification cycles were measured. The change in the moisture content of the internal face of the CLT panels exposed to the indoor climate showed increases in deformations of up to 1.74 mm/m.

KEYWORDS: Monitorig CLT, Moisture expansion, hydrothermal performance, CLT Radiata pine.

1 INTRODUCTION

Since the climate of Chile is quite varied, the moisture content of the wood in service varies from one region to another according to the differences in temperature and humidity. Consequently, there are 9 climatic zones, from the desert north to the extreme south [1].

Each building must be subject to a site assessment that considers the impact of seasonal weather conditions associated with the location, the structure, and its behavior in use. Its conditions of use will also have repercussions on the behavior of the building. For example, structures with exposed CLT are not usually used due to construction regulations associated with fire. However, knowing the behavior of uncovered CLT panels allows us to propose its behavior for combination with other interior and exterior cladding materials.

Hygroscopic materials can absorb moisture from the air when its relative humidity rises and release moisture into the air when it falls. These humidity variations result in dimensional variations in the wooden elements, which can cause problems in their connections or sheathings [2], resulting in post-sale costs in the buildings. The damp-absorbing effect of building materials can greatly influence the indoor hygrothermal environment [3]. Moisture absorption/release by hygroscopic materials can be calculated with the basic MBV factor, where the density and porosity of the materials are essential properties in the theoretical calculation of moisture buffering because these factors are likely to influence moisture transport. In addition, air velocity plays a relevant role in the sorption performance of materials. To obtain comparable results, various humidity buffering protocols require that the air velocity be constant and around 0.1 m/s during the tests [4]. Humidity and buffering capacity depend on several factors, from which porosity and temperature are influential; therefore, the moisture buffer values for bio-based materials have been measured at a constant temperature of 23°C [5].

One of the performance demands for buildings is durability, which in the case of wood can be greatly affected by prolonged exposure to moisture [6]. Moisture changes in wood are accompanied by deformations such as shrinkage and swelling. In particular, the prolonged exposure of wooden constructions to the effects of

humidity affects the durability and safety of the constructions [7].

Wang et al. (2018) point out that dimensional changes [8], moisture damage and microbial growth must be considered. These can eventually occur with short-term wetting or high relative humidity (RH) (80% to 95%), where the cycles of contraction and swelling of the wood can compromise the mechanical connections due to the degree of humidity exposure. On the other hand, it is pointed out that cracks are attributed to seasonal variations influenced by the internal climate that occurred in the buildings, which is associated with the process of contraction and swelling of the wooden elements. Also, shrinkage and swelling can affect the durability and stiffness of the connections [9].

Sung & Gi (2019) studied the swelling and contraction behavior of Larix kaempferi and Pinus koraiensis, analyzing CLT boards in a controlled environment [10]. From the results, they were able to distinguish that larger deformations were observed in the "y axis" (radial axis, perpendicular to the growth of the fibers) with respect to those perceived in the "x" and "z" axes. They also discriminated that the thickness does not lead to a tendency in the swelling and contraction behavior. However, the combination of the layers is of great relevance since the layers in the longitudinal direction of the panel give it dimensional stability in the x and z axes. According to the research carried out by the authors Schmidt et al. (2017), it is possible to accelerate or stimulate the wetting process to evaluate the performance of CLT panels against deformationsn using a multi-chamber modular environmental conditioning method.

Authors as McClung et al., Wang, Lepage et al., Kordziel and Schmidt et al., cited in the work of Schmidt et al. [6], carried out laboratory-scale experiments emphasizing the monitoring of the wetting and drying behaviors of large CLT samples, thought as the effect of water attacking the faces of the panels (rain). In addition, McClung et al. found that 5-layer CLT samples soaked by immersion for one week with epoxy-sealed edges and subsequently integrated into assemblies of variable permeability were generally within acceptable MC ranges (<26%) after one month, and most of them were dry after 4 to 6 months [6].
According to EN16351 [11], Service Class (SC) 1 is characterized by a moisture content in materials corresponding to a temperature of 20°C, and the relative humidity of the surrounding air only exceeds 65% for a few weeks in a year. In SC 1, the average moisture content in most softwoods will not exceed 12%. Service class 2 is characterized by a moisture content in the materials corresponding to a temperature of 20 °C, and the relative humidity of the surrounding air only exceeds 85% for a few weeks of the year. In SC 2, the average moisture content in most softwoods will not exceed 20%. For its part, SC 3 is characterized by climatic conditions that lead to higher moisture content than in SC 2. Additionally, the standard propose values for the adjustment of the in-plane moisture deformation (0.0002) and perpendicular to the plane (0.0024). These parameters are considered in an expression for the correction of the size for moisture contents within the range from 6% to 25% in the species recognized in the standard. The existing formula in the EN standard predicts CLT contraction and expansion as a function of the CLT coefficient. The limitation of this approach is that the dimensional change of CLT cannot be estimated before measuring the actual CLT coefficient. CLTs of various layer combinations can be manufactured, thus, the dimensional characteristics would differ depending on the layer combinations [10].
A study on moisture in edge-glued wood panels found that a 1 percent change in moisture in White Pine will change the width of a 75mm wide board by 0.05 to 0.15mm. In addition, the study showed that boards gain or lose moisture 10 to 15 times faster from the ends than from the faces and sides of the panel. In contrast, for CLT panels, this is less due to the element's configuration, but a different behavior is expected at the ends of the pieces.

Han et al. [7] used samples with different moisture contents in the layers that make up the CLT elements to study the effect of the moisture difference. The humidification processes were carried out within a period of 3 weeks. After humidification, the changes in width and thickness of the samples were measured during drying under two conditions (80% and 40% relative humidity). The results showed that the dimensional changes of the CLT samples tended to be repeated in shrinkage and swelling, which depended on the humidity variation. Both the shrinkage and the swelling in the width of each sample varied from 0.492 to 2.145 % and from 0.459 to 2.542 %, respectively [7]. For the samples made with a similar moisture content between the inner and outer layers (difference less than 1.6%), the variation in shrinkage and swelling were less than 1.5%.

Schwab et al. [12] investigated the swelling coefficient for a thickness of 20 mm in sheets of European spruce CLT. They found that in the X,Y,Z directions the swelling ceofficient was from 0.00031 to 0.00038, respectively. For their part, Gereke et al. [13] investigated the swelling coefficient for a 30 mm sheet thickness Fagus sylvatica CLT. The swelling coefficient found for the X,Y,Z direction was 0.00011, 0.0023, and 0.00009, respectively. The swelling shrinkage coefficient in the Y direction was approximately 21 and 26 times higher than in the X and Z directions, respectively.
3-layer panels (90 mm thick) of Korean larch (larix kaempferi, 500 kg/m3) and Korean pine (pinus koraiensis, 410 kg/m3) were investigated to predict the dimensional change of CLT from the dimensional change of the sheets. In order to know the swelling, small samples were conditioned at 7.7% moisture

https://doi.org/10.52202/069179-0070

content, which were then brought to 19% and later to a saturated state. For this type of panels of the Korean larch species, in the x direction, a swelling and contraction value of 0.000217 and 0.000507 respectively was achieved; for the z direction 0.000150 and 0.000223 respectively. Using the same CLT panel configuration, but of the Korean pine species, in the x-direction, a swelling and contraction value of 0.000216 and 0.000467 respectively was achieved; for the z direction 0.000117 and 0.000183 respectively. [10]

Given the lack of knowledge about the moisture-deformation behavior of Radiata pine CLT boards subjected to temperature and humidity variations under operation conditions, this work studies the dimensional variation of a full-scale CLT module located in the University of Bio-Bio (Concepción, Chile).

2 MATERIALS AND METHODS

This work focuses on the behavior of a CLT prototype against inner climate variation by monitoring the variation in the in-plane CLT climate response. The workflow considered five humidity cycles of 3 weeks long each.

During the entire test period, the University of Bío-Bío on-site weather station recorded the outdoor weather data, and monitoring equipment recorded the indoor weather. A daily humidity production cycle was chosen, whose maximums are short but intense depending on the relative humidity level necessary to reach the value established by the control equipment.

Sensors were installed in the prototype to continuously record the following parameters: temperature and relative humidity in the center of the module. Here only the measurement parameters temperature and relative humidity are considered.

The interior temperature is maintained at 20°C by a control regulating an electric radiator. The relative humidity is measured in the center of the room at a height of 1.2 m. In addition, the air from the fans is kept at 0.1 m/s.

The ambient temperature remained constant at 20 °C except for a few days, in which this temperature was exceeded for some hours due to intense solar radiation. The damping effect on humidity is more important over 50% in relative air humidity, an environment in which fungal growth is favored. According to the type of panels used in this research, those with no treatment, sealing, or sheathing, are defined as open type, which is not always the case employed in common practice.

2.1 PROTOTYPE DESCRIPTION

The CLT panels were manufactured in the Wood Design and Technology Laboratory facilities of the University of Bío-Bío, Concepción. Kiln-dried radiata pine lumber having a 12% (+/-2%) moisture contente were used. The average density of the lumber boards was 398 kg/m^3, and were mechanically classifiedas C16 according to EN338 [14]. Boards were planed to 18 x 130 and 33 x 130 mm thicknesses, and then edge and face glued with PU-1 K polyurethane adhesive. For the curing of the adhesive, a hydraulic press was employed, applaying a pressure of 0.8MPa. The final dimensions of the CLT panles was 99 x 1200 x 1960 mm (33 x + 33 y + 33 x) for the walls and 84 x 850 x 3600 mm (33 x + 18 y + 33 x) for the floor and ceiling. In one of the panels, electrodes were installed to measure and monitor the moisture content from the beginning of the process.

In order to make the joints, a half-wood milling process is carried out on the edges of the CLT panels, with a dimension of 33 x 60 mm. A C16 Radiata Pine board of 33x119mm was employed to produce the joint between panels, fastened with screws arranged every 70 mm. The elements are assembled using the traditional techniques for this type of construction system, which is based on the use of screws in the corners for the wall-wall connection, angle bracket for the wall-floor connection, and screws for the wall-ceiling connection. Figure 1 presents general views of the module used for the study.

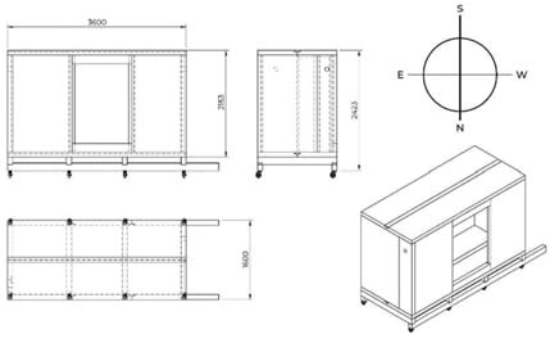

Figure 1: *Floors and elevation plan (left) and 3D view of prototype.*

After the assembly, the sealing tasks were carried out with tapes and membranes that reduce the infiltration and transfer of steam. The edges of the CLT panels were not sealed. Besides, thermal insulation and sheathings were installed on the exterior face. The module has an access door of 42 x 600 x 2300 mm and windows of 500 x 1600 mm located on the north side, which use a thermopanel with a U value of 1.8 W/m^{2}K. The thermal transmittance value of the envelope for the wall is U=0.46 W/m^{2}K, which is obtained from the constructive

conformation of the wall (99 mm CLT of Radiata Pine with 50 mm of mineral wool).

On the outside and at the height of 2500 mm, a temperature and relative humidity recorder was located in the shade, which captures the climate data of the surrounding zone. Inside, two Yowexa-Japan temperature and relative humidity recorders were installed, located at the same interior height (1200 mm) but in 2 different positions. To regulate the indoor climate, a climate unit and a series of humidifiers are installed and connected to an automatic temperature and humidity control system, which was set to control each cycle.

2.2 INSTRUMENTATION

The panels were coded as N, S, E, O (North, South, East, and West), gridded every 300 mm, and in selected zones of the grid, humidity sensors (electrodes) and digital transducers were installed on a Whittemore-type device. The humidity sensors were installed at different depths (P1=21 mm, P2=27 mm, and P3=32 mm), completing a thickness of 1 lamina constituting the CLT, as shown in Figure 2.

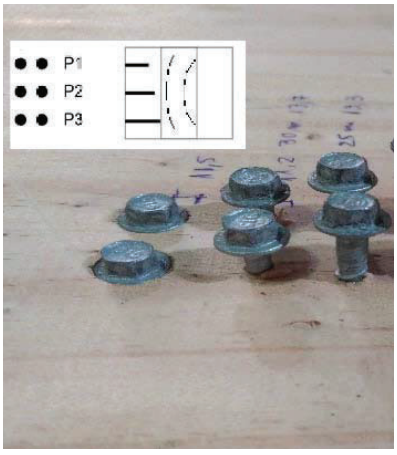

***Figure 2**: Installation of the moisture monitoring electrodes at different depths (P1, P2 y P3)*

Displacement transducers were installed in the area close to the moisture measurement points to evaluate the in-plane deformations of the panel (X, Z plane). Two measurement zones were considered to evaluate the horizontal deformations in the same panel (SX1, SX2), one to measure the complete deformation of the panel plus one joint (SX3), and one for the evaluation of the vertical deformation (SZ3). Depending on the sensor installed, the distance between these two points is around 500 mm to 600 mm. and 1085 mm for SZ3. The layout of the instruments is schematized in Figure 3.

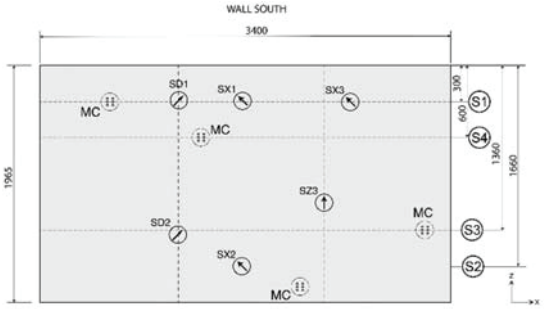

***Figure 3:** Layout for moisture (MC) and displacement metering (S X and SZ) metering.*

2.3 CLIMATE CONDITIONS

The climate used to develop of the experiment considers a temperature of 20 ° (+/- 2°C), and relative humidity (RH) that varies by stages, increasing from 60% to 90% (+/- 3%). Consequently, five stages of indoor climate conditions were defined (Table 1), distinguishing Stage 1: (conditioning) 60% RH; Stage 2: 65% RH; Stage 3: 75% RH; Stage 4: 85% RH and Stage 5: 90% RH. The measurements began on November 2, 2021, and ended on February 3, 2022. The module's external weather conditions corresponded to the Nonguén area's climate (Concepción, Chile) during spring 2021 and summer 2022.

***Table 1:** Climate conditions during the experiment*

Cycle	Days	Inside		Outside	
		Mean RH (%)	Mean temp (°C)	Mean RH (%)	Mean temp (°C)
Stage 1	0-20	59,6	20,5	64,6	16,3
Stage 2	21-43	66,0	21,0	65,3	16,8
Stage 3	44-62	77,1	21,7	68,2	17,7

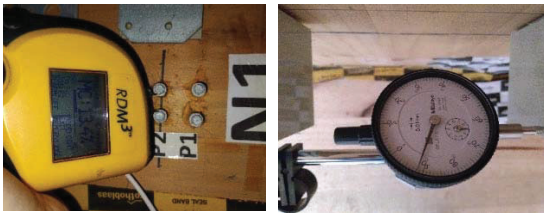
Stage 5	79-94	90,6	21,4	70,1	17,2

2.4 MONITORING SETUP

The deformations in the CLT panels were recorded at constant intervals (two times a day) using Mitutoyo instruments. In addition, the moisture content of the different panels was recorded three times a week, through a RDM[3] Delmhorst resistive xylohygrometer (Figure 4). Additionally, it was necessary to measure the interior climate of the module (Temperature and Relative Humidity) at 30 min intervals, measuring the room temperature at two different points.



https://doi.org/10.52202/069179-0070

Figure 4: *Moisture content (left) and displacement (right) measurement instrument.*

Critical aspects of installing the moisture content electrodes and the measurements included: (1) avoiding gaps and knots between electrodes, (2) using guides for exact electrode spacing, (3) drilling holes to the exact length of the insulated casing used for the electrode, (4) insert the screws at the same speed and leaving the insulated base leveled with the wood, and (5) ensuring communication with the manual system [15].
The analog displacement gauge has a measuring range of 12mm with a resolution of 0.01mm. However, Huston et al. suggest that electronic instruments are more practical for long-term measurements [16].
The instrumentation arrangement on the wall was intended to monitor the displacements and moisture content of the wood in the nearby area (Figure N°5).

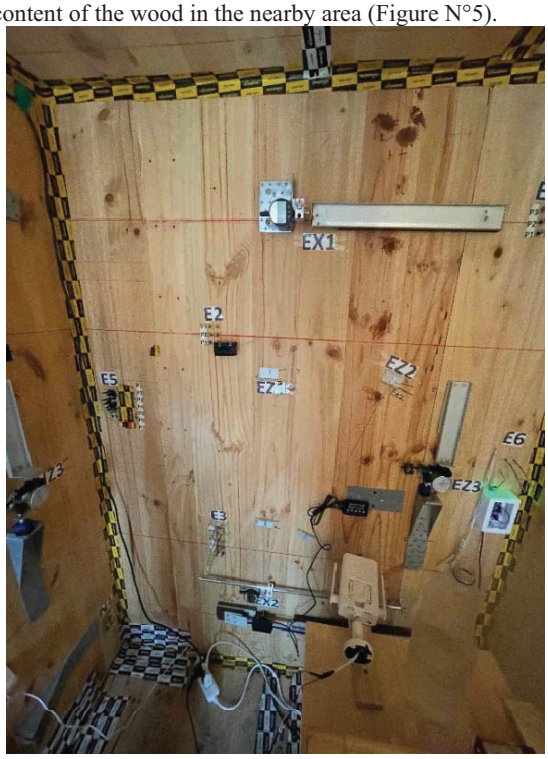


Figure 5: *Instrumentation and monitoring system arrangement for the East Wall.*

2.5 DIMENSIONAL CHANGE IN CLT WALLS

The expression proposed in the EN16351 standard was used to determine the dimensional change, which establishes a coefficient that depends on the direction (in-plane or out of plane).

$$a_{cor} = a_a \, x \, (1 + K_{cor,\propto} x \, (H_{ref} - \, H_a)) \qquad (1)$$

Where a_{cor} = effective dimension (mm); a_a = actual dimension (mm); $K_{cor,\alpha}$ can be either $K_{cor,90}$ = stability coefficient perpendicular to the fiber or $K_{cor,0}$ = stability coefficient in the plane, both expressed for to 1% variation in moisture content between 6% and 28%; H_{ref} = 12%, reference moisture content; and H_a = actual moisture content (%).

3 RESULTS AND DISCUSSION

3.1 POST PROCESAMIENTO DE DATOS Y LA INCERTIDUMBRE DE MEDICIÓN

The literature provides estimates of measurement uncertainty for moisture content based on wood strength, biological variability within a given wood species, and at different moisture contents [15]. In this study, the discontinuous readings were not corrected for the radiate pine CLT given the calibration of the instrument manufacturer for this specie. Moreover, the data collected during the assessments suggest that most of the time, local moisture content fluctuations were clearly correlated with internal weather conditions and the depth of masurement in the CLT panels.

To keep under control the uncertainty, two pieces of 100 x 300 x 450 mm of radiata pine CLT were placed inside the monitored module, and the moisture content was controlled through the instrument and in the laboratory. The moisture content sensors' performance in the CLT module's different positions during the 90 days of the evaluation was consistent with the data obtained from the control samples.

For their part, the instruments that captured the module's temperature and relative humidity were permanently contrasted. Their measurements resulted in being consistent.

The obtained data consist of discontinuous readings for the moisture contents in different positions (North, South, East, and West walls) and depths (P1, P2, and P3), for the deformation of the panel on its corresponding X or Z position. On the other hand, the internal and exterior climate values were recorded continuously.

Both the moisture content data and displacements in the CLT walls are presented in the tables in the following sections. The indoor climate data, as well as the exterior climate data (temperature and relative humidity) are shown as 1-day central moving averages.

https://doi.org/10.52202/069179-0070

3.2 MOISTURE CONTENT MEASUREMENTS

The increase in moisture content inside the prototype module induces an increase in the moisture content of the different panels that set up the walls. Figure 6 shows a comparison of the increases in moisture content at depth P1in the different positions of the module walls (North, South, East, and West).

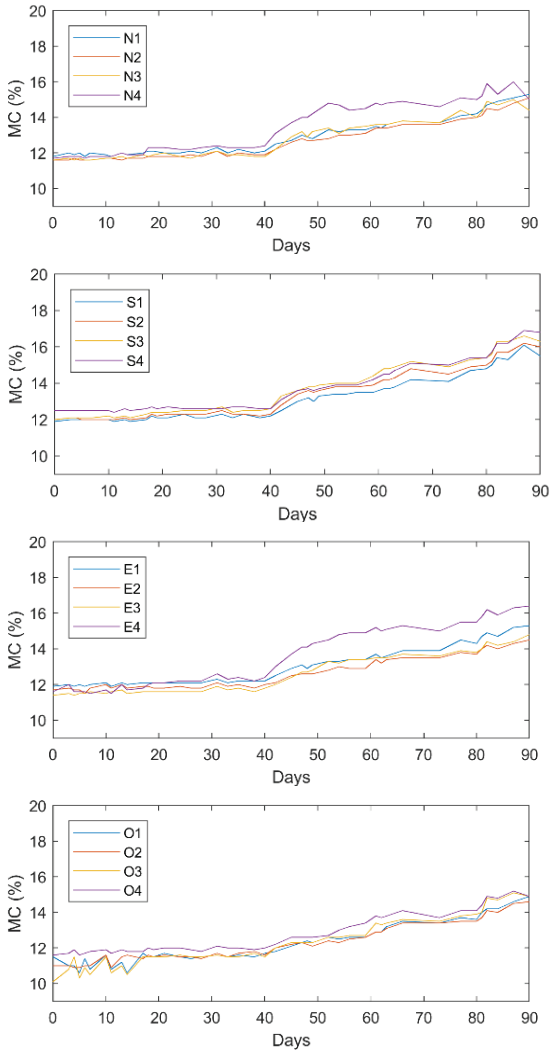

Figure 6: *Moisture content variations at P1 depth in walls North, South, East, and West.*

In cycle 1 with a temperature of 20 °C and 60% relative humidity (days 1 to 20), the values of moisture content in position P1 have an average value of 11.6 %; which is very similar to the averages at depths P2 and P3 (11.7% and 11.5%, respectively). Besides, for cycle 2 with a temperature of 20°C and 65% relative humidity (days 21 to 43), the moisture content in position P1 is 11.8% on average. In contrast, the moisture contents increase in the other two depths (P2 and P3).

In cycle 3 (days 44 to 62, temperature of 20°C and 75% relative humidity), the moisture content average in the three depths tends to be 12%. For cycle 4 (days 63 to 78, temperature of 20°C and 85% relative humidity), once again, the three depths showed similar average values equal to 13.5%. Finally, in cycle 5 (days 79 to 94, temperature of 20°C and 90% relative humidity), the average moisture content in position P1 are slightly higher than P2 and P3, with values of 14%, 13.7%, and 13.3%, respevctively. The different data are shown in Table 2.

Table 2: *Moisture content mena values in the CLT walls for each climate cycle and measurement depth*

Stage	RH (%)	Measurement Depth	Initial MC (%)		Final MC (%)	
			Mean	SD	Mean	SD
1	60	P1	11.6	2.11	11.8	0.78
2	65		11.8	0.78	12.0	0.79
3	75		12.0	0.79	13.5	0.65
4	85		13.5	0.65	14.0	0.82
5	90		14.0	0.82	15.4	1.15
1	60	P2	11.7	2.13	11.9	0.81
2	65		11.9	0.81	12,0	0.81
3	75		12,0	0.81	13,0	0.89
4	85		13,0	0.89	13.7	0.84
5	90		13.7	0.84	14.7	1.16
1	60	P3	11.5	2.15	11.8	0.84
2	65		11.8	0.84	11.9	0.82
3	75		11.9	0.82	12.8	0.89
4	85		12.8	0.89	13.3	0.84
5	90		13.3	0.84	14.2	1.17

The results show an important moisture content gradient for cycle 5 in the three measurement depths. The percentage variations of the moisture contents are 15.4% for P1, 14.7% for P2, and 14.2% for P3. These increasings are related to moisture content increments of 3.8%, 3%, and 2.7% for P1, P2, and P3, respectively.

The moisture content measurements also highlighted the trend of the moisture to concentrate at the interface of the first two CLT layers rather than just on the surface. A recent Morrell et al. [17] study also showed this trend. In the results obtained, the damping effect of the CLT without protection can be noticed since the temperature and relative humidity of the environment should have induced an equilibrium moisture content close to 18 %. However, this value is closer to some measurements of the wall panels on the module's south side, as seen in Figure 7.

https://doi.org/10.52202/069179-0070

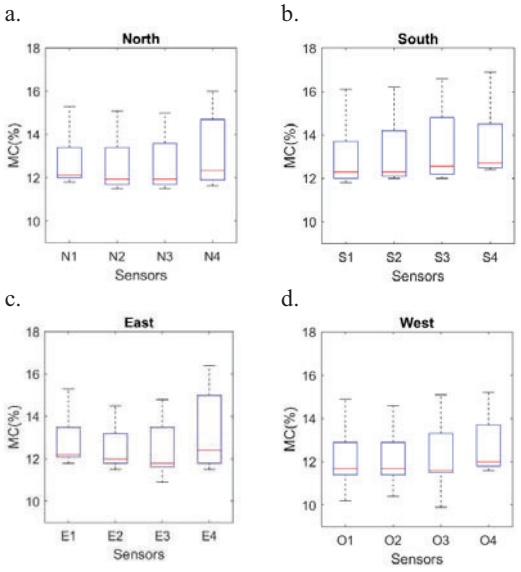

***Figure 7**: P1 depth moisture content box plots for walls a) North; b) South; c) East; and d) West.*

The difference between the moisture content measured the north and east wall, appears to be related to the overheating of the wall due to solar exposure in the summer season.

3.3 DIMENSIONAL STABILITY

The dimensional variation suffered by the CLT module during the experiment is presented in Figure 8, which presents the south side wall results. The expressed values correspond to the differentials that happened in the measurement zone (from 500 to 600 mm) detected by the Whittemore gauge system.

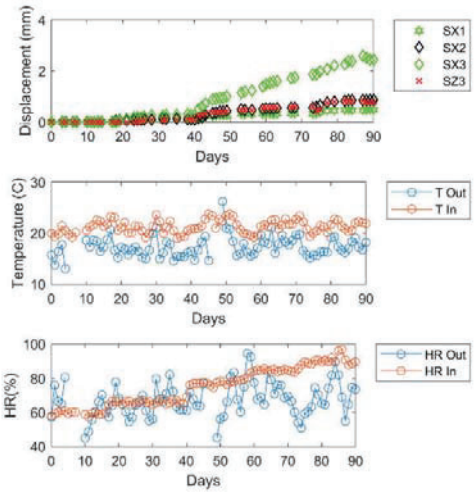

***Figure 8:** In-plane dimensional change of South panel (top), interior and exterior average temperature (middle) and relative humidity (RH, bottom).*

The results of absolute experimental dimensional variations for the different walls are shown in Table 3 for the North, East, and South walls. It is noticed that the total displacement values fluctuate from 0.45 mm to 1.59 mm (SX1 and NX2, respectively), depending on the CLT panel and its orientation. The value measured by the SX3 sensor is not considered for mean value, since it is an evaluation that takes the entire width of one panel and half of the connection with the other panel, having an evaluation length of 1085 mm. Besides, the nominal value is determined considering the experimental dimensional variation evaluated in one meter of length.

***Table 3:** Total dimensional variation in the different analysis directions in each sensor position and orientation.*

Direction	Sensor	Instrumental value (mm)		Total dimensional Variation	
		Initial	Final	Experimental (mm)	Nominal (mm/m)
X	NX1	0.12	1.29	1.17	2.34
	NX2	0.27	1.86	1.59	3.18
	EX1	10.51	11.37	0.86	1.72
	EX2	-0.06	-0.56	0.50	1,00
	SX1	-0.03	-0.48	0.45	0.76
	SX2	-0.01	-0.87	0.86	1.45
	SX3	0,00	2.45	2.45	2.26
Z	NZ3	-0.02	0.52	0.54	1.03
	EZ3	0.00	0.39	0.39	0.73
	SZ3	0.00	0.77	0.77	1.43

For the X direction (wall width) the average results variate 60% more than in the Z direction (wall height), as presented in Table 4. Besides, it is observed that the nominal displacement that would occur in the panels of 1 meter width (1.74 mm/m) should be considered in the gaps or construction tolerances in order to avoid problems in the connections or differences with the interior sheathings, particularly in wet areas.

***Table 4:** Mean total dimensional variation for X and Z directions*

Climate Variation	Direction - Axis	Mean total dimensional variation	
		Experimental (mm)	Nominal (mm/m)
20 °C; RH 60 to 90 (%)	Z	0,57	1,06
	X	0,91	1,74

Due to the constraining action of the cross laminations, CLT has (relative to uniaxial glulam products) more stable in-plane dimensions when it interacts with the environment. The wall samples tested expanded a maximum of 1.59 mm in width (measured transverse to the surface layers) and 0.77 mm in length (measured longitudinally to the surface layers) during all wetting cycles. These deformations are still notably smaller than the nominal calculated values using recommended standard rates that do not take into account the intrinsic characteristics of the Radiata Pine employed.

https://doi.org/10.52202/069179-0070

3.5 STABILITY COEFFICIENT FOR RADIATA PINE CLT PANELS

Using the moisture content data at depth P1 in the area near the displacement measurement zones, it is possible to calculate the experimental stability coefficients through equation (1). These results are presented in Table 5.

Table 5: *Stability coefficient (swelling) calculated per each measuring sensor.*

Direction	Sensor	Total dimensional Variation		Delta MC	K cor,0	Mean Kcor,0
		Experimental (mm)	Nominal (mm/m)			
X	NX1	1.17	2.34	3.5	0.00067	0.00048
	NX2	1.59	3.18	3.3	0.00096	
	EX1	0.86	1.72	3.5	0.00049	
	EX2	0.50	1,00	4.8	0.00021	
	SX1	0.45	0.76	3.7	0.00020	
	SX2	0.86	1.45	4.3	0.00034	
	SX3	2.45	2.26	4.4	0.00051	0.00051
Z	NZ3	0.54	1.03	3.2	0.00032	0.00029
	EZ3	0.39	0.73	3.4	0.00021	
	SZ3	0.77	1.43	4.2	0.00034	

The average value achieved for the plane in the X direction of the CLT walls is 0.00048, 2.4 times higher than the coefficient recommended in the EN16351 standard for the Radiata Pine species. Moreover, the value of the SX3 sensor, which has a longer evaluation length, is close to the mean coefficient calculated, being 0.00051. In the other direction of the plane, Z or longitudinal direction, the average value is 0.00029.

Figure 9 presents a graphical comparison of the experimental stability coefficients with respect to the recommended values of the EN16351 standard.

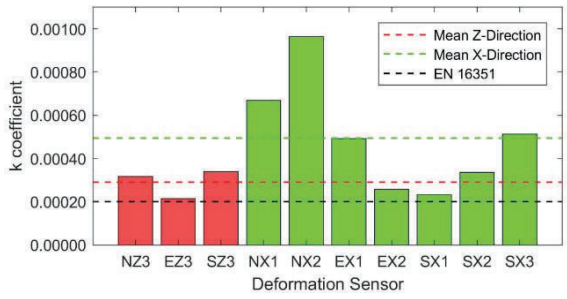

Figure 9: *Comparison of the experimental and recommended stability coefficient values for Radiara Pine CLT panels.*

Finally, in Table 6 is possible to appreciate the values of the swelling coefficient that different authors have achieved.

Table 6: *Comparison of experimental stability coefficient values recommended in different studies.*

4 CONCLUSIONS

This research monitored the moisture content and dimensional variation based on the relative humidity of the internal climate of a conditioned CLT module, aiming to evaluate if the dimensional changes are within the parameters established in the EN 16351 standard: 2016.

The deformation of the CLT elements under humidity cycles was measured. The in-plane deformations of the CLT increase as the relative humidity of the environment increases in the experimental module. The most important deformations appear when the relative humidity of the environment rises above 75%. After these cycles, the deformations continue to increase.

The Radiata Pine CLT wall panels appear to be dimensionally stable during the development of the experiment. The observed zones expanded on mean 0.91 mm in width and 0.57 mm in height during the conditioning cycles. During the conditioning, the CLT moisture content increased 5.1% at a depth of 21 mm from the surface. The experiment was carried out considering potential conditions of short and long periods of climatic exposure. Even though the construction configuration of the prototype CLT module is atypical (no lining or sheathings were used), this type of test revealed the most critical behavior that the system could have in service. Therefore, it provides relevant information for the variety of climates existing in Chile.

The experience only considered the increase in humidity in the interior climate; thus, only the swelling coefficient was studied to stablish stability. It is suggested to develop experimets to study the behavior of Radiata Pine CLT panels under contraction cycles.

In the tested configuration, the direction of the outer most layer produces a distortion of the CLT laminations on the surface. Those points in which the outer layers of the CLT have pith or central wood suffered larger displacements, especially in the north wall.

Regarding the in-plane dimensional change that the CLT elements of the prototype module experienced, it was observed that these were greater than the values determined using the coefficient recommended in the

https://doi.org/10.52202/069179-0070

EN16351 standard, especially in the direction which is related to the direction of the cut of the wood.

EFFECTS OF PANEL DIRECTION, LOAD LEVEL AND AMBIENT HUMIDITY ON THE CREEP OF DOWNSCALED CROSS-LAMINATED TIMBER

Dawei Wang[1], Meizhen Chen[1], Meng Gong[2], Zhuo Cheng[3]

ABSTRACT: The creep behaviour of wood or engineered wood products is an important factor in the consideration of the serviceability of a timber structure. This study evaluated the effect of creep of downscaled cross-laminated timber *(CLT)* specimens by considering panel direction, load level and relative humidity *(RH)*. The test materials were spruce-pine-fir (*SPF*) lumber and polyurethane adhesive. Static bending, one-week creep and four-month creep tests were conducted. It was found that: 1) *CLT* specimens had an average proportional limit *(PL)* of around 3,024 N and 817 N in the "Major-strength" and "Minor-strength" directions, respectively; 2) Panel direction strongly impacted time-dependent deflection, with the "Minor-strength" specimens exhibiting a 2 to 2.5 times as large deflection as the "Major-strength" ones; 3) Load level clearly affected the load-deflection behaviour due to the layup of the specimens; 4) Ambient humidity had a little effect on 7-day creep, but impacted the 4-month mechano-sorptive creep to some degree; and 5) The "Generalized Kelvin" model seemed to be suitable in simulation the creep of the downscaled *CLT* specimens used in this study. The upper limit of the model at 95% confidence level could be a good approach to simulate the creep of the specimens under cyclic *RH*.

KEYWORDS: Cross-laminated timber, Relative humidity, Load level, Panel direction, Creep, Mechano-sorptive behaviour, Modelling

1 INTRODUCTION

The use of cross-laminated timber (*CLT*), an innovative green building material, has gained widespread popularity in recent years, particularly for the construction of mid- and high-rise timber structures. The advanced cross-laminate technology utilized in *CLT* production provides the panels with improved dimensional stability and high in- and out-of-plane stiffness and strength properties, leading to its two-way action capability and enhanced high-strength construction [1]. Additionally, *CLT* offers a cost-effective alternative to traditional building materials such as concrete and steel, as its light weight reduces the size and cost of foundations. The great seismic and fire performance of *CLT* panels further adds to their suitability for use in various building environments [1].

The evaluation of the serviceability of a timber structure requires a thorough understanding of the concept of creep, which can be classified into two types: "pure" creep and mechano-sorptive creep. "Pure" creep is defined as the time-dependent deformation caused by a material under constant load [2], while mechano-sorptive creep is the deformation affected by an interaction between humidity variations and mechanical loading [3]. The creep behaviour of wood is subject to various factors, including temperature, relative humidity (*RH*), grain direction of wood, strength direction of a product, loading condition, member size, and anatomical features of wood. However, the mechano-sorptive creep of *CLT* is specifically influenced by the ambient temperature and humidity when it happens [2]. Despite its importance, research on the mechano-sorptive creep of *CLT* remains limited.

In the early stage of research, the evaluation of creep behaviour in wood materials was primarily conducted through experiments utilizing both small clear wood specimens and full-scale timber products [4-5]. These wood materials were analysed by utilizing rheological and viscoelastic theories, leading to a thorough understanding of their creep behaviour. Under variable temperature and moisture conditions, the time-dependent behaviour of wood is highly complex [6]. Phenomenological studies, similar to those conducted by Schniewind [4], were performed to investigate the impact of environmental factors on creep behaviour, with results obtained for both constant and varying conditions during the course of an experiment. Subsequent studies indicated that creep was often more vulnerable to changes in temperature, moisture content (*MC*), and physical ageing than its elastic properties [2, 7]. Since then, efforts have been made on the studies that included creep by considering multiple influencing factors such as humidity effect, as well as the development of creep models. Over the past several decades, there has been a remarkable advancement in the study of the viscoelastic properties of wood. This has been achieved largely through the innovation and improvement

of testing methods, the collection of experimental data, and the formation of rheological models. These progresses have occurred in parallel with the rapid expansion of the wood-based products industry and uses of wood-based products in construction, leading to a corresponding invention and development of various types of engineered wood products (*EWPs*), such as *CLT*. Bengtsson [8] conducted a third-point bending test using Norway spruce (*Picea abies*) specimens and observed that *MC* and density strongly influence the creep behaviour of timber. The study also demonstrated a strong correlation between the relative creep and modulus of elasticity. O'Ceallagh et al. [9] conducted third-point bending tests under constant stress levels using Sitka spruce (*Picea sitchensis*) for 75 weeks to investigate the mechano-sorptive creep behaviour of unreinforced and fiber-reinforced polymer (*FRP*) plate-reinforced glued laminated timber beams with the variable *RH* ranging from 65±5% to 90±5%. The results indicated that variable *RH* values significantly influenced creep behaviour. The first *RH* cycle caused a statistically significant reduction in both total and creep deflection. Takanashi et al. [10] conducted long-term out-of-plane bending tests on full-scale seven-layer Japanese larch (*Larix kaempferi*) *CLT* panels and estimated a mean relative creep of 1.49 after 50 years using a power-law function developed by Holzer [6]. The authors also recommended avoiding *CLT* products made from Japanese larch when subjected to loading levels of 70% or more. Hunt [11] proposed a unified approach to modelling the creep behaviour of Ponderosa pine (*Pinus ponderosa*), who was aimed at developing a mathematical model that could accurately predict the long-term deformation of wood under varying stress levels and environmental conditions. He reported that the full extent of the mechano-sorptive effect would require the timber to reach equilibrium moisture content (*EMC*) under new environmental conditions. Therefore, multiple changes of *RH* in full-scale tests may yield inaccurate results. Due to the lack of a harmonized standard for examining the mechano-sorptive effect in *EWPs*, the duration of creep tests and *RH* cycles vary significantly between test programs. Liu et al. [4] analysed different models for simulating creep in laminated veneer lumber products by using third-point bending test under short- and long-term constant loading and found that the modified Burger model provided good simulation. Cai et al. [12] used the specimens of southern pine (*Pinus spp.*) to give two sets of tests for creep and creep recovery, which presented new models for creep and creep recovery, which could be well fitted to both primary and secondary stages of creep deformation using modified power-law functions.

This study was aimed at investigating and simulating the creep behaviour of *CLT* using the downscaled specimens by considering panel direction, load level and ambient humidity.

2 MATEIRALS AND METHODS

2.1 MATERIALS AND SPECIMENS

Downscaled *CLT* specimens consisting of three-layers were produced using 2×6 No.2 Spruce-Pine-Fir (*SPF*) with moisture-activated polyurethane adhesive (*PUR*) with reference to the standard ANSI/APA PRG 320 and *CLT* Handbook [13-14]. The dimensions of each lamination were 11 mm in thickness, 63 mm in width, and 710 mm in length. The dimensions of each three-layer downscaled *CLT* were 33 mm in thickness, 63 mm in width, and 710 mm in length. Two types of three-layer specimens were fabricated, taking into account the panel direction, i.e., "Major-strength" and "Minor-strength" directions. Table 1 provides the specimen information, in which the notation "S" stands for static bending, "A" for "Major-strength" direction, "O" for "Minor-strength" direction, and "C" and "D" for one-week and four-month creep tests. The manufacturing process is illustrated in Fig. 1. The test specimens were conditioned at 20°C and 65% *RH* until they achieved a constant *MC* of 12%.

Table 1: *Groups and sets labelling of specimens.*

Tests		Panel direction	Load level	RH level	Groups/ sets
Static (S)		Major	/	/	SA
		Minor	/	/	SO

2.2.1 Static bending test

The third-point bending tests were conducted at a loading rate of 5 mm/min and a span ratio of 16.4 with reference

to ASTM D198–15 [15] with an aim at determining the limits of proportion (*PL*s) of the *CLT* specimens in the "Major-strength" and "Minor-strength" directions, Fig. 2. A Linear variable differential transformer (*LVDT*) was used to measure the deflection at the mid-span of each specimen, Fig. 2.

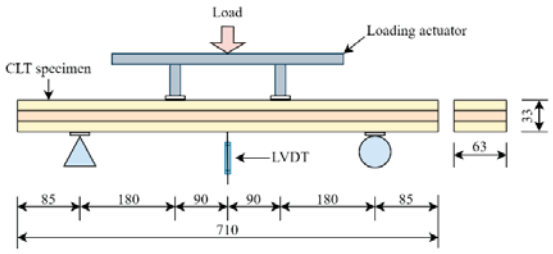

***Figure 2**: Static bending test setup (Unit-mm).*

2.2.2 One-week creep test

A third-point bending setup was employed to conduct a one-week creep test in a conditioning chamber, with a temperature of 20±1°C, Figs. 3 and 4. Two types of specimens were used, "Major-strength" and "Minor-strength". Two levels of *RH* were employed, 30±5% and 65±5%. Two load levels were set at 30% and 60% of the *PL*. The target load was achieved by placing steel plates on each specimen, Fig. 3.

***Figure 3**: Creep test setup with an LVDT at the mid-span of each specimen.*

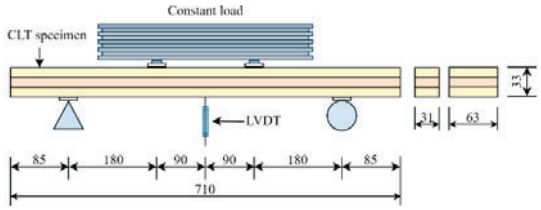

***Figure 4**: Creep test setup (Unit-mm).*

The deflection at the mid-span of each specimen was recorded using an *LVDT* connected to a data logger with a frequency of 1 Hz. In order to safely and efficiently apply the constant load up to 60% *PL* on those specimens, a given *CLT* specimen was ripped into two narrow specimens along the middle line, see the two different cross sections in Fig. 4. The load applied on each narrow specimen (i.e., after ripping) was half of that on the specimen of full width (i.e., before ripping). The loading duration was of 7 days. Six specimens (three specimens per type) were tested at a given load level and *RH*, generating a total of 24 specimens in this phase of testing.

2.2.3 Four-month mechano-sorptive creep test

The four-month mechano-sorptive creep tests were carried out using the same setup as that in the one-week one, Figs. 3 and 4. The load level and panel direction considered were the same as those of 7-day creep tests. The tests were conducted under a constant temperature of 20±1°C in a conditioning chamber with two levels of *RH* (i.e., 30±5% and 65±5%) with an interval of 7 days. The test specimens for the four-month mechano-sorptive creep tests were obtained from the same specimens that had been subjected to a 7-day loading duration and recovered in the chamber for about one year in a conditioning chamber of a temperature of 20°C and 65% *RH*. This allowed the completely release of any residual stress in a specimen. The specimens at 30% *PL* were completed a 4-month mechano-sorptive creep. However, the specimens at 60% *PL* were only terminated to 2 months because of the relatively large deflection that caused a specimen to fracture and/or collapse.

2.2.4 Modelling

Great efforts on modelling the creep behaviour of wood and wood composites have been made [16]. Classical models have been developed that can provide a meaningful approximation of the time-dependent deformation of wood, which offer valuable insights into the mechanical behaviour of wood and wood composites. These models are typically based on a combination of a spring(s) and a Newtonian dashpot(s), representing the elastic and viscoelastic nature of a composite such as wood [12]. The models such as the "Maxwell" model, "Kelvin" model, "Generalized Kelvin (*GK*)" model, and "Burger (*B*)" model are commonly used to describe the mechanical response of viscoelastic materials and involve the arrangement of elastic and viscous elements in either series or parallel configurations [2, 16-17].

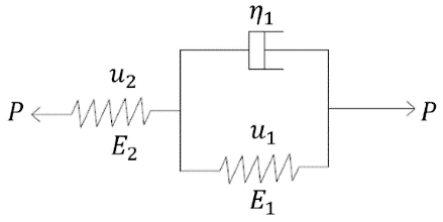

***Figure 5**: "Generalized Kelvin" model [2].*

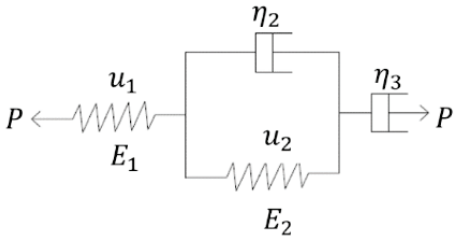

***Figure 6**: "Burger" model [2].*

https://doi.org/10.52202/069179-0071

This study adopted the "*GK*" model and "*B*" model to simulate the creep behaviour of the downscaled *CLT* specimens. The "*GK*" model was chosen due to that it is a derivation from the widely used "Kelvin" model, which can accurately represent the delayed elastic component of a material. The "*B*" model was selected due to its simplicity as well as the model parameters are expressed on a unit basis, relating time-dependent stress-strain behaviour to the modulus of elasticity and rigidity and to the coefficients of the viscosity of a composite [2].
These two models are illustrated in Figs. 5 and 6, in which, E is the modulus of elasticity of a spring; η is the viscosity coefficient of a dashpot; P is the force applied; τ is the relaxation-time constant which is η/E; u is the displacement; t is creep time [4].

***Table 2**: Two creep model equations.*

Creep Model	Creep Equation
"Generalized Kelvin" model	$u = -Ae^{-Bt} + D$
"Burger" model	$u = -Ae^{-Bt} + Ct + D$

Table 2 gives the simplified forms (equations) of two creep models. Where, $A = P_1/E_1$, $B = 1/\tau_1$, and $D = P_1/E_1 + P_2/E_2$, in "*GK*" model; $A = P/E_2$, $B = 1/\tau_2$, $C = P/\eta_3$ and $D = P/E_1 + P/E_2$, in "*B*" model.

3 RESULTS AND DISCUSSION

3.1 STATIC BENDING TEST

Fig. 7 illustrates the load-deflection curves of two groups. Groups SA and SO represent the groups in the "Major-strength" and "Minor-strength" directions. It can be found most specimens failed in a brittle way. It can also be found that one specimen in group SA exhibited an abnormal response, which could be due to the existence of imperfects during manufacturing of specimens such as lack of adhesive causing delamination between laminations. Consequently, this specimen was eliminated from the data analysis. The average peak loads of groups SA and SO were approximately 6,094 N and 1,249 N, respectively. The average *PL* values of groups SA and SO were around 3,024 N and 817 N, respectively. The average stiffness of group SA was approximately 610 N/mm, which was approximately 10 times larger than that of group SO.
Table 3 summarizes the test results of two groups including stiffness, *PL* and P_{max}, plus the deflection at P_{max}. It is not surprising that the group SA (i.e., the "Major-strength" group) exhibit higher strength and stiffness. The deflection at the peak load is around 11 mm, which is about 35% lower than that of the group SO. The maximum bending capacity of the group SA was about 3 times greater than that of the group SO. Subsequent to the static bending test, two load levels were then determined, based on the *PL,* to be 30% *PL* and 60% *PL* for the "Major-strength" and "Minor-strength" groups for the following creep tests.

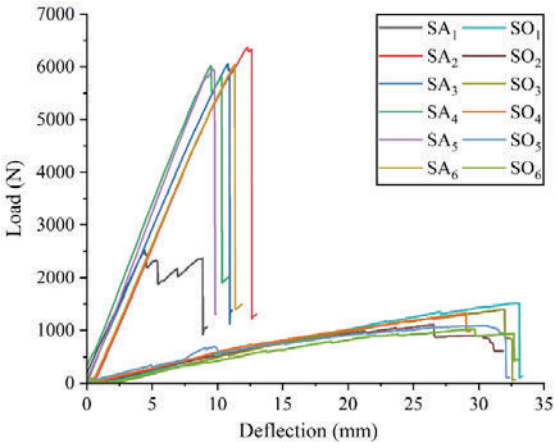

***Figure 7**: Load-deflection curves in the "Major-strength" and "Minor-strength" directions.*

***Table 3**: Mean properties of downscale CLT specimens under the static bending tests (Note: Numbers in parentheses are standard deviations).*

Property	Mean	
	Group SA	**Group SO**
Stiffness (N/mm)	610 (4)	60 (0)
PL (N)	3,024 (431)	817 (238)
P_{max} (N)	6,094 (163)	1,249 (196)
Deflection (mm)	11.36 (1.16)	32.13 (1.46)

3.2 ONE-WEEK CREEP TEST

Fig. 8 was used to illustrate the creep deflections of all specimens under two-panel directions, two load levels, and two *RH* conditions, with each curve representing the average deflection-time response of the corresponding set. It can be obviously seen that the load level had a significant impact on the creep. Each curve consists of two stages, namely the initial creep stage and the steady creep stage. The maximum load applied on a specimen in this study was 60% of *PL*, the accelerated creep stage did not appear in the 7-day creep test, which suggests that the maximum deflection had not exceeded the specimen's deflection limit and caused failure in the 7-day [18]. Thus, only the initial creep stage and steady creep stage were discussed and simulated in 7-day creep test. It can be discovered that the eight sets largely conformed to the general law of creep.
It can be found from Fig. 8 that 1) For the panel direction: the average deflection reached by the "Minor-strength" groups (sets CO1 and CO2) loaded at 30% *PL* are approximately 11.85 mm, which is 2.2 times larger than that made by the "Major-strength" groups (sets CA1 and CA2). For the sets loaded at 60% *PL*, the average deflection of the "Minor-strength" groups (sets CO3 and CO4) was approximately 21.83 mm at 172 hours, which is 2.71 times larger than that of the "Major-strength" groups (sets CA3 and CA4) with a deflection of 8.07 mm.

https://doi.org/10.52202/069179-0071

This is well in agreement with the findings by He et al. [19]; 2) For the load level: "Major-strength" groups bewteen sets CA1-2 and CA3-4 were compared, which revealed a small difference in deflection values at the termination of testing, with average values of 5.39 mm and 8.07 mm, respectively. "Minor-strength" groups bewteen sets CO1-2 and CO3-4 exhibited a much larger difference with the average values of 11.83 mm and 21.83 mm. Especially, set CO3 is about 22.74 mm, the maximum deflection set in 7-day creep test, which is 1.93 times that of set CO1 with a deflection of 11.81 mm at the time of 172 hours; 3) For the *RH*: A comparison made between two *RH*s revealed that the deflection in higher *RH* sets was greater than lower *RH* sets, while keeping other conditions unchanged. This observation can be attributed to the difference in the *MC* of the specimens used, which well aligns with other findings [2, 7-8].

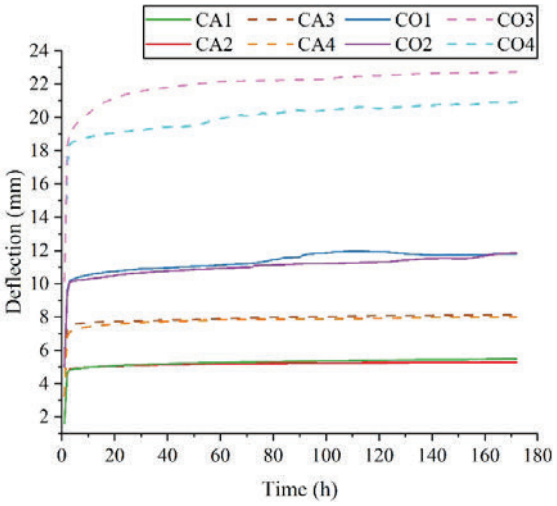

***Figure 8**: Average 7-day creeps of eight sets tested.*

3.3 FOUR-MONTH MECHANO-SORPTIVE CREEP TEST

Fig. 9 depicts the 4-month mechano-sorptive creeps of all sets under two-panel directions, two load levels, and cyclic *RH* ranging from 30% to 60% with a time interval of 7 days. Each curve represents the average deflection-time response of a given set. It can be clearly seen that all setting factors mentioned above had a significant effect on the creep of the specimens tested. It can be discovered that sets DA1 and DO1 largely conformed to the general law of mechano-sorptive creep.

Fig. 9 shows that sets DA2 and DO2, which were loaded at 60% *PL*, had to be halted at the time of about 900 hours due to the collapse of two "Major-strength" *CLT* specimens and the destruction of one "Minor-strength" *CLT* specimen. Based on Fig. 9 and Table 3, the initial deflections of sets DA1-2 and DO1-2 were 1.61 mm and 3.27 mm in the "Major-strength" direction and were 4.99 mm and 10.14 mm in the "Minor-strength" direction, as presented in Table 4. Those initial deflections were using average static bending test data. Additionally, Table 4 presented the total deflection that the specimens experienced on average, derived by considering initial deflection and maximum creep deflection together. Remarkably, the deflections of sets DA2 and DO2 at the end of loading were 9.64 mm and 28.88 mm, respectively, which almost reached the ultimate deflection at a given direction, Table 3, namely, 11.36 mm or 32.13 mm for the "Major-strength" or "Minor-strength" direction. The specimens in sets DA2 and DO2 were speculated to have exceeded the bending yield point and created a high creep deflection causing the specimens to collapse or destroy during the test. Therefore, only the 4-month mechano-sorptive creeps of sets DA2 and DO2, i.e., those subjected to 60% *PL* load level, were excluded from the data analysis and discussion in this study.

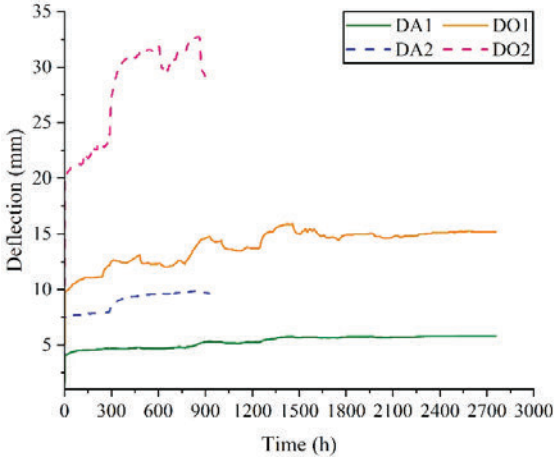

***Figure 9**: Average four-month mechano-sorptive creeps of four sets tested.*

***Table 4**: Average deflections of the specimens tested under the cyclic RH (Unit-mm).*

Test sets	Initial deflection	Deflection at the end of testing	Total deflection
DA1	1.61	4.18	5.79
DA2	3.27	6.37	9.64
DO1	4.99	10.20	15.19
DO2	10.14	18.74	28.88

It can be discovered from Fig. 9 that the panel direction significantly affected the creeps of the specimens under 30% *PL*. Specifically, set DO1 exhibited a deflection of approximately 14.59 mm at 900 hours, which is 277% larger than set DA1 that had a deflection of 5.27 mm. As the testing of sets DA1 and DO1, the deflection curve gradually increased from the initial stage. The sets DA1 and DO1 reached the maximum discrepancy in deflection at 1459 hours, with deflections of 5.76 mm and 15.90 mm, respectively. At the steady stage, which is at 2755 hours, the deflection was 5.79 mm and 15.19 mm for the sets DA1 and DO1, respectively. It is apparent that the

https://doi.org/10.52202/069179-0071

deflection of set DO1 was 262% larger than that of set DA1 to a large degree.

Fig. 10 illustrates the changes in temperature and *RH* values during the 4-month mechano-sorptive creep tests. It can be found thatt temperature was well mainained at 20°C, while *RH* was not well controled at the preset range, i.e., from 30±5% to 65±5%, due to the out-of-control of the chamber during the creep test duration. Fig. 9 indicates that significant increases in deflection were observed at approximately 300, 900, and 1300 hours. The increase in deflection of set DO1 ranged from 12.49 to 15.13 mm, while that of set DA1 was only 4.68 to 5.49 mm when the *RH* increased from 30% to 70% at the times of about 300, 900 and 1300 hours.

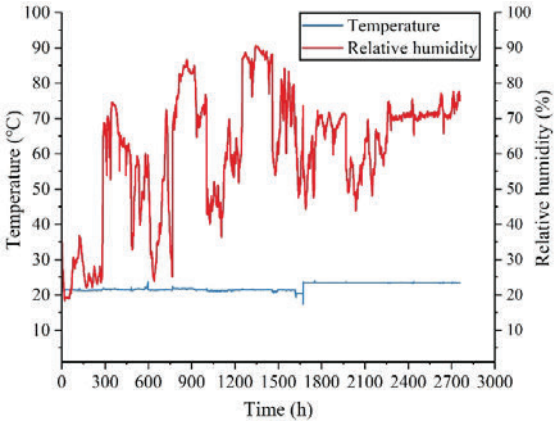

***Figure 10**: Changes in temperature and RH during the creep tests of sets DA1 and DO1.*

There are some shortcomings existed during the mechano-sorptive creep tests in this study, resulting in unsatisfactory results. Firstly, the application of a 60% *PL* load level for the long-term creep test was inappropriate (sets DA2 and DO2) since it could cause a relatively large deflection at 900 hours, which exceeded that at the maximum load under the static tests. Secondly, the *RH* in the conditioning chamber used was not well controlled to some degree as planned. Thirdly, the 4-month duration of the mechano-sorptive creep test could not be sufficient, which was due to the duration (only 1 year) of a project-based master's student's study. Finally, the downsized *CLT* specimens were not good enough to represent the full size *CLT* panels. Hence, there is a need for further research to overcome these shortcomings.

3.4 MODELLING

The "*GK*" model and "*B*" model were selected to simulate the creep of downscaled *CLT* specimens loaded at 30% *PL* in this study. The Curve Fitting Function in Origin software developed by OriginLab Corporation was used to determine the parameters in each model by the non-linear fitting method. The fitting results are provided in Table 5, and Figs. 11 to 12. The R-square values of over 0.85 suggests that both models well fit the experimental data and seems the fitting curve of the "Major-strength" set is slightly better than that of the "Minor-strength" one at a given model. The 95% of prediction bands (filled colour) of each model are plotted in Figs. 11 and 12 as well. Considering the fluctuation of time-dependent deflection due to the cyclic *RH*, the upper limit of 95% confidence level is employed to build "*GK*" model or "*B*" model, which reflects the worst-case scenario for downscaled *CLT* specimens used in this study in a given direction. The creep models developed in this study are given in Table 6.

***Table 5**: Determination of model parameters based on the 4-month creep test results of two sets (DA1 and DO1) in both "Major-strength" and "Minor-strength" directions.*

Sets	Model	Parameters				R-Square
		A	*B*	*C*	*D*	
DA1	GK	1.9317	0.0007	/	6.1452	0.9235
	B	0.2452	-0.0008	0.0012	4.5253	0.9384
DO1	GK	5.4571	0.0013	/	15.4085	0.8786
	B	13.6279	0.0006	-0.0022	23.7686	0.8842

The deflections of specimens DA1 and DO1 at 3 months, 6 months, 1 year, 10 years, and 50 years can be predicted using the models developed above, which are listed in Table 6. It can be found that the "*GK*" model could produce more reasonable results than the "*B*" model based on the data in this study. Also, it could be discovered that the deflections predicted by the "*GK*" model become a constant after 1 year. This suggests that a duration of 1 year, or even 6 months, could be good enough for building a creep mode for *CLT* specimens. However, such a speculation requires further verification. Also, a more complex model should be developed by considering panel direction, load level and relative humidity.

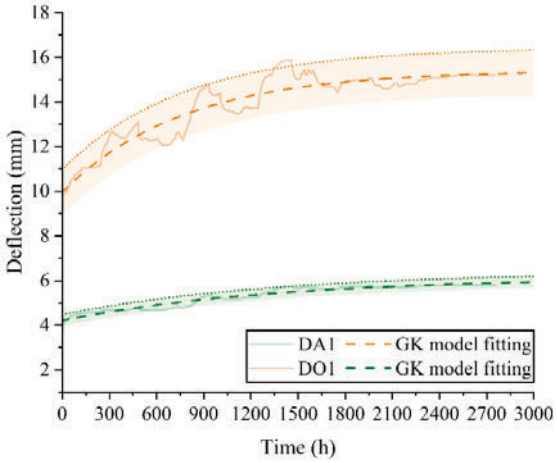

***Figure 11**: "GK" models and prediction bands at 95% confidence level for 4-month mechano-sorptive creep.*

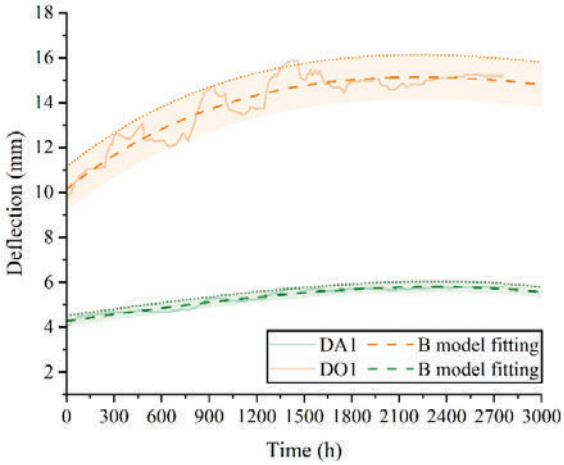

***Figure 12**: "B" models and prediction bands at 95% confidence level for 4-month mechano-sorptive creep.*

***Table 6**: Creep models and predicted deflections at given times.*

Set	Model	Equation	Deflection (mm)				
			Month 3	Month 6	Year 1	Year 10	Year 50
DA1	GK	$u=-1.9319e^{-7.3109t}+6.4080$	6.01	6.33	6.40	6.41	6.41
	B	$u=-0.2518e^{0.0008t}+0.0012t+4.7672$	6.03	2.71	-216.19	-1.09×10^{29}	-3.82×10^{147}
DO1	GK	$u=-5.4555e^{-0.0013t}+16.4243$	16.10	16.40	16.42	16.42	16.42
	B	$u=-13.5727e^{-0.0006t}-0.0022t+24.7067$	16.12	14.20	5.59	-165.55	-926.60

4 CONCLSUIONS

Based on the above analysis and discussion, the following conclusions could be drawn:

(1) The *CLT* specimens had average *PL*s of approximately 3,024 N and 817 N in the "Major-strength" and "Minor-strength" directions, respectively.

(2) The results of the one-week creep tests indicated that the panel direction of *CLT* specimens was the most influencing factor on their creep behaviour, with the "Minor-strength" specimens exhibiting an average creep deflection being 2 to 2.5 times larger than that of the "Major-strength" ones. The initial deflection of those specimens loaded at a level of 60% *PL* was approximate twice as large as that at a level of under 30% *PL*. The effect of *RH* on the creep of the specimens during the one-week loading was found to be less significant than that of the panel direction or load level.

(3) The four-month mechano-sorptive creep results showed that the panel direction, load level and *RH* all played a critical role in contribution to the creep of downscaled *CLT* specimens. A reduction of *RH* to 30% from 65% reduced the creep to some degree.

(4) The "Generalized Kelvin" model seemed to be suitable in simulation the creep of the downscaled *CLT* specimens used in this study. The upper limit of the model at 95% confidence level could be a good approach to simulate the creep of the specimens under cyclic *RH*.

SHEAR CREEP OF POLYSTYRENE CORES IN WOOD-BASED PANELS

André Jorissen[1], Johnny van Rie[2], Jeff Modderman[3], Hèrm Hofmeyer [4]

ABSTRACT: This paper reports on an experimental study of shear creep in load bearing sandwich panels with a polystyrene core and wood-based faces. This is ongoing research at Eindhoven University of Technology (TU/e), in cooperation with industry, to provide scientific and experimental backgrounds to roof panels used for residential housing. For these panels, loaded perpendicular to plane, faces are loaded in tension or compression, whereas the core is mainly loaded in shear. Both the polystyrene core and the wood-based faces show time dependent behaviour (creep) of which only the time dependent behaviour of the core is dealt with in this paper. This by including experiments on panels of which the wood-based faces are replaced by steel, thus isolating the creep of the core. Furthermore, conform other studies on this subject, e.g. Taylor et al. [1], and Kilpeläinen et al. [2], the study presented in this paper indicates that the creep depends on the load ratio, i.e. the quasi-permanent shear relative to the shear stress at failure (strength). Therefore, load ratios were systematically varied. Results indicate that when the shear stress exceeds more than 50% of the shear strength, the tertiary creep phase is reached, and collapse will occur within 4 -5 years. When the shear stress is lower than 40% of the shear strength, the deformation is likely to stabilise in the secondary creep phase.

KEYWORDS: Sandwich panels, Shear creep, Polystyrene (EPS), Wood-based faces

1 BACKGROUND RESEARCH

When using sandwich panels with rigid foam cores for roofs, the panels are predominantly loaded perpendicular to plane. The deflection is usually decisive for the maximum allowed span. Suggested by current European regulations [3], the shear deformation is often the largest part of total deformation, regardless the type of rigid foam applied for the core. For the rigid foam the creep factor k_{def}, defined as $k_{def} = \frac{u_{fin} - u_{inst}}{u_{inst}}$ with u_{fin} = final and u_{inst} = instantaneous deflection, is set to k_{def}=7.0 [3], which causes high predicted deformations. For steel sandwiches, which are usually loaded with low permanent loads at large spans this is not a problem, but for residential building roofs covered with tiles, i.e. large permanent loads at short spans, shear deformation is a considerable part of the total deformation and therefore has a serious impact.

Since there is obviously a difference in behaviour of thermosetting and thermoplastic materials, as shown by Gibson et al. [4], it was seen as an opportunity to allow for higher performance of wood-based sandwich panels by demonstrating that the value for k_{def} for polystyrene loaded in shear is much lower than specified above. Knowing that the core is mainly loaded in shear, as shown in figure 1, and that the shear zones mainly occur in the vicinity of the supports, the research focuses on the shear creep. Furthermore, shear stresses in the core are relative low compared to the shear capacity: In a practical example, e.g. a sandwich panel with a thickness of 200 mm and a span of 4 m, with a dead load (self-weight and roof tiles combined) of 0.65 kN/m², a maximum shear stress of 6.5 kPA results, whereas the characteristic shear strength of a polystyrene core is approximately 80 kPA. Consequently, the deflection is governing the design and therefore, as figure 2 illustrates, an accurate value for k_{def} is necessary.

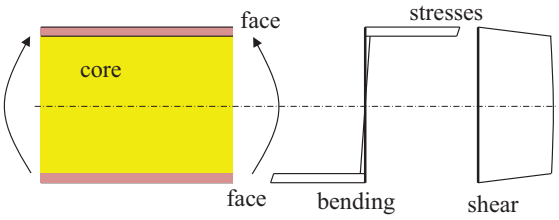

Figure 1: *Stresses in a sandwich panel with thin faces: by approximation, uniform axial stresses in the faces and uniform shear stresses in the core exist* [5]

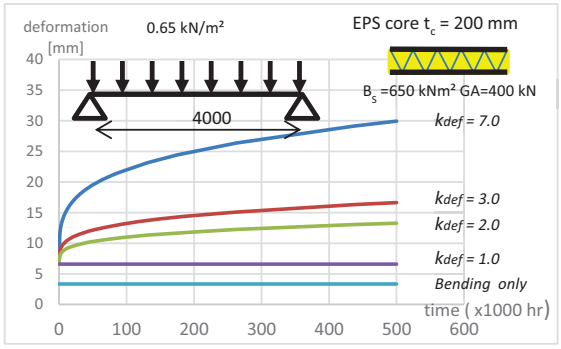

Figure 2: *Effect of different values of k_{def} on time dependent deformation of a given single span sandwich beam.*

2 OBJECTIVE

The objective of this study is to describe the shear creep as a function of the shear load relative to the shear strength of a polystyrene core as applied in wood-based sandwich panels. Therefore, two types of tests are carried out. Pure compact shear tests, according to EN 12090 [6], and tests on beams with Uniform Distributed Loads (UDL), for which the shear stresses and deformations are analysed. The objective of these tests is to show that the different set-ups, for which the bending test is the more realistic one, result in comparable finding for time dependent behaviour. Comparable time dependent behaviour allows small and simple tests on creep in the future, while making sure the creep results do agree with the end use situation. Furthermore, after unloading, being loaded for a long period, the specimen are loaded up to failure and the characteristic residual strength is determined to provide an indication on the strength degradation in time. Results are compared with the results found in previous studies [1,2].

2.1 TIME DEPENDENT DEFORMATION BEHAVIOUR

In engineering practice, time dependent deformations (creep) are calculated according to Equation (1) showing a proportional relationship between the instantaneous deformation u_{inst} and the creep deformation u_{creep} (= u_{fin} – u_{inst}).

$$u_{creep} = k_{def} u_{inst} \qquad (1)$$

Due to creep, part of the stress strain behaviour is non-linear. Furthermore, part of the creep deformation obtained during loading will not recover; part of the deformation remains at time *t*. Figure 3 shows the qualitative deformation behaviour of a polymer affected by creep (or a structure consisting of this material), including unloading after time *t*.

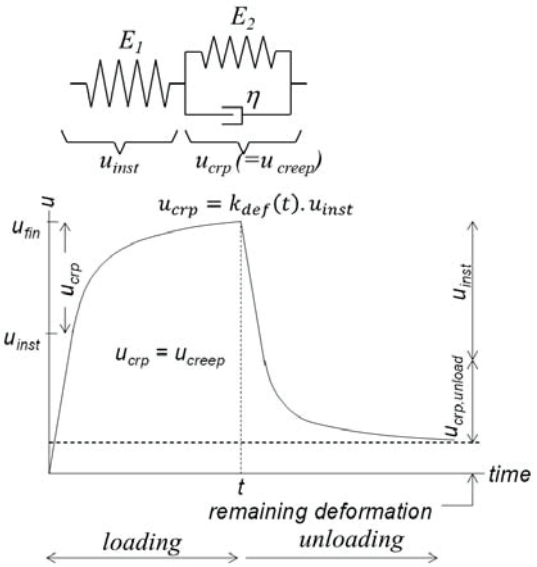

Figure 3*: Top: Shear creep model, Bottom: Deformation behaviour of a polymer affected by creep* [7]

Consequently, both the instantaneous deformation u_{inst} and the creep deformation = k_{def} * u_{inst} are governing the final deformation u_{fin}. The creep factor k_{def} is generally assumed to be only time dependent and is defined as a fixed value for the ratio u_{creep}/u_{inst} after 50 years of permanent loading. Furthermore, at least for wood and wood-based products, the creep factor is influenced by the material moisture content and its fluctuations. In engineering practice, the creep factor is generally assumed not to be affected by the load. For polymers however, the creep factor does not only depend on time but also on the load (stress) level, and significantly so, as shown in Figure 4. The dotted line indicates the stress level which is not to be exceeded. If stress levels are high, progressively higher strains will occur, the so-called tertiary phase is reached, and collapse is due to happen.

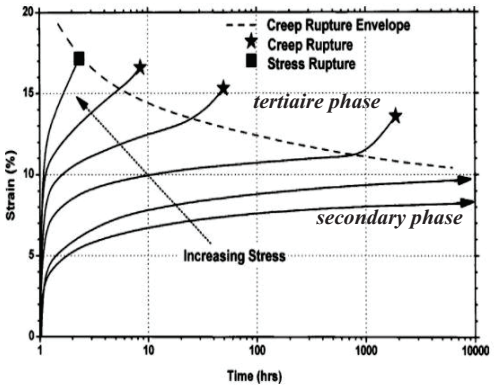

Figure 4: *Strain over time for different stress levels* [8]

https://doi.org/10.52202/069179-0072

At lower stress levels the creep rate decreases and creep stabilises, reaching the secondary phase, as such avoiding failure.

3 MODELLING SHEAR CREEP

3.1 SHEAR CREEP AS NONLINEAR MATERIAL BEHAVIOUR

Previous studies have shown that polystyrene foam reacts differently to various load types. When compressed, the foam behaves as a cellular material, i.e. it has an elastic, by approximation quadratic stress-strain relationship, whereas most solids are about linear [1]; under stresses due to bending it will react purely elastic until failure (brittle) [1]. As discussed in relation to figure 1, in a sandwich panel the core is predominantly loaded in shear and consequently this research focuses solely on shear and the determination of the shear creep. Models describing shear creep both as linear and nonlinear have been developed by Taylor et al. [1], Kilpeläinen et al. [2], and Findley et al. [7], and will be introduced by first presenting the so-called Burgers Model for which the arrangement of the spring and dashpot elements are shown in figure 5.

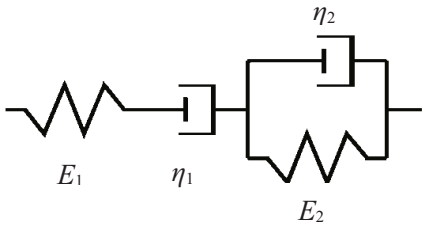

Figure 5*: Creep according Burgers model*

Representing for the spring elements $\sigma = E\varepsilon$ and for the dashpots $\sigma = \eta\frac{d\varepsilon}{dt}$, the Burgers model results in:

$$\varepsilon(t) = \sigma\left[\frac{1}{E_1} + \frac{t^p}{\eta_1} + \frac{1}{E_2}\left(1 - e^{-\frac{E_2}{\eta_2}t}\right)\right] \qquad (2)$$

in which t equals the time, and p is a factor to be determined. If p=1, the behaviour of the first part of the model, represented by the spring (E_1) and dashpot (η_1) is completely linear in time. With p < 1, the tertiary phase can be postponed or avoided. With p > 1, creep will grow progressively, entering the tertiary phase, which must be avoided.

Findley et. al [7] used the above model, and demonstrated it functioned correctly for viscoelastic materials, such as polymers, with their typical time dependent behaviour: They start with instantaneous elasticity, followed by delayed elasticity and visco-elastic flow.

Taylor et al. [1] tried several different creep deflection models, to fit the data measured over 3 months and to predict the creep after 6 months, and concluded that the so-called power model and the 5-element model are suitable to predict relative deflection on beams with EPS or PUR cores. To derive the 5-element model, they

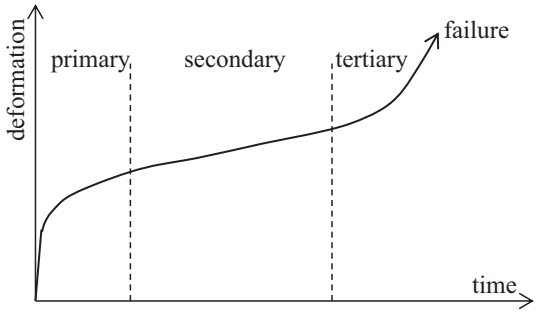

Figure 6: *Creep phases*

rephrased the Burgers model and changed η_1 into $\eta_1(t)$, resulting in Equation (3).

$$\Delta(t) = \Delta_0 + B_1(1 - e^{-B_2 t}) + B_3 t^{B_4} \qquad (3)$$

In which $\Delta(t)$ is the deformation, Δ_0, B_1, B_2, B_3 and B_4 are parameters, and k_{def} can be found by equation (1).

Kilpeläinen et al. [2] applied the power model, and used Equation (4) as a method to fit the data:

$$k_{def}(t) = A_1\, t^{A_2} \qquad (4)$$

Based on this latter model, the k_{def} is low for steel sandwich panels since these panels are used for long spans and relatively low loaded.

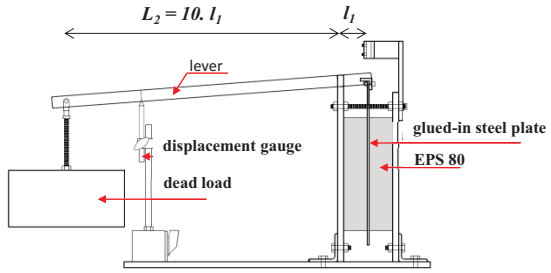
3.2 PANEL STRENGTH

Given the presented studies, it is obvious that to find the proper value for k_{def} of a sandwich panel with steel faces, the focus must be on the shear creep in the polystyrene core. Additionally, it should be realised that polystyrene foam transfers shear via and along the walls of each cell, thus the proper fusion, the so-called sealing of the cells, is important. Therefore, in the experiments below not only identical grades of EPS foam are used, but also exactly identical procedures for the production of the core are applied, and fusion strength is tested too. This is not only carried out on "fresh" elements, before applying loads, but also after the experiments, to demonstrate that the residual strength is hardly degraded in time, thus showing that the polystyrene is still in the secondary phase, where the load level is below a certain upper limit.

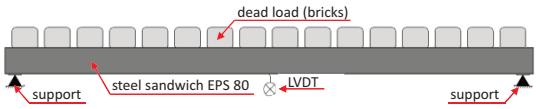
4 EXPERIMENTS

Two different types of experiments have been carried out: (a) polystyrene specimens loaded in shear (compact shear test according to EN 12090) and (b) panels loaded in bending. Both test setups are shown in Figure 6a and 6b respectively. The bending tests are positioned and monitored in a climate-controlled environment.

https://doi.org/10.52202/069179-0072



(a)



(b)

Figure 6: (a) *Shear test EN 12090 as modified for long term loading.* l_1 *=40 mm;* l_2 *= 400 mm;* (b) *Bending test setup for long term loading. Core thickness = 100 mm. Steel plate thickness = 0.4mm. Panel width =200 mm. Panel length =2100 mm.*

The compact shear tests (See Figure 6a and 7) comprise of 3 series of 6 samples each, loaded relative to the average shear strength by 27%, 41% and 54% respectively (no round percentages due to recalibration and resulting shear strength adjustments). These shear tests ran from June 2011 to April 2020, in a dry and heated, but not climate-controlled environment. After the tests ended, a shear test up to failure was carried out to check the residual strength.

Figure 7: *Overview of compact shear tests*

Measurements were carried out at "regular" time intervals: a small time period (30s) in the beginning (June 2011) going up to once a month at the end (April 2020). This since at the end hardly any changes were visible, using a displacement resolution of 0.05 mm.

The second type of experiments consists of series of simply supported panels carrying bricks as a Uniform Dead Load (UDL), see Figure 6b, 8 and 9. These tests were done in a climate-controlled room at Eindhoven University of Technology.

Figure 8 *side view of all UDL samples, showing data loggers and LVDT's*

Figure 9: *front view of the UDL samples, percentage per column, 6 samples per percentage*

For the specimens in bending, the focus is on the study of the polystyrene core, and the normally wood-based faces are replaced by steel faces.
Four different load levels are applied: 10%, 20%, 30%, and 40% relative to the characteristic shear strength of the

https://doi.org/10.52202/069179-0072

polystyrene core (80 kPA). These percentages differ slightly from those used for the compact shear tests. The reason for that is that the percentages for the compact shear tests are determined after loading comparable specimen to failure.

The measurement of the total deflection is carried out at bottom side of the beam, in the middle, thus excluding measuring compression at the supports. Also these experiments were part of a long running experimental program, which was halted after 5 years due to a failure in the climate room. Afterwards the residual shear capacity was tested. In order to test a part of the polystyrene core that was well loaded by shear, the test specimens were taken near the supports.

5 RESULTS

5.1 PANELS LOADED IN BENDING

The single span tests show, although there are quantitative differences between series, very similar qualitative behaviour. Since the frequency of sampling is rather high, it is possible to discern even climate effects and similar.

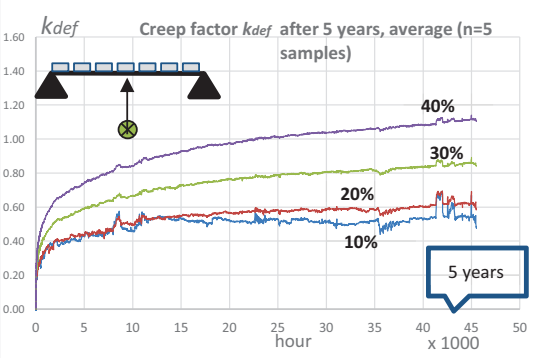


***Figure 10**: averages for series loaded from 10% to 40% of the characteristic strength; single span uniform distributed load experiment.*

Figure 10 shows there is a strong relation between the load and the relative displacement over time. Also, the smaller the load, the more vigorously the beam responds to other events, mostly climate effects. Also, the lower load levels show a lower increase of creep, and thus a lower strain rate. At 42000 hours a serious disturbance occurred, visible for all series. The reason for the disturbance is unknown.

5.2 COMPACT SHEAR TESTS

As mentioned earlier, the compact shear tests consist of three series, namely using load ratios equal to 27%, 41%, and 54%. Also here, a strong dependency on the relative shear stress was visible, as shown in figure 11. The most interesting result was that all samples of the 54% series failed after 4 years, indicated by the cross.

Exact failure times cannot be determined, for data logging was carried out at quite large intervals (700h). It is obvious that since the load was active for a very long period, the degradation of the core was due to progressive creep, and it may be concluded that a shear stress of 54% is well within the tertiary phase. The series of 27% and 41% were monitored for 9 years. After that period, these samples had still not failed.

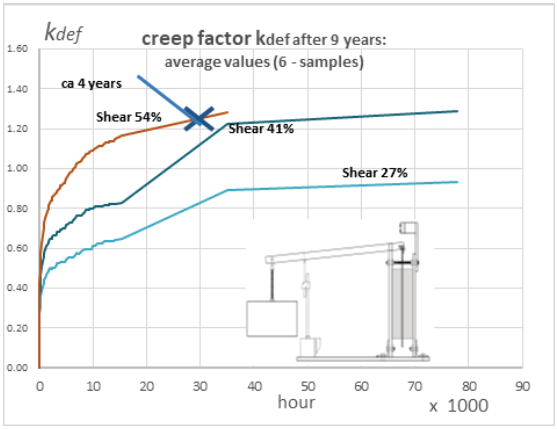

***Figure 11:** average per series of shear tests*

Final measurements were carried out after 12 years, but since the tests were not monitored properly in between 9 and 12 years, the deformations after 9 years were excluded from the study. However, since the samples did not fail, the residual strength could still be determined. At least it is known that 41% still holds after 12 years, so it is likely that when the shear stress is lower than 40% of the shear strength, the deformation stabilises in the secondary creep phase.

5.3 COMPARISON COMPACT SHEAR TEST WITH PANELS LOADED IN BENDING

All experimental results, but as average values of the 6 samples per series, are shown in figure 12.

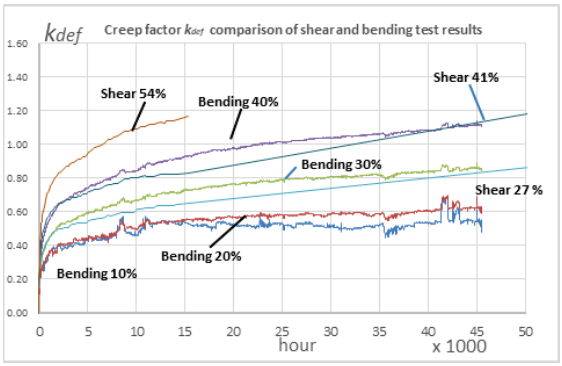

***Figure 12:** Comparison averages of all experiments*

The compact shear experiments show resemblance with the panels loaded in bending, particularly for load ratios up to 30%. It seems that the k_{def}'s found in shear tests are slightly higher than those found in the bending tests.

https://doi.org/10.52202/069179-0072

5.4 COMPARISON PANELS IN BENDING WITH RESULTS OF KILPELÄINEN

Kilpeläinen et al. [2] performed bending tests and modelled the results according to the power model. Using equation (4) for fitting the data, Kilpeläinen found for A_1 = 0.195 and for A_2 = 0.177.

Figure 13 shows the Kilpeläinen et al. predictions for our bending experiments (dotted lines), equation (4) with the above values by the "Design envelope", and our panels in bending.

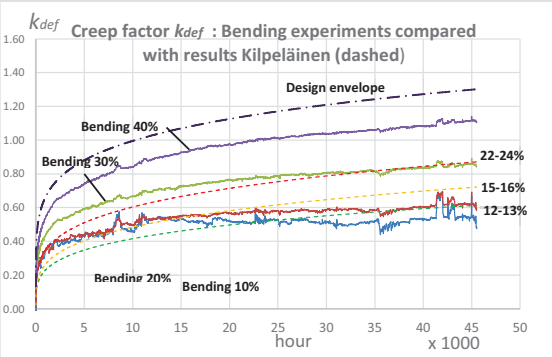

Figure 13: *Comparison averages of beam experiments with* [2]

Overall, predictions agree reasonably well. The power model used by Kilpeläinen et al. seems to underestimate at the start, but agrees after 5 years. Also the proposed upper limit ("Design envelope") is well above the 40% level; This design curve indicates a value for k_{def} = 1.95. For Finnish conditions (following Kilpeläinen et al.), including high quasi-permanent snow loads this is understandable, but for more average conditions, a 40% shear stress level will not be reached.

5.5 DESIGN LIMITS AND EXPERIMENTS

Three design limits are compared with both type of experiments. The design limits are the equation (3) as found by Kilpeläinen et al. [2]; the envelope equation by Kilpeläinen et al. [2], which leads to a k_{def} = 1.49 based on the power model (Equation 5); and the limit using the five points model of Taylor et al., leading to k_{def} = 1.60, Equation 6. This last equation (6) shows only four parameters, however, for determining k_{def} the parameter Δ_0 (Equation 2) vanishes.

$$k_{def}(t) = 0.053\, t^{0.275} \qquad (5)$$

$$k_{def}(t) = 0.171(1 - e^{0.0065\, t}) + 0.143\, t^{0.174} \qquad (6)$$

Kilpeläinen et al. [2] equation (3) is the dashed line almost at top. Clearly the 54% compact shear test was above this line and would have been rejected by all design limits. The second limit, the envelope equation by Kilpeläinen et al. [2] is just above the 30% and well above the 20% bending results. Finally, the Taylor et al. approach (Equation 6) is fitted on the data of this experiment and extrapolated to k_{def} (t=50 years) = 1.60. It is almost coincident with the 30% bending tests.

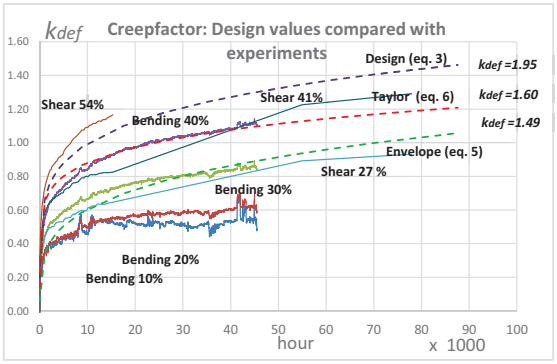

Figure 14: Compact shear and bending experiments compared with 3 proposed design limits

This latter design limit shows a better similarity up to 10.000 hr compared to the power model, which obviously is due to the higher number of parameters fitted. Also, when the permanent relative shear stress is lower than 25%, using k_{def} = 1.60 is an upper limit for the expected relative deformation after 50 years. This is a sound limit, since in the Ultimate Limit State (ULS) state (following EAD 140022 [3]) the EPS for the load duration class "permanent" is limited to 25%. Besides, applying k_{mod} and γ_m also will reduce the actual occurring stress in the Service Limit State (SLS). The limit by the envelope equation of Kilpeläinen et al., green dotted in figure 14, represents the 25% relative shear stress and is derived from results in [2], so it is similar to the design limit but considerably lower. If this later limit (envelope equation) is applied for permanent load duration in SLS states then the conclusion would be that indeed the bending experiments at 10% and 20% are acceptable, and that the compact shear tests at 54% and 41% are rejected. The 27% compact shear test is close to the Envelope (Eq.5), just slightly above, but is rather uncertain in development in time, so no conclusion can be drawn here. At least there is no safety margin. The 30% bending test seems to get under the 25%, but to be sure, this measurement is simply too short.

5.6 RESIDUAL STRENGTH AFTER CREEP TESTS

To determine the residual strength of the bending tests afterwards, several parts of their cores were tested for shear. These parts were taken near the support of the beams, and results are shown in Table 1. The results agree with the shear capacity at the start of the experiment, which was characteristically 80 kPA: the strength of most of the specimen was above 80 kPA, and the characteristic value was about 80 kPA, so it seems that the capacity was not affected. Possibly because stresses were too low, or that there was some 'restoring' effect: For the series up to 20% strains are most likely to be recoverably. For the 27% and 41% series, this is more uncertain.

Table 1*: Residual shear strength of samples bending tests*

https://doi.org/10.52202/069179-0072

No.	S10% [kPa]	S20% [kPa]	S30% [kPa]	S40% [kPa]
1	92.84	86.17	97.44	88.03
2	85.30	86.89	96.03	92.59
3	92.22	83.84	93.29	89.52
4	90.72	82.40	90.82	92.59
5	95.23	83.95	92.76	86.35
6	94.79	81.09	95.37	89.69
7	95.04	81.39	96.34	89.05
Char. 5%	**84.94**	**78.97**	**89.66**	**84.91**

Also, the compact shear test samples were tested for strength, by placing the entire setup in a pressure bench. Results on average were slightly lower than the original 80 kPA, see Table 2.

***Table 2**: Residual shear strength of shear samples*

No.	S27% [kPa]	S41% [kPa]	S54%
1	91.59	77.05	x
2	91.34	79.04	x
3	82.95	86.91	x
4	79.23	91.18	x
5	76.86	86.46	x
6	94.33	x*	x
Char. 5%		**72.88**	
*Sample used for calibration			

This may be the effect of the series 41%, since these are a bit lower, but not dramatically. Sample 6 was lost while measuring; the value was 72 kPa, but Young's Modulus was suspiciously low, and so results were not trusted.

6 CONCLUSIONS

The study in this paper shows for EPS a strong relationship between creep (deformation) and load levels. Also, it is demonstrated that different experimental set-ups (bending and compact shear) agree well with respect to determination of shear creep, with the notion that compact shear tests seem to lead to slightly higher creep values. Furthermore, it shows that, the bandwidth in between tertiary creep (5 years at 54%) and the upper limit of secondary creep (9 years at 40%) is rather small.

Those samples that 'survived' the bending experiments still have the original shear load capacity, which supports the small bandwidth hypotheses. In general, when a shear stress at 25% of the shear strength is applied in serviceability limit state conditions, the creep factor k_{def} will never be larger than 1.6 after 50 years. This is the case for a power model similar to Kilpeläinen et al. [2] as well as for a model according to Taylor et al. [1].
The residual strength of the samples after the test is reassuring. It proves that a long-sustained load on polystyrene can be accepted. Additional details related to this paper can be found in Modderman [9].

ACKNOWLEDGEMENTS

INTEGRATED APPROACH TO PREDICT DETERIORATION OF MECHANICAL PROPERTIES OF DECAYING WOOD

Petr Hradil[1], Stefania Fortino[2]

ABSTRACT: The aim of this paper is to present a methodology to predict bending or compression resistance of structural wooden elements during the onset and growth of the material decay. Two methods are proposed to calculate remaining bending and compression resistance under the attack of brown rot and white rot are presented: (1) reduction of material strength or (2) reduction of the cross-section of the wooden element. The methods are based on the bending and compression tests of material exposed to extreme moisture and are demonstrated as a part of the structural integrity online calculation tool introduced in this paper. They are applicable to planed wood where the decay is expected to progress from the surface inwards. It should be noted that the prediction of structural resistance is in the present state limited to specific loading conditions and decay mechanisms and it is not recommended to replace structural design according to the building codes. However, the estimation of the remaining structural integrity of the material may be very important for the planning of maintenance actions in the structures, such as bridges, where the immediate replacement is not possible or for better safety measures in removing, renovating or demolishing decaying wooden construction.

KEYWORDS: Structural Integrity, Wood decay, Dose-response model, Mass loss, Bending, Compression

1 INTRODUCTION

Exposure of timber products to the external climate, condensate or accumulated water in interiors may lead to biotic degradation of the material. One of the common problems related to the prolonged periods of high moisture is rotting that can lead to material loss and degradation of its mechanical properties [1].

Wood rot, also known as decay, affects the durability and integrity of wood products. It is caused by fungi that grow and feed on the cellulose, hemicellulose, and lignin, breaking down these materials and causing the wood to soften, weaken, and eventually collapse. This paper focuses on the effect of two most common types of rot, brown and white, on the mechanical properties of wood. Brown rot is the most common type of rot and causes the wood to become brittle and crumbly. White rot, on the other hand, affects the lignin in the wood, causing the wood to become stringy and fibrous. The less common forms of decay such as soft rot are not discussed herewith, but the methodology presented in this paper can be easily extended to account for their effect as well.

In order to prevent the decay, it is important to control the moisture levels in the environment surrounding the wood. This can be done by properly sealing and finishing the wood elements to prevent moisture from penetrating, providing adequate ventilation to prevent moisture build-up, and keeping the wood away from sources of moisture like leaky pipes or standing water. If wood rot has already occurred, it is often necessary to remove and replace the affected wood to restore its structural integrity.

The severity of degradation caused by the rot is typically described as decay rating and can be tested on site [2]. The loss of wood mass and mechanical properties due to the decay can be verified experimentally [3].

It was observed that both, the decay rating and mass loss, correlate with the cumulative duration of the high-moisture state above the fibre saturation point at suitable temperature rate (see Figure 1).

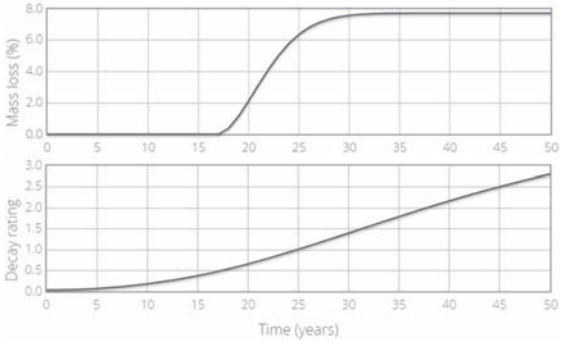

Figure 1: *Example of mass loss (top) and decay rating (bottom) prediction due to brown rot in 80x160 mm softwood member exposed to a constant dose of 10 points per year [4].*

[1] Petr Hradil, VTT Technical Research Centre of Finland Ltd, Finland, petr.hradil@vtt.fi
[2] Stefania Fortino, VTT Technical Research Centre of Finland Ltd, Finland, stefania.fortino@vtt.fi

https://doi.org/10.52202/069179-0073

In order to predict those effects several so-called dose models were introduced earlier [4] by some of the partners of ClickDesign project (Delivering fingertip knowledge to enable service life performance specification of wood) coordinated by the Building Research Establishment in UK. Dose stands for the normalized time of exposure of the material to temperature and moisture levels favourable for the development and growth of wood decay. The aim of the work under the ClickDesign project was to extend the knowledge of the dose-related material loss and to provide practical indicators about the structural integrity of decaying material under the external loads. The tool developed in the ClickDesign project will be then used in Horizon Europe research project 5G-Timber [5] to provide estimation of the quality of the wood waste generated during the service life of modular wooden building.

2 PREDICTIVE MODELS

The most computationally demanding part of the estimation of moisture-induced effects is the numerical prediction of the moisture and temperature dose from the external conditions. This is typically done by hygro-thermal simulation of moisture diffusion, heat conduction and their respective surface emissions implemented in finite element or finite difference models with boundary conditions corresponding to the external climate. For the practical reasons, we assume that the total yearly dose is pre-calculated for untreated wood and the effect of wood treatment, impregnation and surface coating that affects the moisture dose is added explicitly. The following predictive models are based on the existing theories, extended and modified for the practical use in the structural verification of sawn timber

2.1 Mass loss

The loss of material mass ML in % can be modelled by the dose-response function in Equation (1), where the accumulated dose D is obtained either by logistic dose model (LM) or simplified logistic dose model (SLM) [4] and the initial dose before the onset of decay D_0 is assumed to be 150 days. It should be noted that the time before decay cannot be estimated very precisely and in the case of verification of material already contaminated by fungi, we recommend the term $D - D_0$ to be the cumulative dose during the real observed decay period. The final (reduced) mass m_{red} of the wooden element can be then calculated from Equation (2) where its original mass is m.

$$ML = A_{ML}\left(1 - exp(-k_{ML}(D - D_0)^{n_{ML}})\right) \quad (1)$$

$$m_{red} = m(1 - ML) \quad (2)$$

The regression parameters A_{ML}, k_{ML} and n_{ML} in Table 1 and Table 2 were obtained on 15 x 25 x 50 mm specimens of sapwood from *Pinus sylvestris* L.(Scots pine, softwood) and *Fagus sylvatica* (Beech, hardwood) inoculated by *Coniophora puteana* (brown rot) and *Trametes versicolor* (white rot) [6].

Table 1: *Parameters of the mass loss prediction based on logistic dose model LM [6].*

Decay type	A_{ML}	k_{ML}	n_{ML}
Brown rot			
- softwood	52.15172	0.00092	1.72185
- hardwood	41.03166	0.00102	1.69278
White rot			
- softwood	21.557946	0.000732	1.66255
- hardwood	21.188634	0.001542	1.947474

Table 2: *Parameters of the mass loss prediction based on simplified logistic model SLM [6].*

Decay type	A_{ML}	k_{ML}	n_{ML}
Brown rot			
- softwood	42.12828	0.00109	1.86345
- hardwood	32.78056	0.00104	1.88263
White rot			
- softwood	12.776551	0.000591	2.011779
- hardwood	20.833677	0.001235	2.166626

In this paper, the wood decay is assumed to be surface phenomenon (progressing from the surface inwards), and therefore the mass loss ML will be different for wood components with different cross-section from the test samples. In order to generalize mass loss calculation, the value of ML has to be corrected by the shape factor k_{sh} depending on the real width b and height h of the cross-section (see Equation (3)).

$$k_{sh} = 7.9\frac{b + h}{bh} \quad (3)$$

2.2 Decay rating

Decay rating DR is modelled in this paper by the dose-response function in Equation (4). The parameters a_{DR} and b_{DR} are calibrated on the softwood samples of from *Pinus sylvestris* L. (Scots pine), *Pseudotsuga menziesii* Franco (Douglas fir), *Larix decidua* Mill. (European larch) and *Picea abies* Karst. (Norway spruce) and presented in Table 3 [7]. The hardwood rating is not used in the present decay rating model.

$$DR = 4 \cdot exp\left(-exp(a_{DR} - b_{DR}D)\right) \quad (4)$$

Table 3: *Parameters of the softwood decay rating model [7].*

Decay type	a_{DR}	b_{DR}
Brown rot (shade)	2.026	0.0037
Brown rot (no shade)	1.564	0.0054
White and soft rot	1.7716	0.0032

https://doi.org/10.52202/069179-0073

2.3 Structural integrity

Apart from the loss of wood mass, decay causes changes in the material behaviour, especially reduction of its strength. The knowledge of wooden element cross-section and characteristic strength of the material is typically needed to estimate the element's resistance to external loads. For the practical reasons, only one of those parameters can be modified, while the engineers may continue using the nominal value of the second one (nominal cross-section with reduced equivalent strength or vice versa).

Therefore, two methods to calculate bending and compression resistance were developed: reduction of material strength and reduction of element's cross-section. They are based on the bending and compression tests [9] and are demonstrated as a part of the structural integrity online calculation tool [10] introduced in this paper.

2.3.1 Reduction of the material strength

The calculation of reduced material strength is directly based on the approximation model of tested bending or compression resistance at different levels of mass loss [9]. It represents equivalent strength of the homogeneous material with the nominal cross-section (see Figure 2).

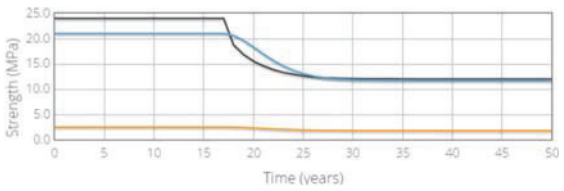

Figure 2: *Example of predicted material characteristic strength degradation in bending (black line), compression parallel to the grain (blue line) and perpendicular to the grain (yellow line) of 80x160 mm member from C24 grade wood.*

The loss of material strength FL can be calculated from the mass loss ML using sigmoid function in Equation (5) with parameters A_{FL}, k_{FL} and n_{FL} fitted to the experimental data for bending [8] and compression [9] in Table 4, Table 5 and Table 6 and the shape factor k_{sh} is obtained from Equation (3). The reduced material strength f_{red} can be then obtained from Equation (6), where f is the characteristic strength of the specified timber grade.

$$FL = A_{FL}\left(1 - exp(-k_{FL}(k_{sh}ML)^{n_{FL}})\right) \quad (5)$$

$$f_{red} = f(1 - FL) \quad (6)$$

In our models, we use experimentally calibrated parameters for bending and compressive strengths, and therefore the applicability of the method is currently limited to structural components subjected to the respective loads.

Table 4: *Parameters of the bending strength reduction model [8]*

Decay type	A_{FL}	k_{FL}	n_{FL}
Brown rot			
- softwood	0.8833	9.6601	0.6155

Table 6: *Parameters of the compressive strength perpendicular to gran reduction model in softwood [9].*

Decay type	A_{FL}	k_{FL}	n_{FL}
Brown rot	0.989291	5.823211	1.103143
White rot	1.049224	3.977650	0.775042

2.3.2 Reduction of the cross-section

Alternatively, it is possible to describe the effect of degrading resistance as an artificial reduction of structural member's cross-section from the surface towards its centre. The reduced cross-section represents equivalent section of the wooden member and shall be used together with the original material strength (see Figure 3). The reduction depth d is equal from all sides and will be different in different loading situations.

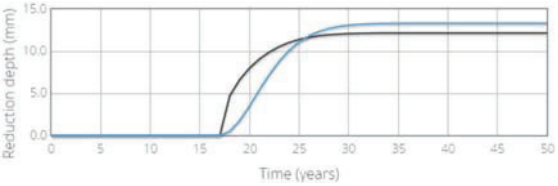

Figure 3: *Example of predicted depth of nominal cross-section reduction in bending (black line) and compression parallel to the grain (blue line) of 80x160 mm member from C24 grade wood.*

It is assumed that the equivalent rectangular cross-sectional area of the compressed member is proportional to the reduction of material strength as in Equation (7).

$$A_{red} = A(1 - FL) \quad (7)$$

We can then express the depth d in compression from Equation (6) as function of cross-section b width and height h and strength loss FL. The solution for root of quadratic Equation (8) is expressed in Equation (9).

$$(b-2d)(h-2d) = bh(1-FL) \tag{8}$$

$$d = \frac{bh - \sqrt{(bh)^2 - 4bh \cdot FL}}{4} \tag{9}$$

Similarly, the bending load requires proportional reduction of the section modulus in Equation (10).

$$W_{red} = W(1-FL) \tag{10}$$

For bending along the horizontal axis of rectangular cross-section, the root of cubic Equation (11) has analytical solution in Equation (12) with coefficients k_1 to k_6 present in Equations (13) to (18).

$$\frac{(b-2d)(h-2d)^2}{6} = \frac{bh^2}{6}(1-FL) \tag{11}$$

$$d = k_1 - \frac{k_2}{3k_1} - \frac{k_3}{3} \tag{12}$$

$$k_1 = -\left(\frac{k_4 + \sqrt{k_4^2 - 4\,k_2/27}}{2}\right)^{1/3} \tag{13}$$

$$k_2 = k_5 - \frac{k_3^2}{3} \tag{14}$$

$$k_3 = \frac{(4b+8h)/bh^2}{k_6} \tag{15}$$

$$k_4 = \frac{FL}{k_6} + \frac{2k_3^3 - 9k_3k_5}{27} \tag{16}$$

$$k_5 = \frac{(-4b-2h)/bh}{k_6} \tag{17}$$

$$k_6 = -\frac{8}{bh^2} \tag{18}$$

2.4 The effect of surface treatment

If the moisture and temperature dose is pre-calculated for untreated wood, it can be later modified (reduced) concerning a specific material protection. This is not as computationally demanding as numerical pre-calculation of dose for every specific surface treatment. Moreover, it enables a wide range of possible treatments, coatings or structural protective measures with temporal variation of their performance. For instance, the effect of paint that starts degrading after 15 years and is renewed after 25 years is demonstrated in Figure 4. Similar scenarios can be studied in real-time using the ClickDesign structural integrity calculator [10].

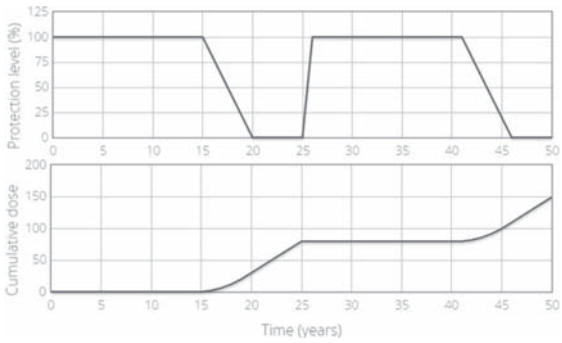

Figure 4: *Example of simulated performance of surface paint (top) and a corresponding delayed dose response (bottom).*

Such behaviour can be modelled using the following three parameters affecting the cumulative dose D entering Equations (1) and (4): treatment maximum protection k_p is the percentage of dose of untreated wood that is avoided by the surface treatment during the first year after its application; treatment durability t_0 expresses the duration (in years) of the maximum level of protection; and finally, the third factor, treatment degradation rate k_d, stands for the percentage loss of the maximum protection k_p per year. Then the total yearly dose of treated wood D_t can be obtained from the pre-calculated yearly dose of untreated wood D_u following Equation (19) where t is the time (in years) from the last renewal of the surface treatment. The value of D_t is limited to interval $\langle 0, D_u \rangle$.

$$D_t = D_u\Big(1 - \big(k_p - k_d(t - t_0)\big)\Big) \tag{19}$$

Figure 4 (top) shows the protection level $k_p - k_d(t-t_0)$ for parameters $k_p = 1$, $k_d = 0.25$ and $t_0 = 15$ years. The cumulative dose D in Figure 4 (bottom) is then a sum of the total yearly doses D_t calculated over a given period (e.g. design life of a building).

3 STRUCTURAL INTEGRITY TOOL

The predictive models described in the previous Section are included in the Python script and integrated in VTT's Modelling Factory simulation environment "modellingfactory.org". This platform enables efficient online publication of various calculation tools developed in different programming languages or spreadsheet editors and it provides powerful user interface builder with links to the calculation inputs and outputs. The source code of the scripts and user interface are typically published with the Modelling Factory tools.

3.1 Architecture of the tool

The Python script calculates a series of values of cumulative dose D by summing up the yearly dose D_t modified by the optionally defined effect of surface treatment (see Section 2.4) from 0 years until the design life of the wooden element a_{max}. Then the calculation follows the flowchart in Figure 5 generating time series data of different model variables.

https://doi.org/10.52202/069179-0073

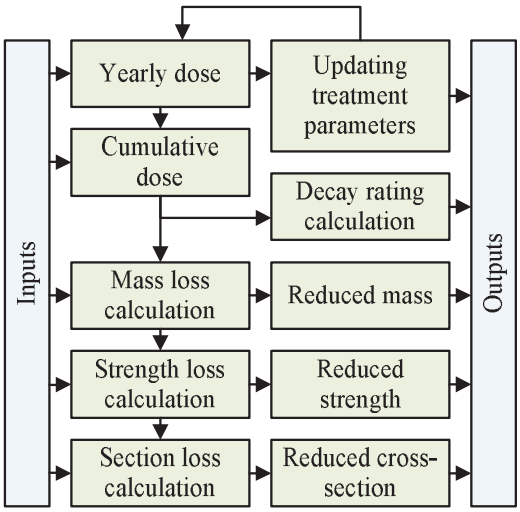

Figure 5: *Architecture of the structural integrity tool with elements of user interface (blue) and Python script (green).*

Mass loss ML and decay rating DR are calculated according to methodology described in Sections 2.1 and 2.2 respectively. Then the value of mass loss is used to estimate the loss of material strength FL in bending or in compression. The prediction of reduced characteristic strength or cross-section is then based on the FL value and follows the methods described in Sections 2.3.1 and 2.3.2.

3.2 User interface

In the case of ClickDesign structural integrity calculator [10], the user interface is divided into two parts: input forms on the left side (Figures 6-8) and output graphs on the right side (Figures 1-4). Since there is no numerical simulation of moisture transport (yearly dose D_u is entered directly in the form), the graphs on the right side are regenerated in real time. The graph data can be also downloaded in a spreadsheet form. For the convenience of the user, brief explanation of the required inputs is provided after clicking on the top-right button next to each input form. The irrelevant parts of the form are automatically hidden.

The dimensions of the wooden element in mm (width b, height h and length l) are entered in the first form (see Figure 6) together with the hardwood or softwood strength class according to EN 338 [11], design life a_{max} (e.g. based on the Eurocodes [12]) and method of structural integrity calculation according to sections 2.3.1 and 2.3.2 of this paper. The length of the member l is used only for the estimation of the full material volume in LCA calculation, which is not discussed in this paper. The design life a_{max} sets the limits of the calculated yearly results. The script then automatically selects the nominal characteristic strength f according to the selected material class. Structural engineers are typically familiar with those design parameters.

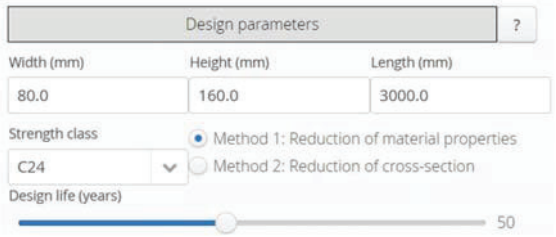

Figure 6: *Basic design values such as dimensions, strength class and design life, and selection of the reduction method.*

The second form (Figure 7) asks the user for additional parameters required for the predictive models. Our goal was to simplify this part and reduce the number of inputs as much as possible. The main requirement is the pre-calculated yearly dose D_u and the method, how it was obtained (logistic model or simplified logistic model [4]). The parameters of decay can be changed by the user, but the default selection (brown rot, no shade) represent the most conservative assumption.

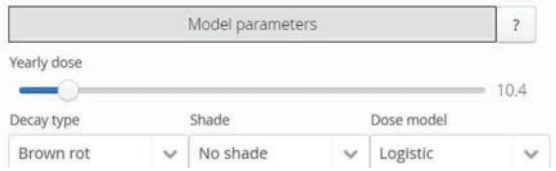

Figure 7: *Additional parameters required for the decay models.*

If the user wishes to simulate the effect of surface treatment, optional form is displayed with the parameters affecting the yearly dose calculation. Those values are not standardized and at the moment there is no experimental procedure how to determine them directly. Therefore, this part is non-compulsory and is hidden from the user by default. The link between commonly used properties of wood treatment (such as surface emissivity) and the model parameters can be the topic for further research and development of the tool.

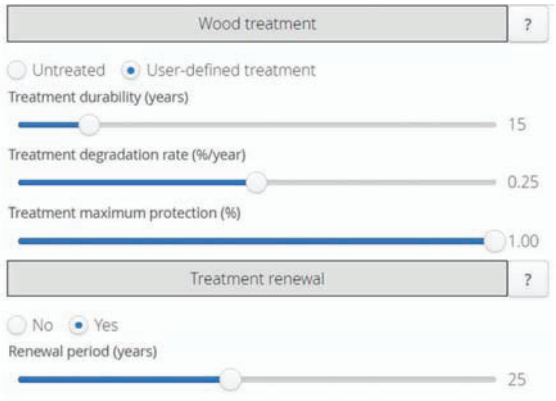

Figure 8: *Optional inputs for the surface treatment simulation.*

https://doi.org/10.52202/069179-0073

It should be noted that it is still possible to utilize the knowledge of the surface emissivity or water vapour resistance by providing pre-calculated yearly dose of the model with appropriate surface properties corresponding to the selected treatment in the "Model parameters" form. However, then the model will lose its real-time regeneration capabilities and possibility to simulate surface renewal in the pre-defined periods.

4 SUMMARY AND CONCLUSIONS

The estimation of the remaining structural integrity of the material is important for planning of maintenance actions in the structures, such as bridges, where the immediate replacement is not possible or for better safety measures in removing, renovating or demolishing decaying wooden construction. It is also useful for estimation of the quality of the end-of-life material in order to optimize wood waste recovery, reuse and recycling.

The presented tool and models integrated in the tool can be a powerful instrument to estimate remaining structural capacity of the wooden elements affected by rot. However, they are at the moment limited to specific loading conditions and rot types and are applicable only to planed wood where the decay is expected to progress from the surface inwards.

The next step in the model development are:

- to integrate material circularity and lifecycle indicators for the assessment of the embodied carbon and generated waste quality of the simulated solution;
- to connect numerical (finite element or finite difference) calculation of the moisture in wood such as already existing Modelling Factory tool called Hygro [13] together with the appropriate dose model;
- to extend the scope of the tool with the knowledge of more wood and fungi species and additional mechanical properties of wood;
- to provide full guidance how the values can be used together with the new Eurocode 5 and the future Eurocode provisions for the assessment of the existing structures [14].

ACKNOWLEDGEMENT

This study and its presentation was supported by Horizon Europe project 5G-TIMBER (Secure 5G-Enabled Twin Transition for Europe's TIMBER Industry Sector), Call: HORIZON-CL4-2021-TWIN-TRANSITION-01, Project number: 101058505. Development of the calculation toolset was supported by ClickDesign project under ERA-NET action ForestValue co-found by the European Union's Horizon 2020 research and innovation programme under grant agreement No 773324 and the Finnish Ministry of the Environment.

CREEP TESTS ON PARTIALLY DRIED NOTCHED BEAMS OF SILVER FIR WOOD (ABIES ALBA)

Arthur Bontemps[1], Gaël Godi[2], Rostand Moutou Pitti[3,4], Eric Fournely[5], Joseph Gril[6,7]

ABSTRACT: Silver fir is an important species in the wood French industry but its application is facing drying issues. This paper presents the results of displacement-imposed bending tests and bending creep tests made on green or partially dried silver fir notched beams. The material consists in a batch of thirty beams that were characterised by measurements of basic density and longitudinal modulus of elasticity. The results suggest that the instantaneous strength is independent from the moisture content. During the creep tests, central deflection, crack parameters, shrinkage-swelling and meteorological parameters were measured. The time-dependent compliance is computed and takes into account crack propagation and multi-steps loading. The results show that the initial moisture content has an impact on the maximum time-dependent compliance reached but solar exposure and knots position are also significant parameters. The contribution of cracks to the deflection was also estimated and never exceeded 10% of the total deflection. Finally, observations showed that all crack trajectories were rising whatever the grain angle.

KEYWORDS: Creep, wood, Silver fir, notched beam, bending

1 INTRODUCTION

Silver fir (*Abies alba*) is an important species for European wood industry and accounts for 8% of the French forest. Its wood is mainly used in timber construction but is currently facing drying issues due to wetwood in Auvergne-Rhône-Alpes region [1]. Understanding and forecasting the mechanical behaviour of green or partially dried wood could promote the industrial development of new construction techniques. Traditional frameworks, made with undried wood for many centuries, could inspire the design of agricultural buildings or historical restoration. However, constraints imposed on building construction must be considered. Indeed, Eurocode 5 penalizes green wood by considering a higher final deflection, to account for mechano-sorptive effect resulting from drying under load [2]. However, creep of green timber structural elements depends on several complex factors that are not completely understood. There are several studies on green wood long-term mechanical properties, but mainly realised on small clearwood samples under controlled environments [3], [4]. This paper presents results of an experimental campaign on green or partially dried full-scale notched wooden beams in outdoor semi-sheltered conditions. Scientific challenges involve full-scale outdoor measurements and coupling between fracture mechanics and creep.

2 MATERIAL AND METHODS

2.1 NON-DESTRUCTIVE EXAMINATIONS

The material consists in a batch of 30 notched beams from local silver fir at structural element scale, Figure 1. Most of it is quarter sawn lumber (21/30), and the rest is rift sawn. The batch has been received in green wood state and characterised by non-destructive examination.

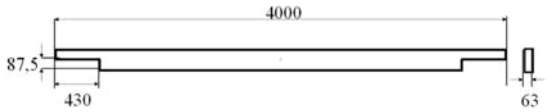

Figure 1: *Beam dimensions (mm).*

2.1.1 Natural vibration tests

The BING© method has been used to measure longitudinal modulus of elasticity (MOE) and shear modulus. It consists in measuring the frequency spectrum of free vibrations of a beam and calculating the stiffness properties using the resonant frequencies. This test was realised before notching the beams. The dynamic MOE measured with this method is known to be 4% higher than the static one [5]. Results are given in Table 1. E^d is the dynamic MOE and G^d is the dynamic shear modulus in the longitudinal-tangential plane. It is observed that the batch is highly heterogeneous, E^d varying from 7.54 to 16.34 GPa.

Table 1: *Free vibration results*

	E^d [GPa]	G^d [GPa]
Minimum	7.54	0.451
Maximum	16.34	0.672
Mean	11.01	0.553
Standard deviation	2.3	0.055

2.1.2 Basic-density measurements

A thin slice of each beam where the green volume V_g and the ovendried mass m_{anh} were measured allowed to calculate the basic density as $\rho_{BD} = (m_{anh}/V_g)$.

The basic density is supposed to be an intensive property, hence the same for the thin slice and for the rest of the beam. As the beams were received in green wood state, their initial volume was V_g and the basic density allows to compute m_{anh} of the whole beams and thus the moisture content (MC) at each weighing. Finally, the basic specific modulus is computed as $E_S^d = (E^d/\rho_{BD})$. The results are given in Table 2.

Table 2: *Basic-density measurements, MC at receipt and* $\boldsymbol{E_S^d}$ *computations.*

	MC [%]	ρ_{BD} [kg.m^{-3}]	E_S^d [Mm^2.s^{-2}]
Minimum	25.1	333	21.49
Maximum	117.5	430	40.84
Mean	60.3	379	28.9
Std	23.9	27.4	4.7

The unit of E_S^d is Mm^2.s^{-2} as it is the square of the sound speed in the material [6]. It is observed that the initial MC is also highly heterogeneous, from 25.1% to 117.5%. However, the hypothesis that the beams are all initially in green state was not verified for every beam and led to approximate results of MC and E_S^d.

2.1.3 Repartition

The experimental campaign was divided into 4-points bending tests with incremental imposed displacement to study the strength as a function of MC, and 4-points bending creep tests to study the long-term mechanical evolution. Both types of tests were realised on wood above fibre saturation point (FSP, MC > 30%), partially dried wood (20% < MC < 30%) and dried wood (MC < 20%). For the creep tests 6 beams were loaded in Spring-Summer 2021, 6 in Autumn-winter 2021-2022 and 6 in Spring-Summer 2022. Figure 2 shows their repartition regarding their mechanical properties (E_S^d and ρ_{BD}). The whole range of mechanical properties has been tested at different MC.

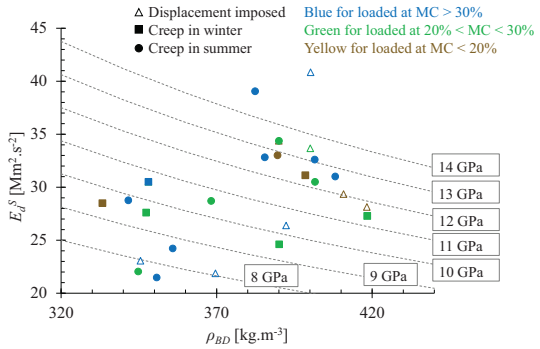

Figure 2: *Beam repartition plotted with specific modulus* ($\boldsymbol{E_S^d}$) *as a function of basic density* ($\boldsymbol{\rho_{BD}}$). *Filled circle: creep test in Summer; filled square: creep test in Winter; empty triangle: displacement-imposed test. Colours indicate initial moisture content (MC). Iso-module curves are added in grey dashed lines.*

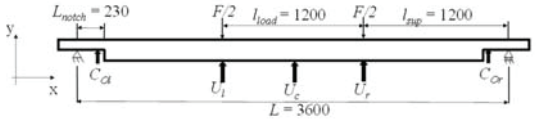
2.2 BENDING TESTS

2.2.1 Displacement-imposed

The displacement-imposed 4-points bending tests were performed to correlate the strength with the initial MC and mechanical characteristics. The experimental set-up complies with the norm NF EN 408+A1 [7] and is represented in Figure 3. The central and intermediate deflections (respectively U_c, U_l and U_r) and the crack opening on the "left" and on the "right" (respectively C_{Ol} and C_{Or}) are measured using linear displacement transducers (LDT). The applied load is measured using two load cells.

(a)

https://doi.org/10.52202/069179-0074



(b)

Figure 3: *Experimental set-up of the displacement-imposed tests: (a) picture of a test; (b) position of the devices. Numerical values are in millimetres.*

2.2.2 Creep tests

The creep tests aimed at studying the long-term mechanical behaviour of partially dried wood. The experimental set-up, shown in Figure 4, was in outdoor semi-sheltered conditions (i.e., sheltered from the rain but some beams were not sheltered from solar radiation). The load was applied using 350 kg waterproofed concrete blocks, incremented by 30 kg every month for 5 months and then every day, so that the duration of the tests never exceeded 7 months. Linear variable differential transformer (LVDT) sensors were used to measure the central deflection. A weather station close to the tests recorded temperature (T), relative humidity (RH) and solar radiation. Furthermore, two thermometers were stuck in the centre of each beam. A marker-tracking technique developed for these tests was used [8]. The relative displacement between markers allowed to measure the variation of beam height due to shrinkage-swelling and the crack opening, length and tip height.

(b)

Figure 4: *Experimental set-up of creep tests: (a) picture of three loaded beams; (b) positions of measurement (values in mm).*

3 RESULTS AND DISCUSSION

3.1 INSTANTANEOUS RESPONSE

3.1.1 Comparison with non-destructive data

The displacement-imposed bending tests never exceeded 30 min and the mechanical response is hence considered as instantaneous. The axial stress is computed according to beam theory, and the strain, following [9], is given by:

$$\varepsilon \approx \frac{4\Delta U_{spa-r} H}{l_{load}^2} \quad (1)$$

where ε is the maximum normal strain in the centre of the beam, H the height of the beam, l_{load} the distance between the loading points and $\Delta U_{spa-r} = U_c - (U_l + U_r)/2$ the spatial-relative deflection. This allows to plot the stress-strain curves and calculate the static MOE with the slope of the linear part. An "instantaneous" central deflection of the creep tests was estimated by considering the central deflection at 10 minutes U_c^{10min}. An approach adapted from [10] allows computing the static MOE E using U_c^{10min} of the notched beam:

$$E = \frac{A \times f(\beta_0) \times \Delta F}{\Delta U_c^{10min}} \quad (2)$$

with:

$$A = \frac{23 l_{sup} L^2}{36 e H^3} \quad (3)$$

where e is the beam's thickness, L the beam length and l_{sup} the distance between support and loading point. Also:

$$f(\beta_0) = \left(1 + \frac{189\beta_0^3}{23}\right) \times \left[1 + \frac{108}{115}\left(\frac{H}{L}\right)^2 \left(\frac{E}{G}\right)^d \frac{1 + (3/2)\beta_0}{1 + (189/23)\beta_0^3}\right] \quad (4)$$

where $\beta_0 = (2L_{notch})/L$ is the notch factor. The comparison between the instantaneous results with the non-destructive examinations is given in Table 3.

Table 3: *Comparison between dynamic (E^d) and static (E) MOE. ΔE_{rel} corresponds to the relative difference such that $\Delta E_{rel} = (E^d\text{-}E)/E^d$.*

	E^d [GPa]	E [GPa]	ΔE_{rel} [%]
Minimum	7.54	6.02	-23
Maximum	16.34	13.96	32.8
Mean	11.25	9.74	12.4
Std	2.34	2.27	14.5

If the initial MC in a static test is below 30%, E is corrected by 0.15 GPa/% [11] as E^d is supposed to had been measured in green state. The relative difference $\Delta E_{rel} = (E^d\text{-}E)/E^d$ is explained by the natural dynamic and static difference and because E^d was measured on unnotched beams rather than E on notched beams.

3.1.2 Instantaneous strength

In Figure 5 the maximum force reached during the displacement-imposed tests is plotted as a function of ρ_{BD}, with the indication of MC.

https://doi.org/10.52202/069179-0074

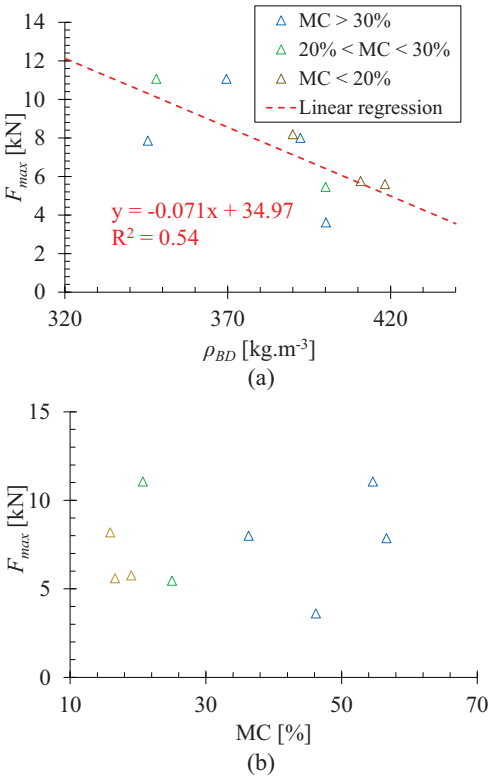

Figure 5: *Maximum force reached during the displacement-imposed tests: (a) as a function of the basic density; (b) as a function of MC.*

Although with a bad coefficient of determination ($R^2 = 0.54$, Figure 5(a)), F_{max} seems to be inversely proportional to ρ_{BD}. This is counterintuitive as the density should increase the MOE and thus F_{max}. As fracture mechanics occur in notched beams, it is supposed that a low MOE implicitly involves several knots that are reinforcements against crack propagation, increasing F_{max}. No correlation is observed between instantaneous F_{max} and initial MC of the tests, Figure 5(b).

3.2 DELAYED RESPONSE

3.2.1 Time-dependent deflection

The delayed response of the creep tests is observed using the time-relative central deflection $U_{time-r}(t)$ defined by:

$$U_{time-r}(t) = q(t) \times \frac{U_c(t) - U_c^{10min}}{U_c^{10min}} \qquad (5)$$

where $q(t)$ is the ratio of initial applied mass m_{ini} over total mass $m_{tot}(t)$ that is increased with load increments and the self-weight of the beam: $q(t) = m_{ini}/m_{tot}(t)$. The height variations due to shrinkage-swelling are measured by the marker tracking, hence correcting their impact on the central deflection: $U_c(t) = U_c(t) - \Delta H(t)/2$. Therefore, $U_{time-r}(t)$ is equivalent to the so-called K_{def} that takes creep into account in Eurocode 5, such that $U_{fin} = U_{inst}(1 + K_{def})$ for permanent load. For a class of service 3 (MC > 20% due to outdoor condition) and starting from green state, K_{def} is fixed at 3.

In Figure 6 the time-dependent deflection for all creep tests is plotted.

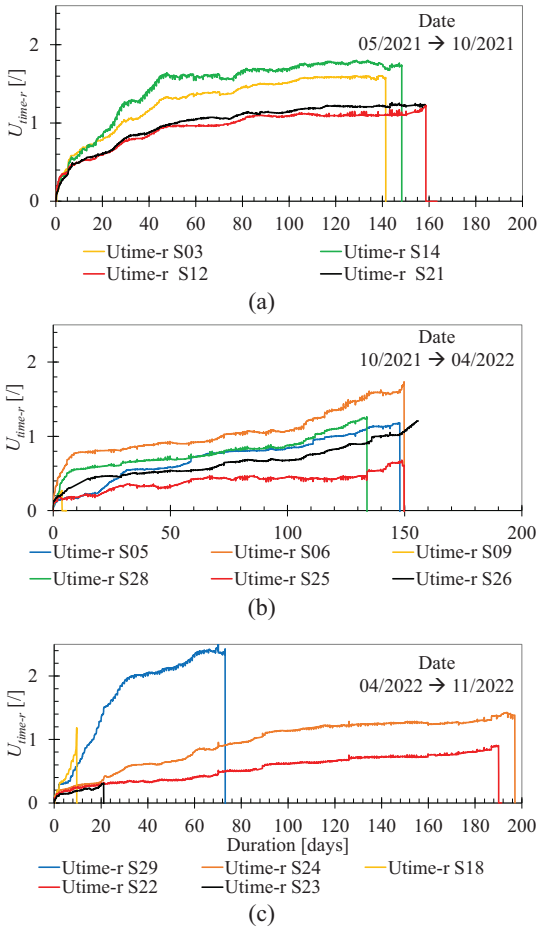

Figure 6: *Time-relative deflection as a function of time: (a) for the first 6 loaded beams in summer 2021; (b) for the 6 beams loaded in winter 2021-2022; (c) for the 6 beams loaded in summer 2022. Sij indicates the number of the considered beam.*

The measured time-dependent deflection never reached 3 as predicted for K_{def}, suggesting that it indeed integrates a safety factor. The beams loaded during Summer show on average a higher $U_{time-r}(t)$. Similar creep tests on initially dried silver fir wood never reached a time-dependent deflection above 2 for 2-years loading [9].

3.2.2 Time-dependent compliance

The time-dependent compliance J_{time-r} was calculated as:

$$J_{time-r} = \frac{E}{E(C_L, t)} - 1 \qquad (6)$$

where E is the initial computed MOE and $E(C_L, t)$ the stiffness evolution based on Equation (2), given by:

https://doi.org/10.52202/069179-0074

$$E(C_L,t) = \frac{A \times f(\beta) \times F(t)}{U_c(t)} \quad (7)$$

where *F(t)* is the updated applied force (adding load increments), $f(\beta)$ uses the crack factor β instead of β_0 by considering the crack length measurement as a notch extension:

$$\beta = \frac{2(L_{notch} + C_L)}{L} \quad (8)$$

This procedure discards the impact of crack propagation and load increments on J_{time-r} and allows comparing beams independently from these effects and from initial MOE. J_{time-r} should depends only on the wood creep itself that is impacted by MC and environmental conditions. In Figure 7 the maximum time-relative compliance reached is plotted as a function of the initial MC at the beginning of the creep test. The external beams exposed to solar radiation (Figure 4(a)) are indicated on the Figure as it has a significant impact on the maximum J_{time-r} reached.

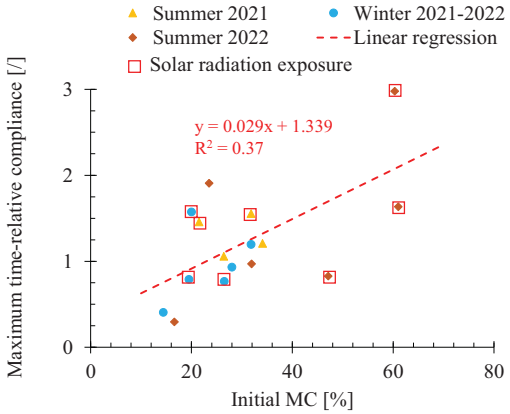

Figure 7: *Maximum time-relative compliance reached as a function of the initial MC at the beginning of the creep tests. Exposure to solar radiation is highlighted by red square.*

There is a slight tendency for the most dried beams to have a lower creep, but there is no strong correlation between initial MC at the beginning of a creep test and maximum time-relative compliance reached after 7 months ($R^2 = 0.37$). Exposure to solar radiations increases creep and brings an unpredicted factor in long-term wood mechanics. Therefore, it should be considered in the same way as moisture content.

3.3 FRACTURE MECHANICS

3.3.1 Deflection involved by fracture

Starting from the function of the notch factor β_0 in Equation (4), the ratio $f(\beta_0)/f(\beta)$, where β is the crack factor that supposes a crack propagation as a notch extension, can be defined. This ratio equals 1 if no crack occurred and decreases with crack propagation. Therefore, a "crack deflection" $U_{crack}(t)$, i.e., a deflection only due to crack propagation, is defined as:

$$U_{crack}(t) = U_c(t)\left(1 - \frac{f(\beta_0)}{f(\beta)}\right) \quad (9)$$

$U_{crack}(t)$ is the total deflection $U_c(t)$ minus the computed deflection as if the beam were free from crack. In Figure 8, $U_{crack}(t)$ is plotted as a function of time for two beams that represent the whole range of observed crack deflection. Thus, $U_{crack}(t)$ varies from 0.8 mm to 4.5 mm, that is at most about 10% of the total deflection. Although assumptions are strong in that computation, it is worth noting that crack seems to have a marginal impact on the observed deflection.

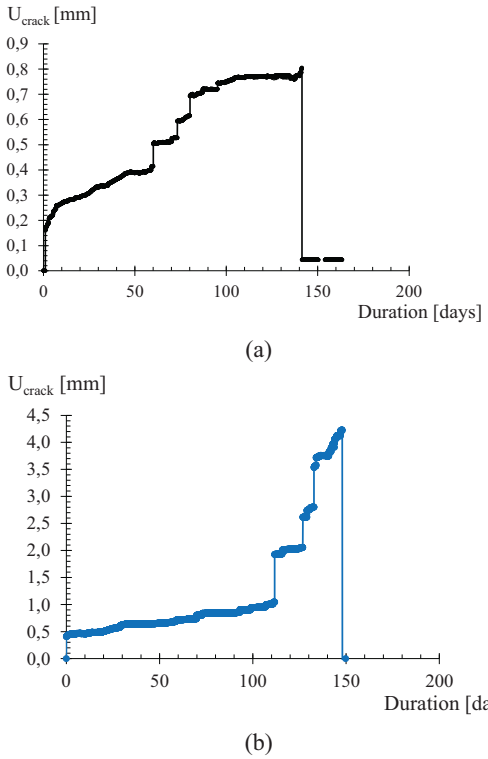

Figure 8: *Crack deflection as a function of time: (a) for beam S03 loaded in summer 2021 with few crack propagation; (b) for beam S05 loaded in winter with lots of crack propagation.*

3.3.2 Fracture facies observation

Observations of fracture facies were made a posteriori. In most cases beams with low strength but high stiffness were free from knots in the crack trajectory. On the contrary, high strength beams with low stiffness had either a knot into the trajectory or slanted facies, Figure 9(b)(c). Indeed, slanted facies requires more energy to propagates because surfaces that must be separated are larger. This result support the assumption that knots and anatomical configurations may increase a beam's strength. Furthermore, it is worth noting that all crack propagations occurred through rising toward the compression zone, whatever the grain angle (Figure 9(a)). It is surprising because the crack usually follows the grain. Reasons that may explain this observation are: (i) a descending crack would not break the beam but only

remove a piece; (ii) in a rising crack trajectory the section is progressively reduced and that is the opposite with a descending trajectory; (iii) in softwoods the overlapping of tracheids [12] allows a crack to rise slightly with no additional energetic cost.

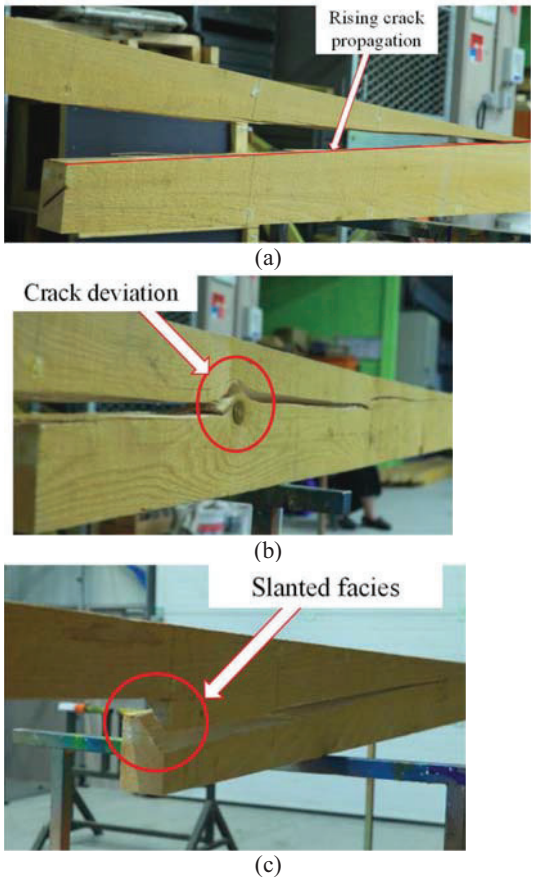

Figure 9: *Fracture facies observations: (a) A low strength beam with a rising crack propagation without knots; (b) crack deviation due to a knot; (c) a high strength beam with low basic density but slanted facies.*

4 CONCLUSION

This paper presents the results of an experimental campaign on full-scale notched beams of silver fir wood. Displacement-imposed bending tests and bending creep tests were realised on wood above FSP, partially dried and dried wood. The studied beam's batch is highly heterogeneous, but the experimental campaign is representative of the mechanical properties range. Both the dynamic and static MOE are consistent, but the estimated MC is not very accurate due to uncertainties on the green volume V_g. All other things being equal, initial MC has no visible impact on instantaneous strength. The basic density seems inversely proportional to that strength, and observations show that low basic density beams with high strength presented either knots on the crack trajectory or slanted facies that increased their strength. On the contrary, the time-dependent central deflection and compliance during creep tests tends to be proportional to the initial MC, but never exceed K_{def} proposed by Eurocode 5. This is explained by the important drying phase that increases the creep due to a mechano-sorptive effect. Nevertheless, exposure to solar radiation and knots position that resists to crack propagation also have a significant impact on the maximum time-relative compliance reached and have to be considered. The deflection only due to crack propagation was estimated to be less than 10% of the total deflection, meaning that crack has a marginal effect on the observed deflection. Finally, all fracture propagations rise whatever the grain angle. This is surprising and only intuitively explained: a rising crack propagation is energetically optimal. A finite element simulation of 4-points loaded notched beams may explain the rising crack trajectory.

ACKNOWLEDGEMENT

The authors would like to thank the Auvergne Rhône-Alpes region for the Ph.D. scholarship as well as the fundings of the Hub-Innovergne program of the Clermont Auvergne University.

SIMPLIFIED ENVIRONMENTAL ANALYSIS OF THE LONG-TERM PERFORMANCE OF WOOD CLADDING AND DECKING

Jonas Niklewski[1], Jakub Sandak[2], Philip Bester van Niekerk[3], Christian Brischke[4], Richard Acquah[2], Anna Sandak[2]

ABSTRACT: The performance of timber in exposed environments is affected by several biotic and abiotic factors. For timber cladding and decking, two important aspects include reduced structural performance due to fungal decay and aesthetical changes resulting from superficial effects such as photodegradation and moulds. Predicting the long-term performance of timber is important because it enables rational material (species and treatment) and design (detailing) choices and reduce the risks of unexpected repairs and premature replacement of timber products. In this paper, we use available data on material performance in conjunction with environmental analysis to model, in a simplified way, (1) the time until onset of fungal decay and (2) the long-term aesthetical appearance of timber facades and decking. The results demonstrate how the analysis can be used on a detailed geometry where wooden boards were modelled as separate objects and the choice of material affects the outcome. Several steps needing further development were identified, including a dose model linking microclimate to colour change and a better model for predicting moisture content. The study is part of a long-term effort to make holistic performance-based assessment of wood available for public use through easy-to-use procedures and accessible open-source software.

KEYWORDS: Wood, Aesthetics, Fungal decay, Durability, Long-term performance, Material database

1 INTRODUCTION

There are many different wood species, treatments, and material modifications available on the market. Selecting a material that meets a set of defined user criteria is far from trivial, in part because knowledge of long-term performance is fragmented or incomplete. The long-term performance of timber is affected by both biotic and abiotic mechanisms, and the time until non-performance depends on several aspects. In addition, the definition of non-performance depends on the application. For example, the main concern in the design of structural timber in outdoor applications, such as timber bridges, is generally the impaired structural performance caused by fungal decay. For other applications, such as cladding and decking, both structural integrity and long-term aesthetical performance/visual appearance are important aspects to consider.

Fungal decay leads to wood mass loss and reduced structural integrity, with wood moisture content being one of the main vectors for material deterioration. Free water is a prerequisite for the degradation process, so attack by decay fungi is usually not seen as a risk when the wood moisture content is below cell-wall saturation or when the wood temperature is below freezing [1]. Wood in outdoor exposure is also subject to superficial damage and colour changes not directly associated with structural damage. Colour change is caused by both chemical changes and biological growth. Solar irradiance and wind-driven rain have been cited as the most influential factors driving colour change [2]. Surfaces exposed to UV and visible light will develop a cellulose-rich grayish surface layer, in part due to the decomposition and leaching of lignin [3].

While these two modes of material deterioration lead to different outcomes and consequences, both can be described as functions of material characteristics and environmental exposures. Figure 1 shows, conceptually, a model for deterioration caused by environmental effects. The material database describes how the material (species and modification/ treatment) in question responds to environmental exposure. The environmental exposure can be modelled from the local weather and the geometry of the building envelope. The dose model evaluates these exposures (e.g. rain, temperature) and converts them to a unitless measure of dose. If other input variables are required, such as as moisture content and surface temperature, then those are derived from environmental exposures prior to dose modelling. The exposure dose can then be compared against the resistance to infer the material's response.

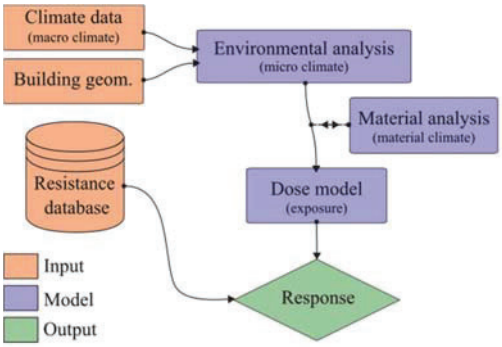

Figure 1: *Conceptual illustration of the models linking the material database to environmental exposures.*

Dose modelling has previously been used as a basis for factorised guidelines targeting service life of wood in above-ground applications [4]. Here, a 'factor' is a unitless measure describing the relative change in service life of a reference case stemming from, for example, a variation in climate conditions or design detailing. Dose models allow factors to be derived from moisture- and temperature conditions, which can be measured or simulated. Factorisation generally relies on simplified interaction between exposures, meaning that synergistic or antagonistic effects are not adequately accounted for. To address this problem, some efforts have been made to limit the use of factorisation by instead expanding the scope of moisture modelling [5]. This study is a continuation of this work, targeting wind-driven rain and shelter through environmental analysis.

Environmental conditions affect the performance of the building envelope. Exposure to wind-driven rain (WDR) and sunlight both vary with orientation and surface tilt, but also depend on design detailing. For example, deep roof eaves have long been used to limit the exposure of WDR on walls. Solar radiation is relatively predictable and can be modelled by ray-tracing. WDR is more chaotic, but can be modelled by computational fluid dynamics (CFD) [6]. As a simpler alternative to the computationally heavy CFD analysis, WDR can also be modelled through ray-tracing [7]. A simple method for environmental analysis of buildings using ray-tracing has previously been proposed by Charisi et al. [8], including both WDR and solar radiation.

The focus of the present paper is to demonstrate how (simplified) environmental analysis combines with other models to link environmental exposures to existing material databases for fungal decay and photodeterioration. WDR and solar radiation were modelled in Blender 3D [9] through particle- and ray-tracing, respectively. The resulting exposures were used as input to calculate moisture content and combined fungal dose. A basic fuzzy inference system (FIS) was used to create semi-realistic colour changes from exposure to WDR and solar radiation. While the FIS model assumptions are subjective, the system can easily be tuned when additional validation data becomes available. The analysis as a whole is simple, relatively fast and relies entirely on OA software to ensure high accessibility.

2 METHODS

This section describes the models involved in predicting aesthetical and decay performance of wooden cladding and decking. The nature of the models involved differs depending on the deteriorating mechanism in question. In both cases, the analysis is based on a specific 3D geometry of the building and the local climate. Climate data were obtained from the Swedish Metereological and Hydrological Institute (SMHI), measured in Gothenburg, Sweden, between 1st of January and 31st of December in 2021.

2.1 MATERIAL DATABASE

Material data for the relative resistance to fungal decay of treated, modified and natural wood species were obtained from Brischke et al. [10]. The data are based on a meta-analysis of measured data on moisture dynamics and inherent resistance. These measurements were used with the Meyer-Veltrup resistance model [11] to estimate the resistance to fungal attack in above-ground applications.

Material data for the colour change of modified and treated wood species were obtained from Sandak et al. [12]. The data set is based on a test-setup where the colour of different wood products was recorded monthly during 24 months of outdoor exposure. The database describes how the late- and earlywood colours vary over time. While a dose model for linking the colour change to weather variables has not yet been developed, the material data alone can be used in conjunction with a simplified exposure criterion to predict the final visual appearance of wood cladding and decking.

2.2 ENVIRONMENTAL ANALYSIS

The environmental analysis is performed in Blender 3D (v.2.83.20.0), an open-source 3D-modelling environment with limited physics-based simulation and analysis capabilities. Since Blender is not a dedicated numerical software, some simplifications are necessary. It should be noted, however, that the functionality to use the software for more sophisticated environment analysis, even CFD, is possible by integration of other open-source software [13].

The 3D geometry of a smaller playhouse (see Figure 2) is used here to demonstrate the concept. The model was obtained from a third party, meaning that the geometry was not tailored to simplify the analysis. The cladding is designed with vertical boards (125x20 mm^2) and battens (45x20 mm^2), i.e. vertical boards in two planes. Each board is modelled as a separate object, with eight vertices and six faces. The geometry was never remodelled or manipulated to facilitate the analysis.

https://doi.org/10.52202/069179-0075

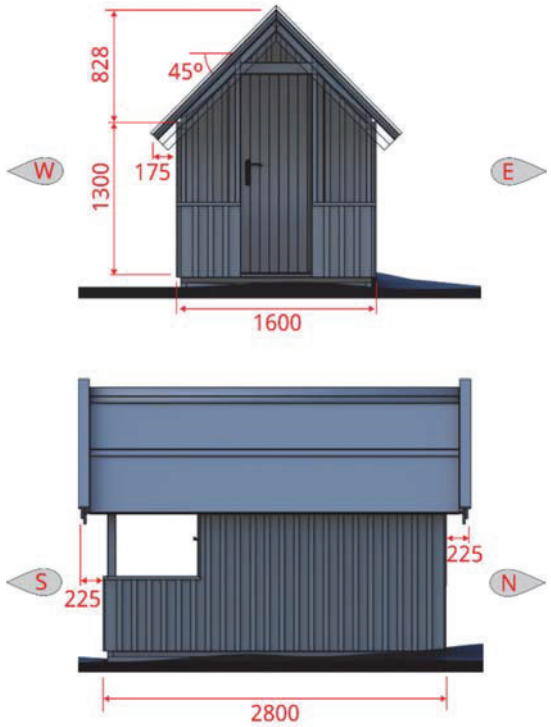

Figure 2: *Object geometry and dimensions. The annotated arrows (E and N) indicate orientation.*

After importing the geometry to Blender 3D, wooden objects to be included in the environmental analysis are inspected to verify that surface normals are consistent with respect to their orientation. The object surfaces are then projected onto a combined flat surface (UV map), using a method to maintain consistent scale between objects. The UV map is a flat representation of object surfaces linking vertex coordinates (xyz) to texture coordinates (uv). This map is used here to store the results from the environmental analysis, such as WDR and solar radiation. With a resolution of 1024x1024, a single pixel represents an area of about 10x10 mm^2, meaning that the width of a board (125 mm) is about 13 px with a thickness (20 mm) of 2 px. A single pixel is hereafter referred to as a node.

The methodology for calculating WDR and direct radiation follows the same principle. Both effects are assumed to follow straight trajectories. The trajectory of direct beam radiation depends on the sun's position, and that of precipitation depends on the wind speed, wind direction and terminal velocity. Following the assumption of straight trajectories, hourly solar radiation and WDR obtained from climate data were projected onto the surface normals of the geometry. In a subsequent step, binary masks were used to filter out exposure in shaded or sheltered regions of the geometry. The binary masks were obtained through different methods depending on the exposure in question, as explained in the following sections.

2.2.1 Exposure to wind-driven rain

The protocol for simplified environmental analysis of WDR presented here builds on a set of software-specific features, including animations, particle physics, 'dynamic paint' and 'texture baking'.

WDR is modelled as a particle system using the Blender physics engine. A particle system has two components: an emitter plane and particles. Particles are emitted from the emitter plane with an initial velocity and follows trajectory based on predefined physics , see Figure 3. The particle behaviour on collision with other objects can be set to, for example, disappearing, sticking or bouncing off the surface with or without damping. Here, particles are set to drop all momentum on collision and then continue in the direction of gravity, thus emulating water runoff.

The feature 'dynamic paint' is used to map particle collisions to the geometry. In general, dynamic paint is used to modify a surface (canvas) based on its proximity to another object (brush). Here, the particle system was defined as brush and the wooden objects (cladding/deck) were defined as canvas. The canvas was set to change colour from white to black (binary) on direct contact with a particle. The radius of brush (particle) on contact was set to 10 mm. The radius of the resulting patch was set to expand to a final radius of about 40 mm. The latter ensured that regions near the point of particle collision were also categorised as exposed.

A square horizontal emitter plane (8x8 m^2) was defined approximately 1 m above the geometry. The plane was set to emit particles in a uniform grid with a resolution of 250x250, which for the given geometry resulted in sufficient detail. The initial vertical velocity (v_z) of the particles was set to 4.5 m/s. This value is commonly used as the terminal velocity of raindrops with a drop diameter of 1.2 mm and can be used for light to moderate intensity rain spells [6]. The horizontal velocity (v_x,v_y) was varied to simulate different wind speeds and directions. Wind directions and speeds were modelled between 0 and 315 degrees in increments of 45 degrees and 0 to 6 m/s in increments of 1 m/s, respectively, resulting in 49 different unique scenarios. Note that v=0 m/s is was not run for varying orientations. The simulations were run programmatically in batch using the Blender API for Python. The outcome of the analysis resulted in 49 binary masks describing the exposed regions for each scenario of precipitation.

The terminal velocity of rain-drops combined with the wind direction and velocity gives the trajectory, $\mathbf{R}$. The projection of $\mathbf{R}$ on the surface (unit) normal of each node $\hat{\mathbf{n}}_{uv}$ is given by the dot-product. The magnitude of this vector divided by the terminal velocity gives the ratio of WDR in the node relative to rain passing through a fictive horizontal plane, which is also known as the wall factor. The wall factor is a convenient metric which can be multiplied by precipitation measured through a horizontal

https://doi.org/10.52202/069179-0075

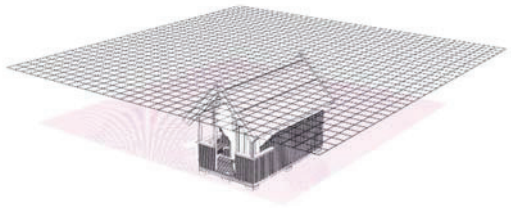

Figure 3: *Particle system simulating rain from a southeast orientation. The corresponding binary exposure map is projected on the cladding/deck, where white colour indicate sheltered areas.*

plane to calculate the amount of rain on a surface with arbitrary orientation and inclination. The binary maps obtained in the previous step were then used to zero out any nodes which were sheltered from rain. For each hour, the binary map corresponding to the nearest velocity (wind speed) and orientation was used.

2.2.2 Exposure to solar irradiance

Solar irradiation is limited to direct (beam) and diffuse irradiation. Here, the effect of reflected irradiance is not considered. Similar to the analysis of WDR, the calculation of solar irradiation on surfaces with different shading, tilt and orientation is performed in two steps. In a first step, the exposed regions of the geometry are identified using ray-tracing. In the second step, the irradiation incident on each node is calculated by projection onto the surface normals.

Regions shaded from direct solar irradiation were identified using the built-in ray- tracing algorithm of the 'cycles' renderer, a 'sun' light source and the built-in sun path algorithm. In Blender, the 'sun' is a directional light source with constant intensity, meaning that the scene lightning depends only on a given angle. This angle is given by the position of the sun in the sky relative to the location of the building, i.e. the azimuth, α, and altitude, β. The position of the sun is a function of geographical coordinates and time. For each hour, the shadow caused by the sun is mapped, resulting in 8760 binary images.

The hourly direct irradiation in each node was calculated from the direct normal irradiance, I_d, measured via satellite by SMHI [14]. The azimuth and elevation angles translate to a unit vector, $\hat{\boldsymbol{n}}_{\mathrm{Id}}$, which multipled by scalar I_d gives the vector, $\mathbf{I}_d$. The procedure is then analogous to the one presented in section 2.2.1, but the vector $\mathbf{R}$ is substituted by $\mathbf{I}_d$. For each hour, the direct beam irradiance normal to each surface was calculated by the projection of $\mathbf{I}_d$ on the surface normal of each node $\hat{\boldsymbol{n}}_{\mathrm{uv}}$. The corresponding shadowmap, as described in the previous paragraph, was then used to zero out any shaded nodes on the geometry.

Figure 4: *Skydome used to estimate the sky view factor.*

Diffuse isotropic irradiation was modelled using the sky view factor (SVF). The SVF is a dimensionless value describing the proportion of visible sky from a node. The SVF depends on surface tilt and obstacles. For example, the SVF of a vertical wall facing a free horizon is 0.5. The diffuse irradiation incident on any node on the geometry can be calculated by multiplying the measured diffuse radiation by the corresponding SVF.

The SVF was calculated by modelling the atmosphere as a dome discretizised into 600 triangular sky patches having equal area, see Figure 4. The surface normal of each sky patch was used to set the direction of a sun light source. The built-in ray-tracing algorithm was then used to map the visible part of the geometry from each sky patch. For this part of the geometry, the incident irradiation in every node was calculated. Finally, the sum total irradiation in every node were divided by that of a horizontal unobstructed surface, to obtain the SVF.

2.3 DECAY PERFORMANCE

The development of fungal decay over time is a function of the material climate (moisture content and temperature) and the material resistance (presence of extractives, treatment, etc.) to decay. The material climate depends on the environmental conditions (exposure) but is also inherently dependent on the moisture dynamics (permeability) of the wood product. For a simplified analysis following the structure in Figure 1, the exposure dose is modelled as material independent, and the moisture performance is instead considered as part of the material resistance.

2.3.1 Moisture performance

The moisture content is estimated from daily averages of relative humidity and temperature and daily sums of precipitation using an existing model developed by Frühwald et al. [15]. The equilibrium moisture content, u, is here calculated as follows:

$$u(\phi) = 0.7\phi^3 - 0.8\phi^2 + 0.42\phi + 0.0077 \qquad (1)$$

where ϕ is the daily average relative humidity. The daily average moisture content of a fictive sheltered board, u_{01}, is calculated from the average equilibrium moisture content over two consecutive days. During rainy periods, the actual moisture content of a board will increase and temporarily exceed that of the sheltered board. In the

https://doi.org/10.52202/069179-0075

model, a rainy day is defined by the daily sum of precipitation exceeding 4 mm, and a rainy period, t_r, is defined by the number of consecutive days when this condition is met. The moisture content during rainy periods, u_1, is then described as:

$$u_1(t_i) = u_{01}(t_i)[1 + k_r] \quad (2)$$

where k_r depends on the wood species and duration of the rain event. Here, a value of k_r=0.8 was used, as proposed by Frühwald et al. [15]. When the rainy period ends, the moisture content, u_1, will decrease towards the moisture content of the sheltered board, u_{01}. The duration of this decrease, t_d, depends on the length of the previous rainy period (number of consecutive days with rain), and is described as t_d=2.5t_r. The moisture content *k* days after a rainy period can then be calculated as:

$$u_1(t) = \max\begin{pmatrix} k(u_{01}k_r)/t_d \\ u_{01} \end{pmatrix} \quad (3)$$

The exposure to precipitation [mm/day] depends on the surface normal (orientation and inclination) and the degree of sheltering. Every node in the geometry is associated with a time-series of precipitation, obtained from the environmental analysis. Relative humidity and temperature were obtained from the weather data and were assumed uniform over the building geometry. In practice, solar irradiance will affect the temperature and relative humidity of the wood surface.

2.3.2 Dose model

In this paper, the 'logistic' dose model from [16] was used to estimate the progression of decay from the moisture- and temperature variation. The model is comprised of two functions: the moisture-induced dose, $D_u(u)$, and the temperature-induced dose, $D_T(T)$, as shown in Figure 5. The dose is a dimensionless value which describes the development of fungal decay between unfavourable (0) and ideal (1) conditions. The functions are mechanistic in the sense that their cardinal points (minimum, maximum, optimum) are based on mycology research [1]. If either D_T or D_u is zero, then it is assumed that no decay development can occur on that day. If both terms are positive, then the daily dose is calculated as a weighted average of the two components, according to:

$$D = \frac{3.2D_T + D_u}{4.2} \quad (4)$$

The dose, D, accumulates over time, with no setback, and relates directly to the decay rating. The relationship between decay rating and dose is based on long-term field trials where the moisture content, temperature and decay rating of Scots pine sapwood (*Pinus sylvestris*) and Douglas-fir heartwood (*Pseudotsuga menziensii*) were monitored [17]. It was found that decay rating 1 corresponds to a dose of approximately D=325, meaning that the species used in the test sustain about 325 days in ideal conditions (for fungal decay) prior to the initiation of fungal decay [18].

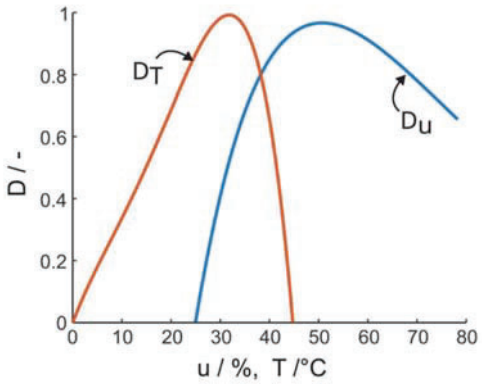

Figure 5: *Dose functions describing the relative temperature- and moisture conditions for fungal decay.*

The limit state is herein defined as the time until the onset of decay. The time until the limit state is reached is calculated as the ratio D_{Rd}/D_{Ed}, where D_{Rd} is the resistance dose obtained from the material database based on [10].

2.3.3 Factorisation

Due to its simplicity, the factorised approach has been commonly used for design guidelines. Here, the annual exposure dose, D_{Ed}, is calculated as follows:

$$D_{Ed} = D_0 k_1 k_2 k_3 \quad (5)$$

where D_0 is a reference value depending on the ambient climate and k_1, k_2 and k_3 are factors to account for moisture trapping, sheltering and distance to ground, respectively. Other factors can also be included.

In this paper, the dose derived from the environmental analysis explicitly considers ambient conditions, D_0, and sheltering, k_2, in the process of modelling moisture content variation. Distance to ground is considered in analogy with the factor-based method by calculating the distance in every node to a ground plane and then using the relationship in [19] to calculate the relative increase in dose:

$$k_3 = \begin{cases} \dfrac{700 - a}{300} & a < 400 \\ 1.0 & a \geq 400 \end{cases} \quad (6)$$

The distance in every node was here obtained through dynamic paint by defining the ground plane as a brush and the wooden elements collectively as canvas. Each node on the canvas was then coloured based on proximity to the brush with a linear falling intensity from direct contact with the ground (1) to a distance exceeding 400 mm (0).

2.4 AESTHETICAL PERFORMANCE

The change in visual appearance is modelled by combining a map of exposure dose and a generic procedural wood texture with the colour database from [12]. A fully functional dose model linking microclimate to colour change does not yet exist. Instead, conditional

https://doi.org/10.52202/069179-0075

statements and fuzzy logic were used to create pseudorealistic weathering patterns.

Colour change caused by photodegradation requires solar radiation to break down the wood cell structure and water to wash off the by-products [20,21]. Whether or not a surface is subject to weathering can thus be infered from a conditional statement. It can futher be assumed that, given a sufficiently long time horizon, surfaces exposed to both solar irradiance and WDR converge to a fully weathered state. This logic is useful for binary classification but is unable to reproduce the characteristic gradual weathering patterns between weathered and non-weathered regions. Here, a multivalued conditional approach based on (fuzzy) logic was used to define a function for interpolating between the two extremes. To demonstrate the concept, a set of subjective assumptions was made.

The function describing the degree of weathering depends on two crisp (numeric) input variables: solar radiation and precipitation. To make use of fuzzy logic, these input variables were fuzzified into two linguistic terms: low, and high exposure. Similarly, the output was described as low and high degree of weathering. The following rules were defined:

1. D == low || R == low → W = low
2. D ~= low & R~=low → W = high

The first rule states that both precipitation and solar radiation may limit the rate of degradation, i.e. if either of the two is zero, then no degradation will occur. The second rule simply describes that if (1) is false, then the degree of weathering is high. Membership functions and the resulting response surface are shown in Figure 6. The membership functions were, for simplicity, assumed triangular with their centre of gravity at 0 and 1, respectively. The resulting response surface shows that no weathering occurs if the node is subject to less than about 5% of the maximum precipitation or solar irradiance, respectively. The shape of the interpolated region between 5% and 10% is determined by the shape of the input membership functions.

The node colour is determined from wood texture and the degree of weathering using colour data from the database. The FIS determines the degree of weathering in each node and the resulting distribution is hereafter referred to as the 'dose map'. In addition to the degree of weathering, the colour depends on whether the node is late- or earlywood, which is determined from the material texture. Here, a procedural wood texture is used where the intensity describes the wood type, i.e. white (1) being earlywood and black (0) being latewood. A value between 0 and 1 describes a mix of latewood and earlywood where the colour is interpolated.

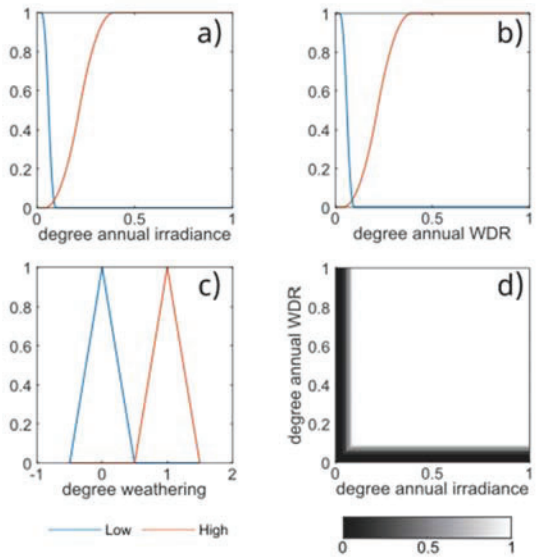

Figure 6: *Input membership functions (a,b), output membership functions (c) and response surface (d).*

3 RESULTS AND DISCUSSION

3.1 ENVIRONMENTAL ANALYSIS

Figure 7 shows the sky view factor (SVF) of the geometry, the total irradiance (direct + diffuse) and the annual exposure to wind-driven rain. The SVF shows that isotropic diffuse radiation is not orientation-dependent, but depends on the degree of sheltering and surface tilt. Therefore, horizontal surfaces on the cladding absorb approximately the same amount of diffuse radiation. The vague light vertical lines on the façade is a result of the design of the cladding, where the outer layer (battens) partially shades the inner layer (boards).

Exposure to solar radiation is higher in the southern orientation, which is typical for buildings in the northern hemisphere. The southern cladding is also subject to more WDR than the other vertical faces, which is typical for Sweden. The maximum WDR (500-600 mm) can be observed on the horizontal boards of the deck. Vertical surfaces close to the ground facing south, west, east and north were subject to approximately 300, 150, 150 and 100 mm of WDR, respectively. These values are consistent with values calculated without considering any sheltering effects.

The environmental analysis was performed for a given time, site, and geometry. However, redoing the entire analysis is necessary only when the geometry is changed. This is an advantage stemming from the fact that weather data was not integrated directly with ray-tracing and particle simulations. Particle simulations were performed based on generic scenarios and are therefore independent of both time-period and location. Ray-tracing on the other hand depends on geometry, location and time-period. The effect of calender year on the sun position is for practical

https://doi.org/10.52202/069179-0075

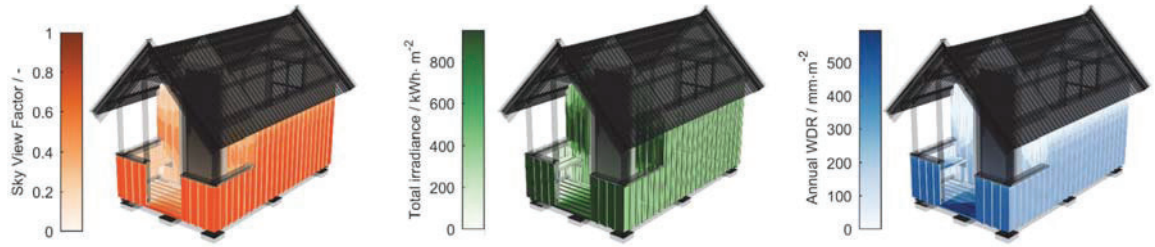

Figure 7: *Sky view factor (a), total solar irradiance (b) and annual wind-driven rain (c), viewed from southeast.*

purposes negligible, so the analysis can be reused for different years. Similarly, location can be varied within reasonable limits without introducing major errors stemming from variatrions in sun position. Alternatively, ray-tracing could be made independent of time-period and location by using generic scenarios of sun position. The analysis of sky view factor is only dependent on the geometry.

3.2 Fungal decay

Figure 8 shows the variation of exposure dose. The dose values range between 1 and 50, depending on orientation, tilt, degree of shelter and distance to the ground. The highest dose values are found close to the ground on the horizontal decking boards, while values close to zero are found on interior surfaces and other locations completely protected from rain, e.g. below the roof eaves. The high dose values seen on the decking boards can be explained by them being exposed to WDR from the most severe (south) orientation in conjunction with unfavorable surface normals (horizontal boards) and small distance to the ground.

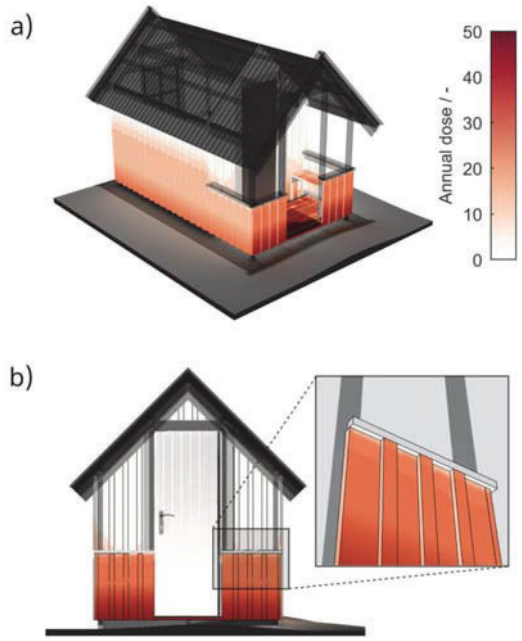

Figure 8: *Distribution of fungal dose viewed from southwest (top) and south (bottom).*

Fully sheltered elements categorised in use class 2 [22] would, under normal circumstances, not be expected to decay. Yet, the results indicate a non-zero dose also for surfaces completely sheltered from WDR. This can be explained by the moisture model employed, specifically equation 2 exceeding the lower threshold for fungal decay (25%) when the relative humidity exceeds 90%. However, the dose values registered on surfaces sheltered from WDR are very small relative the values on exposed surfaces, and therefore have little or no influence on the service life of the building as a whole.

It should be noted that the dose shown Figure 8 does neither account for detailing nor for end-grain absorption. Therefore, the depicted dose should be regarded as a reference value to be multiplied by factor k_3 in regions affected by moisture trapping or exposed end-grain. For example, Figure 8b shows a southern view with a set of vertical exposed boards connected to a horizontal member. The vertical boards are subject to a dose of approximately 20 in the connection to the horizontal board. If the end-grain is directly exposed to precipitation and no ventilated gap (minimum 5-8 mm to facilitate drying) is provided, then the dose will increase by a factor of k_3=1.6 up to 32, following the guideline by Isaksson et al. [19].

The dose shown in Figure 8 is only dependent on the exposure conditions and is thus independent of the wood species, treatment and modification used. The actual service life depends to a great extent on the moisture-performance and inherent resistance of the wood product. These factors are considered by the material resistance dose, which is listed [10] for many different wood products. For example, untreated Norway spruce (*Picea abies*) and European larch (*Larix decidua*) have material resistances in above-ground applications of D_{Rd}=325 and D_{Rd}=1800, respectively.

3.3 AESTHETICAL PERFORMANCE

Figure 9 shows the change in colour from newly built to weathered, with materials including natural and treated pine wood. The wooden materials were rendered without passing the materials through a shader. This means that interaction between material and lightning was not modelled. For demonstrative purposes this was deemed desirable.

https://doi.org/10.52202/069179-0075

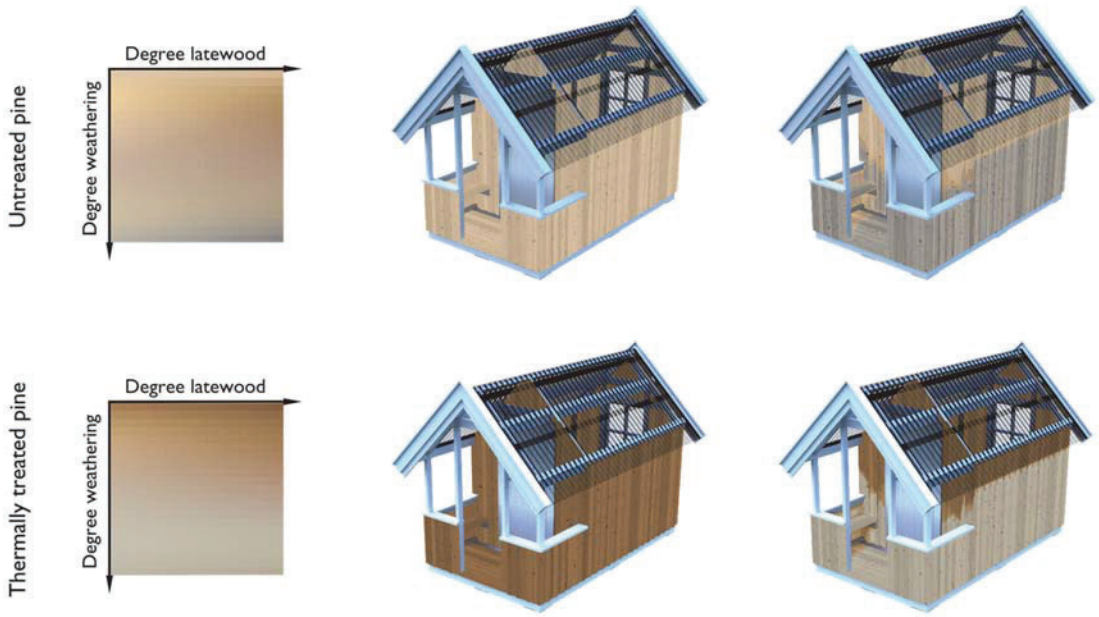

Figure 9: *Colour of newly built (centre column) and fully weathered building (right column) made from natural (top row) and thermally modified (bottom row) pine wood, viewed from southeast. The left column shows the interpolated colour maps, based on the database.*

As can be seen by comparison to Figure 7, the extent of the weathered regions correspond quite well with the coverage of WDR. The reason for this is that the FIS require both exposure to precipitation and solar irradiance for weathering to occur. Regions exposed to WDR are predominantely exposed also to direct and/or diffuse radiation, thus making exposure to precipitation the limiting factor.

It should be reiterated that the FIS model used to determine the dose map is very simplified and is used in lieu of an accurate dose model. The approach presented here can be used for binary classification of regions subjected or not subjected to weathering and for smooth interpolation between those regions. However, the model cannot be used to describe the kinetics of weathering, i.e. the aesthetical appearance at a specific point in time.

4 CONCLUSIONS

Exposures to WDR and solar radiation were modelled on a multi-object geometry. Ray-tracing for solar radiation and particle tracing for WDR were performed in the open-source software Blender 3D. The results were then used to model exposure to fungal decay and to identify areas subject to surface deterioration, respectively. These results, in conjunction with existing material databases, can be used as a basis for service life prediction.

The methods demonstrated here can be used to support decision-makers in the choice of material and design. The results provide a visual overview which can be used to qualitatively identify critical locations where detailing should be designed with caution, as well as regions where detailing is less important. Based on the results, the designer can decide whether the long-term performance, in terms of service life and aesthetics, is acceptable. If not, then the design can easily be adapted with material less prone to weathering and/or with higher resistance to fungal decay.

Future work will focus on improving the model used to estimate moisture content and developing a quantitative dose-response model relating colour change to environmental effects. The scope of the moisture content calculation could also be expanded to include distance to ground and detailing, further reducing the need for factorised design. Finally, the method can be integrated with life cycle costing and maintenance scheduling, as it provides detailed information of exposure for individual components. However, model validation against real examples is needed.

ACKNOWLEDGEMENT

World Conference on Timber Engineering Oslo 2023

ON THE USE OF ARUCO MARKERS IN LONG TERM MONITORING OF TIMBER STRUCTURES

Jiří Kunecký[1]

ABSTRACT: For research and monitoring purposes, there is a need to measure long-term displacements of parts, joints, etc. Of course, existing solutions (LVDT, Tell tales, etc.) can be used, but they are relatively expensive or inaccurate. The article describes a simple procedure based on an optical method using ArUco markers originating from computer vision applications (robotics). This technique uses not only marker tracking, but also along with it image rectification using projective transformation, and thus works well in 2D structures (beams, walls). The illustrated principle allows to take only two images (the original and another one after a certain time) and to quantify the displacement and rotation of the markers identified in the images. Reference points have to be specified. The displacement fields are then interpolated and a final map is produced. This can be of interest to anyone working in practice, conducting research on the long-term behavior of joints, monitoring the creep of wooden structures or for any monitoring purpose - including laboratory tasks. The article describes accuracy and error estimation and shows an example of use.

KEYWORDS: Monitoring of timber structures, ArUco markers, measurement of displacement, long term monitoring.

1 INTRODUCTION

The work presented in the article was created and inspired in everyday practice, both in the laboratory and in-situ. Measuring long-term displacement fields in wood joints or in wood research in general (e.g. shrinkage due to moisture changes) is a complicated matter, as expensive in-situ equipment is not preferred due to possible damage, suffering also from issues like a need of stable power supply, data storage or simply because of the fact that the device is blocked for a period of time for further activities, etc. What is then needed for reliable displacement measurement not only in the wood engineering industry? It is an inexpensive practice that can be used repeatedly, which keeps the data for further analysis and is sufficiently accurate. Such a solution can be attained when taking the advantage of computer vision algorithms. Since many algorithms in this field have been already developed [1], the users need to understand them and use them properly to ensure a reliable result of the analysis.
Optical measurement of movements or strain fields can be performed using marker tracking (e.g. the ones commonly spotted in car crash tests) or based on minimization of warping of a subset in a sequence of images leading directly to digital image correlation (DIC). Because digital image correlation is very sensitive to any moves of the camera, usually it is the choice for laboratory testing, where there is no need of repositioning of the optical device etc. Further text is thus focused on CV [1] and marker-based procedures, which allow (re)moving the camera and return it later after some time.

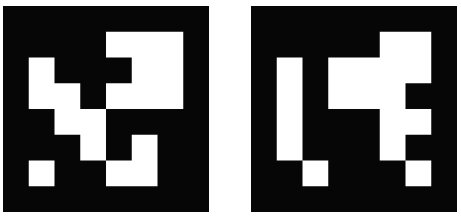

Figure 1: *Samples of two distinct ArUco markers*

The idea is to use an industrial camera (or even an ordinary one) to obtain a picture of the scene and compute the precise position of markers of known dimensions. There are more types of markers [7], but the very simple ones, the ArUco markers [2] have multiple advantages: their area and corners are relatively big to ensure good contrast. The markers have been developed for use in robotics, where cameras are serving as the eyes of the robot and let it orientate in 3D space using found points. Such a marker has simple geometry (see Figure 1) and has also an ID coded in the binary map. That allows to recognize the markers from each other and use further processes to track their relative change. It should be noted that these markers can be printed out very cheap way by a standard laser printer (whose precision 1200 DPI is expected) and glued to the surface use a glue or an adhesive gum. This setup is the starting point for further analysis.
Of course, measurement of precise point displacement can be done using standard geodetic approaches, such as total station or laser-based methods, however, this article goes

[1] Jiří Kunecký, Czech Acad Sci, Inst Theoret & Appl Mech, Czech Republic, kunecky@itam.cas.cz

https://doi.org/10.52202/069179-0076

its own way because a gap in monitoring techniques has been found, especially for rigid body motion assessment: a very cheap technique, that can be done using basic equipment without additional cost and which is relatively powerful. To attract the interest of the professionals and public, the author decided to spread and discuss it in the conference.

2 METHODS

2.1 PRINCIPLE

Theoretical starting point is the image rectification based on projective transformation [3,4]. The method uses the alignment of the image sequence to one image plane (usually to the reference one). The principle requires presence of four rigid reference points in the scene. In next step the algorithm determines the point differences in this (already aligned) reference image plane. Because of this fact the validity of the method is to 2D planar problems because projective transformation is limited to it. The number of problems where this approach can be used is high in civil engineering (beams from the side, walls, crack monitoring). Clearly enough, there is a lot of errors that can be made during the process and which are more in detail discussed later.

2.2 STEP BY STEP ANALYSIS

For clarity the methodology is outlined in following steps and commented more in detail in the paragraphs below:

1. Choose the object for monitoring
2. Print the markers in corresponding size and resolution
3. Select the 'reference part' in the scene and glue 4 markers to represent it
4. Glue the rest of the markers; the more, the better
5. Prepare the camera and perform the camera calibration (needed just once for given lens-camera system)
6. Take one reference image (t_0)
7. Come after some time and place the camera in similar place
8. Take another image (t_n)
9. Repeat step 7 and 8 as many times as needed
10. Analyze the result using the above outlined CV procedures
11. Interpolate and review the displacement field

The object dimension of course affects the precision of the process, since the precision of determination of the marker corners can be in practice considered 0.1 pixel (sub-pixel resolution up to 0.01 px is possible, but not realistic). That is also the key parameter to consider the size of the marker, as minimum 50x50 pixels representation of one marker in the whole scene can be recommended for reliable analysis. Generation of ArUco markers is included in the ArUco OpenCV-contrib package [1], and is coded using a simple Python script. Parameters of such a generation are image size and ID range to generate. The markers should be printed using a laser printer with high resolution; here the method uses the fact, that laser printer is usually the most precise mass-produced device in the office: 1200 DPI means 21 μm dot size! Markers do not have to be printed only on paper, but there exist also vinyl (PVC) sheets for printing. This is very important in the case of humid conditions when paper and timber can have significant shape changes.

The scene has to include the part which is rigid and not moving, since tiny shifts of reference points can jeopardize heavily the analysis results. That is why it is not good to measure members (or joints), which have still strong moisture-related volumetric changes, namely joints made of fresh timber. Such problems can be solved different way: using a matrix of reference points which can be after analysis of their relative displacement (distribution of strain has to be even) reduced to 4 reference points (rarely used). Highest precision is attained if the four reference points are close to four corners of the image, but this is rather an uncommon case, since the part that is monitored has to be inside the reference area. Reference points and actually the whole monitored object should be in the paraxial part of the picture, centered, which ensures lowest distortion.

Markers should be glued using a glue that does not change the shape with change of conditions and which is cheap, standard office glue is often the best one. For rough surfaces can be used an elastic adhesive gum glue.

Camera and lens should be selected carefully. Here an understanding of basic optical principles is needed. Best solution is a HQ camera with at least 5 MP resolution as is used during testing of the setup here: Basler Aca2440-20gm (see Figure 2). Global electronic (preferably not mechanic) shutter with rather bigger chip size should be selected. Field of view (FOV) is the key for proper lens selection, nevertheless, avoid fish-eye effect as much as possible, go for longer lens if the chip size allows it. Always use fixed focal length. In the test a Basler C23-1620-5M-P 16 mm lens with polarizing filter to evite reflections. Camera can be mounted to any camera stand, preferably with all DOFs adjustable.

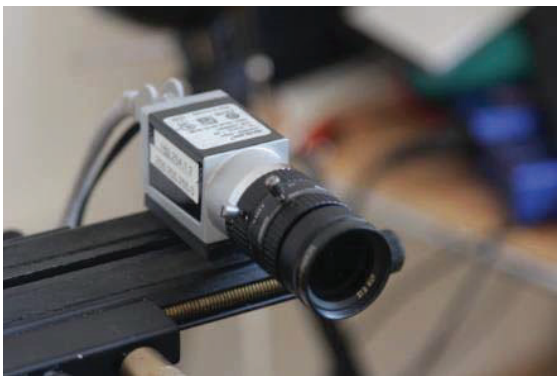

Figure 2: *Camera and lens used in the tests*

For proper measurement, camera has to be properly calibrated [6] and its intrinsic matrix assessed. This technology allows for rectification of the images taken and remove the lens distortion (undistort them). Such a process is made using OpenCV routines described in [7] and a simple chessboard, see Figure 3.

https://doi.org/10.52202/069179-0076

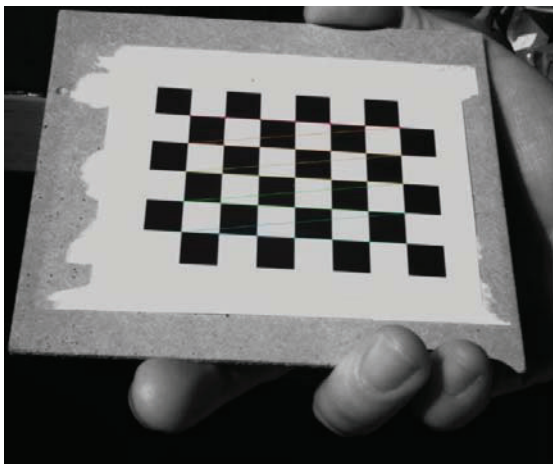

Figure 3: *Camera calibration using a chessboard*

The image acquisition is best, if the takes multiple images and computes an average out of them, since it significantly removes the noise and increases the precision of the measurement. Highest possible illumination along with highest aperture is always preferred.
The whole procedure is programmed using Python and is available for download in [5] under 3-clause BSD license. All people interested in the details can go through the code and look at the solution row by row.
Doubts arise about precision of camera repositioning when the image acquisition is repeated after some time and the camera was removed in between. As an answer it is important to assess the error. Abstractly the error estimation consists of multiple sources of possible error: lens distortion, chip noise, marker position assessment, marker printing, camera calibration error, paraxiality of the marker position (it is always not preferable to undistort the images as it is another idealization), camera repositioning (distance and angular), roundoffs in the CV algorithms. It is not possible to describe such a complexity here, the error estimation would be valid for the particular case and cannot be simply evaluated here in the extent of this article. That is why an example is shown here, which shows the method when focused on *absolutely stable testing plane*: in such case all movements measured would be made by errors of the measurement itself and not made by the displacements. That is how the reader of the article can have an idea about the error present in the measurement.

2.3 TEST AND ERROR ESTIMATION

The test can be shown in Figure 4, when four markers in the left paper (A4, 297x210 mm) are taken as reference points and four in the right are being evaluated. Marker size was 25 mm, their distance was horizontally 120 mm and vertically 169 mm (center-center), working distance 1.382 m, height of the optical axis (chip axis) was 0.819 m.
The goal of the test was to estimate the error if the camera is moved with precision that one can achieve in-situ if there is a marker on the floor for example. Two linear sliding plates were mounted on each other to be able to simulate the precise displacement simulating errors in repositioning, see Figure 5.

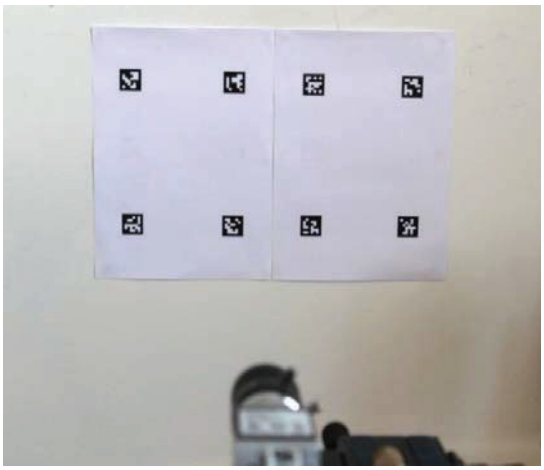

Figure 4: *Testing rig (papers not moved) for the error estimation*

The precise position changed to (points are referred later in results as e.g. 2.3.1 – the first one):
1) -5 cm in X and -5 cm in Z axis (for orientation see Figure 5, going to the left and farther from the object),
2) +5 cm in Z direction (moving closer to the object)
3) yaw - rotate 5 degrees (rotation towards upper left corner in the image)

Output of the analysis is shown in the results section.

Figure 5: M*ount allows for defined camera (re)positioning in two axes (x and z, bottom)*

2.4 EXAMPLE FROM TIMBER JOINTS MONITORING

To show the measurement system described here more in the context of timber structures, another artificial example of use has been made: lap timber joint with slight rotational move – 5 mm timber peg was placed under the joint (see Figure 5). The movement amplitude is not important here, this case is for illustration of use only. The height of the joint is in reality 60 mm, marker size 8 mm. The same camera was used, lens was 55 mm telecentric

(not fully) Computar TEC-M55MPW, same procedure as described above, however, camera was only removed and clicked back to the stand.

Figure 6: *Illustration of use in a timber joint, two images are aligned onto each other and the relative move of the markers is computed*

3 RESULTS

3.1 TEST AND ERROR ESTIMATION

For the analysis of the camera movement see Figure 6-8. The results are very positive, case -5 cm in both axes is depicted in Figure 6. Maximal error is 0.09 mm, however, remember the whole area is 300 mm by 150 mm.

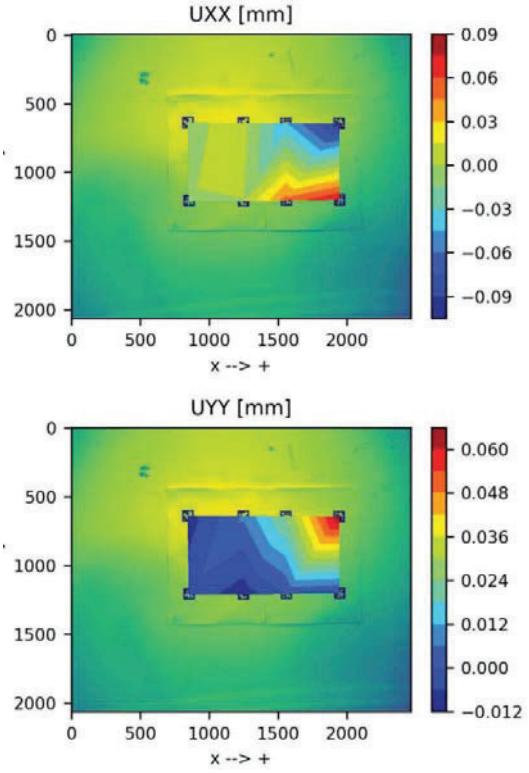

Figure 7: *Interpolated displacement field case 2.3.1)*

Second configuration, 5 cm movement towards the object provides even better results, maximum is 0.016 mm.

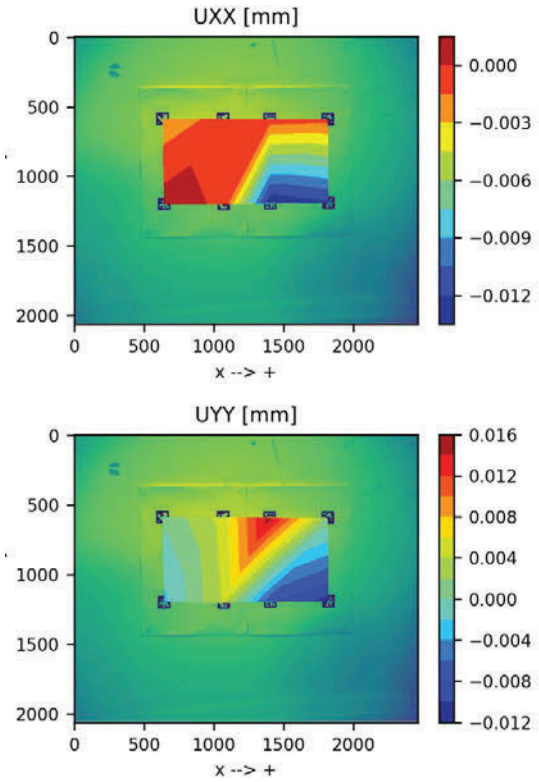

Figure 8: *Interpolated displacement field case 2.3.2)*

As the worst can be seen the angular rotation 5°, as can be seen in Figure 8. However, the results are still not bad, only 0.12 mm. So, the usability of the method is dependent on the precision in structure displacement one wants to measure and can expect.

If case 2) is compared to 1) and 3) it can be concluded, that biggest errors are present in case there is a big move for from the optical axis outside the paraxial area and the curvature of the lens can produce this amount of distortion (although the image was undistorted). Based on the lens focal length and thus its curvature, this error will be higher in case smaller chip size and shorter focal length is selected.

3.2 EXAMPLE FROM TIMBER JOINTS MONITORING

The results of this analysis from 2.4 can be found in Figure 9. Because not precise prescribed move was made using universal testing machine or similar machine, the results cannot be compared directly to the 5 mm peg size. This example is of course intended to show the potential of the methodology for monitoring of structures in time. Note the fact, that the number of colors in the images is directly specified as the number of contours during plotting of the graphs.

https://doi.org/10.52202/069179-0076

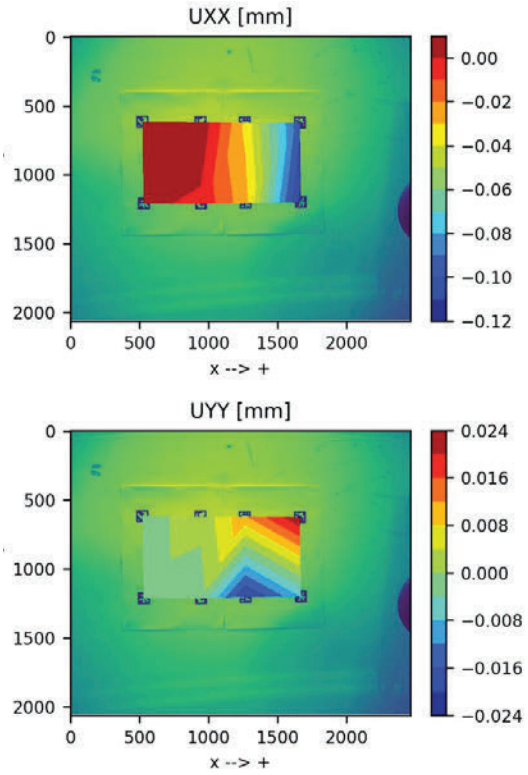

Figure 9: *Interpolated displacement field case 2.3.3)*

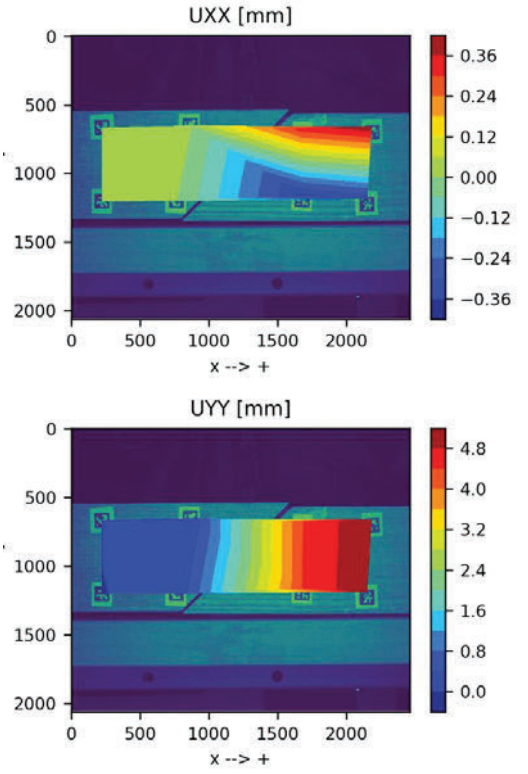

Figure 10: *Interpolated displacement field – half lap joint*

3.3 FINAL REMARKS AND DISCUSSION

The results show according to the author very precise determination of the studied quantities. This enables the method to be used in many applications, where some reference can be found and where only 2D movements take place.

It is good to mention that the displacement field is not continuous enough due to low number of points. That is also the case why one cannot think about strain measurement and stay only in the domain of displacements. Of course, more markers can be glued, the mesh densified and the computed field smoothed using splines; but the quality of strain field will be never the one seen in DIC.

It is a question if one is able to place precisely the camera with say 5 cm error to the place where it was before; from author's experience it definitely is possible, and, actually, it is possible even with higher precision.

The marker-based approach is very convenient because it does not need the same light conditions – markers are recognized even in different light intensity. Such a thing would be never possible when thinking about time-lapse digital image correlation. It should be pointed out that the technique overgoes the problems with shadows in DIC, a problem very often found in rough surfaces and annual rings when the light is repositioned back. The markers can be also removed without any stain remaining on the body. If swelling or shrinking is present, the inspector can put a reference piece of (metal or glass) ruler. Another option is to use markers made of material that do not swell (e.g. silicone-based).

The algorithm takes images which are saved and which can be also analyzed by somebody else later. This can play a significant role when survey of the joint shape is required. It can be used in relatively short periods to quantify the amount of creep, and the results are so precise, that the trend can be assessed (is the crack active or is it already not moving/opening?). Big magnification can be used as well, in this case the precision of repositioning is a very sensitive parameter.

As the biggest disadvantage thus remains the need of reference points inside the picture. This can be, however, solved using another precise positioning system: a rigid and stable object can be mounted before the 2D object and use the advantage of depth of field to focus properly both objects. ArUco detection of not well focused markers is possible and can be valid.

4 CONCLUSIONS

The paper describes a procedure that is able to monitor very precisely marker displacement in time. The marker position and density as well as the whole procedure is based on experience and precision, and thus depends also on the person who prepares it. Error estimation and a sample of use is described. The marker tracking itself – not along with the projective transformation - can be used for other uses as well – e.g. assessment of stiffness of a testing rig using optical measurement (MMB test). However, the original use could be broad and might be very cheap and fruitful for all interested in long term

https://doi.org/10.52202/069179-0076

monitoring of timber structures or in-situ survey. Since it is not based on a commercial code, the method is provided to the scientific community as is. The technique is not a solution for everything and needs proper selection of use. For some types of long-term structure monitoring it is perfectly suitable.

EXPERIMENTAL STUDY OF THE EFFECTS OF ACCELERATED AGING CYCLES ON THE FIRE REACTION PERFORMANCE OF FIVE WOOD SPECIES

María Pilar Giraldo[1], Alina Avellaneda[2] Laia Haurie [2], Marcel Vilches[1], Ana M. Lacasta[2].

ABSTRACT: The objective of this study is to evaluate the influence of the degradation caused by atmospheric agents' exposure over time (weathering) on the fire behaviour of five species of wood with different natural durability, according to known durability classes (UNE-EN 350:2016). Two laboratory tests were carried out for assessing the wood of Chestnut (Castanea sativa), European larch (Larix decidua), Black pine (Pinus uncinata), Paulownia (Paulownia tomentosa) and Scots pine (Pinus sylvestris), the later with and without durability impregnation-treatment by autoclave. Laboratory tests involved two processes of accelerated aging cycles (without and with spray) for four weeks following the protocols based on the ASTM G154:2016 and UNE-EN 927-6:2019 standards, in order to make reference to the use classes of exposure to humidity 3.1 and 3.2 defined in the UNE-EN 335:2013 standard. Analysis of the variation of the colour and the appearance of deformations and splitting after accelerated aging were performed. Flammability tests were also carried out to analyse the fire reaction performance of the samples in each stage of the aging test. Differences in colour changes were observed depending on the spraying presence in the aging processes. The results indicated that weathering significantly influences the fire reaction on a wooden surface, especially in softwoods with a medium and low degree of natural durability. Surface roughness and splitting hinder the ability to extinguish the flame. On the other hand, larch proved to have both a good resistance to degradation and good fire behaviour.

KEYWORDS: Natural durability of wood, weathering degradation, fire performance of wood, aging cycles.

1 INTRODUCTION

Natural wood durability is generally associated with hardwoods and tropical woods. Their density, hardness, and composition (extractive compounds) make them highly resistant to degradation by abiotic agents (weathering) and attack by organisms such as fungi and insects.

However, some resinous softwood species, such as larch (Larix decidua) (*L in this study)*, offer better-than-average natural degradation resistance, so it is widely used for facade claddings.

Durability varies, not only between different wood species but also within each species. In most wood species, the heartwood, which is the inner part of a log, is naturally more durable than the sapwood, the outer layers of the log [1].

When wood is exposed to outdoor conditions, a complex combination of chemical, mechanical, and light energy factors contribute to natural weathering [2].

The three primary sources of wood degradation are fungi (decay or rot), insects, and weathering. So, we can distinguish between wood decay and wood degradation. The repeated actions of wet (rain) and dry, the changing exposure to high and low temperatures and sunlight results in physical and chemical degradation of the wood over time. Physical deterioration consists of surface roughening, checking, splitting, and wood cell erosion [2,3]. Chemical deterioration involves a complex sequence of free-radical reactions. The degradation of wood by any biotic or abiotic agent modifies some of the organic components of wood [2]. These components are primarily polysaccharides (cellulose, hemicelluloses) and polyphenols (lignin).

One of the most relevant weathering factors responsible for changes in the wood surface is moisture in all its varieties: dew, rain, snow, and humidity. The classes of use described in the UNE-EN 335:2013 standard consider the risks to which a wooden building element may be subjected depending on its exposure to ambient moisture. A facade cladding is subject to use classes 3.1 and 3.2,

which consider outdoor exposure without contact with the ground. Class 3.1 refers to limited wetting conditions with wood temporarily above 20% of moisture content (MC), while class 3.2 refers to prolonged wetting conditions with wood frequently above 20% MC (Fig. 1). Accordingly, the design of appropriate construction details facilitates fast and constant water removal and quick wood drying.

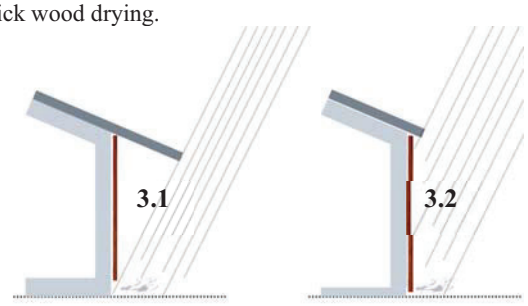

Figure 1. *The use classes of facade cladding are 3.1 or 3.2, depending on ambient moisture exposition. Building details are essential to avoid moisture excess and prevent water sorption by capillarity from taking place causing decay effects.*

Colour is one of the main attributes of wood from an aesthetic point of view, and it is therefore important to analyse its stability against weathering [4]. One of the most important causes of photodegradation in wood is ultraviolet (UV) (visible, and infrared light), light, which induces chemical reactions between its main constituents. Colour differences can be determined according to the CIE-L*a*b* (CIELAB) standard from the International Commission on Illumination CIE. The determination of the colour coordinates according to this standard, before and after aging, allows the quantification of their variations. Research on different wood species reveals an important darkening effect depending on the time and type of aging (natural or accelerated) [5,6].

Wood is a combustible material that exhibits smouldering due to the char layer generated during its burning process. Many research papers focusing on the reaction to fire of wood define the most important factors influencing the fire characteristics of wood are mainly density, orientation concerning the heat source, moisture content, and quality of wood surface treatment [7,8]. In some wood species, particularly rich in extractive substances and exudates, the composition may have more influence on fire behaviour than the density [9]. Weathering factors, especially rain moisture cause leaching which degrades lignin the most thermally stable component of wood as well as the least thermally stable hemicelluloses and extractive substances [10]. As a result, the cellulose in the fibres becomes more apparent and can protrude and produce a fibrous surface and roughness [1]. Defects of wood and cracks influence the persistence of flames on the surface [11].

This study intends to focus on the long-term degradation of wood and how this affects its fire behaviour. This issue is especially important in façade claddings, given the increasing use of this material in both private and public building construction. In some countries, such as Spain, the height limit for timber cladding (D, S2,d0 reaction to fire classification) is 10 m, and the use of flame retardants to improve the fire performance of wood is not an option, because guaranteeing the durability of these products against weathering remains a challenge.

2 MATERIALS

Five wood species were studied. Two hardwoods: chestnut (C) and Paulownia (P) and three softwoods: European Larch (L) Black Pine (PN) and Scots pine, the latest with (PRN) and without treatment (PRT). The natural durability of the heartwood in each of them according to UNE-EN 350:2016 standard is shown in table 1.

Table 1*: Natural durability of studied species*

Code	Density Kg/m^3	wood-decay attack	Insects attack	
C	520	2 (1)	DC2	(D) Durable
L	584	3 - 4	DC2	(D) Durable
*PN	517	-	-	(P) Not very durable
PRN	516	3 - 4	DC2	(D) Durable
P	266	5	DC5	(ND) Not durable

Wood-decay from better to worst 1 → 5. *Data from [12]

Scots pine (*Pinus sylvestris*) has an excellent impregnation capacity (Class 1), a natural (PRN) and treated (PRT) sample was tested. The treatment preventive and curative were impregnated by autoclave with a penetration level of NP5 (UNE-EN 351).

3 METHODS

3.1 TESTINGS

In order to carry out the accelerated aging processes on the wood samples and the subsequent analysis of the colour degradation and the fire behaviour analysis the tests described below were performed.

3.1.1 Accelerating aging tests

Two different exposure conditions (A1 and A2) have been tested for four weeks through an equipment QUV/spray accelerated weathering tester. The A1 process (no sprayed) was conducted according to the protocol of ASTM G154:2016 cycle 1, consisting of 56 alternating cycles of an 8-hour UV-A 340 radiation period and 4 hours of condensation. The A2 process was carried out following the protocol of the standard UNE-EN 927-6:2019. In this process, a one-week exposure cycle begins with 24 hours of condensation, followed by 48 cycles of 3 hours that combine a 2.5-hour UV-A 340 radiation period and a water spray period of 0.5 h. Table 2 shows the total time for each period. The A1 and A2 aging conditions represent the use class 3.1 and 3.2 respectively according to UNE-EN 335:2013 standard.

Wood specimens of 300 x 100 x 15 mm were previously stabilized in a climatic chamber for one week under controlled conditions of 20 ± 2 ° C temperature and 65 ± 5% relative humidity.

https://doi.org/10.52202/069179-0077

An accelerated aging process of 4 weeks resulted in a significant deterioration of the samples. Some studies indicate that 4 weeks under accelerated aging may be equivalent to 2 years of natural aging [13]. Table 2 shows details on the total hours of each cycle.

***Table 2**: Protocols followed for accelerated aging processes A1 and A2.*

Standard	Tests	Exposure periods throughout the trial (h)			
		Condensation	UV-A	Water spray	Total test time
ASTM G154:2016 C.1	A1	224	448	No	672
UNE-EN 927-6:2019	A2	96	480	96	672

3.1.2 Colour measurements

A PCE-TCR 200 colorimeter has been used to measure the CIELAB colour coordinates L^*, a^* and b^*. L^* is the lightness, going from 0 (black) to 100 (white) whereas a^* and b^* are the colour coordinates, from green (negative) to red (positive) and from blue (negative) to yellow (positive) respectively. The total colour differences ΔE_{ab}^* can be calculated as:

$$\Delta E_{ab}^* = \sqrt{(L^* - L_0^*)^2 + (a^* - a_0^*)^2 + (b^* - b_0^*)^2}$$

where L^*, a^* and b^* are the measured values after aging and L_0^*, a_0^* and b_0^* are the corresponding reference values from non-aged samples. Each colour data corresponds to the average of measurements taken from four different points.

***Figure 2.** Points on the sample for colour analysis*

3.1.3 Epiradiator test

Wood samples of 100 x 100 x 15 mm were tested with the device described in the Spanish standard UNE 23727-90. The samples were placed on a metallic grid 3 cm below a heat source of 500 W. The heating source was removed and put back after each ignition and extinction. The parameters determined were the time to ignition, the number of ignitions, and the average time of flame persistence during the first 5 minutes of testing. The results obtained are detailed in section 4.3.

4 RESULTS AND DISCUSSION

4.1 VISUAL OBSERVATIONS

Overall, the degradation of all samples during the four weeks is significant. Remarkable differences are observed between the specimens exposed to the aging cycles without spray (A1) and with spray (A2). Samples tested under A2 testing showed greater surface degradation consisting of cracks and fissures.

The Scots pine (PRN and PRT) and Black pine (PN) samples showed the most significant degradation. These samples developed different sizes of checking and cracking, some of them deep, especially in PRN. Additionally, some of the PRN specimens were curved (Fig. 3).

However, no cracks or texture changes were observed on the surface of the Paulownia (P) samples. Paulownia pieces exhibited exceptional dimensional stability and smooth surface without roughness or cracks, even for the specimens of week 4. Larch (L) also showed a good appearance and dimensional integrity during the 4 weeks, with some small cracks.

***Figure 3.** Photographs of three of the samples studied in three different views: (left) lateral side, (middle) frontal, and (right) fontal after the flammability test. All of them aged with the A2 process (with sprayed). (a) Scots pine (PRN) after 2 weeks of aging. The specimen exhibits several cracks and curved deformation. (b) Paulownia (P) after 4 weeks of aging. The sample remains smooth, with a good appearance, without deformations and no cracks are visible to the naked eye. (c) Larch (L) after 4 weeks of aging. The specimen remains with a good appearance without deformations, with small cracks little perceptible.*

Figure 4 shows a series of photographs, comparing non-aged samples (NA) with those subjected to accelerated aging according to the two procedures summarized in table 2, for 1, 2, 3 and 4 weeks. Samples exposed to the test without spraying (A1) show a progressive darkening and a colour change towards reddish tones. On the other hand, after the A2 test, the samples show less noticeable colour changes. The general trend is towards darkening, except in the case of paulownia (P) which becomes progressively lighter. The tonalities after A2 exposure are bluish.

4.2 COLORIMETRY RESULTS

The colour changes observed visually and discussed in the previous section can be quantified by the CIELAB colour parameters in Figure 5, the lightness L* is shown for both accelerated aging processes A1 (top) and A2 (bottom). In the non-spraying case (A1), for all the wood species, there is a significant decrease in L*, i.e. a darkening of the surface, in the first week of exposure. Over the following

weeks, the samples continue to darken, although at a slower rate. The behaviour is similar for all species, being more remarkable for paulownia (P), where L* is reduced by about 45%. The Scots pine samples darken the least, showing no significant differences between natural (PRN) and treated (PRT) Scots pine. In the case of the A2 aging process, which introduces periods of water spraying but has a shorter condensation time, the samples hardly darken at all. Indeed, in the case of paulownia, some lightning is observed.

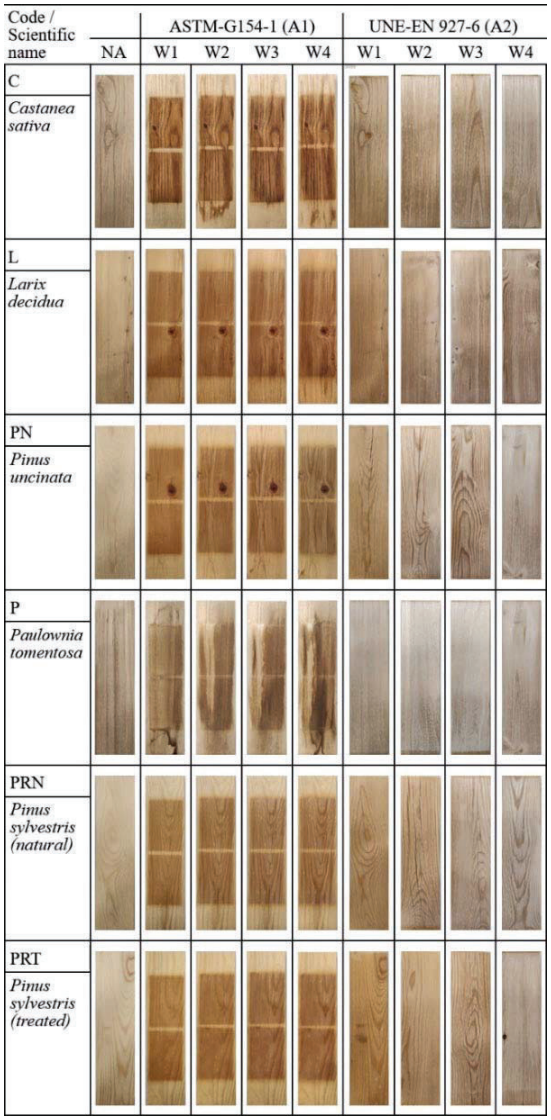

Figure 4. *Four-week aging test. For each specie, photographs of a non-aging (NA) sample and for each week under aging procedures A1 and A2 are present.*

The differences between the two types of aging can be seen more clearly in Figures 6-7, where only the results of week 4 (W4) are compared. Figure 6-top represents the L* values corresponding to no-aging (NA), aging type A1 and aging type A2. Figure 6 (bottom) plots the difference in colour coordinates a* and b* from the initial condition to the situation after 4 weeks of exposure. The arrows show the direction of change for each wood specie, both for A1 (left) and A2 (right) aging. The results obtained in both cases concerning the colour coordinates are quite different. While the unsprayed aging process (A1) increases the values of a* (red) and b* (yellow), the sprayed process (A2) decreases both coordinates. These results are in good agreement with the tonalities towards red in the case of procedure A1 and blue in the case of procedure A2 that were observed in Figure 4.

Finally, as an indicator of the total colour differences, figure 7 shows the ΔE_{ab}^{*}parameter. As expected, the overall changes are more significant for the A1 procedure than for A2 for all species, with Paulownia showing the most significant differences.

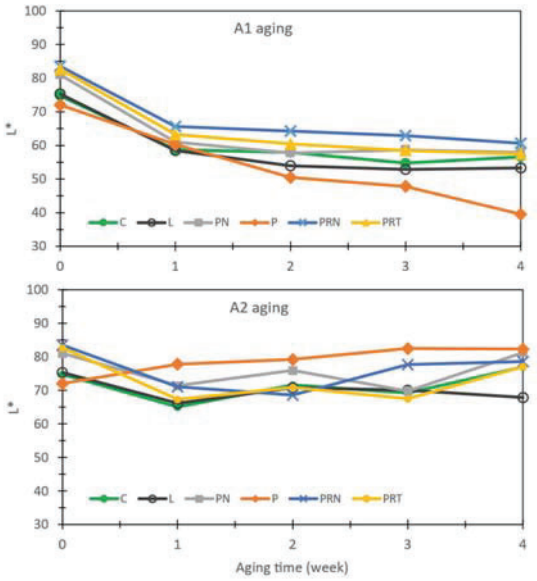

Figure 5. *Lightness L*, as a function of the aging weeks, for the different species analysed. The figures correspond to the accelerated aging processes A1 (top) and A2 (bottom).*

The arrows indicate the direction of the change, from the initial to the final situation.*

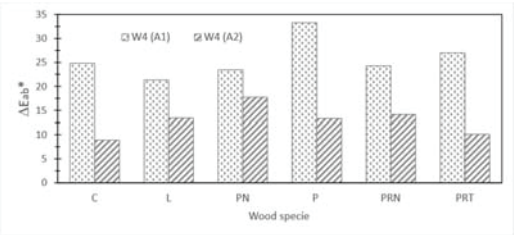

Figure 7. *Total colour differences after 4 weeks of exposure according to aging procedures A1 and A2*

4.3 FIRE BEHAVIOUR

Fire behaviour of the different wood species without aging and after A1 and A2 accelerated aging programs have been evaluated with the epiradiator test. In the case of the non-sprayed aging procedure (A1), samples of each species were tested after 4 weeks of aging, while for the sprayed aging procedure (A2) the fire tests were performed after each week of aging up to 4 weeks.

Figure 8 shows the time at which the first ignition occurs for non-aged, and samples aged under A2 spray conditions. It can be observed that Paulownia has a significantly lower initial ignition time. This hardwood has a low density, 266 kg/m^3, and therefore a highly porous structure that facilitates the release of flammable gases. Larch and Scots pine exhibit higher initial ignition times for non-aged samples with a density of 584 and 516 kg/m^3 respectively.

The time of the first ignition tends to increase with aging which can be explained by the leaching of low thermal stable constituents of wood such as extractives and low molecular weight polysaccharides from hemicellulose [10,14]. The self-extinguish ability of wood samples is related to the average value of flame duration depicted in figure 8 (bottom). Larch exhibits the best behaviour both for non-aged and aged samples. Its good durability and the absence of remarkable cracks are responsible for its good fire behaviour. On the other hand, the porous structure of Paulownia contributes to increasing the duration of the combustions and the propagation rate.

Although there exists some variability, the general trend is a worsening of the fire behaviour with A2 aging, observed through an increase in the persistence of the flames. Several factors can explain this behaviour, one of them is the reduction of the charring ability of wood samples due to the loss and photodegradation of hemicellulose and lignin [10,14]. Hemicellulose and lignin play an important role in wood charring, which is one of the main mechanisms for wood protection in case of fire [15,16]. Another effect is the occurrence of splitting after the dry and wet cycles of aging, as can be observed in figure 3. The presence of cracks favours the release of flammable gases and the persistence of the flames. Black pine and Scots pine are the species that show a higher level of splitting with aging.

Aging under spraying conditions (A2) is more aggressive than non-spraying aging (A1) and the variations in the first ignition values and the average flame durations are more pronounced for A2 samples after 4 weeks of aging.

Figure 10 compares the behaviour of non-treated (PRN) and treated (PRT) Scots pine. The presence of an organic protective treatment shows a positive effect on delaying the ignition of non-aged samples. This could be due to the clogging of the cellular structure that hinders the release of flammable gases. PRT sample also exhibits a smaller number of cracks after aging and this can explain the lower flame duration of week 4 samples aged under A2 procedure. However, in order to assess the effect of the treatment on splitting a higher number of samples would be needed.

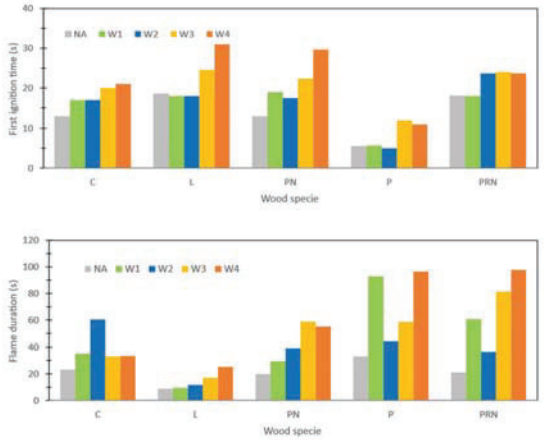

Figure 8. *Comparison of the flammability between species for each week of the A2 accelerated aging procedure. The graphics correspond to the first ignition time (top) and flame duration (bottom).*

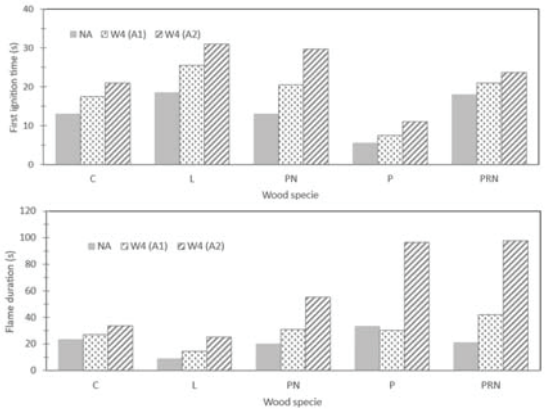

Figure 9. *Comparison between species for no aging (NA) and aged samples in both procedures A1 and A2 at week 4. The graphics show the comparison of first ignition time (top) and flame duration (bottom).*

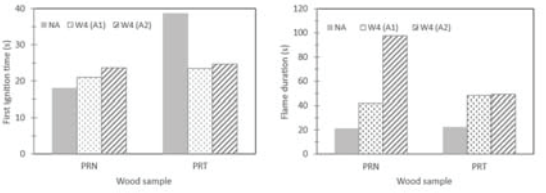

Figure 10. *Comparison between Scots pine non-treated (PRN) and treated (PRT) for no aging (NA) and aged samples in both procedures A1 and A2 at week 4. First ignition (Left) and Flame duration (right).*

5 CONCLUSIONS

Overall, the results show a correlation between weathering degradation and a gradual worsening in the fire behaviour of the samples. Despite the initial ignition time increases for the samples aged with both procedures, the self-extinguish ability worsens leading to a higher flame persistence. Photodegradation and leaching of different components of wood and the appearance of cracks and deformations play a major role in fire behaviour. The good durability of Larch and the absence of remarkable cracks contribute to a good response in fire reaction. On the other hand, although Paulownia does not present cracks and deformations after aging, it exhibits fast propagation of flame and low time of ignition due to its low density and porous structure. Aging causes darkening in most of the samples and changes in colour, being more significant for the non-spraying procedure (A1). The aging process (A2) also produces a progressive darkening of the specimens except for Paulownia, which becomes increasingly lighter. In both cases, Paulownia shows the most relevant differences in its appearance.

LONG TERM BEHAVIOUR OF A TWO-WAY SPANNING TIMBER CONCRETE COMPOSITE SLAB WITH STEEL TUBE CONNECTOR

Julian Brogli[1], Andrea Frangi[1]

ABSTRACT: Timber-concrete composite (TCC) plays increasingly important roles in today's timber construction. Using timber in the tension zone and concrete in the compression zone uses both materials to their strengths. A novel two-way spanning TCC slab using steel tubes as connectors of the timber and the concrete members was developed at ETH Zurich. As both, concrete and timber have independent long-term behaviours the long-term effects of the slab system are to be determined. This paper discusses the set-up of planned long-term tests and the development of a finite element model to describe the long-term behaviour of the slab system that then can be verified once enough data is acquired.

KEYWORDS: Timber-concrete-composite, TCC, Long-term, Numerical modelling, Steel tube connector, Biaxial

1 INTRODUCTION

Due to the ongoing discussions about the climate in recent years, sustainable construction has become increasingly important. The increasing use of wood in construction leads to a long-term storage of CO_2 and a lower expenditure of gray energy. Since it is estimated that 4 - 7 % of global anthropogenic CO_2 emissions come from cement production, it is not sufficient to modify only manufacturing methods or cement composition [1].

As floor slabs account for one of the largest shares of volume in any building and have been made largely out of reinforced concrete a way of addressing this concern is the development of more climate-friendly alternative systems. Today slabs often are made of high-performance timber products as cross-laminated timber, dowel-laminated timber or timber concrete composite (TCC) [2]. Uniaxial line-bearing timber-concrete composite slabs have already been researched with extensive experimental and numerical investigations, and reliable design bases have been developed [3] [4] [5].

With the current increase in demand for wooden high-rise buildings, the need for slab systems that enable their construction is also growing. In addition to the load-bearing capacity, important requirements for the ceiling system include the need for architectural freedom concerning the floor plan, the thickness and the weight of the slab. Architectural freedom can be achieved by using a two-way spanning system and low weight and thickness of a slab directly translate to a more efficient building as less foundation measures are needed and more usable floor area can be achieved with the same amount of total building height.

With these boundary conditions in mind, a novel biaxial-bearing TCC slab system was developed at ETH Zürich using steel tubes as connectors. The system consists of a 60-100mm thick timber member. Depending on the needed performance, this timber member consists out of beech laminated veneer lumber (LVL), cross-laminated timber (CLT) or a newly developed intermediate product of both using 10mm thin birch lamellas. The concrete member is 90mm thick. The novelty of the slab consists in the non-bearing intermediate layer that separates timber and concrete and is filled with cellulose, stone wool. A heavier recycled material can be used as filling instead if it is needed to comply with sound or vibration criteria. The sheer connection between the timber and concrete layers consists of steel tubes. The general concept of the system is depicted in Figure 1.

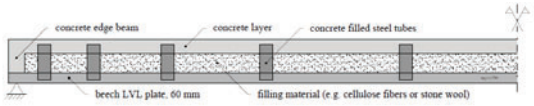

Figure 1: *Concept of the developed TCC slab system with steel tube connector* ***[6]****.*

As a common design problem of timber and TCC slabs are the deflection criteria that need to fulfill a given serviceability limit state (SLS) enforced by structural design guidelines [7] and both concrete and timber have a rheological behaviour, the long-term properties of the slab system have to be investigated.

2 METHODS

2.1 LONG-TERM TESTS

To investigate the long-term behaviour of the slab system long-term tests are investigated in a climate-controlled bunker chamber in Niderweningen, Switzerland. The specimens installed include:

- Uniaxial bending specimens for different two materialisations in both loading directions and 3 loading levels

[1] Institute of Structural Engineering, ETH Zürich Switzerland.
Julian Brogli, brogli@ibk.baug.ethz.ch
Andrea Frangi, frangi@ibk.baug.ethz.ch

https://doi.org/10.52202/069179-0078

- Several connection specimens in a double shear push-out layout to investigate the behaviour on a connection level, with different types of connection layouts,
- bending tests on timber-only beams to investigate the long-term behaviour of different timber materialisations

Space limitations prevent long-term investigations on a biaxial-bearing specimen.

2.1.1 Bending specimens design

The beech LVL configurations timber member consists of a 60mm thick beech LVL (BauBuche Q) plate. For both loading directions (longitudinal and transverse to grain) 5000mm long, 600mm wide and 240mm high bending specimens on three different loading levels in each grain direction are investigated. The steel tubes are arranged according to the expected shear force distribution. The outer steel tube diameter is 101.6mm with a wall thickness of 3.6mm. The steel tubes are embedded into the timber member using a 2mm thick layer of 2C-epoxy resin. The embedment depth of the steel tube into the timber member is 50mm. The embedment depth of the steel tube into the concrete (C40/50) is 60mm. Except for the concrete layer everything was prefabricated by Implenia Holzbau AG. The specimens tested in transverse to grain direction additionally feature two BARTEC connections that connect the timber members, as the maximal production width of BauBuche Q is 1850mm. Therefore, 3 individual pieces have to be connected for the total 5000mm lenght. The layout and dimensions for the specimens in the longitudinal direction are depicted in Figure 23.

2.1.2 Push-out specimens design

As previously conducted short-term tests conducted showed [6], that the global slab behaviour is highly influenced by the local connection behaviour, investigations on the connection level are carried out. For this investigation adapted versions of a double shear push-out test with an appearance as depicted in Figure 2 are used. The outer dimensions of the specimens measure 480 x 400 x 220 mm. With these specimens, the influence on the connection configuration is investigated. These tests include investigations on:

- the type of glue used,
- the thickness of the glue line,
- the local behaviour of different materialisations,
- the embedment depth in eighter layers and
- the influence of the steel tube diameter.

The push-out specimens are carried out in a symmetrical single-material set-up to be able to retrieve the local stiffness behaviour for every embedment type. The combined connection behaviour can be later predicted with a procedure developed by Kreis [6].

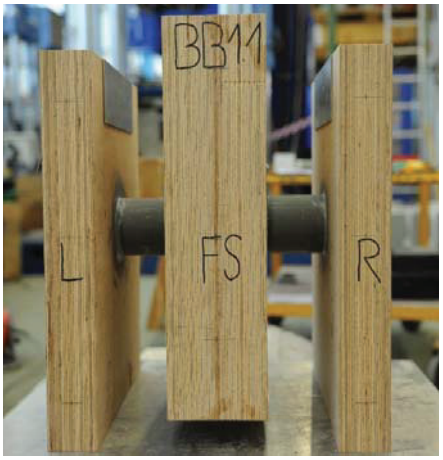

Figure 2:*Example of push-out specimen in beech LVL*

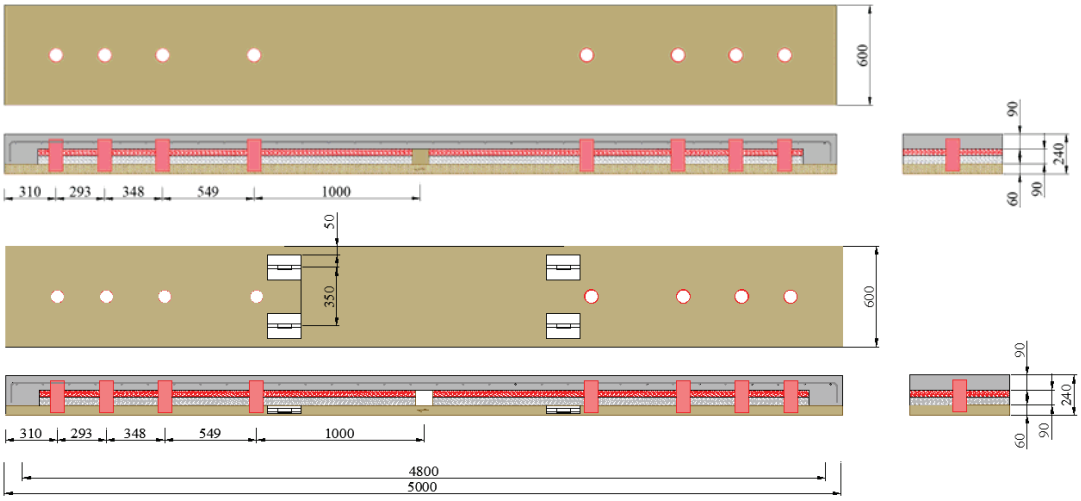

Figure 3: *Uniaxial bending specimen series with dimension longitudinal (top) and transverse (bottom) to grain loading direction.*

2.2 NUMERICAL MODELLING

2.2.1 Software and Subroutines

As the adjustable parameters of the slab systems are extensive and the number of possible experimental tests limited a numerical a parametric simulation model was developed for a 3D analysis. The commercial software Abaqus FEA of the company Dassault Systèmes was used. For the Finite Element analysis, the Abaqus/Standard solver was used. The choice to use Abaqus for the modelling process was strengthened by the fact that the user can adapt functionalities with the use of user subroutines. For the modelling process described in this work the user subroutines UMAT and UEXPAN were applied to define user specific material behaviour and thermal expansion.

2.2.2 System

A separate model for the uniaxial bending and the push-out set-up was developed to be able to simulate the outcomes on both levels of detail. The model of the connection level (push-out) is primarily used to simulate the (non-linear) short-term behaviour that the system shows for short-term push-out tests. With this data the short-term behaviour of the whole slab can be predicted reliably as shown by Kreis [6]. The assembly and boundary conditions are shown in Figure 5. Symmetry conditions help to reduce the total calculation costs.

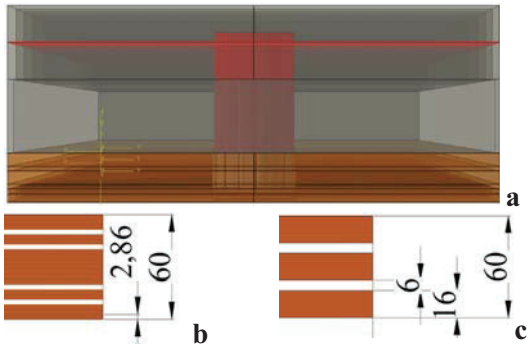

Figure 4:*(a) face view of the model, (b)timber member structure in reality and (c)model simplification, with layers loaded parallel to grain in brown layers loaded transverse to grain in white.*

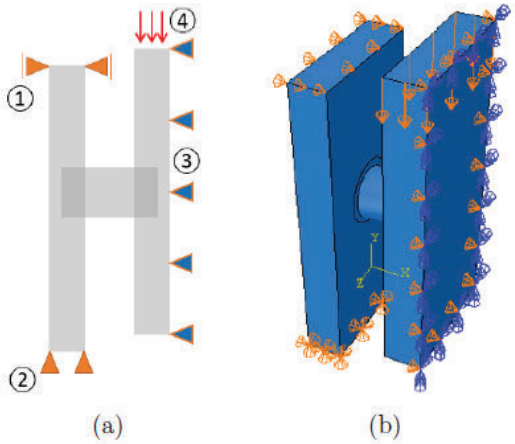

Figure 5 *(a) Boundary conditions: ①support in horizontal direction ② support in vertical, horizontal and out of planel direction ③symmetry conditions ④loading (b) boundary conditions on the 3D model.*

For long-term modelling primarily the bending-test set-up is used. If the whole slab is simulated the time-dependent rheological processing can be captured and processed. Further, they can be translated into a beam midspan deflection, which can be compared to hand calculations or SLS conditions.

The bending set-up model with the configuration using beech-LVL as a timber-member is visualized in Figure 6. This configuration is exemplatory used for the further proceedings of this work. The model consists of an LVL-plate, eight steel-tubes, gluelines connecting steel and timber and the concrete layer that is reinforced with shrinkage reinforcement-bars.

To model the LVL layer some simplifications are made. For numeric reasons the real structure of the beech LVL shown in Figure 4b is simplified with the approach depicted in Figure 4c. The four transverse layers are reduced to two so a simpler 5-layered structure is achieved.

The individually modelled lamellas of the timber member, the steel tubes and the timber, the glue-lines and the concrete layer are connected with tie-constraints with the other parts they are connecing with respectively. For the mechanical modelling, this leads to connections with

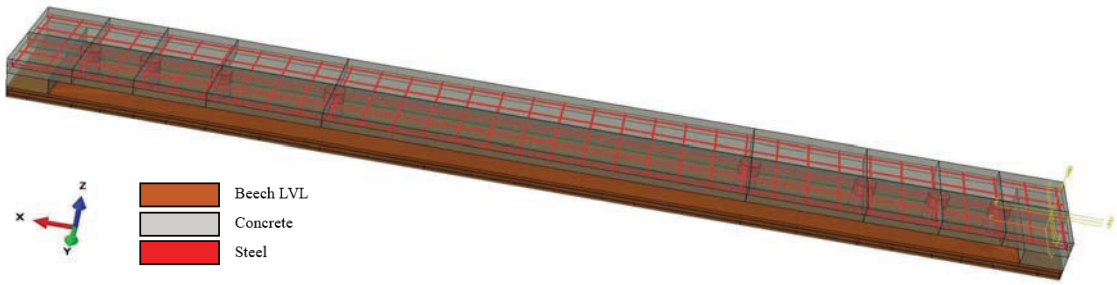

Figure 6: *Visualisation of the model in the uniaxial bending set-up.*

https://doi.org/10.52202/069179-0078

higher stiffnesses as in reality. For the purpose of long-term modelling this is assumed to be acceptable as a lot of computing cost can be saved.

2.2.3 Material models

As both main materials (timber and concrete) used have distinct but different long-term behaviour according material models have to be introduced for the finite element (FE) simulation.

To describe the complex time-, load- and moisture dependent behaviour of european beech (*fagus sylvatica*) the rheological model of Hassani [8] is used. The model was numerically implemented via a UMAT subroutine, as the available Abaqus tools could not provide the needed material behaviour. The basis of the model lays in the implementation of a series of serial-switched Kevin-Voigt-elements, representing the elastic and plastic strains, hygroexpansion (swelling and shrinking) and the strains resulting from visco-elastic and mechano-sorptive creep (see Figure 7).

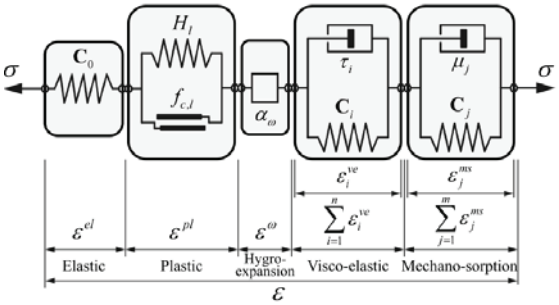

Figure 7:*Rheological material model to describe the time-dependent behaviour of timber* ***[8]****.*

Because of the serial switched strains in the system the total strains can be calculated with Equation (1):

$$\epsilon = \epsilon^{el} + \epsilon^{pl} + \epsilon^{\omega} + \sum_{i=1}^{n} \epsilon_i^{ve} + \sum_{j=1}^{n} \epsilon_j^{ms} \qquad (1)$$

A more detailed description of the numerical implementation of the timber member will not be given in this paper.

The E-modulus of concrete is assumed to be linear-elastic for the model. Modelling a plastic material behaviour in concrete would be possible, but it is assumed that the stresses in the concrete will not reach the plastic range for the this application. A plastic model would unnecessarily increase the already high computational costs. Due to continuous hydration of concrete the E-modulus of concrete is time-dependent. The expected development is described with the CEB-FIB-90 model [9] in Equations (2) – (4)

$$E_{ci}(t) = \beta_E(t) \cdot E_{ct} \qquad (2)$$

$$\beta_E(t) = \sqrt{\beta_{cc}(t)} \qquad (3)$$

$$\beta_{cc}(t) = e^{s\left(1-\sqrt{\frac{28}{t}}\right)} \qquad (4)$$

with s=0.2 and E_{ci} = E-modulus after 28 days.

The modelling of the shrinking and creep- behaviour that is part of the long-term effects of concrete is done by implementing the CEB-FIB-90-Modell that is part of EC 2 [10]. This is numerically done using the UEXPAN subroutine developed by Hampel [11]. With this subroutine the strains coming from shrinking and creep effects calculated after EC2 can be introduced into the model for each time-step. For this the creep and shrinkage effects have to be rewritten as increments $\Delta\epsilon$ that is calculated for each time step $\Delta t = t_n - t_{n-1}$

A more detailed description of the numerical implementation of concrete will not be given in this paper.

2.2.4 Loads

The long-term simulation is made for a time span of 61 months to simulate the first five years after the experimental set-up additional to the first 28day hardening time after concreting. In the first 28 days only 10% of the dead load is simulated as exterior load for convergence purposes. After 28 days the full dead load and an additional areal load is enabled to act on the model. For the exemplatory model presented in this paper the areal load sums up to a total of 3.5 kN/m² representing the 2 kN/m² live load and the additional weight of the slab structure above the load-bearing layer of 1.5 kN/m². The changing moisture content of the air that leads to changing moisture contents in the timber due to its hygroscopic behaviour is simplified. During the simulation process the exposed surfaces of the timber specimen is subjected to a changing surface moisture content that is varying with a sinoical function between 8% and 12%. This is representing a effective moisture content change of 4% in the timber during a year. In Figure 8 the loading conditions for the first 2 years is shown.

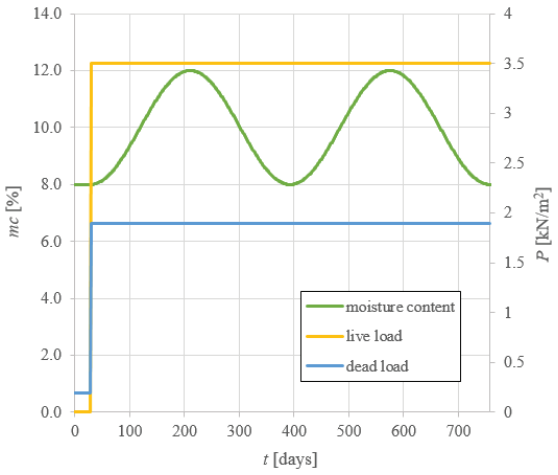

Figure 8: *Loads and subjected moisture content to exposed surfaces for the first 2 years of the model.*

https://doi.org/10.52202/069179-0078

2.2.5 Modelling process and elements

As the moisture content distribution within the timber over time is initially unknown, first an analysis is made with the only external load being the induced moisture content on the exposed timber surfaces. For this process DC3D20 elements are used. In this step the moisture content for each node in the timber member for the total simulation time of 5 years is calculated.

In a second step a mechanical analysis can be carried out using C3D20R Elements. In this second step all loads and boundary conditions are enabled. The moisture content needed to calculate the additional stresses and strains considering the rheologicals effects in the timber are read from the output- file of the first analysis.

3 RESULTS

3.1 MOISTURE DISTRIBUTION

The resulting moisture distribution for the first simulated year is shown in Figure 10. At day 0 the initially defined moisture content of 8% throughout the whole timber member is visible. After 198 days the moister content induced to the models exposed surfaces reaches its maximum of 12%. It can be observed that somewhere around the 300 day mark a maximal moisture content just short of 11% is reached in the middle of the timber member. It can be seen, that when all 4 sides of the timber member are exposed to a seasonal change in relative humidity in the environment, the whole timber cross-section is subjected to significant changes in equivalent moisture contents.

3.2 MIDSPAN DEFLECTIONS

The simulated midspan deflections are displayed in Figure 9. It can be observed, that the changing moisture content has a high influence on the midspan deflections. The initial high displacements due to initial loading appear to slow down after 2 years of simulation. Going forward a slight increase in midspan deflection is observed every year.

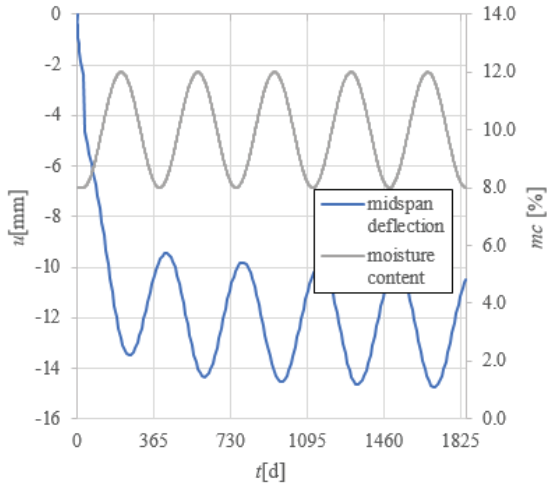

Figure 9: *Midspan deflections of the slab system in relation to the moisture content of the timber member.*

3.3 MIDSPAN STRAINS

For a point on the bottom of the timber member the strain componets are displayed in Figure 11. The total strains consist of shares from elastic, visco-elastic, swelling/shrinkage and mechano-sorptive strains. It can be observed that the swelling and shrinking component is the highest compared to the other strain components. After that the visco-elastic creep component appears to have the second highest influence. The mechano-sorptive creep has the least influence on the total strains even with the high moisture change during a simulated year.
In Figure 12 the midspan strains in a representative point on the concrete member area are shown. The total strains consist of shares from creep shrinkage and elastic strains.

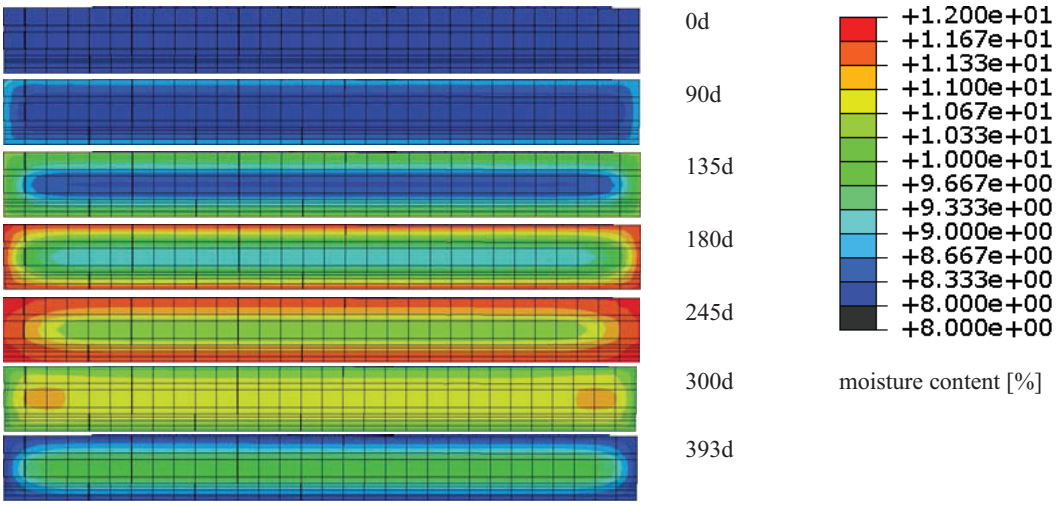

Figure 10: *Moisture distribution at midspan inside in the timber member with four exposed sides during the first year of simulation.*

https://doi.org/10.52202/069179-0078

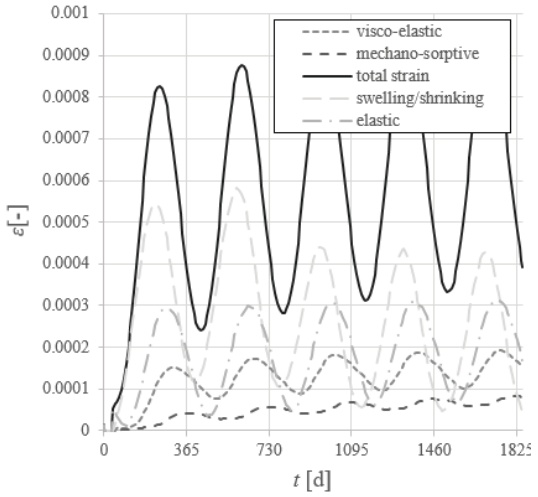

Figure 11: *Visualisation of the strains components at midspan in the timber member*

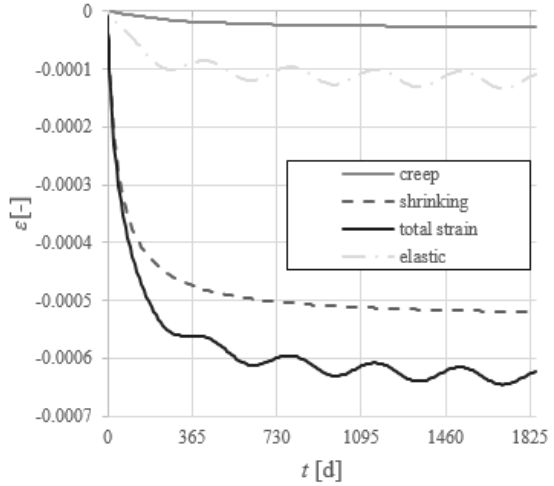

Figure 12: *Visualisation of the strains components at midspan in the topsurface of concrete member.*

4 DISCUSSION

4.1 MOISTURE DISTRIBUTION

The assumption of a 4-sided exposure to moisture of the timber member in the testing set-up can be justified by the fact, that contrary to an area-wide system (real case) the sides of the specimen are exposed. Additionally, the filling material of the interlayer is permeable to moisture. With this chosen 4-sided exposure the moisture content inside the timber member changes almost uniformly. As in the real slab system only exposure from the bottom side is to be expected it has to be accounted for in the proceeding investigations.
It has to be noted, that the way the LVL plate is modelled could have a big bias on the resulting moisture distribution. The simplifications used do not take into account the possible reduction in moisture transport through the glue lines. Especially in a LVL, where the veneers are only 3-4 mm thick, this can have a big influence on the resulting moisture distribution. It is assumed that in reality the moisture is less able to spread through the thickness of the board. This has especially an influence on the result when only one-sided (real case szenario) moisture penetration can take place.
Furthermore, the exact moisture transport conditions in beech LVL is still unknown and has yet to be investigated.

4.2 MIDSPAN DEFLECTIONS

In the first 28 days of the simulation the shrinking of the concrete member presumably is the driving factor for a large amount if the initial midspan deflections. Reducing these shrinking deformations to a minimum within the production process has to be a goal. It is obvious that also the changing moisture content has a big influence on the midspan deflections. The assumed 4% change in yearly moisture change within the timber member is with high probability on the safe side. It is assumed that in reality the resulting moisture exchange is much lower. Nevertheless, it is shown that the moisture content at the time of installation can have a big influence on the total deflections and has to be considered.

4.3 MIDSPAN STRAINS

The high amplitudes of the swelling and shrinking strains in the timber member stand in direct context with the changing moisture content. Because of the 4-side exposed timber specimen moisture exchange happens rapidly and thus high swelling and shrinking is simulated. Only a slight time deviation between the maximally induced moisture and maximal swelling and shrinking components is registered. It is assumed, that with only one side exposed to moisture change, this deviation in time will be bigger.

For the concrete member, the biggest influence on the total strains is coming from shrinkage. After five years the total value for the shrinkage strain corresponds to the analytical solution of EC 2 which is $5{,}13 \cdot 10^{-4}$. This is the result of autogenic and drying shrinkage only being dependent on the time. In the contrary creep is dependent on the elastic strains at the respective time. Through creep the concrete escapes external loads and thus reduces elastic strains.

4.4 GENERAL DISCUSSION

The manual calculation of the presented slab system is based on many assumptions due to the complex geometry and the only partially explored connection. Because the model also still has to make do with many assumptions and not enough experimental data could be collected yet, no verification and validation of the model can be shown within the scope of this work. It is therefore to be noted that up to this point the model shown is only theoretical.

https://doi.org/10.52202/069179-0078

Nevertheless, the model can be used to further understand the system and its general behaviour.
For a reliable simulation of the long-term behaviour of beech LVL, input-material parameters are also missing. Up to now, one has to make do with solid wood parameters for certain parameters that influence the long-term behaviour. However, it can be argued if beech LVL has a lot in common with solid beech wood, if one takes a closer look at its production process.
In addition, further studies with Hassani's material model are necessary. No validation of the model is available for a simulation period longer than one year [8].

5 CONCLUSION

It has to be stated that the presented results exemplify what the model output can be and can not be regarded as concluding. The main task of this paper is to show to opportunities and challenges of long-term modelling with Abaqus.
Modelling such a complex system seems in many parts a balancing act between the level of detail and the introduction of necessary simplifications to keep the computational costs under control.
In the next step acquired experimental data will be used to validate the model for the push-out and uniaxial bending set-up.
Further ahead lies the challenge to adapt the model to an actual biaxial bearing system. Although the system can also be used uniaxial-only it's full potential is only reached with the biaxial application and it's additional influence on the load-bearing behaviour.

INVESTIGATING THE EFFECTS OF MOISTURE INGRESS ON THE PERFORMANCE AND SERVICE LIFE OF AUSTRALIAN MASS TIMBER PANELS-CHARACTERIZATION OUTCOMES.

Maryam Shirmohammadi[1]

ABSTRACT: Composite timber systems made of timber and massive wood products used in construction are susceptible to moisture fluctuations during transport, construction, and post-construction. The wetting dynamics, both ingress and egress, of Australian timber species and mass panels exposed to Australian climate conditions have not been extensively explored. Understanding moisture movement in timber is crucial for predicting the design life of timber products and developing decay modelling protocols. An experimental testing has been conducted in detail to comprehend water movement and moisture gradients in massive wood-based composites. The testing results presented in this paper include the density, porosity, gas, and liquid permeability of three Australian timber species (radiata pine, southern pine and shining gum). The experiments have been designed to explore the hygroscopic properties of timber species in different directions, including face, edge and end and of CLT (2P and 3P) and LVL sections. The porosity values for the three tested species were 56% ± 5, 57% ± 3 and 42% ± 8 for radiata pine, southern pine and shining gum respectively. The experimental results presented in this paper showed that CLT samples made from radiata pine with edge gap (3P) had higher porosity and permeability values than solid radiata sample sections. The CLT 2P sections had lower porosity values than the solid radiata pine samples. The porosity values determined for LVL (made from pine) samples (51% ± 3) were slightly lower than southern pine samples tested. The outcomes of this project will facilitate the prediction of product response to moisture and enable the development of maintenance protocols and remedial solutions for the industry to minimize the potential impacts of moisture penetration in mass timber products in the future.

KEYWORDS: Mass timber panels, moisture ingress, service life, cross laminated timber, laminated veneer lumber.

1 INTRODUCTION

Timber and composite timber systems as building materials provide significant advantages such as low embodied energy, excellent insulation properties, and cost-effective construction processes. However, they are vulnerable to dimensional instability, aesthetic deterioration, and fungal decay if exposed to moisture for a prolonged period. Additionally, poorly designed or maintained timber products and buildings can be impacted by biodegradation. The extent and rate of damage can vary, depending on the environmental conditions to which the products are exposed [1-8]. Moisture intrusion into solid timber or mass panel composites and cyclic variation in moisture during and post-construction could cause changes in appearance and structural properties that can be difficult and costly to repair. Southern pine (*Pinus elliottii x Pinus caribaea)* (SP), radiata pine (*Pinus radiata)* (RP) and shining gum (*Eucalyptus nitens)* (SG) are three commercially available timber species in Australia. Various studies [9-12] have focused on the properties of wood during drying; however, the movement of water in these three species during periodic and long-term wetting when exposed to free water still requires further research. Specifically, the effects of species' anatomical features (cell arrangement and direction) and variations between solid timber products and engineered wood products (EWPs), on the wetting and drying process need to be investigated [9-12]. The differences between species and the effects of their anatomical characteristics (such as pore size/types, permeability, chemistry and cell size) on moisture movement over time are important when longer-term durability and structural stability of products are estimated [13-17]. The hygroscopic properties of building elements affect the different aspects of building design and performance, including durability, performance and thermal comfort [18-21]. The EWPs' structure specifically the direction of boards/the arrangement of veneers, glue lines, edge gaps and cracks, impact the EWPs' long-term performance in-service [19, 22-26]. Moisture ingress into solid wood and EWPs could occur through different wetting events and due to poor site management during erection, poor building design, types of construction or poor maintenance [27]. In addition to the complexity of moisture ingress and egress scenarios for EWPs, there is also a need for further research relevant to long-term performance aspects of these components when used in the wide variety of Australian environments in which timber is employed (e.g. higher decay hazard situations)

[28, 29]. This paper discusses porosity, density, and permeability measurements of solid timber (sawn timber) from three Australian species and Australian mass timber panels. The study was conducted as a part of a larger project developing a mathematical model of moisture ingress/egress into EWPs.

2 MATERIALS AND METHODS

2.1 SAMPLES

Kiln-dried boards of radiata pine (*Pinus radiata* D. Don), Caribbean pine/Slash pine hybrid (*Pinus caribaea* Morelet/*P. elliottii* Engelm,), and shining gum (*Eucalyptus nitens* H. Deane & Maiden) were cut into samples oriented to allow moisture movement to be studied in three different directions. Before testing, three-layer radiata pine cross-laminated timber (CLT) and laminated veneer lumber (LVL) were cut into small sections. Figure 1 shows the sample directions, including the end grain orientation (L (longitudinal)/ D3, R (radial)/D1 or T(tangential)/D2) of boards; for CLT samples, directions included face/D1 (radial/tangential), edge/D3 and end/D2. For LVL samples, directions included face/D1 (radial/tangential), edge/D3 (mostly radial) and end/D2 (longitudinal). All samples were conditioned to constant weight (65%RH/25°C) at approximate 12% EMC, and the initial dimensions of each were recorded.

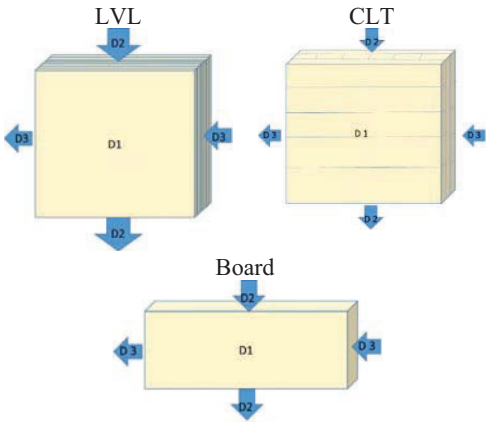

Figure 1: *Directions of water movement that were studied.*

2.2 DENSITY AND POROSITY

The density porosity of samples was determined for blocks of 20x20x20 mm that were conditioned at 12% EMC before being weighed, and their dimensions were measured to determine the density (Table 1). A helium pycnometer [30] was used to measure the density and porosity of the samples. Five replication of material type was used for the density and porosity measurements.

Table 1: *The average sample weights and density used to determine the samples' porosity.*

Material Type	Weight (g)	Density (kg/m3)
Shining gum	4.72 ± 0.2	589.82 ± 32
Radiata pine	4.53± 0.2	583.69 ± 58
Southern pine	4.81± 0.3	607.45 ± 87
LVL	5.98 ± 0.2	688.65 ± 23
CLT-3P	4.04 ± 0.1	506.13 ± 12
CLT 2p	4.1 ± 0.1	519.20 ± 17

Note: ± are standard deviation values

For CLT and LVL sample types are presented in Figure 2. Apparent density (D_a) in kgm^{-3} using the volume of the piece, including void space, was calculated using Eq. 1. For true density (D_t), the density of samples without voids, samples were placed in a gas pycnometer where density was recorded five times and average values were used for data analysis.

$$D_a = \frac{Mass}{Volume} \qquad \textit{Eq. 1}$$

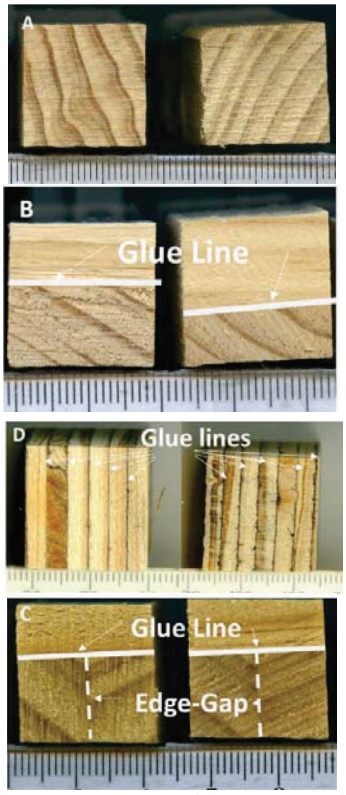

Figure 2: *Sample blocks used for porosity and density measurement ((A)solid, (B)CLT-2P (sample with glue line), (C)CLT-3P (sample with glue line and edge gap) and (D)LVL)*

The porosity of samples was calculated using the true and apparent density values. The porosity (∅) of samples was calculated using Eq. 2.

$$\emptyset = \left(1 - \left(\frac{D_a}{D_t}\right)\right) \times 100 \qquad \textit{Eq. 2}$$

https://doi.org/10.52202/069179-0079

MICROSCOPIC IMAGING AND CELL DIMENSION MEASUREMENT

In this study, the impact of cell pore size and porosity was evaluated on samples obtained from different surfaces (i.e., face, end, and edge) of a given material. To examine and quantify the cell type and size of the samples, a Nikon ECLIPSE LV100ND/LV100NDA microscope was used, and the images were captured at magnifications of 10x, 20x, and 50x (Figure 3). The average size of the cell lumen was determined for 3-5 anatomical images of each species using ImageJ software [34]. In softwood samples, the size of the cells in earlywood and latewood sections was measured, along with the diameter of resin canals and vessels (Figure 3).

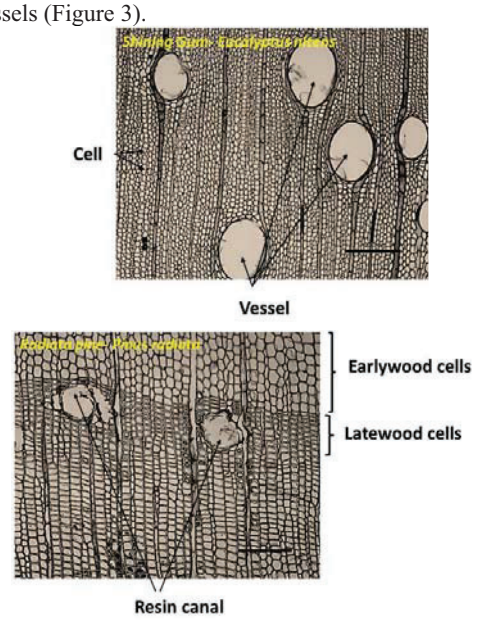

Figure 3: *Example images used for determining the cell dimension at 10x magnification [31] .*

2.3 PERMEABILITY

The gas and liquid permeability of the three solid timber species, CLT and LVL composite panels were determined in the laboratory. Gas permeability was calculated using Darcy's law (Eq. 3) as shown in [15, 32].

$$K = \frac{Q\mu eP}{A\Delta P\overline{P}} \qquad \textit{Eq. 3}$$

In this equation, K is the intrinsic permeability (m^2); Q is the air flux ($m^2\ s^{-1}$); μ is the dynamic viscosity of air (Pa); e is the sample thickness (m); P is the pressure at which flux Q is measured (Pa); A is the sample area (m^2); ΔP is the pressure difference between the air outlet and inlet sides of the sample (Pa); and $\overline{P}$ is the average pressure inside the sample (Pa). Samples (8-10 mm thick) were cut along the radial, tangential and longitudinal direcitons using a 24 mm diameter hole-saw. Ten replicates were tested per sample type and direction. Water movement into the side surfaces of the sample and guarantee air tightness was restricted by the application of two layers of epoxy resin [15].

The effects of glue line and edge gaps were studied for LVL and CLT samples using the sample shown in Figure 4.

Figure 4: *Sample sections (A) CLT (2Piece/2P) (B) CLT (3Piece/3P), (C) LVL (End), (D) LVL (face- one glue line), and (E) LVL (face- two glue lines).*

The study tested the permeability of LVL samples with one (4-5 mm thick) and two (7-8 mm thick) glue lines.

3 RESULTS AND DISCUSSION

3.1 POROSITY

The type and size of wood cells influence the hygroscopic properties of products exposed to in-service conditions. Previous research has explored the relationship between pore size and porosity, permeability, and treatability of products, with a focus on natural weathering and water absorption, porosity and sorption isotherm, and capillary condensation in mass timber buildings [33-36].

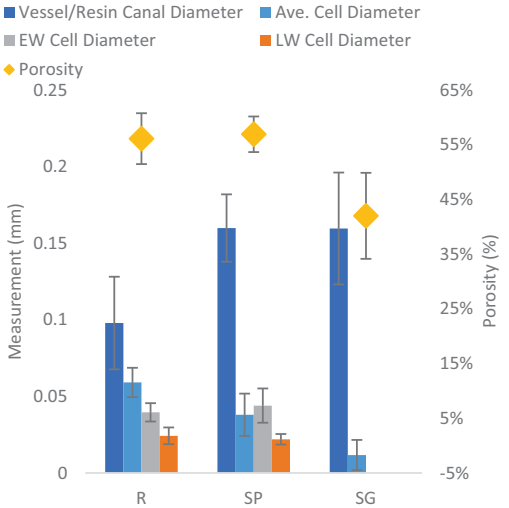

Figure 5: *Anatomical features measurements for radiata pine, southern pine , and shining gum samples and calculated porosity. Errors bars represent one standard deviation.*

The relationship between the porosity values and anatomical features showed higher cell diameter and porosity values following similar trends (Figure 5). Similarly, previous studies showed higher porosity of timber species linked to lower resistance to moisture flow in the product's structure [30]. The porosity of southern pine samples was higher than that of radiata pine samples, and the anatomical features measured were similar except for a higher resin canal diameter for southern pine samples. Shining gum had lower porosity than the pine samples. A higher percentage of pore in timber product's structure can lead to higher water gain when exposed to moisture [37, 38], so it is important to consider product and species porosity values when modelling wetting and drying processes.

As shown in Figure 5, porosity and true density values were higher for radiata pine and southern pine than for shining gum samples. Southern and radiata pine samples had higher true density than shining gum samples. The bulk densities of all three species were in the sample range (as reported in Table 1).

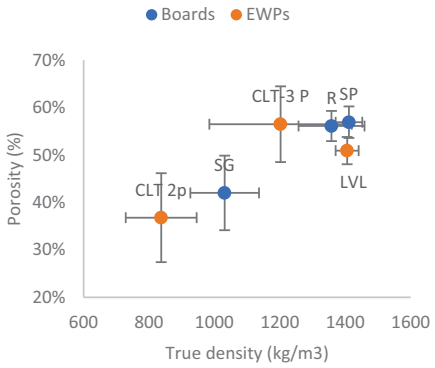

Figure 6: *Average porosity versus true density of solid shining gum (SG), radiata pine (R), Caribbean/slash pine (SP) hybrid timbers, radiata pine LVL, or southern pine CLT with 2 or 3 glue lines.*

The CLT 3P sections (with glue line and edge gap) showed higher porosity values than CLT 2P (with glue line only) samples. The presence of an edge gap can affect the higher values. The average porosity value for solid radiata pine samples was slightly higher than for CLT 2P. This can result from the glue line in the 2P sample structure. Previously, the effects of cracks and edge gaps in the timber product structure are reported to increase the liquid flow and water trapping into the bulk material. This has been considered a factor affecting the structural and aesthetic performance issues of EWPs if not managed appropriately [39, 40]. The average porosity and density value for LVL samples was lower than the average value for southern pine solid samples.

3.2 PERMEABILITY

As expected, solid wood's gas and liquid permeability results were higher in the longitudinal direction than in the tangential and radial directions for the three species [14, 15, 41]. Shining gum samples showed higher variability in gas permeability data in the longitudinal direction. The gas permeability values determined for shining gum were close to zero in the radial and tangential directions (Figure 7). Southern pine samples had the highest gas permeability than southern pine and shining gum samples.

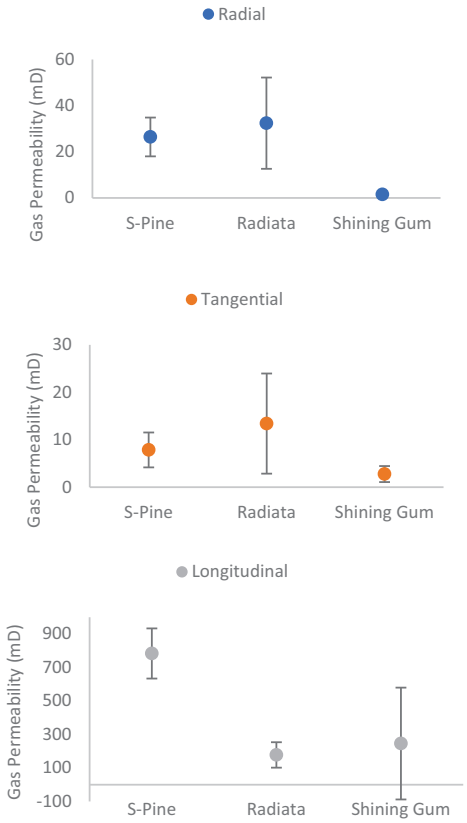

Figure 7: *Gas permeability data for species tested, (SP is southern pine, R is radiata pine, SG is shining gum and L, R and T refer to longitudinal, radial and tangential directions).*

A higher ratio of gas permeability anisotropy was observed for shining gum in K_L/K_R than radiata or southern pine samples (Table 2). The longitudinal to tangential liquid permeability ratio (K_L/K_T) was much higher for shining gum compared to southern pine and radiata pine. The longitudinal to tangential gas permeability ratio (K_L/K_T) was higher for southern pine and shining gum and lower for radiata pine. These ratios suggest that the pressure required for the movement of liquid and gas in the sample affects the hygroscopic properties of timber boards and composites when exposed to free water. The same process happens when the product is exposed to repeated wetting and drying, which leads to a moisture gradient development inside the product's structure [36]. It is reported that the anisotropic ratios could influence the scale of wetting and drying processes and lead to dimensional changes and internal stresses that are critical factors, especially in CLT connection design

https://doi.org/10.52202/069179-0079

and maintenance [13, 14, 17]. The ratios (K_R/K_T) were much lower for both gas and liquid permeability values in the radial to tangential direction than K_L/K_T and K_L/K_R and shining gum had lower values than the pine samples. The very low permeability caused the high KL/KT (ratio of K in longitudinal over tangential directions) value for southern pine in the tangential direction.

Table 2: *Anisotropy ratios of sample permeability values determined for solid timber of three species.*

Species	Permeability	K_L/K_R	K_L/K_T	K_R/K_T
Southern pine (SP)	Gas	29.65	99.80	3.37
	Liquid	202.66	1396.53	0.00071
Radiata pine (R)	Gas	5.48	13.25	2.42
	Liquid	16.46	233.62	0.0043
Shining gum (SG)	Gas	159.35	88.88	0.56
	Liquid	-	7579	0.00013

± values are the standard deviation.

Figure 8 shows that southern pine samples had a higher liquid permeability in the longitudinal direction when compared to radiata and shining gum samples. Shining gum had the lowest radial and tangential liquid permeability, while radiata pine samples had the lowest longitudinal liquid permeability.

Figure 8*: Liquid permeability data for species tested.*

The lower permeability rates in shining gum can be attributed to its small cell size arrangement compared to the softwood samples [45]. The other factors, including the extractive and resin content, must be considered when permeability. Southern pine samples had the highest gas permeability compared to other species tested. Southern pine samples also had the highest longitudinal permeability than the other two species.

Figure 9 shows the permeability values determined for CLT 2P and 3P samples. Higher gas and liquid permeability was observed for CLT 3P sections. This result shows the importance of moisture management programs, especially when CLT panels are exposed to weathering, such as flash flooding and heavy rain during construction. The CLT structure and pathways for higher water ingress into the structure (due to edge gaps and cracks) can result in accelerated moisture intrusion leading to more conducive conditions for the fungal attack in the longer term. The LVL gas permeability values determined were 28.8 ±17 and 20.4±13 mD for samples with one and two glue lines, respectively. The liquid permeabilities were 1.21 ± 1 and 0.63 ± 1 mD for samples with one and two glue lines, respectively.

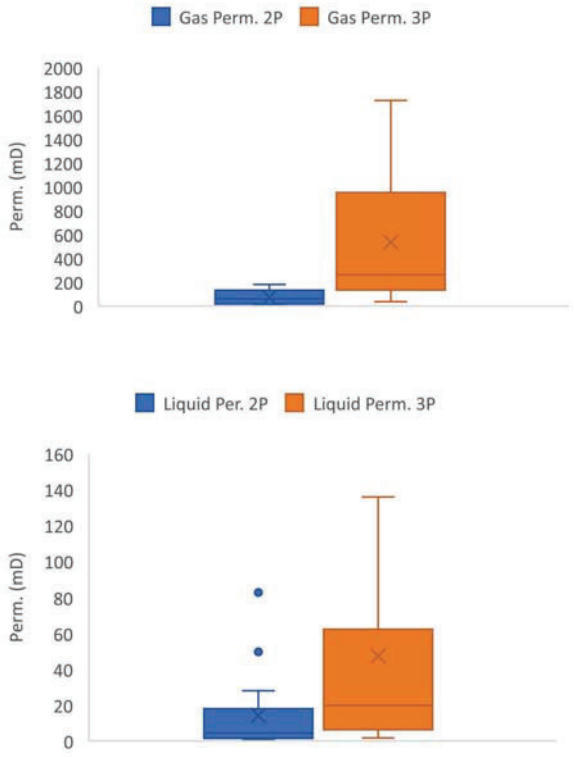

Figure 9: *Average gas and liquid permeability values recorded for CLT 2P and 3P sections.*

4 CONCLUSIONS

This study determined some hygroscopic properties of Australian timber species and EWP (CLT and LVL) samples. The study focused on determining the porosity, density and permeability properties of the products tested. The determined porosity showed that CLT 2P (sections with glue line) made from radiata pine had lower porosity than the radiata pine samples tested. The CLT section with glue line and edge gaps had higher porosity values than the 2P sections. LVL samples had lower porosity than the radiata and southern pine samples tested. Southern pine samples had higher gas permeability in all directions than radiata pine and shining gum samples. The liquid permeability of southern pine samples was higher in the longitudinal direction than the other two species tested. The observed variations in porosity and permeability values between CLT sections with glue line (2P) and glue line and edge gap (3P) should be considered as potential factors that could affect moisture gain and the development of moisture gradients within the CLT layered structure.

ACKNOWLEDGEMENT

The paper's author would like to acknowledge the National Centre for Timber Durability and Design life (NCTDDL) for funding this study and the technical team at the Salisbury research facility for assistance during sample preparation and experimental testing.

World Conference on Timber Engineering Oslo 2023

EXPERIMENTAL INVESTIGATION ON LONG-TERM BEHAVIOR OF TIMBER-TO-TIMBER SHEAR CONNECTIONS MADE BY INCLINED SELF-TAPPING SCREWS

Alessandra Gubana[1], Massimo Melotto[1], Luca De Cillia[1], Alessandro Mazelli[1]

ABSTRACT: Self-tapping screws are an interesting solution for timber-to-timber shear connections due to their performance, their economic advantages and their ease of use. The screws are preferably used inclined with respect to the shear flow direction, to improve the stiffness and the strength of the connection. The shear transfer mechanism is influenced also by the withdrawal capacity of the screw and by friction between timber elements.
These connections are useful for the bending reinforcement of existing timber floors, but the design of these composite-sections requires the knowledge of the connection behaviour. However, very few data are available on the long-term behaviour.
An experimental campaign to follow the connection behaviour during time has been performed. The results of a first group of twenty-four identic specimens were already presented. The last results of another group of sixty-three specimens are here reported. One half of the specimens was stored in a controlled environment, one half was stored in a not-controlled environment. Air temperature and humidity were regularly recorded. Push-out tests (as soon as built and after 6, 12 and 24 months) were performed and the main mechanical parameters of the connections as strength, stiffness and ductility at different ages are here compared.

KEYWORDS: Timber-to-Timber Shear Connections, Self-Tapping Screws, Long Term Behavior

1 INTRODUCTION

Self-tapping screws are nowadays commonly used for the connections and for the reinforcement of timber structural elements due to their performance, their economic advantages and their ease of use. This type of connection is largely applied for local reinforcement [1-5] and in timber-to-timber connections [6]. Besides, self-tapping screws are particularly useful for structural interventions on existing timber structures, reinforced by overlaying and joining timber or timber-based elements. The so created composite section is able to increase the bending strength and stiffness of the floor and to reduce vibrations under service loads. Examples of refurbishments of timber floors by means of timber-to-timber solutions are presented in [7-10]. Several studies in literature face the application of self-tapping screws to join together Cross Laminated panels [11,12], Cross Laminated panel and light frame timber structures [13] and to obtain timber-to-concrete composite sections [14]. The screws are preferably used inclined with respect to the shear flow direction as, in this case, the stiffness and the strength of the connection are strongly improved. The shear transfer mechanism is influenced also by the withdrawal capacity of the fastener and by the friction between the timber elements.

Several short-term tests have been performed [7-9, 15] and formulations have been proposed in literature to calculate the load-bearing capacity and the stiffness under shear/compression or shear/tension load [6, 14-17]. In addition, recent studies provide correlation approaches for Push-Out tests [18,19].
However, very few data are available on the long-term behavior [20], which can be influenced by timber moisture variation, shrinkage and creep.
An experimental campaign to follow the connection behavior during time has been performed. The results of a first group of twenty-four identic specimens were already presented [21]. Another group of sixty-three specimens were prepared in May 2020 to be tested, in clusters of nine. One half of the specimens was stored in a controlled environment, the other half was stored in a not-controlled environment, to simulate the real weathering. Air temperature and humidity were regularly recorded. Push-out tests (as soon as built, after 6 months, after 12 months and after 24 months) were performed and the experimental results are here presented. The main mechanical parameters of the connections as strength, stiffness and ductility at different ages are compared.

2 MATERIALS AND METHODOLOGY

The experimental campaign on the long-term behaviour of wood connections was conducted in the laboratory of the University of Udine (Italy), between May 2020 and May 2022.
Seven sets of nine specimens were built in May 2020. A first group was tested immediately. The others were left to age in the laboratory. Half of the specimens was stored in a controlled environment, the other in a non-controlled environment. Air temperature and humidity were recorded regularly for the non-controlled environment.
The mechanical behaviour of the connections at different aging times was characterized in terms of strength, stiffness and ductility with push-out tests.

2.1 TEST SPECIMENS

The specimens consist of one glued-laminated spruce timber element of strength class GL24h (EN 14080:2013 [22]), and two CLT elements symmetrically arranged (Figure 1). The connection is made by four VGZ 7X180 single-thread self-tapping screws. The screws are inclined at 45°, two for each side of the specimen, and they are subjected to shear-tension loading during the test.
The screws are inserted in order to have half of the thread length in the central element and half of the length in the lateral element. The central element has a cross-section of 160x160 mm, whereas the side elements 60x160 mm. The timber longitudinal grain is aligned with the loading direction.

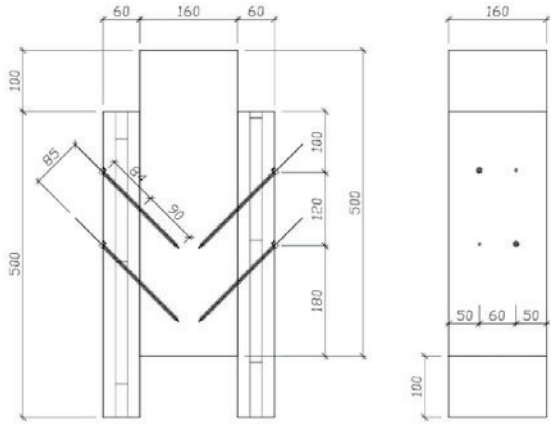

Figure 1: *Specimen geometry.*

The connections were realized by means of VGZ screws (Figure 2), which are characterized by a total thread, by a cylindrical head and by a pronounced cutter on the tip. The geometrical and mechanical properties were provided by the manufacturer and are reported in the relative European Technical Assessment ETA-11/0030 [23] and in Table 1, where $M_{y,k}$ is the characteristic yield moment, $f_{ax,k}$ is the characteristic extraction strength, $F_{tens,k}$ is the characteristic tensile strength and $f_{y,k}$ is the characteristic yield strength.
Seven groups of nine specimens each were built on the same day in May 2020.

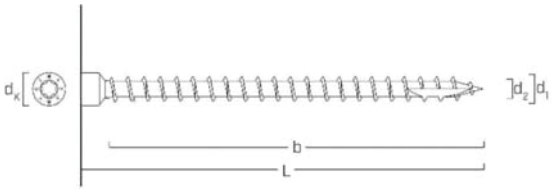

Figure 2: *Geometry of the VGZ 7x180 self-tapping screw.*

Table 1: *Geometrical and mechanical properties of the VGZ 7x180 self-tapping screw.*

Property	Symbol	Value
Length	L	180 mm
Nominal diameter	d_1	7 mm
Head diameter	d_k	9.5 mm
Tip diameter	d_2	4.6 mm
Characteristic yield moment	$M_{y,k}$	14174 Nmm
Characteristic extraction-resistance parameter	$f_{ax,k}$	11.7 MPa
Characteristic tensile strength	$F_{tens,k}$	15.4 kN
Characteristic yield strength	$f_{y,k}$	1000 MPa

All the specimens have the same configuration. A template was used to guarantee homogeneous geometrical characteristic and to correctly incline the screws on all the specimens. The timber elements were cut from different GL beams and CLT panels of the same supplies in order to reduce as much as possible the differences in terms of mechanical properties among the specimens. Every connection sample is identified by an acronym.
The first letter (from A to G) identifies the specimen group. Each group refers to a different age of testing, from 0 months (the test was performed in the same day when the specimens were built) to 24 months. The number (from 1 to 9) identifies the specimen in its group. The test groups are summarized in Table 2, where the time of testing T, the Controlled (C) or Non-Controlled (NC) environment (Env), average mass and average moisture content at time T are also reported.

Table 2: *Specimens description.*

Group	Time of testing T	Env	Avg. Mass at T [g]	Avg. Moisture content at T
A	0 months		9424	10.9
B	6 months	NC	9897	10.5
C	6 months	C	9466	10.8
D	12 months	NC	9560	10.2
E	12 months	C	9488	10.7
F	24 months	NC	9795	10.6
G	24 months	C	9407	9.9

https://doi.org/10.52202/069179-0080

Environmental conditions were constantly monitored and recorded during the ageing of the NC groups specimens. A thermo-hygrometer FHT70 with datalogger was used to register air temperature and humidity every 15 minutes (accuracy ±1°C on temperature and ±2% on air humidity). The moisture content of the specimens was measured before each push-out test by averaging 5 measurements. The electronic moisture meter "Aqua-boy" by KPM (accuracy ±0.1%) was used.

The recorded air temperature and humidity are shown in Figure 3, where the test dates are also highlighted. It can be noted a period without record due to the second phase of the Covid19 pandemic, when the laboratory was not accessible.

On the other hand, the specimens of the controlled environment were stored in a separate room of the laboratory, in order to avoid wide fluctuations in temperature and humidity.

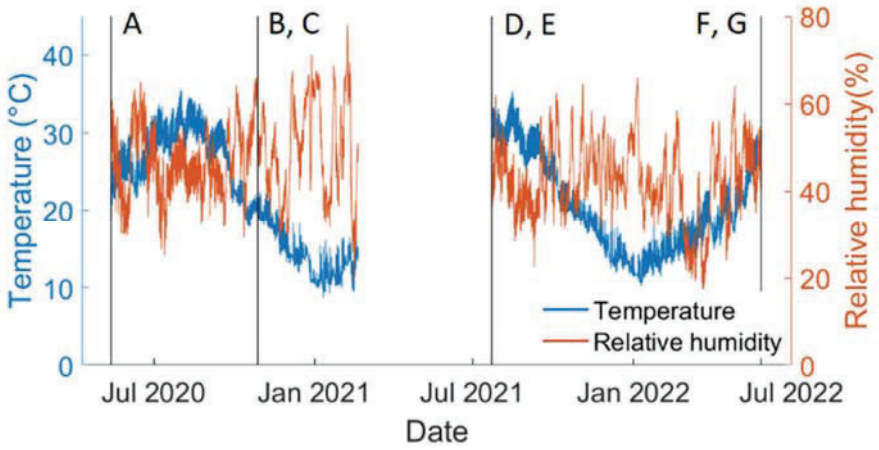

Figure 3: *Temperature (in blue) and relative humidity (in orange) during the test campaign.*

2.2 TEST SETUP AND PROCEDURE

The load-slip behaviour of the connections was obtained by push-out tests according to EN26891:1991 [17]. All the specimens are symmetric with respect to the loading plane and 4 screws are tested at time, 2 for each side of the specimen.

The test setup is shown in Figure 4.

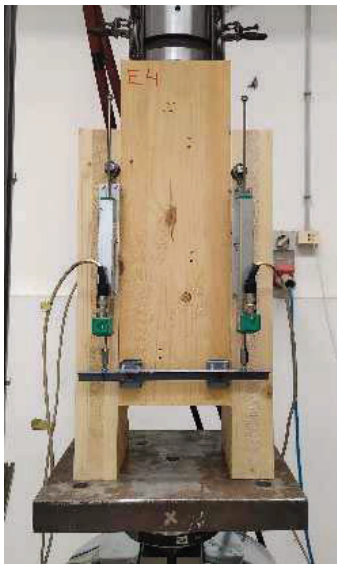

Figure 4: *Test setup.*

Load was applied in compression by a universal testing machine through a hydraulic actuator. During the test, the load was recorded by means of a load cell and the relative displacement was acquired by 4 transducers Gefran PY-150 (150 mm stroke, ±0.05% linearity). Two transducers were located on the front of the specimen and two on the back. The slip is then evaluated as the mean value of the four measures.

The load procedure according to EN 26981:1991 [17] is shown in Figure 5.

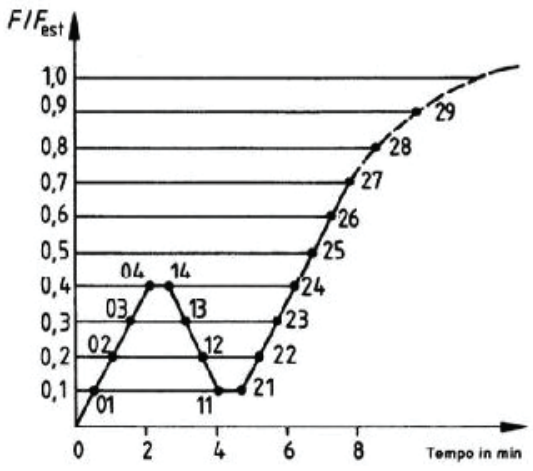

Figure 5: *Loading procedure according to EN 26981:1991 [17].*

https://doi.org/10.52202/069179-0080

The load is applied up to a value of $0.4F_{est}$, where F_{est} is the expected resistance, and maintained for 30s. Then, the load is reduced to $0.1F_{est}$ and again increased up to $0.7F_{est}$. After the reaching of this value, the machine is set into displacement control (speed of 0.05 mm/s). The specimen is pushed up to the actual failure limit state, in order to evaluate the residual capacity also for high values of displacement. As prescribed, the collapse load or a slip of 15 mm is considered as ultimate condition.
The estimated load F_{est} was assumed after the first test, and then it was considered constant for all the specimens.

2.3 ESTIMATION OF THE MECHANICAL PARAMETERS

Stiffness, strength and ductility are evaluated for each connection according to EN12512:2006 [24].
The secant stiffness K is evaluated by means of equation (1):

$$K = \frac{0.4F'_{max} - 0.1F'_{max}}{s_{0.4} - s_{0.1}} \quad (1)$$

where F'_{max} is the actual maximum value when the corresponding slip is less than 15 mm, otherwise the load corresponding to a 15 mm slip is chosen, and $s_{0.4}$ and $s_{0.1}$ are the slip of the connection corresponding to loads equal to $0.4F'_{max}$ and $0.1F'_{max}$ respectively.
The ductility of the connection μ is defined in equation (2):

$$\mu = \frac{s_u}{s_y} \quad (2)$$

where s_u and s_y are the ultimate slip and the slip at the yield point respectively.
The ultimate slip corresponds to $0.80F'_{max}$. According to [24], when the curve does not have two well-defined linear parts, yield value is determined by the intersection of the following two lines: the first is the line drawn between points $0.4\ F'_{max}$ and $0.1\ F'_{max}$ of the curve, the second is the tangent line with an inclination of ⅙K. (Figure 6).

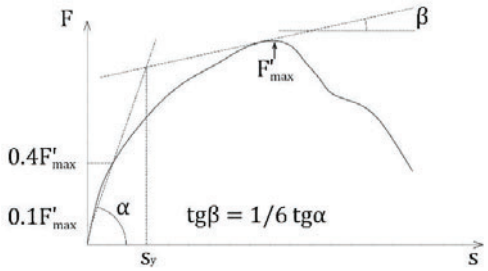

Figure 6: *Evaluation of the yield slip s_y according to EN 12512:2006 [24].*

3 EXPERIMENTAL RESULTS AND DISCUSSION

Figure 7 shows a few specimens at the end of the push-out test. Most of them gave evidence of a ductile rupture mode, consisting in the occurrence of two plastic hinges in the screws. In several samples, at the ultimate condition, screw head penetration was observed, in some cases the tip withdrawal took place.
The specimen experimental results for each group are shown in Figure 8, where the load-displacement relationships are illustrated. The reported load is the one on a single screw (i.e. the total measured load divided by 4). The slip is the average reading of the 4 transducers.
The results are generally dispersed. The dispersion is lower in groups A, D and G. It is worth noticing that specimen B2, D2 and G4 were damaged and the results are not shown.
Maximum load F_{max}, secant stiffness K and ductility μ are evaluated for each specimen with the procedure previously described. Average value (Avg) and coefficient of variation (CoV) are reported in Table 3.

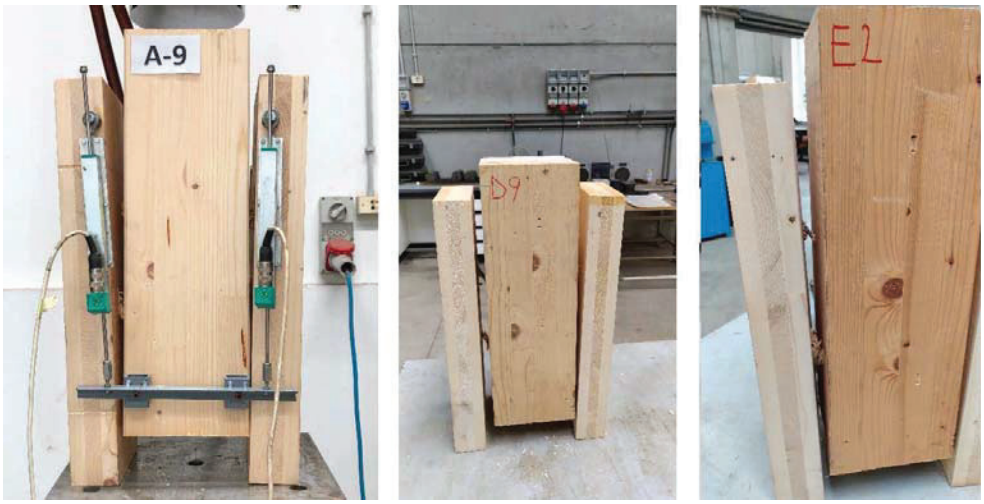

Figure 7: *Specimens of different groups after the tests.*

https://doi.org/10.52202/069179-0080

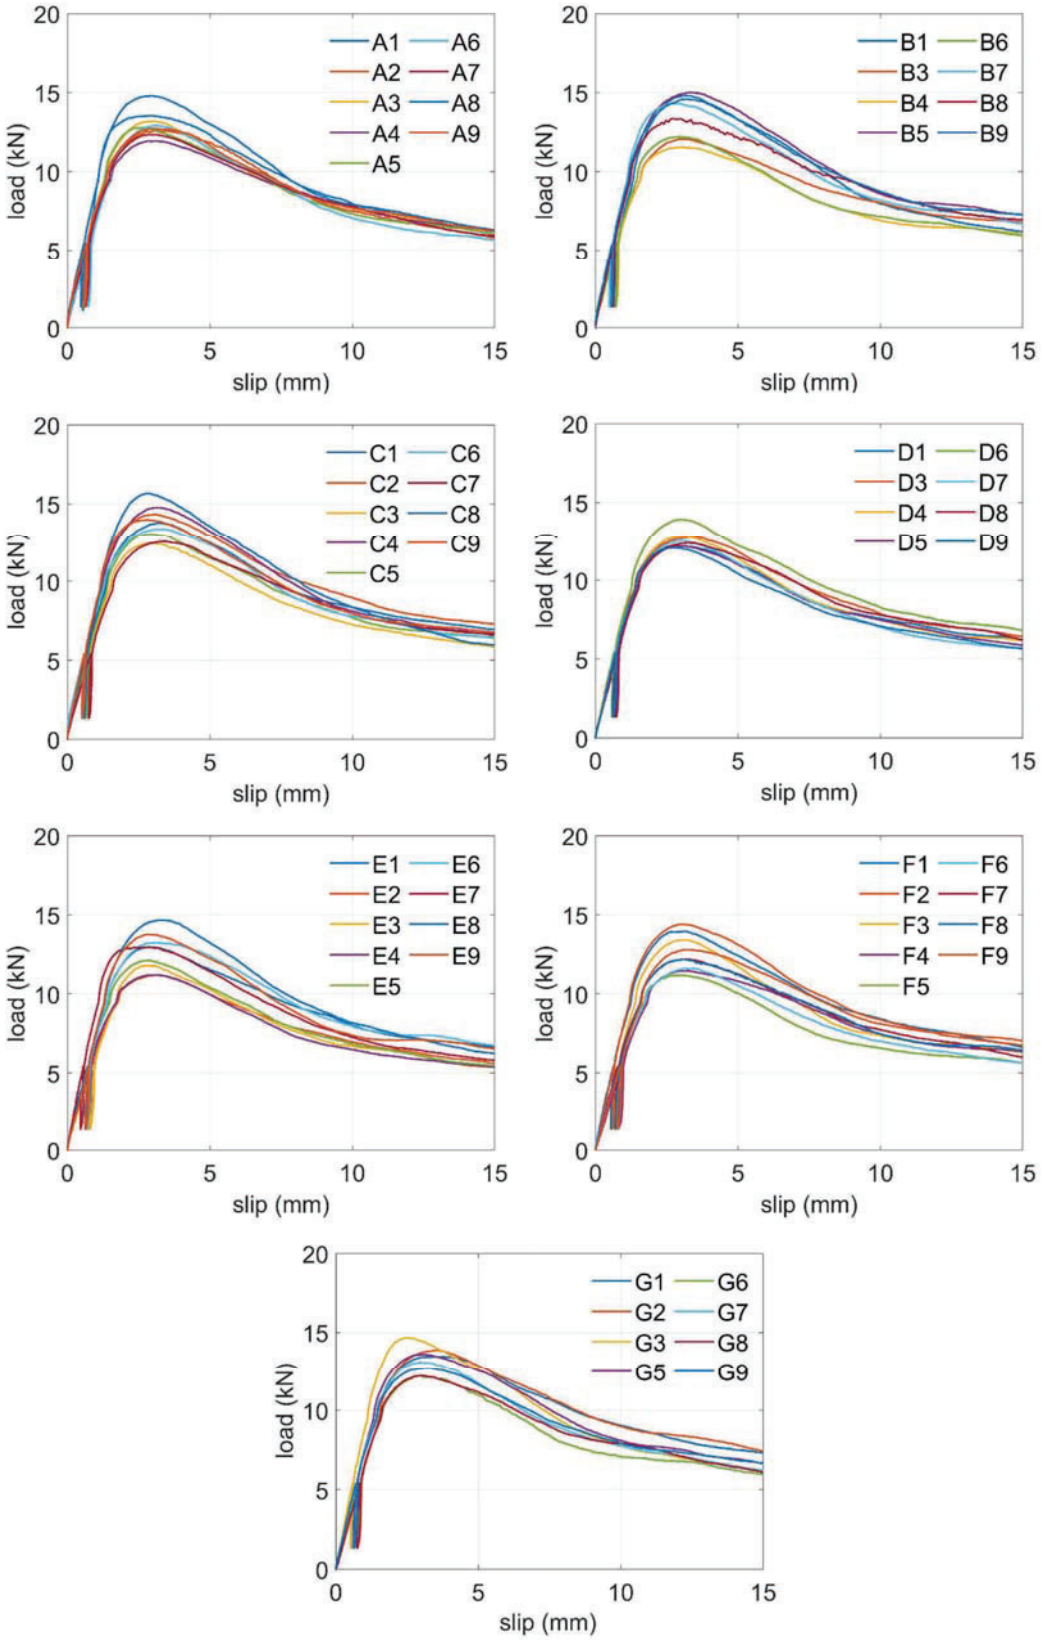

Figure 8: *Load-slip experimental curves for each specimen of the 7 tested groups.*

https://doi.org/10.52202/069179-0080

Table 3: Summary of the test results. (NC: Non-Controlled environment, C: Controlled environment).

Group	Environment	Time of testing	Secant Stiffness K		Maximum Load F_{max}		Ductility μ	
			Avg [kN/mm]	CoV	Avg [kN]	CoV	Avg [-]	CoV
A	-	0 months	7.21	8.9%	12.99	6.0%	4.06	11.9%
B	NC	6 months	7.24	10.4%	13.49	9.6%	4.06	10.3%
C	C	6 months	7.28	7.2%	13.77	7.3%	3.86	9.0%
D	NC	12 months	7.37	7.5%	12.59	4.5%	4.24	9.4%
E	C	12 months	7.06	13.2%	12.66	8.8%	3.91	12.9%
F	NC	24 months	6.87	9.7%	12.58	8.5%	4.04	6.9%
G	C	24 months	7.18	12.2%	13.22	6.1%	3.98	9.7%

For an overall view of the results, all the curves are reported together in Figure 9, where the unload-reload branches were removed to improve the clarity of the chart. The results highlight a difference of 7% between the maximum and the minimum value of the secant stiffness, which reached a minimum after 24 months (6.87 kN/mm). The maximum force reached a peak value after 6 months, both in the controlled and in the non-controlled environment (maximum load increased by 6%). The results highlighted a slight decrease of F_{max} after 12 and 24 months.

Ductility showed variation for specimens of the same age but stored in different environments (difference of 5% between groups B and C, 8% between groups D and E, 1% between groups F and G). The ductility values calculated in the controlled environment are always lower than the starting ductility value of group A (ductility decreased by 5%).

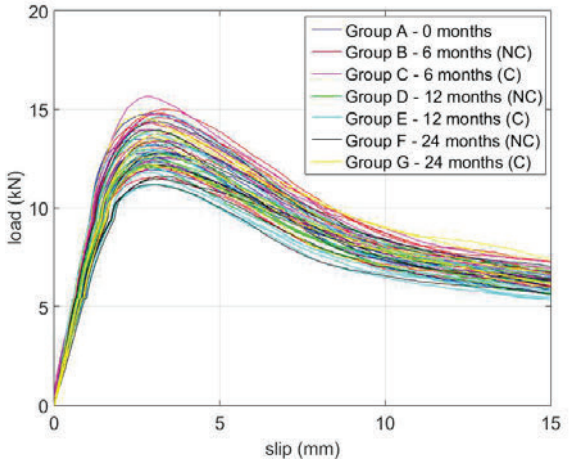

Figure 9: Load-slip curves of the 7 tested groups. (NC: Non-Controlled environment, C: Controlled environment).

4 CONCLUSIONS

An experimental campaign to study the self-tapping screw timber-to-timber connection during time was performed at University of Udine between 2020 and 2022. Samples of different ages were tested by a push-out procedure. The tests were performed for specimens as soon as built and after 6, 12 and 24 months. Half of the specimens was stored in a controlled environment, the other in a non-controlled environment. Air temperature and humidity were recorded regularly for the non-controlled environment.

The mechanical parameters of the connections were calculated after each test. In this paper, the results in term of secant stiffness, maximum force and ductility were compared. The trend now seems to signal only a slight variation of the mechanical characteristics over time. A minimum value of the secant stiffness was reached after 24 months and a peak in term of maximum strength was found after 6 months. Besides, the results showed a decrease in ductility for samples stored in a controlled environment compared to those in the non-controlled environment.

In the following post-processing phase of the data, it will be necessary to highlight the influence of the environmental humidity and the consequent variation of wood moisture content on the mechanical characteristics of the connections.

ACKNOWLEDGEMENT

This research was partly financed by the ReLUIS consortium (Italian University Network of Seismic Engineering Laboratories), within the frame ReLUIS-DPC 2019-2021 project “WP13 Contributi normativi relativi a strutture in legno” and the frame ReLUIS-DPC 2022-2024 “Contributi normativi – Strutture in legno”. The support of ROTHOBLAAS S.r.l.m Cortaccia (BZ), Italy, that offered the self-tapping screws, is gratefully acknowledged.

PATINA AND ITS FORMATION ON A WOODEN CHURCH FLOOR – CASE PETÄJÄVESI OLD CHURCH AND VIIKKI CHURCH IN HELSINKI

Jonna Silvo[1]

ABSTRACT: Scratches and other kind of wearing on the floor are caused by everyday actions, such as walking, soiling or for example dropping goods on the floor. During the time they might transform into patina. The aim of this study is to examine wooden patina in selected church floors: an old wooden floor and a modern one. The study also discusses the possibilities of a modern wooden floor to be patinated, when the modern maintaining culture is strong today. The research was done using both literature research and own observations. This study shows that aging and patination of wooden floors, especially new ones, is a wide and sometimes also complex combination of people's opinions, traditions, and maintenance concerns.

KEYWORDS: Patina, Wooden floors, Church, Finland

1 INTRODUCTION

Patina is an obvious and natural thing when looking the old wooden floors in historic churches. The wooden floors have worn for decades and centuries because of use, and most people think they are beautiful. Scratches and other kind of wearing on the floor are caused by everyday actions, such as walking, soiling or for example dropping goods on the floor. Technical features and choices such as wood species, wood structure and wood surface treatment affect how permanently the traces of use remain on the floor. Heating and air conditioning together with the outdoor conditions, determine the current conditions every time when wearing of the wooden floor happens.

The aim of this study is to examine wooden patina in selected church floors. What is patina, how does it appear in old wooden church floors in Finland, for example in Petäjävesi Old Church. What kind of thoughts are faced concerning the wearing of the modern wooden floor in Viikki Church where the floor is expected to patinate over time. This study also discusses the possibilities of a modern wooden floor to be patinated, when the modern maintaining culture is strong today. The research was done using both literature and own observations.

In previous studies wood and wooden floors have been evaluated from the viewpoint of how wood feels and how it influences people. Rametsteiner [1] has found out that people consider wood as a pleasant material and they feel that the presence of wood make them comfortable. It is also known that wood has a healthy and calming effect on people [2]. Rice et al. [3] has noticed that people have a natural understanding of that wood creates a healthy environment. Tuuva-Hongisto [4] adds that in people's minds feeling of aesthetic, warmness and authenticity is connected to wood.

In Finland the attitudes towards using wooden floors are contradictory. On the one hand wood as material is considered natural, warm, ecological and in all ways pleasant to use, on the other hand wood is often considered a material with poorer durability than other common floor materials such as laminate and plastic in Finland have [5].

2 PATINA

The word patina has multiple origins [1]. It is partly a borrowing from Latin but also partly a borrowing from Italian. The word paten was used already in 17th century to mean the layer coming to the surface of the copper. In Latin, paten means a shallow flat vessel or bowl from which the Italian word patena is inspired. As a descriptive concept, patina means a gloss or sheen; specification that on wooden furniture or surface is produced by age and polishing.

All buildings carry their history on their surfaces and that means that also time is written in every building. Mattinen [7] writes that buildings are not static entities; they are constantly evolving and changing, and their appearance

[1] Jonna Silvo, Oulu School of Architecture,
Faculty of Technology, University of Oulu, Finland,
jonna.a.silvo@gmail.com

https://doi.org/10.52202/069179-0081

reflects the changes that have taken place over time. The different signs and marks on buildings, whether they are intentional or unintentional, contribute to the overall character and story of the building [7].

An old environment can be comforting and familiar, offering a sense of safety and continuity. This is because the built environment serves as a tangible reminder of the past, offering a message that can be deeply personal and meaningful. In this way, the patina that accumulates on a building's surfaces can serve as a bridge between the past and present, connecting us to the people and ideas that came before us [7].

The concept of patina refers generally to the desirable surface changes that occur over time due to natural weathering, aging, or use. These changes can add character and depth to a building, giving it a sense of history and uniqueness. In contrast, soil and dirt usually refer to unwanted surface contaminants that accumulate on a building due to neglect or lack of maintenance [7].

2.1 PATINA AND WOOD

In Finland there are naturally just a bit more than 20 wood species [8]. Most utilized species in Finland are pine (Pinus sylvestris), spruce (Picea abies) and birch (Betula pubescens and Betula pendula). Wood patination refers to the natural aging and weathering of wood, which often results in changes in color, texture, and overall appearance (Figure 1.). This process is influenced by several factors, including the wood species, exposure to light and moisture, and the presence of microorganisms.

Figure 1: *An old patinated wooden floor in Finland. Wearing is characteristic for wooden floors.*

Understanding the mechanisms and effects of wood patination is useful for several reasons in modern wood architecture. First, it can provide valuable insights into the durability and long-term performance of wood-based materials in various applications. Second, it can enhance the aesthetic appeal of wood products, particularly in fields such as architecture and interior design.

Sometimes there is only a fine line between what is patina, wearing and what is soiling in people's opinions. When designing modern wide solid wooden floors in public buildings, wearing of the surface must be taken into consideration. Even though wearing is characteristic for wooden floors, people doesn't "know" wood as they did in the past. And that makes it harder for them to accept all the changes on the surface of the wood and changes on the surfaces of wooden floors.

3 PETÄJÄVESI OLD CHURCH

The oldest still existing wooden floors in churches in Finland are from the 18th and 19th centuries. Petäjävesi Old Church (Figure 2.) is one of the UNESCO World Heritage Sites located around the world.

Figure 2: *Petäjävesi Old Church. Photo taken in the beginning of the 21th century.*

The architecture of the church has been described as follows [9]:

> *Petäjävesi Old Church is representative of the architectural tradition of wooden churches in northern Europe. The Old Church is a unique example of traditional log construction techniques applied by the local peasant population in northern coniferous forest areas. European architectural trends, which have influenced the external form and layout of the church, have been masterfully applied to traditional log construction. The adaption of forms and techniques of varied provenance makes this church a multi-layered landmark and an outstanding example of Nordic church architecture. The church is built entirely of pine wood, worked in a constructive and economical manner.*
>
> *The interior's hand-carved log surfaces with their silky patina and the silvery sheen on the seasoned walls lend the hall its unique atmosphere, which is further enhanced by the slightly irregular placement of the floor beams and pews. The distinctive features of the interior are the elaborately carved pulpit, pews,*

https://doi.org/10.52202/069179-0081

chandeliers, and galleries with balustrades, which are entirely the work of local craftsmen and artists.

The interior of the church is presented in Figure 3. and 4.

Figure 3: *The dimensions of wooden planks of Petäjävesi Old Church floor are large, which was the standard at that time when the sawing was not industrial as today. The surface of the floor has worn unevenly.*

Figure 4: *The patinated interior of Petäjävesi Old Church somehow feels timeless.*

3.1 PATINA OF THE FLOOR OF PETÄJÄVESI OLD CHURCH

The wooden floor of Petäjävesi Old Church is a good example of an old patinated wooden plank floor. The patination process of the floor in this church or in others as well has thought not been documented. It is unknown what the Petäjävesi Old Church floor looked like, for instance, 20 or 50 years after its construction.

Today the church floor is beautiful, and the surface of the wooden planks has worn very smooth. The floor is thought uneven. The knots and other harder places have not worn as much as the softer parts of the planks. The surface of the floor is untreated.

4 VIIKKI CHURCH IN HELSINKI

Viikki Church (Figure 5.), built in 2005 and designed by JKMM Architects, represents modern Finnish wood architecture [10]. The main parts of the church are wooden. In the church the bundle-like glulam pillars function as load-bearing vertical designs. The frame has been partly braced with reinforced concrete. The spruce panels and boards of the hall walls and all the floors are of radially sawn spruce, which minimizes the movement of the wood indoors. The flooring material is massive spruce boards and the base floor is stone structured. The furniture has been tailor-made to suit the church activities. The interior of the church hall is presented in Figure 6.

Figure 5: *Viikki Church in winter 2006. The exterior of Viikki church is clad in cleft aspen shingles and they have turn grey during time as originally planned.*

The large wooden floor of the Viikki Church (Figure 3.) is made of feathered spruce floor boards (30 mm x 120 mm) sawn between the tangential and radial directions. The floor is treated with a mixture of lye and oil.

https://doi.org/10.52202/069179-0081

Figure 6: *The large wooden floor of Viikki Church is built with the combination of under-floor heating together with a reinforced concrete foundation. When the floor is serviced annually, the chairs are moved out of the way.*

4.1 PATINA OF THE FLOOR OF VIIKKI CHURCH

When designing a wide solid wooden floor in a public building, wearing of the surface must be taken into consideration. Wearing is characteristic for wooden floors, still sometimes there is only a fine line between what is wearing and what soiling in people's opinions.

The spruce floor in Viikki Church has worn during the past 15 years after completion of the floor (Figure 7). When designing the church, the original idea was that like in many old churches the floor would patinate beautifully over time. In Viikki Church, however, soon after the building was completed it was noticed that the wearing of the floor was very uneven. Some of the boards were also splitting. In discussions with the persons responsible of the maintenance in Viikki church in Finland it has occurred that these persons fear that the users of the church consider a worn floor as a soiled one and not aesthetically pleasant.

For getting more information the users of the Viikki Church were interviewed around this theme [11]. In the comments from Viikki Churh the sticks splitting of the floor came up. Some of the respondents connected the wearing of the floor to the splitting of the boards. If the splitting would not have occurred, the wearing would not have disturbed that much. The splitting of the boards (Figure 8.) were especially irritating parents of children that were visiting the church. Unlike the adults, children did walk with socks on the church floor and got sticks on their foots.

One interviewee commented concerning patina that: *"After all, patina is not dirt and sticks, but how is patina then created!?"*. The changes in the floor led to discussions of what patina is and could the changes of the surface of the floor even be called patina in such a new modern building.

Figure 7: *The wearing of the floor in front of a frequently used cabinet, has been intense compared to the surrounded floor.*

Figure 8: *Splitting of the boards in has been a problem in Viikki Church.*

5 DISCUSSION

In the Viikki Church the user and visitors have been quite satisfied with the wooden floor in the church hall, but some of the people think that wood as material has not been technically the best choice because of splitting of the boards.

There was a small experiment to change the lye-oil treatment to lacquer in the secondary rooms, but this was

not considered as a successful solution. In addition to that lacquer changes the feeling and atmosphere of the whole floor compared to the natural lye-oil treatment.

In retrospect can be said that splitting and sticking of the boards could probably have been prevented by being more precise about the quality of the floorboards, so that all the boards would have been exactly radially sawn. Even if the costs in this way would have been higher in the design and building phase, from a wood technical point of view, the better quality floor probably would have paid for itself during the decades if the floor does not have to be maintained as often.

A random visitor in the church does of course not face the same problems with the floors that a permanent visitor, or people working in the churches every day do. It is true that it does not help that a floor looks beautiful if it complicates you of doing your work for example when you are cleaning (Figure 9.). It can be stated that wearing of the floors has been more a functional problem than an aesthetic one.

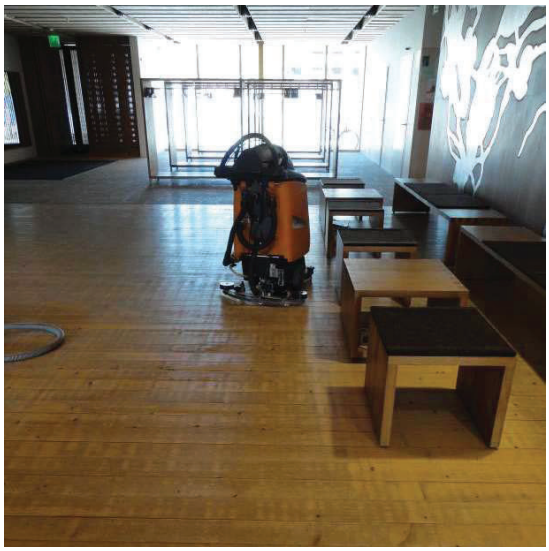

Figure 9: *The wooden floor of Viikki Church is regularly machine washed but only some moisture is absorbed in the floor.*

Besides the wearing of the wooden floors, the floors have of course also been soiled during the years and it is impossible to have them look like new ones with the existing cleaning methods. Still, it can be asked should a wooden floor look like a new one when time goes by. In figures 10. and 11. we can see the difference between a worn floor and a newly sanded floor.

Figure 10: *The floor before it had been sanded. The small round marks are caused by the spikes of the anti-slip pads people use on the shoes when it is slippery during winter time in Finland.*

Figure 11: *The floor after it had been sanded the first time after fifteen years. If the floor will be sanded regularly, it is impossible that the surface would start to patinate as the old wooden floor. On the other hand also the used dimensions are smaller than in the past.*

6 CONCLUSIONS

In this study patina has been examinated and the difference between patina, soil and wearing discussed. The wooden floor of Petäjävesi Old Church is a beautiful example of patination. The wearing of the young wooden floor in Viikki Church has instead caused debate throughout the life cycle of the floor.

It is impossible to know for sure how the floor of the Viikki church will begin to patinate and how the floor will look like during decades, as well as what kind the patinate result will be. It may be that it will look very different

https://doi.org/10.52202/069179-0081

from of what the floor of Petäjävesi Old Church does today. Probably it will not look the same because the dimensions of the floor planks were much larger in the old durable wooden floors. In addition to that the wood material used in past was usually denser in average.

One viewpoint is to think what the wearing and patination of wooden floors bring to architecture and the way we experience it. Could the qualities of wood that are considered problems, such as marks of use and inhomogeneity, also be considered as positive signs of the naturalness of the material. Thinking in this way, the characteristics typical of wood would be precisely those that connect people with nature and thereby affect the experience of the space and material.

However, the main question remains – what is the balance between soil, wearing and patina. How much can both be tolerated, and can they even be completely separated from each other.

It is not known if the wearing of the floor will turn to patina during time. On the other hand, patina is not only aging but also marks of use and wear on the surface. The question remains how much wearing can be tolerated in a new building to obtain patination in the future. This study shows that aging and patination of wooden floors, especially new ones, is a wide and sometimes also complex combination of people's opinions, traditions, and maintenance concerns.

ON THE UTILISATION OF THE WORKSPACE OF AN INDUSTRIAL ROBOT FOR MILLING STRUCTURAL TIMBER COMPONENTS – EXPERIMENTAL TRIALS WITH DIFFERENT ARM POSITIONS AND EVALUATION OF MACHINING QUALITY

Marc Pantscharowitsch[1], Finn Linzer[2], Hans-Berndt Neuner[3] Benjamin Kromoser[4]

ABSTRACT:

Within subtractive manufacturing of timber construction components, industrial robots equipped with a milling spindle hold great potential for efficiency increases and new production methods. A key difference to modern joinery machines is the larger workspace, especially in the horizontal and vertical direction. This pushes the limits for the dimensions of workpiece cross sections and allows for newly thought-out workpiece placement and possibilities for batch processing. However, a basis must be created to assess the quality and to evaluate the effects of different robot positions on the machining quality. The subject of this paper is therefore the machining of pockets in glued laminated timber using the same parameters yet in two test series: A) four different robot positions and tool orientations B) the reach is set to four different values with each two workpiece orientations. The processing quality is then assessed based on four different scales of magnitude: 1) nominal/actual geometry comparison; 2) optical and haptic surface quality assessment; 3) stylus method surface roughness measurements; 4) 3D scans. The results show effects of the position especially in machining directions influenced by longer static levers and mass inertia. Nevertheless, compared to reference workpieces the machining quality is competitive.

KEYWORDS: 3D Scan, Automation in Construction, Glued Laminated Timber, Glulam, Quality Assessment, Robotic Manufacturing

1 INTRODUCTION

Industrial robots (IR) are already state of the art in the automotive and electronics industries [1]. Equipped with a machining spindle they have a high potential to increase the efficiency of subtractive manufacturing of engineered timber construction components. The advantages of IRs over the widely used joinery machines (JM) lie in the lower acquisition costs, the higher technological development and innovation, as well as the availability of robots and spare parts. In terms of their machining properties, they offer opportunities to increase productivity through higher degrees of freedom (DOF), larger workspace and higher flexibility. [2] To determine the applicability of IRs in engineered timber construction, a comprehensive scientific study is required. Therefore, as a first step, the quality of the machining results of IRs was analysed by the authors [3]. The milling of elementary geometries such as lines, rings and pockets using an IR was investigated and showed that the surface quality is satisfactory for the use in timber construction. Furthermore, the geometry and surface quality of milled pockets was compared to pockets manufactured with JMs. The comparison showed that the mean machining quality of the IRs is 11.52 % higher (indicated by the quality deviation value QDV) than that of the JMs. [4] Following these results, the same assessment methods were applied to another type of timber connection: the tenon. This study showed a 24.53 % higher machining quality of the JM compared to the highest quality IR specimen. Nevertheless the surface quality and geometry precision of the IR manufactured specimens was still high enough to meet industry standards. [5]

Having demonstrated the feasibility of subtractive machining using IRs by studying elementary geometries and application examples (pockets and tenons), this investigation looks into the potential of the larger workspace available when using IRs, specifically if the machining quality meets the requirements in terms of dimensional accuracy and surface quality. The idea is to identify potential causes for instability and ultimately lower machining quality.

2 EXPERIMENTAL SETUP

The machines, tools, the specific machining parameters, and the investigated specimens within the two test series are described in this section. In order to investigate the potential of IRs a reference with state of practice

[1] Marc Pantscharowitsch, University of Natural Resources and Life Sciences, Vienna (BOKU), Austria, marc.pantscharowitsch@students.boku.ac.at
[2] Finn Linzer, Technical University Vienna (TUW), Austria, finn.linzer@tuwien.ac.at
[3] Hans-Berndt Neuner, Technical University Vienna (TUW), Austria, hans.neuner@tuwien.ac.at
[4] Benjamin Kromoser, University of Natural Resources and Life Sciences, Vienna (BOKU), Austria, benjamin.kromoser@boku.ac.at

https://doi.org/10.52202/069179-0082

machinery, in this case JMs, needs to be additionally looked into.

2.1 MACHINES AND TOOLS

First the machines and tools of both used within the investigations are described.

2.1.1 IR

The BOKU robot laboratory (Figure 1) is the home of an ABB IRB 7600-325 IR mounted on an ABB IRBT 6004 external linear axis with the following properties: reach 3.10 m; payload 325 kg; position repeat accuracy 0.19 mm, trajectory repeat accuracy 0.4 mm (according to manufacturer) [6]. The IR can be equipped with various end effectors (EE), however within this study a HSD ES951 A 1112 S spindle with 13.2 kW and 10.5 Nm at 12,000 rpm was used. The machining was done with an insert cutter by Leitz (tool ID: 41927) as depicted in Figure 2 with a diameter Ø of 40 mm, an edge height of 160 mm, and two Z2 carbide milling inserts (HeliCut 11 mm x 11 mm x 1,5 mm and one drill cutting edge), with a cutting angle of 20°, a clearance angle of 20° and helix angle of 15° complemented by the HSK F-63 tool holder. The cutting inserts were unused before and showed no tool wear. A solid 2,400 mm by 1,200 mm steel worktable was used as the machining bed, comprising of 24 lamellae parallel to the short side with slots in between to allow for workpiece attachment.

Figure 1: *BOKU robot laboratory with ABB IRB 7600-325 industrial robot mounted on ABB IRBT 6004 external linear axis with the end effector (EE): HSD ES951 A 1112 S and the steel worktable in the back.*

2.1.2 JM

The reference workpieces were machined on a Hundegger k2i joinery machine (JM) using a 5-axis universal milling unit (15 kW up to 5,200 rpm) at the facilities of Rubner Holzbau GmbH. The tool used was an end mill with a diameter Ø of 36 mm, and a length L of 150 mm.

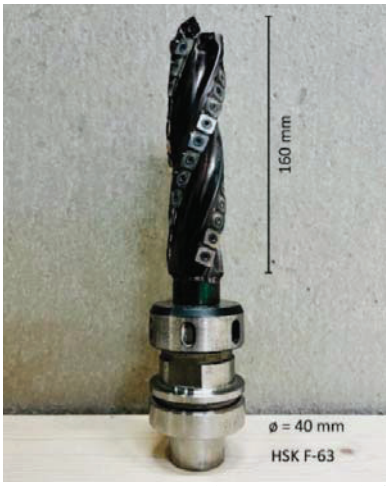

Figure 2: *Leitz insert cutter (tool ID: 41927) with diameter = 40 mm, edge height = 160 mm, 2 x Z2 carbide milling inserts (HeliCut 11 x 11 x 1,5 mm and 1 x drill cutting edge), cutting angle = 20°, clearance angle = 20°, helix angle = 15° and HSK F-63 tool holder.*

2.2 MACHINING PARAMETERS

As not only the used machinery but also the specific machining parameters are of importance within the potential assessment, a statement in regard to the latter is given below.

2.2.1 IR

The machining parameters of the IR were set the same for both test series. The spindle speed was set to 17,900 rpm, with a feed rate of 5,500 mm/min, a radial depth of cut of 35 mm and an axial depth of cut of 20 mm while climb cutting. The machining strategy is visualised blue in Figure 3.

2.2.2 JM

The authors did not have any influence on the machining parameters of the JM as they were set according to the machine operator's experience, relying on best practice and recommendations of the tool manufacturer: spindle speed = 4,000 rpm, feed rate = trajectory speed 5, unknown radial depth of cut, axial depth of cut = 20 mm while climb and conventional cutting. The trajectory speed, as reported by the machine manufacturer Hundegger in an interview [7], is indicated by an integer value from 1 to n. This integer represents the ratio of the set machining speed to the maximum machining speed, which is unique for each toolpath. When looking at a given machining process including cutting, milling and conveying processes and increasing the trajectory speed, the cutting and milling time is reduced but not the conveying time. Therefore, it is not possible to express the speed in SI units as there is no linear relationship. The machining strategy and trajectory of the tool centre point (TCP) are marked red in Figure 3.

2.3 SPECIMENS

The investigated workpieces consisted of four pockets (263 mm x 111 mm x 20 mm) with rounded corners (radius R = 20 mm) as presented in Figure 3. The

https://doi.org/10.52202/069179-0082

machining tests of both series were carried out on glued laminated timber (GLT: Gl24h, spruce, Picea abies L. Kars.).

2.3.1 Reference series

As a reference, two specimens were machined by the previously described JM on a GLT beam workpiece (cross section 200 mm x 200 mm).

2.3.2 Series A

Series A was conducted on a GLT beam with the cross-sectional dimensions of 200 x 200 mm, with the direction of the fibres and lamellae parallel to the long edge of the beam and pockets. The pockets were machined once at the end of the beam on four different opposing surfaces, each with a different orientation. The machining parameters were kept unchanged throughout the investigations, allowing for a comparison of the milling results depending on the robot position as shown in Figure 4. The workpiece was placed upon two vertical supports during all machining trials to achieve the reachability of the workpiece when machining overhead (Figure 4 D).

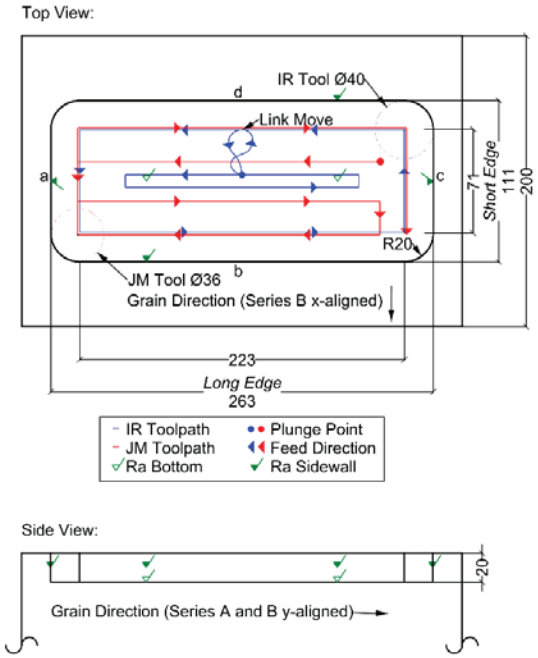

Figure 3: *Specimen [mm]: machined pocket with radial corners. The trajectory of the tool centre point of the toolpath, plunge point and feed direction is represented in blue (IR) and red (JM). Average surface roughness measurement points are marked green. Workpiece of series A and reference series: GLT beam (cross section 200 mm x 200 mm).*

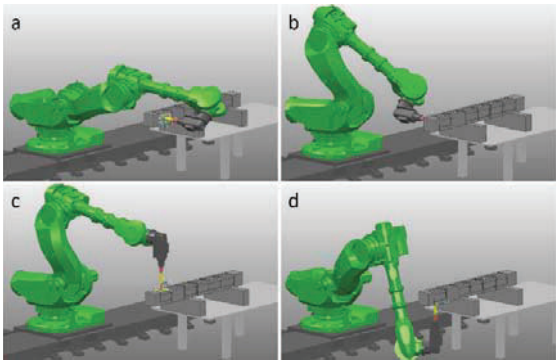

Figure 4: *ABB IRB 7600-325 industrial robot in the four different analysed positions and orientations. A) Long reach, B) Short reach, C) Vertical, D) Overhead.*

2.3.3 Series B

The trials of Series B were conducted on GLT workpieces measuring 2,000 mm x 600 mm x100 mm with the fibre direction parallel to the long edge of the workpiece. This series was subdivided into two subseries. In the first subseries, the pockets were aligned parallel to the long edge of the workpiece (further referred to as y-aligned due to the robots` coordinate system visualised in Figure 5). In the second subseries, the pockets were aligned normal to the long edge of the workpiece (further referred to as x-aligned). Each alignment and reach were machined three times for redundance. The reason for the two different investigated orientations of the specimens relative to the grain is not due to the anatomical structure of the wood but rather the robot motion direction while machining. With the pockets being y-aligned, the longer longitudinal motion requires the robot to increase its reach, while for the x-aligned pockets it is demanding the robot primarily to move laterally and also needs to turn. In Figure 5 top, the workpiece placement in the robot workspace is illustrated with the IR located directly over the central axis of the pockets in y-direction. The four investigated workpiece placement positions are visualised in Figure 5 and were chosen to exploit the entirety of the workspace limits. Position 1 was chosen as close as possible to the robot base while position 4 represented the opposite (farthest away placement still allowing for a undisturbed milling). Positions 2 and 3 were evenly distributed between 1 and 4. As a result, the reach of all four positions varies between the x- and y-aligned test series, as listed in Table 1. Reach is defined by the distance between the robot base (centre of rotation of axis 1 as marked with 0 mm reach in Figure 5 top) and the mid of the pocket. To allow for the investigations of the defined placements with an adequate secure stability, the worktable was extended (marked red) by moving every second lamellae in y- direction.

https://doi.org/10.52202/069179-0082

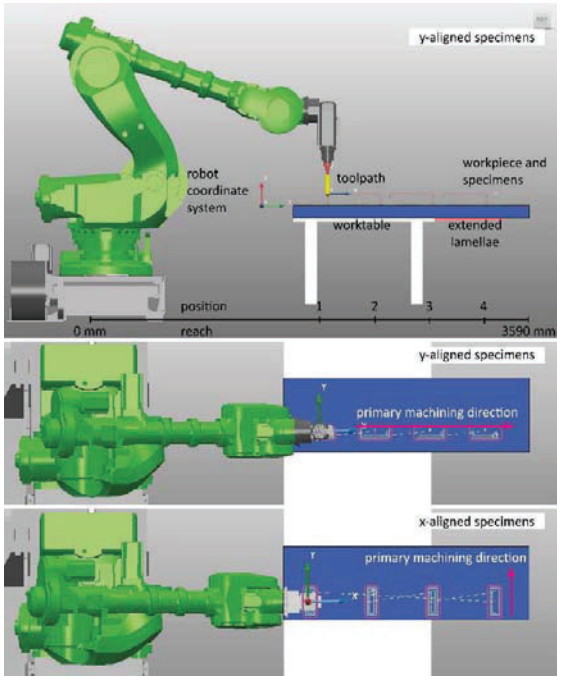

Figure 5: *Top: Workpiece placement, robot positions and reach of y-aligned specimens. Mid: Top view of workpiece placement and primary machining direction of y-aligned specimens. Bottom: Top view of workpiece placement and primary machining direction of x-aligned specimens.*

Table 1: *Specimens positions. * reach is measured from robot base (centre of rotation of axis 1 as marked with 0 mm reach in Figure 5 top) to specimen centre parallel to the y-axis of the robot coordinate system. Δ describes the distance between the positions in y-direction.*

Position	Specimen x-aligned	Reach x-aligned* [mm]	Specimen y-aligned	Reach y-aligned* [mm]
Δ	-	*500*	-	*450*
1	X1	1806	Y1	1882
2	X2	2306	Y2	2332
3	X3	2806	Y3	2782
4	X4	3306	Y4	3232

3 EVALUATION METHODS

In Austria, manufacturing requirements for structural timber can be found in ÖNORM EN 336 [8], with the dimensional accuracy specified in Table NA.L.5 in Eurocode 5 DIN EN 1995 [9] while characteristics for timbre materials like GLT are defined in ÖNORM EN 14080 [10]. Despite these regulations, surface roughness and local geometrical deviations are not considered within the regulations. To evaluate the influence of the different positions and reaches of IRs, the following references and criteria were considered.

3.1 DIMENSIONAL ASSESSMENT

Dimensional measurements were carried out on all specimens of Series A and B using two methods: by hand and by laser profile scans. The results of both methods were combined into mean values before calculating the actual-nominal deviation. Subsequently, the utilisation factor (UF) of each dimension (Length L, Width W, Height H) of every specimen was calculated based on the actual-nominal deviation and regulations specified by ÖNORM EN 14080 [10] (height h ≤ 400 mm: +4 to -2 mm and length l ≤ 2 m: ±2 mm). Note, these regulations do not specify timber in connections. Finally, the cumulated utilisation factor (CUF) of each individual specimen was calculated by determining the mean value of the three individual UFs.

3.1.1 Measurement by Hand

The dimensions (L, W, H) of all specimens were measured by hand using a carpenter´s square. Each measurement was taken three times to avoid discrepancies before the mean values were calculated.

3.1.2 Laser profile Scans

The profile scans were performed using a Keyence LJ-X8900 profile scanner. Mounted to the EE of the robot, the laser profile is aligned parallel to the y-axis of the robot coordinate system (as pictured in Figure 5) producing 2D data. Combined with the robot motion in x-direction, 16,000 profiles are combined into one 3D image. The accuracy in the x-direction is dependent on the robots` speed and the scanners` capture frequency, or in other words the distance travelled in acquiring all the profiles, resulting in this case in 4,000 mm / 16,000 profiles = 0,25 mm. In the y-direction along the profile, the accuracy is given with 25 µm and in the z-direction with 10 µm. The collected data was analysed by the Keyence controller firmware for LJ-X8000 (3D mode) version 1.4. The specimens lengths and widths were measured with the tool gap pitch (edge pairs) from light to dark with 55% edge sensitivity, edge filter width 50 and lower edge intensity 10. The specimen´s pocket depths were assessed with the tool height measurement where the peak-to-peak height was extracted.

3.2 QDV

Currently, there are neither normative regulations nor a consensus within science on an objective assessment system for machined surfaces in timber construction [11]. Therefore, the authors have introduced the quality deviation value (QDV) [3], which is composed of optical and haptic assessment of the geometry as well as the surface roughness R_a measured using the stylus method in addition to optical and haptic inspection.

3.2.1 Geometry Assessment: Optical and Haptic

The geometric quality was assessed both optically and haptically evaluating z-deviations in the bottom area and x- / y- deviations in the sidewall surfaces. The subjective optical and haptic inspection was conducted by two parties to increase objectivity. The characteristics were described by three values: “height criterium” for z-deviations in the bottom area, “lateral criterium short edge” and “lateral criterium long edge” for x- / y- deviations in the sidewall areas with QDV ratings from 1-6 (lower values indicating lower quality). The optic and haptic assessment also includes wood surface defects such as fuzzy grain, which describes wood fibres or fibre collectives that protrude from the surface, or torn

fibre, defined by torn-out wood pieces that do not break directly when cut [12].

3.2.2 Roughness Assessment: Optical and Haptic

Optical and haptic inspection was carried out additionally to analyse the surface roughness caused by the anatomical structure of the wood and machining of the three investigated areas (bottom and short/long sidewalls). Again, the inspection was conducted by two independent parties. As a reference, Figure 6 shows various machined surfaces with associated QDV ratings (min = 1 – good quality, max = 6 – poor quality).[3]

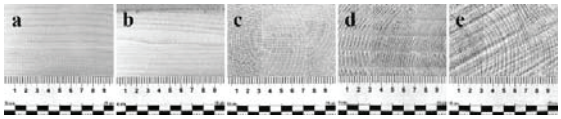

Figure 6: *Assessment of the optical/haptic surface roughness, dependent on the growth direction and machining process. Bottom surface and long edge sidewall surfaces (parallel to the grain): (a) radial/tangential planed, QDV = 1 (b) radial/tangential robot milling with 40 mm insert cutter, QDV = 2. Short edge sidewall surfaces (perpendicular to the grain): (c) axial blade saw cutting, QDV = 3 (d) axial manual chain saw cutting, QDV = 6. [3]*

3.2.3 Surface Roughness Measurement

The stylus method was used to measure the surface roughness of all inspected areas (bottom and short/long sidewalls). The measuring device was a MarSurf PS 10 (PHT 350, 2 µm probe) as shown in Figure 7 with the following settings: evaluation length Lt: 12.50 mm, Gaussian profile filter Ls: 8.00 µm, Lc = 2.5 µm, number of measured subsections N = 5 measuring velocity Vt: 0.5 mm/s, measured points: 30,000. The average surface roughness R_a was chosen as the measured quantity and the data acquisition was performed according to ÖNORM EN ISO 4287 [13] and ÖNORM ISO 16610 [9]. The measured values were scaled by applying a scaling factor (= maximum measured R_a value divided by 6) in order to not distort the QDV.

Figure 7: *MarSurf PS 10 device collecting surface roughness data on bottom area of a specimen of Series B. The stylus is located below the bottom left black tube.*

To increase the validity and reduce the influence of anisotropic and inhomogeneous wood properties, three measurements were conducted on each measuring point. The location of measurement points is depicted in Figure 3 and was marked on the specimens to increase the transparency of the study as recommended by Gurau and Irle [11].

3.3 3D SCANS: POINT CLOUDS

For the micro-scale assessment of the machining irregularities and tracing of tool paths, 3D point cloud scans of Series A were performed. First assessments can be found in [4], [5]. A Leica Absolute Tracker with a Leica T-Scan TS 50-A was used during the examinations to create a point cloud consisting of approximately 1 million points per specimen with the measurement uncertainty to plane surfaces of 80 µm (2 sigma). The data was analysed in the following three steps:

1) Division of the pocket geometry into five sections as presented in Figure 3: bottom surface, left short edge side wall a, lower long edge side wall b, right short edge side wall c and top long edge side wall d.

2) Analysis of the obtained point clouds using the CloudCompare software in the following steps: 2a) Fitting a reference plane to each machined surface a-d and bottom. 2b) Calculation of the difference of each point of the point cloud normal to the reference plane and subdivision into classes. 2c) Assessment of the number of points per class and visualisation in a histogram including a gaussian function graph.

3) Assessment of the data using RStudio. 3a) Preparation and inspection of the QQ-plots of the histograms for normal distribution as this is a precondition for the Wilcoxon rank-sum test. 3b) Assessment of the date using the Wilcoxon rank-sum test to compare the congruency of two identical sections of two different pockets (e.g. bottom surface specimen 1 with bottom surface specimen 2) by their mean values per class. As the null hypothesis states that the true location shift is equal to 0, its rejection ($p < 0.05$) indicates a major difference between the inspected surfaces. The Wilcoxon rank-sum test was performed on pairs of all five congruent areas of Series A specimens Vertical vs. Overhead and Series A specimens Short reach vs. Long reach.

4 RESULTS

In this section, the results of each series and evaluation method are reported.

4.1 SERIES A

Series A concludes the investigation of the four different robot positions Vertical, Overhead, Short reach and Long Reach.

4.1.1 Dimensional Assessment

The results of the dimensional assessment (measurements by hand and laser scanner) are displayed in Figure 8 as nominal-actual deviations. The mean deviations and UF, as described in Section 3.1, were L = 1.85 mm (UF = 92%), W = -1.47 mm (UF = 74%) and H = -0.33 mm (UF = 25%). The CUF per specimen was Vertical = 64%; Overhead = 60%; Short reach = 68% and Long reach = 62%. Calculated differences of CUF for the compared pairs resulted in 4% higher CUF when machined Vertical

https://doi.org/10.52202/069179-0082

against Overhead and 6% higher when machining Short reach against Long reach.

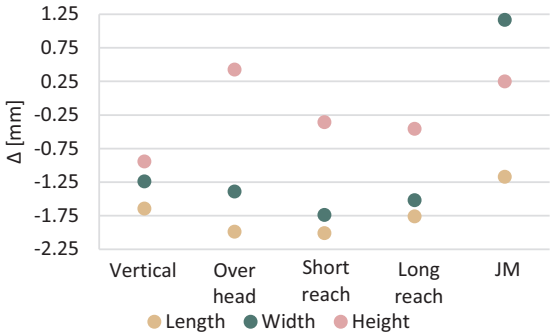

Figure 8: *Nominal-actual deviations for specimens of Series A.*

4.1.2 QDV

The results of the QDV assessment for Series A are displayed in Figure 9 with higher values indicating more deviations and irregularities. The calculated mean QDV of Series A is 19.68 (maximum achievable value 42), while the mean surface roughness R_a equalled 4.7 µm. The mean result of the JM machined reference specimens is also included. The main differences of QDV were observed for the height and lateral criteria and optical and haptic surface roughness assessment.

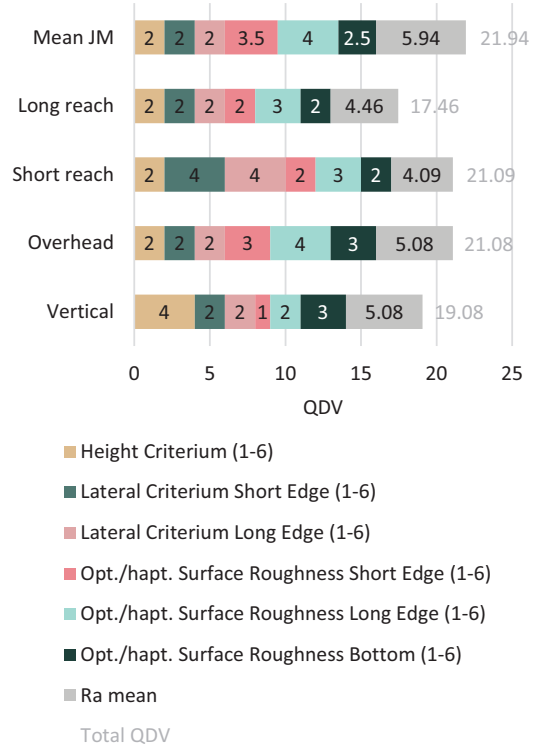

Figure 9: *Quality deviation value (QDV) of individual specimens of Series A. Higher QDVs represent more deviations and irregularities.*

4.1.3 3D Scans

The results of the Shapiro-Wilk normality test (see Table 2) for all inspected surfaces are $p < 0.05$ so the null hypothesis is denied and no normal distribution is present. This is a precondition for the following Wilcoxon rank-sum test for the statistical comparison of two surfaces.

Table 2: *Shapiro-Wilk normality test results. P-values < 0.05 indicate that the null hypothesis is denied and no normal distribution is present.*

Specimen	Inspection area	W	p
Vertical	bottom	0.94628	4.36E-05
Vertical	a	0.85753	6.96E-03
Vertical	b	0.9641	4.00E-07
Vertical	c	0.93584	1.08E-08
Vertical	d	0.95862	1.34E-02
Overhead	bottom	0.77529	2.20E-16
Overhead	a	0.92619	4.06E-03
Overhead	b	0.93049	8.06E-07
Overhead	c	0.90321	1.43E-12
Overhead	d	0.96777	4.07E-04
Short reach	bottom	0.88432	2.20E-16
Short reach	a	0.8998	7.76E-06
Short reach	b	0.88563	2.48E-09
Short reach	c	0.90724	4.40E-06
Short reach	d	0.9673	1.27E-04
Long reach	bottom	0.95337	2.20E-16
Long reach	a	0.92536	4.91E-08
Long reach	b	0.96997	1.80E-04
Long reach	c	0.93647	6.48E-06
Long reach	d	0.93212	9.72E-06

The Wilcoxon rank-sum test was conducted to compare two surfaces of the same type (e.g.: sidewall a). The results in Table 3 represent the significance level for every pair. If $p < 0.05$, the null hypothesis (no significant difference) is denied. In this comparison, the sidewall a of Vertical and Overhead machining and bottom areas of the Short reach and Long reach specimens are significantly different. All other pairs show no significant difference in the point to reference plane distance. As presented in Figure 10 the point cloud to reference plane distances overlaid with an image of the specimen clearly reveal the tool marks and micro-scale irregularities.

Table 3: *Wilcoxon rank-sum test results.*

Specimen and inspection area	W	p	Significant difference
Vertical vs. Overhead			
bottom	90022	0.8573	No
a	2914	0.03946	Yes
b	72058	0.6398	No
c	78927	0.8323	No
d	18428	0.5463	No
Short reach vs. Long reach			
bottom	379543	0.003089	Yes
a	25497	0.0783	No
b	27214	0.07479	No
c	23762	0.1591	No
d	20904	0.1349	No

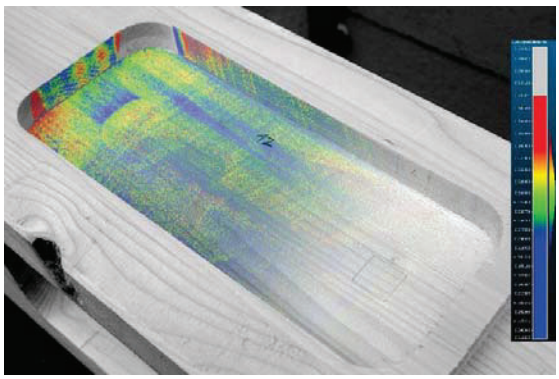

Figure 10: *Specimen 12 with overlaid point cloud with the scalar field indicating calculated point to reference plane distances.*

4.2 SERIES B

Series B includes the analysis of four different reach positions and two different workpiece alignments.

4.2.1 Dimensional Assessment

The results of the dimensional assessment are displayed in Figure 11 as nominal-actual deviations for each measurand and specimen orientation. The mean deviations and UF for the whole test series were L = 1.10 mm (UF = 55%), W = 0.66 mm (UF = 33%) and H = 0.55 mm (UF = 33%). Differentiated for x-aligned specimens the mean deviations and UF were L = 1.33 mm (UF = 66%), W = 0.57 mm (UF = 29%) and H = 0.34 mm (UF = 17%). The CUF per specimen was X1 = 39%; X2 = 32%; X3 = 32% and X4 = 47%. And for y-aligned specimens: L = 0.88 mm (UF = 44%), W = 0.76 mm (UF = 38%) and H = 0.99 mm (UF = 49%). The CUF per specimen was Y1 = 31%; Y2 = 45%; Y3 = 45% and Y4 = 54%. With increased reach, the overall CUF of both alignments and three dimensions increased from 35% to 50%.

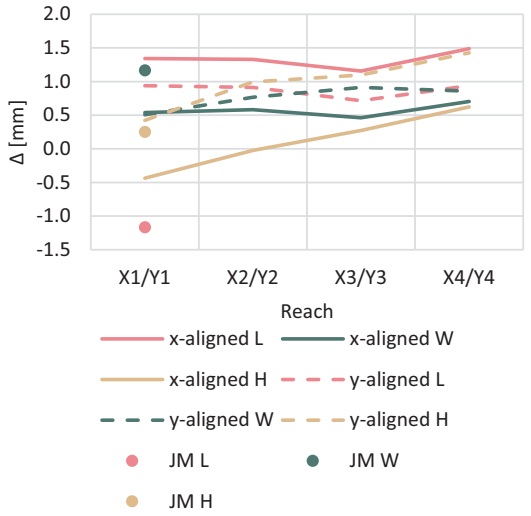

Figure 11: *Nominal-actual deviations and reach for x- and y-aligned specimens of series B as lines and JM reference values as points. Length deviations are marked red, width deviations green and height deviations brown.*

4.2.2 QDV

The QDV assessment was also conducted for Series B with the results displayed in Figure 12 with, as in Series A, the mean results of the two JM specimens also included. The mean QDV of Series B equals 19.52 (maximum value 42), with the x-aligned specimens showing a higher value with 20.55 and therefore more deviations, while the y-aligned show a value of 18.48 (10% difference). The total mean surface roughness is R_a = 4.1 µm, with again the x-aligned specimens showing higher values than the y-aligned specimens with 4.6 µm and 3.7 µm, respectively. The inspection of the short sidewall areas shows a sum over all four specimens and two values (lateral criterium and optical and haptic surface roughness) of QDV = 19 for x-aligned specimens and QDV = 20 for y-aligned indicating slightly higher deviations for y-aligned specimens.

In Figure 13 the QDV of Series B is plotted against the four positions with different reaches for both, the x- and y-aligned specimens. The trend line indicates rising QDV with increased reach implicating more deviations for both alignments. Further, the y-aligned specimens show lower QDV than the x-aligned. As a reference the mean QDV of the JM specimens is marked brown. All specimens of Series A and B except one (x-aligned reach 4) are below those of the JM.

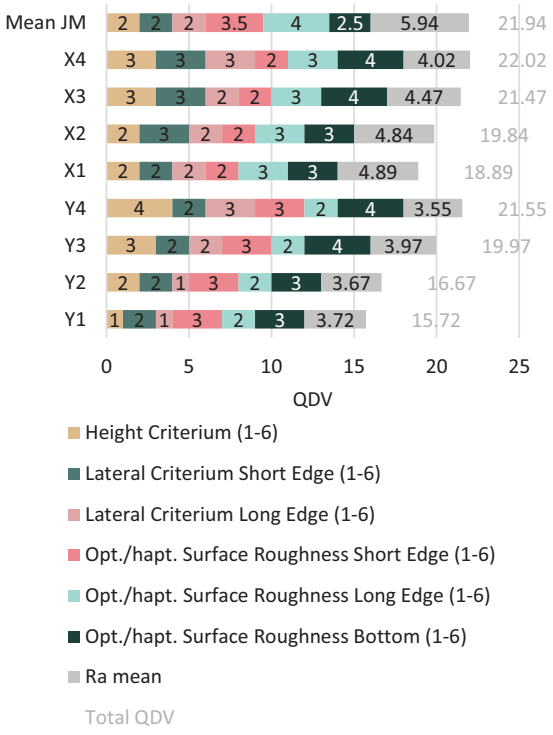

Figure 12: *Quality deviation value (QDV) of individual specimens of Series B. Higher QDVs represent more deviations and irregularities.*

When inspecting the results of the profile line scans, presented in Figure 14, the previously reported change in the pocket depth with varied reach becomes visible. It should however be noted that the height deviations listed

https://doi.org/10.52202/069179-0082

in Figure 11 were measured relative from the bottom to upper edge of the specimens while Figure 14 displays global height differences that could be affected by an uneven workpiece and worktable. The images in Figure 14 are primarily a valuable tool to trace tool marks and irregularities such as fuzzy grain defect that is visible in at least one spot of every specimen where tool trajectories overlap. The bottom pocket machined with a reach of 1806 mm (X1) shows two spots with fuzzy grain defects. Torn fibre defects occur within the specimens with maximum reach in the bottom right corner of the pocket.

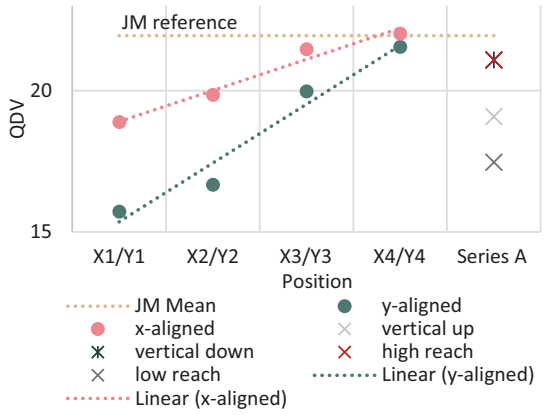

Figure 13: *Quality deviation value (QDV) of x- and y-aligned specimens of Series B. Additionally, Series A values are marked with crosses and the reference specimens machined by JM are marked as lines. Higher QDVs represent more deviations and irregularities.*

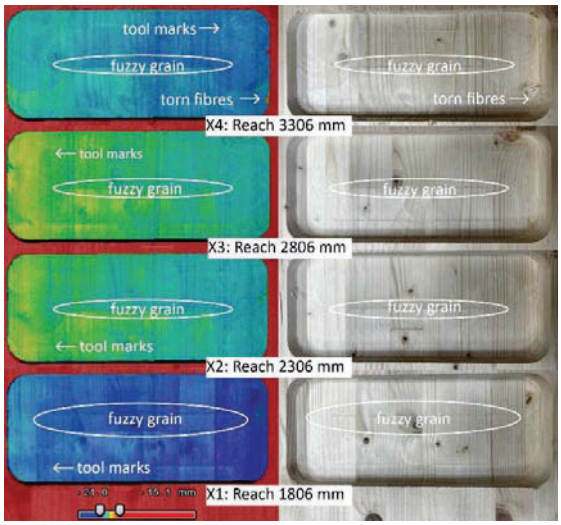

Figure 14: *Topography (left) and photographs (right) of series B x-aligned. The reach was increased from bottom to top. Note: The displayed height is global height difference between sensor and specimen.*

5 DISCUSSION

5.1 General

The dimensional deviations of all specimens of Series A apart from Short reach height and B are within the regulations´ margins defined in ÖNORM EN 14080 [10] with a maximum of -2 mm (UF = 100%).When comparing the dimensional deviations of the IR machined Series A (mean deviations L = 1.85 mm, W = -1.47 mm, H = -0.33) and B (mean deviations L = 1.10 mm, W = 0.67 mm and H = 0.55 mm). with the JM (mean deviations L = 1.17 mm, W = -1.17 mm and H = 0.25 mm) machined references, the results of the JM are more evenly distributed around zero deviation while having a similar span (span IR = 2.44 mm, span JM=2.33 mm). Overall, the achieved machining quality can be considered as sufficiently high with mean deviations of the JM = 0.86 mm as a reference and with slightly higher deviations with Δ = 0.19 mm the mean deviations of the IR = 1.05 mm. The QDV of all except one IR machined specimen is lower than for the JM machined indicating less irregularities. However, the IR tools were previously sharpened as the tool wear of the JM is not known. The main conclusion is therefore that the required machining accuracy and surface quality can be maintained in all positions and reaches when applying the machining parameters validated by previous studies [3], [4]. In addition, the results are equal to those of JMs.

5.2 Series A

When comparing the IR-machined Vertical and Overhead specimens the dimensional deviations in length and width are smaller when machining vertical (ΔL = 0.34 mm, ΔW = 0.15 mm). The nominal-actual difference of height is smaller when machining overhead compared to Vertical (ΔH = 0.49 mm), Short Reach and Long Reach (ΔH = 0.09 mm). Reason for this can be the different robot axis configuration of the compared positions leading to smaller deviations when milling forces are introduced. Another reason can be found in the robot or workpiece support system which is loaded in two opposite directions while machining as lifting and pressing forces can cause different system reactions such as vibrations.

If the QDV is factored in, the previous explanation of smaller horizontal deviations but larger height differences is reinforced by the QDV of the Vertical specimens. At a closer look the larger height deviation when machining vertical is also represented in the QDV height criterium where the vertical value is double that of the overhead manufacturing. When the QDV optical and haptic surface roughness values are inspected, indicating higher values for the sidewalls of the Overhead specimen, the thesis of robot or support system reactions such as vibrations can be underlined. When comparing the QDV of JM with IR specimens, the JM with 21.94 shows 2.31 points (11%) higher results than the IR with 19.63.

The 3D scans show no significant difference between most areas, except for sidewall a. This goes hand in hand with the QDV optical and haptic surface roughness inspection of the short edge and the large length deviation of the overhead specimen which affects the short edge as well. Altogether the mentioned factors indicate lower machining quality for the Overhead compared to the Vertical machined specimen.

During the comparison of short and long reach specimens no significant difference of the dimensional deviations can be identified. On the one hand, the QDV of the short reach specimen is noticeably higher with variance

predominantly in the lateral criteria of the short and long edge.
When inspecting the 3D point clouds, this can statistically not be confirmed. On the other hand, the point cloud indicates a statistically significant difference between the short and long reach bottom areas which cannot be supported by neither the dimensional nor QDV analysis. To sum up the comparison between short and long reach, there is no difference in dimensions but in surface quality favouring the long reach position.
When the 3D point cloud assessment method is applied, the results can be evaluated from two different perspectives. From the timber machining point of view, the deviations are on a scale that is almost irrelevant for practice but conclusions like tool marks and wood defects can be drawn. From the geodetic perspective there is a need of development of a testing strategy similar to the Wilcoxon rank-sum test that fits the quality assessment of both domains.

5.3 Series B

When the reach is increased, the height deviation of both, x- and y-aligned specimens increased (mean increase = 1.03 mm) while length (mean increase = 0.28 mm) and width (mean increase = 0.32 mm) deviations are subject to measuring noise. This effect can be traced back to both, the robot accuracy as well as the inaccurate alignment of the worktable coordinate system that determines workpiece placement. The total QDV is also affected by the reach and increases almost linearly with rising reach (mean increase = 4.48 points). The increased height deviations with rising reach can be supported by the QDV height criterium for both alignments. When looking into detail of the laser profile scans and optical inspection of the specimens, fuzzy grain defect occur more often at short reach, while torn fibre defects are sighted more frequently at high reach. Apart from all that, the tool marks get clearer with increased reach.
The main difference between the milling of x- and y-aligned pockets is, that the turning point of the trajectories requires the robot to primarily change its reach (y-aligned) or to change its lateral position and rotate (x-aligned). In the case of x-aligned specimens, there is not only motion straight in the direction of the reach but also lateral, allowing mass inertia to gain relevance. This is clearly visible in the results, with the larger deviations in length for the x-aligned specimens compared to the y-aligned ones. The investigation of QDV values does support this argument with slightly higher lateral criterium short edge values for the x-aligned specimens. The width measurements on the other hand show similar deviations at minimum and maximum reach. The smaller lateral criterium long edge values indicate less geometrical irregularities of the long edge when they are x- aligned.
The measurement of the average surface roughness R_a indicates a surface with less deviations when machining y-aligned specimens due to the fact that the robot is primarily moving along one direction parallel to the y-axis.

6 CONCLUSION

This study proves that the larger workspace - one of the main benefits of IRs compared to JMs - can be fully utilised without loss in milling accuracy. The required machining quality measured by dimensional deviations is within the margins of both regulations and the JM produced reference specimens. The surface quality of the IR-machined specimens, in the vast majority of cases, remains higher than the JM-produced reference specimens. To sum up, the following observations need to be particularly highlighted:

- The required machining accuracy and surface quality can be maintained in all investigated positions of Series A and B and levels of reach while the results are of higher or equal quality compared to those of a JM.
- The comparison of vertical and overhead machining of Series A reveals slightly higher quality results in terms of horizontal dimensions and surface quality for vertical machining.
- When comparing the opposite short and long reach specimens of Series A, no clear dimensional difference was found, yet the surface quality was higher when machining long reach specimens.
- The dimensional deviations, surface deviations and irregularities (QDV) of specimens machined with identical tool orientation increases when the robots´ reach is increased.
- The dimensional and surface (QDV) quality is decreased when the robot machining trajectories are primarily lateral (x-aligned) compared to primarily longitudinal (y-aligned).

Further research is planned on the machining accuracy of different robot positions in the workspace. For this the location of the tool centre point tracked by ABB´s online signal analysis will be compared with the accuracy of machining results measured by the laser profile scanner.

ACKNOWLEDGEMENT

The authors would like to show their gratitude to Rubner Holzbau GmbH, Leitz GmbH & Co. KG and the Research Unit of Engineering Geodesy at TU Wien for the cooperation. The project is grant by the Austrian Research Promotion Agency (FFG) (project no. 878081).

SHEAR THROUGH THE THICKNESS PROPERTY OF SCREW LAMINATED CROSS LAMINATED TIMBER

Shiro Nakajima[1]

ABSTRACT: This paper focus on the shear through the thickness properties of screw laminated cross laminated timber. The shear through the thickness properties of screw laminated cross laminated timber was verified from the results of the shear through the thickness test. Four test specimens with different joint configuration and one test specimen with opening were tested to verify the effect of the number of joints and the length from the screwed joints to the center point of an over wrapping part of the laminations i.e. the length of the moment arm. The test results indicated that the shear through the thickness properties of screw laminated cross laminated timber depends on the number of screwed joints and the length of the moment arm. To estimate the shear through the thickness properties of screw laminated cross laminated timber a structural model and a calculation method were proposed. The load deformation curve of the screw laminated cross laminated timber derived from the proposed structural model and calculation method well estimated the test results at relatively small deformation level. The force caused by the embedment between the laminations brought a difference at the relatively large deformation level.

KEYWORDS: Shear through the thickness, Screw joint, Cross laminated timber, Structural modelling

1 INTRODUCTION

Cross laminated timber (CLT) is composed of sawn boards cross laminated and jointed with glue. The gluing procedure in manufacturing CLT requires high quality control to confirm adequate performance of gluing. And gluing also requires heavy-duty manufacturing facilities. Alternative methodologies for jointing sawn boards such as using mechanical joints will provide the possibility to simplify the manufacturing procedure of CLT and give a chance for relatively small mills to produce CLT.

The bending behaviour of nailed jointed CLT is reported by Sung-Jun Pang et.al [1]. And in Europe the Massiv-Holz-Mauer (MHM) is manufactured and the characteristic values of the panels are evaluated by European Technical Assessment [2]. To provide design methodologies and characteristic values for CLT composed of mechanically jointed laminations it is important to accumulate data and knowledge. This paper focus on the shear through the thickness properties of screw laminated cross laminated timber (SL-CLT). Screw laminated cross laminated timber discussed in this paper is illustrated in Figure 1. The screw laminated cross laminated timber discussed in this paper is composed of lumbers of domestic species and the laminations are jointed with structural screws. The shear through the thickness properties of SL-CLT was verified from the results of the shear test. And the structural model and calculation method to evaluate the shear through the thickness properties of SL-CLT was proposed.

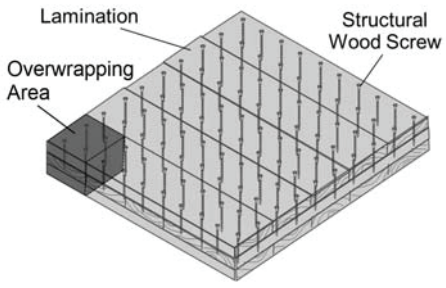

Figure 1: *Screw laminated cross laminated timber (SL-CLT)*

2 SHEAR THROUGH THE THICKNESS TEST

2.1 TEST SPECIMENS

The test specimens are composed of 3 layers of laminations. Each layer is composed of 15 laminations (sawn boards) sized 1800mm in length, 120mm in width and 30mm in thickness (see Figure 2). The species of the lumbers is Japanese Cedar (*Cryptomeria japonica*) of averaged MOE 9.76 (GPa). The detail characteristic

Table 1: *Characteristic values of the lumber*

	Average	Standard deviation
Density (kg/m^3)	386	35.8
MOE (kN/mm^2)	9.75	1.62
Moisture Contents (%)	10.0	1.30

[1] Shiro Nakajima, University of Utsunomiya, Japan, s-nakajima@cc.utsunomiya-u.ac.jp

https://doi.org/10.52202/069179-0083

values of the of the sawn boards composing the test specimens are given in Table.1.

Laminations of adjoining layers are jointed with structural wood screws 5mm in diameter and 80mm in length. The overwrapping parts of the adjoining laminations were jointed with 4 wood screws. The location of the joints is illustrated in Figure 2. There are two different joint configurations, Type A and Type B. Joint Type A has an edge distance of 20mm and for this edge distance the length of the moment arm is approximately 56.6mm. In this paper the moment arm is defined as the distance from the center of the overwrapping part of the adjoining laminations to the wood screw joints. For Type B the edge distance is 30mm and the length of the moment arm is approximately 43.4mm.

For test specimens Type 1 all the part the adjoining laminations overwrap are jointed with four structural wood screws. For test specimens Type 2 half of the overwrapping part are jointed with four structural wood screws. The number of wood screws used to compose the test specimen is 900 for test specimen Type 1 and 452 for test specimen Type 2. Test specimen Type 3 has an opening at the center of the panel and every overwrapping part are jointed with four structural wood screws.

Five types of test specimens with different combination of length of the moment arm, number of screw joints and existence of the openings were prepared and tested. The configuration of the five test specimens is given in Figure 3. All the overwrapping part of the laminations are jointed for test specimen A1 and B1 and the difference between the two test specimens is the length of the moment arm 56.6mm for A1 and 43.4mm for B1. And almost half of the overwrapping part of the laminations are jointed for test specimen A2 and B2 and the length of the moment arm is 56.6mm for A2 and 43.4mm for B2. Test specimen A3 has an opening at the center of the panel and the length of the moment arm is 56.6mm. All the overwrapping part of the laminations are jointed for test specimen A3.

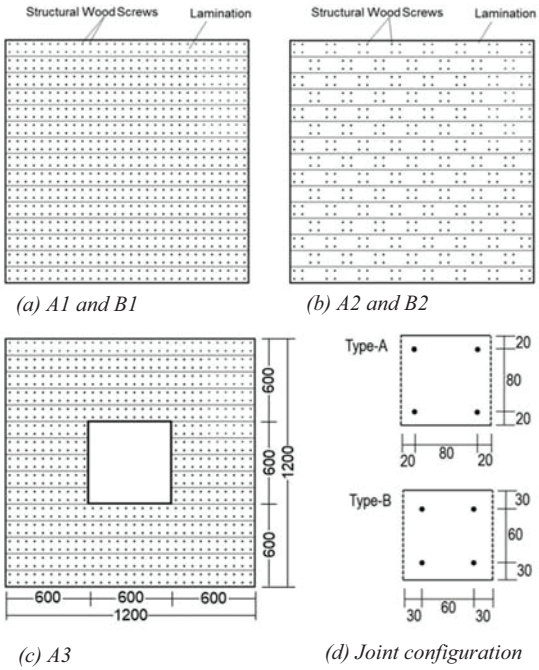

Figure 3: *Type and symbol of the test specimens*

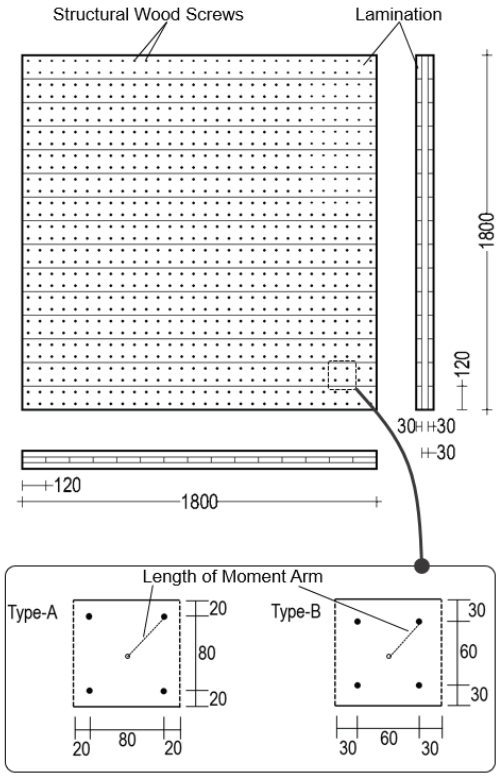

Figure 2: *Configuration of the test specimens*

Note: *The figures in the square line shows the configuration of the joints at the overwrapping part of the laminations.*

2.2 TESTING METHOD

The setup of the shear through the thickness test is given in Figure 4. The out most layer of the laminations located at the top and bottom of the test specimens are extruded to a certain length to setup the test specimens to the testing facilities. And a girder was put on the top of the test specimens to adequately load to the test specimens. The left and right end of the girder were connected to the base frame of the testing equipment by tiedown rods.

Reverse cyclic load was applied to the top of the test specimens. Three repetitive reverse cyclic load was applied at the shear deformation level of approximately $1.67x10^{-3}$ (1/600) rad, $2.22x10^{-3}$ (1/450) rad, $3.33x10^{-3}$ (1/300) rad, $6.67x10^{-3}$ (1/150) rad, $10.0x10^{-3}$ (1/100) rad, $13.3x10^{-3}$ (1/75) rad, $20.0x10^{-3}$ (1/50) rad, $33.3x10^{-3}$ (1/30) rad. And after this cyclic loading the test specimens were loaded to the shear deformation level $83.3x10^{-3}$ (1/15) rad.

The horizontal displacement of the top and bottom of the test specimens were measured and the vertical

https://doi.org/10.52202/069179-0083

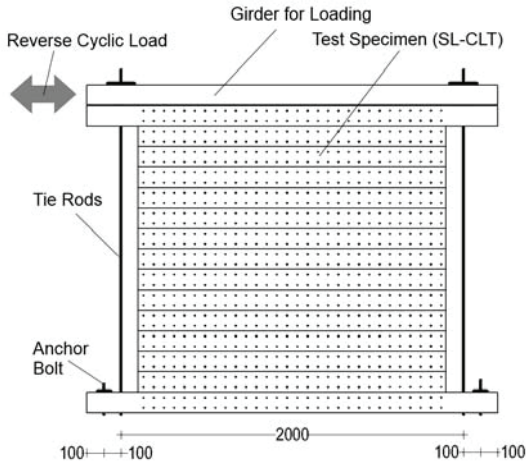

Figure 4: *Setup of the shear through the thickness test*

displacement at both left and right bottom of the test specimens were also measured. The rotation angle of the adjoining laminations was also measured at the vertical cut side of the test specimens.

3 TEST RESULTS

3.1 LOAD DEFORMATION CURVE

The envelope curves of the load deformation curves are given and compared in Figure 5. With an exception for test specimen A1 in general test specimens with longer moment arm length had higher load carrying capacity. And in general, the load carrying capacity was proportional to the number of joints.

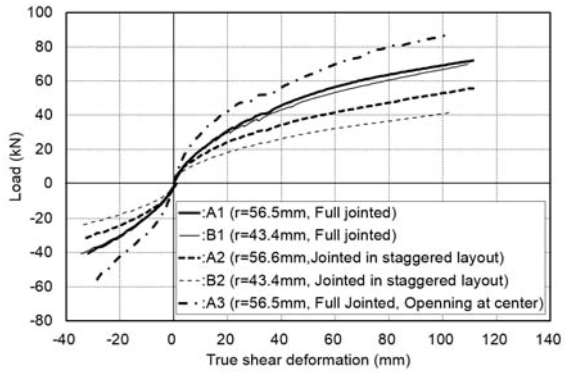

Figure 5: *Envelope curves of the load deformation curves*

Note: *True shear deformation (δ_{true})is calculated by the following formula.*

$$\delta_{true} = \left(\frac{\delta_{h-top} - \delta_{h-bottom}}{H} - \frac{\delta_{v-act} - \delta_{v-free}}{L} \right) \times H$$

Where, $\delta_{h\text{-}top}$ is horizontal displacement at the top of the test specimen,
$\delta_{h\text{-}bottom}$ is horizontal displacement at the bottom of the test specimen,
$\delta_{v\text{-}act}$ is vertical displacement of the bottom edge the loaded side of test specimen,
$\delta_{v\text{-}free}$ is vertical displacement of the bottom edge the unloaded side of test specimen,
H is the hight of the test specimen,
L is the length of the test specimen.

3.2 LOAD DEFORMATION CURVE

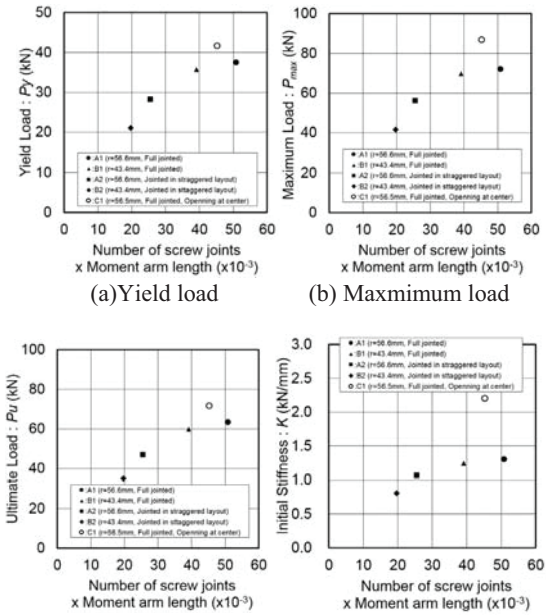
The yield load (*Py*), maximum load (P_{max}), ultimate load (*Pu*) and initial stiffness (*K*) are given in Table 2. Each characteristic value is assumed to has a positive correlation with the value obtained by multiplying the length of moment arm multiplied and the number of joints.

Table 2: *Characteristic values of the SL-CLTs*

Test specimens	Characteristic values			
	Py (kN)	P_{max} (kN)	*Pu* (kN)	*K* (kN/mm)
A1	37.5	71.9	63.2	1.30
B1	35.8	69.8	60.0	1.25
A2	28.2	56.1	46.8	1.06
B2	21.1	41.5	35.1	0.81
A3	41.6	86.7	71.6	2.20

Note: *Maximum load (P_{max}) is the load measured when the specimens had the true shear deformation of $6.67x10^{-3}$ rad..*

The relationship between the values above mentioned and the characteristic values is given in Figure 6. With an exception for test specimen A1 the yield load, maximum load and ultimate load had a positive correlation with the value obtained by multiplying the moment arm length and the number of joints. And with an exception for test



(a)Yield load (b) Maxmimum load

(c) Ultimate load (d) Initial stiffness

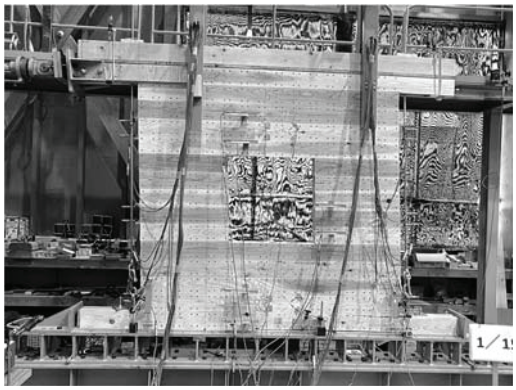
Figure 6: *Relationship between each characteristic value and the value obtained by multiplying length of moment arm and number of joints*

https://doi.org/10.52202/069179-0083

specimen A1 and B1 the initial stiffness had a positive correlation with the value obtained by multiplying the moment arm length and the number of joints.

3.3 DEFORMATION OF THE TEST SPECIMEN

Deformation of the test specimen A3 is shown as an example in Photo 1. The photo shows the deformation of the panel when the top of the panel was deformed to 120mm. Slippage can be observed between he vertically adjoining laminations.



(a) Deformation of the SL-CLT panel

(b) Slippage between the vertically adjoining laminations

Photo 1: *Deformation of the SL-CLT panel A3*

4 ESTIMATION OF LOAD DEFORMATION CURVE

4.1 MODELING AND CALCULATION

The deformation of the overwrapping parts of the screw laminated CLT subjected to in-plane shear force can be model as shown in Figure 7.
When the SL-CLT panel has a shear deformation angle θ (rad) the deformation of the top of the panel x (mm) can be calculated by equation 1.

$$x = \theta \cdot (n \cdot H_{element}) \tag{1}$$

Where n is the number of lamination in vertical direction and $H_{element}$ is width of the lamination.
When the shear deformation angle of the panel is θ (rad) the shear force $F(\theta)$ (kN) generated at the screw joints can be calculated as equation 2.

$$F(\theta) = K_S(\theta) \cdot r \cdot \theta \tag{2}$$

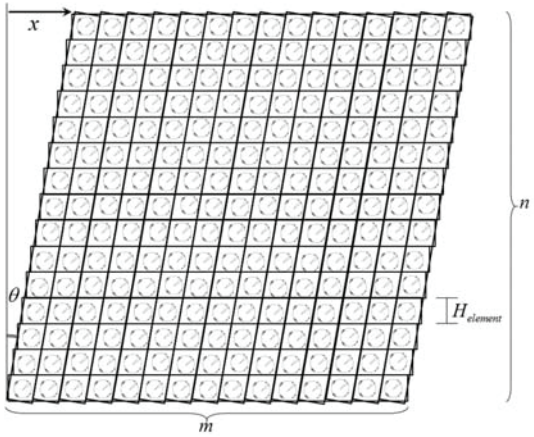
Where $K_s(\theta)$ is shear stiffness of the screw joints at the shear deformation angle θ (rad) and r (mm) is the length of the moment arm.
The internal energy consumption ($E_{INT}(\theta)$) caused by the shear deformation at a single screw joint can be calculated as equation 3.

$$E_{INT}(\theta) = \int_{\theta 1}^{\theta 2} F(\theta) \cdot \theta d\theta = \int_{\theta 1}^{\theta 2} K_S(\theta) \cdot r\theta d\theta \tag{3}$$

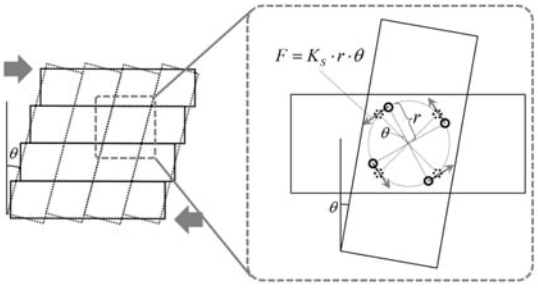
The number of screw joints N_s can be calculated by equation 4.

$$N_S = m \cdot n \cdot 4 \tag{4}$$

Where m is the number of lamination in horizontal direction, n is the number of lamination in vertical direction and 4 is the number of screw joints existing at one overlapping part. By inserting equation 4 to equation



(a) Stuructral model for SL-CLT



(b) Detail of the model

Figure 7: *Structural modelling of SL-CLT*

https://doi.org/10.52202/069179-0083

3 the internal energy consumption for the entire panel $E_{INT\text{-}total}(\theta)$ that is the energy consumed at all screw joints can be calculated as equation 5.

$$E_{INT-total}(\theta) = m \cdot n \cdot 4 \cdot \int_{\theta 1}^{\theta 2} K_S(\theta) \cdot r\theta d\theta \quad (5)$$

The external energy consumption $E_{EXT}(\theta)$ caused by the shear deformation θ (rad) of SL-CLT panel can be calculated as equation 6.

$$E_{EXT}(\theta) = \int_{x1}^{x2} P(x) \cdot x dx = \int_{\theta 1}^{\theta 2} P\{\theta \cdot (n \cdot H_{element})\}\{\theta \cdot (n \cdot H_{element})\} d\theta \quad (6)$$

Where P is the load applied at the top of the SL-CLT panel. As $E_{INT\text{-}total}(\theta)$ is equal to $E_{EXT}(\theta)$ and the stiffness of the screw joint at a certain deformation level θ is known the load necessary to apply at the top of panel to give a certain deformation at the top of the panel can be calculated.
By conducting an incremental displacement analysis, the load deformation curve of the SL-CLT panels was estimated.

4.2 LOAD DEFORMATION CURVE OF THE SCREW JOINT

The load deformation curve of the screw joint was derived from the test results of the joints. When a torsional deformation occurs at the overwrapping part of the adjoining laminations the screw joints will deform at an angle of 45 degrees against the grain direction of wood. The load deformation curve for screw joint loaded at an angle of 45 degrees was estimated by the test results of screw joints loaded at parallel to grain and perpendicular to gran.
Figure 8 gives the load deformation curve of the screw joints. The load deformation curve for screw joint loaded at an angle of 45 degrees was calculated by the Hankinson's formula.

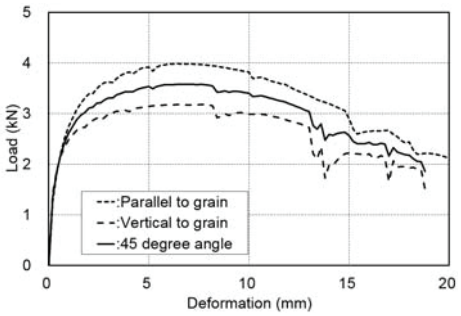


Figure 8: *Load deformation curve the screw joints*

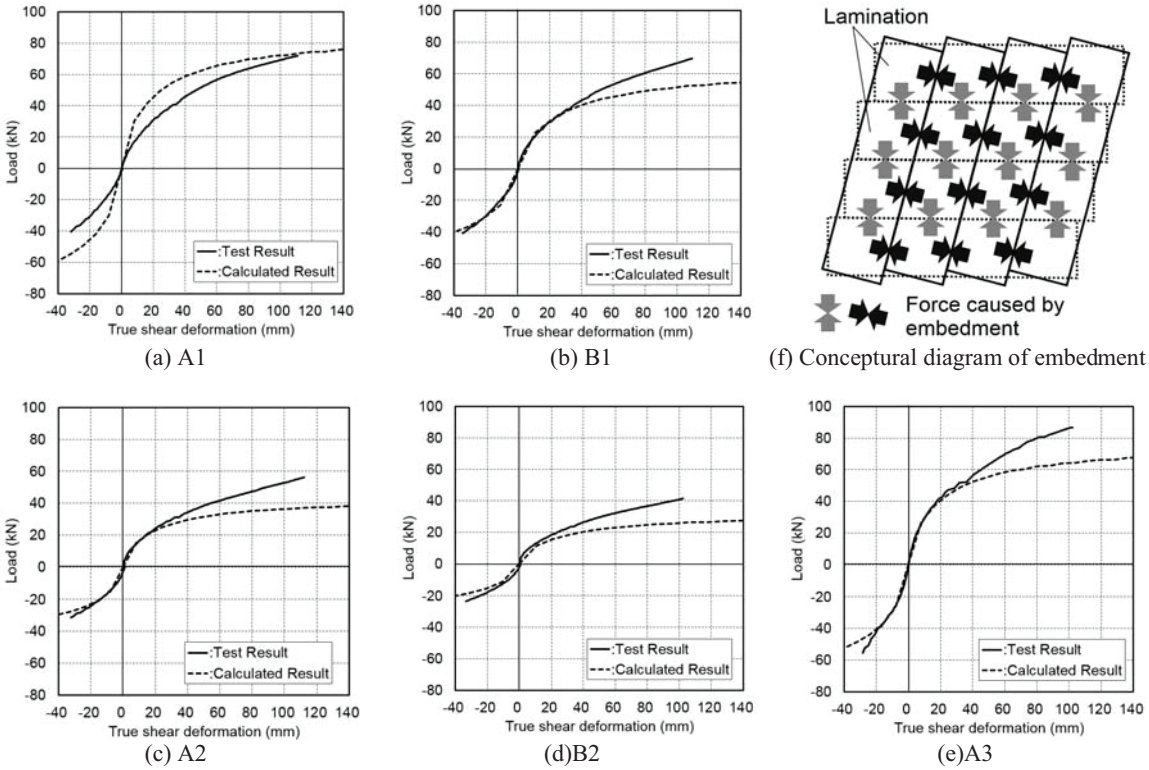
4.3 RESULTS OF CALCULATION

The results of the calculation are given in Figure 9 in comparison with the test results. With an exception for test specimen A1 the calculated load deformation curve well estimated the test results at deformation level



(a) A1 (b) B1 (f) Conceptural diagram of embedment

(c) A2 (d)B2 (e)A3

Figure 9: *Load deformation curve, comparison of experimental results and calculated results*

https://doi.org/10.52202/069179-0083

approximately up to 20mm. Though the load was under estimated when the deformation was approximately 20mm or more. The difference between the calculated load and measured load increased as the deformation increased. The reason for this difference is assumed as follows. When the shear deformation of the SL-CLT increase the gap between the laminations next to each other decrease. And as a result embedment will occur on the side face of the laminations. And the force derived by this embedment will increase as the shear deformation increase. Due to this embedment the load deformation curve calculated only by considering the force derived from the screw joints under estimate the load. The conceptual diagram of the embedment of laminations is given in Figure 9.

The difference between the measured and calculated load deformation curve of test specimen A1 was caused by the high moisture content of the lumbers composing the laminations. The test specimen A1 was manufactured with wet lumbers due to bad storage condition. And the lumbers dried and shrunk after being connected with structural wood screws. Small cracks may propagate and decreased the load carrying capacity of the joints but to conclude the correct reason further test should be conducted.

5 CONCLUSION

The shear through the thickness properties of screw laminated CLT was clarified through testing and the effect of the joint configuration on the shear stiffness was evaluated. A structural model and calculation method was proposed to estimate the load deformation curve. The proposed structural model and calculation method well estimated the load deformation relationship at a relatively small deformation level though at larger deformation level the load was under estimated. The force derived from the embedment between the laminations is supposed increased the load and led this under estimation. A model including the embedment characteristic of the laminations should be considered to accurately estimate the load deformation relationship of SL-CLT.

BIRCH FOR ENGINEERED TIMBER PRODUCTS :: PART II

David Obernosterer[1], Georg Jeitler[2], Gerhard Schickhofer[3]

ABSTRACT: Even though birch (*Betula pendula*) is one of the main tree species in the north of Europe, it is currently hardly used for structural products, except plywood. Due to its excellent mechanical properties, the HASSLACHER group decided to see it as a future tree species for their products. In a series of projects, the material was characterised and products like Glued Laminated Timber (GLT) or Cross Laminated Timber (CLT) made from birch were developed and tested. To improve the properties of the material, a new type of lamella was developed and tested, the so-called "Strip Lamella". By using homogenisation effects, the characteristic values of the mechanical properties were strongly improved compared to birch solid wood lamellas. First tests on GLT beams out of Strip Lamella show, that this effect not only occurs in the lamella, but also in structural timber products using this lamella, leading to higher properties compared to birch solid timber GLT.

KEYWORDS: birch, hardwood, Strip Lamella, homogenization

1 INTRODUCTION

Spruce, by far the main wood species in timber construction in Europe, is under high pressure. Droughts, storm and heavy snowfalls weaken the European spruce forests, followed by enormous bark beetle attacks. In Austria, some mountain areas are already cleared prophylactically from any spruce growing there, because it is just a matter of time until they will be infested.

Meanwhile the demand for structural timber products is constantly increasing. To be able to sustainably meet this demand in the future, new strategies are needed. There are different ways to cope with these challenges:

- **Production efficiency** could be **increased**, by better production techniques or less resource-intensive new products.
- **Old timber elements** from demolished buildings could go into **Reuse** instead of being downcycled to particleboards immediately or even being burned.
- Use of **new timber species** for structural timber products, to increase the resources available for sawmilling industry.

All topics are important to further increase the share of timber buildings while maintaining a sustainable use of forests in Europe. This paper will especially focus on the last one, the use of a new timber species which can create new opportunities in the timber construction industry.

Birch (*Betula pendula*) is one of the main wood species in Russia (11,023 Mio. m³), Scandinavia (817 Mio m³) and the Baltic States (325 Mio. m³) [1]. But birch is not only interesting for the north of Europe, also in Central European countries like Austria, Germany or the Czech Republic this wood species will be more important in the future. Currently for example there just around 6.6 Mio m³ Birch growing in Austria [2], but as the climate changes so does the forest. Especially in areas where spruce is facing more difficulties due to drought, birch-pine-forest could be of interest.

Despite these large amounts available in the north of Europe, birch is currently almost not used for structural applications, except as plywood. In a series of projects, the HASSLACHER group together with the Institute of Timber Engineering and Wood Technology and the Centre of Competence holz.bau forschungs gmbh at Graz University of Technology tried to gain more knowledge on the birch timber. Based on these findings, different products like GLT or CLT made from birch were developed [3].

But when working with new timber species, new challenges can occur. In case of using birch for structural timber products, the more difficult drying of the boards, grading and cutting efficiency due to the smaller log diameters were just some of them. Instead of trying to optimize currently existing standard methods for producing GLT and CLT made from spruce, the HASSLACHER group decided to work on new ways to face these challenges going beyond standard practices.

2 IDEA

The basic idea of the Strip Lamella, already shown e.g. in [4], is to use thinner boards (with a thickness of about 20 mm) than usually used for GLT production. The advantage of using smaller dimensions is the reduced kiln drying time (~ -65 % compared to 40 mm boards) while maintaining a higher yield in the cutting process.
The boards are then glued together to a so called "mini-GLT", which is then cut again into lamellas. The production steps are shown in Figure 1.

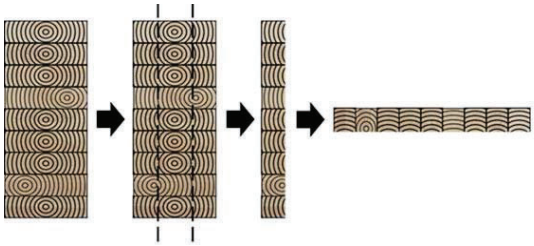

Figure 1: *Process steps of Strip Lamella production*

Despite having higher production effort due to an additional gluing and cutting step, this process is thought to have higher yield. Since production of Strip Lamellas lead to a more homogeneous product, the impact of defects from the original board is reduced. For example, a large knot with a diameter of 50 mm would reduce the strength of the original board dramatically, in the Strip Lamella it is reduced to a maximum width of 20 mm (width of strip), with straight fibres next to it in the adjacent strips.
This leads to fewer rejects when grading and eliminates any cutting of defects in the final Strip Lamella and with that to less loss in the whole production process.

3 STRIP LAMELLA TESTING

3.1 TEST MATERIAL

For production of the test specimen, boards with a dimension of 24 x 150 x 4,000 mm were dried and planed to a thickness of 20 mm. They were then graded following strength class LS7+ [5] and were glued together to a "mini-GLT"-beam with nine boards each using a two component MUF adhesive. The beams were then cut into three lamellas with a dimension of 43 x 169 x 4,000 mm as shown in Figure 1 schematically. A more detailed description of the production process can be found in [4].

As already described in [4], the Strip Lamella was divided into two groups, which were separately tested and analysed:

- **Basic:** middle lamella containing the pith and the pith-near areas, juvenile wood
- **Premium:** outer lamellas without pith, mature wood

Part of the Strip Lamellas produced were cut into shorter sections and finger-jointed together using a two component MUF adhesive.

3.2 TEST METHODS

3.2.1 Tensile Tests

To gain more knowledge on the mechanical properties of the Strip Lamella, tension tests were performed on specimen with and without finger-joints.

Strip Lamellas without finger-joints

For this test 159 Strip Lamellas were cut into specimen with a length of 3,000 mm, while the remaining part was used für the flatwise bending tests described in 3.2.2. The tensile tests were performed using a GEZU 850 tensile testing machine according to [6] with a free span length of 2,300 mm. The test setup and measurements are shown in Figure 2.

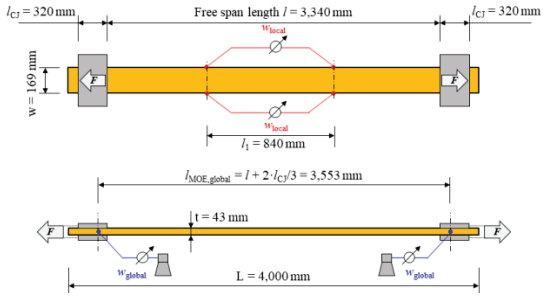

Figure 2: Setup tensile tests | Specimen without finger-joints

Strip Lamellas with finger-joints

The tests on Strip Lamellas with finger-joints were performed at Holzforschung Austria in Vienna. The samples were cut and planed to a size of 40 x 160 x 2,200 mm and were tested according to [7] with a free span length of 200 mm. The test setup can be found in Figure 3.

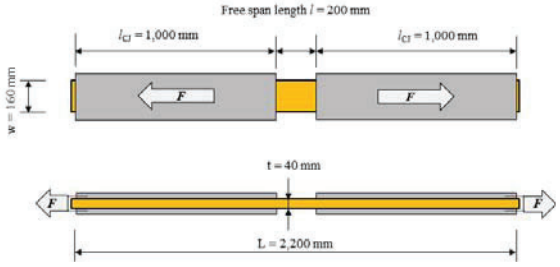

Figure 3: Setup tensile tests | Specimen with finger-joints

https://doi.org/10.52202/069179-0084

3.2.2 Bending Test

The bending tests were performed according to [6] using a Zwick Universal Testing Machine 275. To gain more insight on the bending behaviour in the two different directions, edgewise and flatwise bending tests were performed on Strip Lamellas with and without finger-joints.

Strip Lamellas without finger-joints

The test setup used for the bending tests on Strip Lamellas without finger-joints is shown in Figure 4.

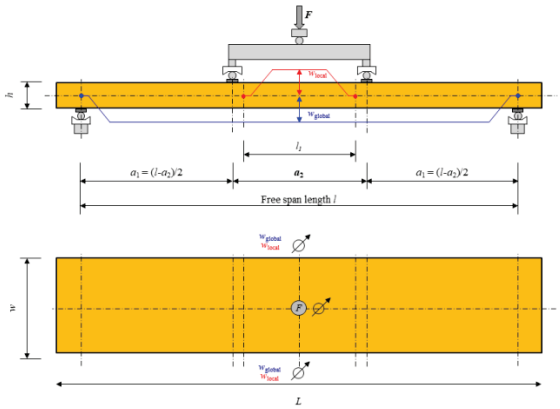

Figure 4: *Bending test setup for lamellas without finger-joint*

Since the test samples were tested flatwise and edgewise, different dimensions had to be used to fulfil the requirements according to [6]. They can be found in Table 1.

Table 1: *Dimensions for test setup of Strip Lamellas without finger-joints in flatwise and edgewise bending in [mm]*

		flatwise	edgewise
Height	h	43	169
Width	w	169	43
Length	L	816	3,211
Free span length	l	774	3,042
Distance force application	a_2	258	1,014
Distance local MOE	l_1	215	845

Strip Lamellas with finger-joints

Since it is not relevant for the characterization of finger-joints, no evaluation of the MOE was performed within these tests. The setup is shown in Figure 5.

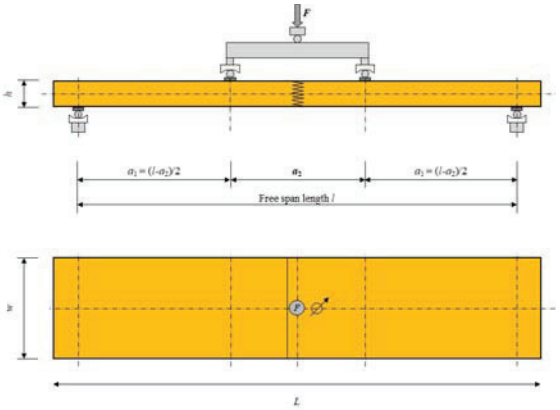

Figure 5: *Bending test setup for lamellas with finger-joint*

The finger-joint was always manufactured horizontally, so the finger-joint profile was visible on the broadside. The dimensions for the tests on Strip Lamellas with finger-joints are shown in Table 2.

Table 2: *Dimensions for test setup of Strip Lamellas with finger-joints in flatwise and edgewise bending in [mm]*

		flatwise	edgewise
Height	h	40	160
Width	w	160	40
Length	L	760	3,040
Free span length	l	720	2,880
Distance force application	a_2	240	960

3.3 Results

3.3.1 Strip Lamella

The mechanical properties of the Strip Lamellas tested are shown in Table 3. Here, the same effect as already discussed in [4] can be observed for all tests: When looking at the "Total" group containing all testes samples, the values are comparable to solid wood boards as shown in Chapter 4. By dividing into the two groups "Basic" and "Premium" according to the position in the log (juvenile vs. mature wood) as shown in Chapter 3.1 and the dynamic MOE as shown in [4], more homogeneous properties can be achieved. This leads to higher characteristic values for bending and tensile strength.

Due to the separation of juvenile and mature wood in the two different groups, also a difference in MOE can be observed, leading to almost 17,000 N/mm² in tensile testing. This shows the high potential birch can have in modern timber construction.

https://doi.org/10.52202/069179-0084

Table 3: *Results of mechanical tests on Strip Lamellas in [N/mm²]*

Results of Strip Lamella testing width: 169 mm | thickness: 43 mm				
		Total	**Basic**	**Premium**
Tensile strength	$f_{t,mean}$	43.7	35.7	47.7
	$f_{t,k}$	29.4	26.1	35.0
Coefficient of variation	COV	20.7 %	16.4 %	15.9 %
MOE	$E_{t,mean}$	15,682	13,238	16,892
Bending strength flatwise	$f_{m,flat,mean}$	81.6	68,3	88.2
	$f_{m,flat,k}$	62.5	57.5	76.4
Coefficient of variation	COV	14.2 %	9.3 %	7.9 %
MOE	$E_{m,flat,mean}$	15,184	13,422	16,084
Bending strength edgewise	$f_{m,edge,mean}$	55.4*	47.7*	59.2*
	$f_{m,edge,k}$	33.6*	33.7*	34.7*
Coefficient of variation	COV	25.3 %	17.7 %	24.8 %
MOE	$E_{m,edge,mean}$	16,523	14,331	17,591

Note: Since the gluing of the Strip Lamellas was not sufficient, the strength values in edgewise bending do not represent the full capabilities of this products but are reduced due to failures in the glue line. These insufficiencies were solved after the here presented test samples were produced and tested, further tests determining this property will follow.

3.3.2 Strip Lamella with finger-joints

The results of testing of finger-joints in Strip Lamellas presented in Table 4 show no significant difference to the values shown for the Strip Lamella itself. This leads to the conclusion, that finger-joints are not reducing the strength of the lamella itself in a critical way, which is essential for developing GLT or CLT using Strip Lamellas.

Table 4: *Results of mechanical tests on Strip Lamellas with finger-joints in [N/mm²]*

Results of Strip Lamella testing width: 160 mm | thickness: 40 mm				
		Total	**Basic**	**Premium**
Tensile strength	$f_{t,j,mean}$	52.8	42.6	58.0
	$f_{t,j,k}$	35.6	30.2	44.9
Coefficient of variation	COV	20.2 %	16.3 %	14.1 %
Bending strength flatwise	$f_{m,j,flat,mean}$	74.1	61.9	80.4
	$f_{m,j,flat,k}$	55.9	49.6	70.7
Coefficient of variation	COV	14.5 %	11.5 %	7.0 %
Bending strength edgewise	$f_{m,j,edge,mean}$	52.5	44.7	56.9
	$f_{m,j,edge,k}$	32.6	28.0	37.3
Coefficient of variation	COV	24.2 %	21.9 %	21.2 %

4 Birch solid wood lamella testing

A randomly selected part of the birch solid wood boards already described in [4] were used for testing using the same methods and dimensions as described in Chapter 3.2. Since they are not in the main focus of this paper, no further discussion will be published here on the preparation of the test samples, but it seems still absolutely relevant to show the results to be able to have a comparison of the newly developed Strip Lamella to more common birch solid wood boards.

Table 5: *Results of mechanical tests on solid wood boards in [N/mm²]*

Results of solid wood board testing width: 165 mm | thickness: 43 mm		
Tensile strength	$f_{t,mean}$	43.9
	$f_{t,k}$	24.2
Coefficient of variation	COV	31.4 %
MOE	$E_{t,mean}$	15,370
Bending strength flatwise	$f_{m,flat,mean}$	89.5
	$f_{m,flat,k}$	64.9
Coefficient of variation	COV	16.8 %
MOE	$E_{m,flat,mean}$	14,851
Bending strength edgewise	$f_{m,edge,mean}$	70.1
	$f_{m,edge,k}$	42.1
Coefficient of variation	COV	24.0 %
MOE	$E_{m,edge,mean}$	16,646

The results of the mechanical tests performed is shown in Table 5 for the solid wood boards and in Table 6 for birch solid wood boards with finger-joints.

Table 6: *Results of mechanical tests on solid wood boards with finger-joints in [N/mm²]*

Results of solid wood board testing with finger-joints width: 160 mm | thickness: 40 mm		
Tensile strength	$f_{t,j,mean}$	53.9
	$f_{t,j,k}$	36.0
Coefficient of variation	COV	21.2 %
Bending strength flatwise	$f_{m,j,flat,mean}$	72.2
	$f_{m,j,flat,k}$	55.8
Coefficient of variation	COV	13.4 %
Bending strength edgewise	$f_{m,j,edge,mean}$	61.4
	$f_{m,j,edge,k}$	36.6
Coefficient of variation	COV	26.2 %

https://doi.org/10.52202/069179-0084

5 GLT FROM STRIP LAMELLA

To further test the mechanical properties, GLT made from Strip Lamellas was produced and tested. The tests were performed at the Institute of Timber Engineering and Wood Technology in Graz.

5.1 TEST MATERIAL AND METHODS

Strip-lamellas with a width of 120 mm (≙ 6 strips) and a thickness of 40 mm were manufactured as described in Chapter 2. Since Basic and Premium lamellas were produced with a ratio of 1:2, a combined beam layup with two Premium lamellas each on top and bottom of the beam and two Basic lamellas in the middle was chosen.

The bending tests were performed according to [6] with a ratio of free span length to height of 1:16. The test setup and measurements are shown in Figure 6.

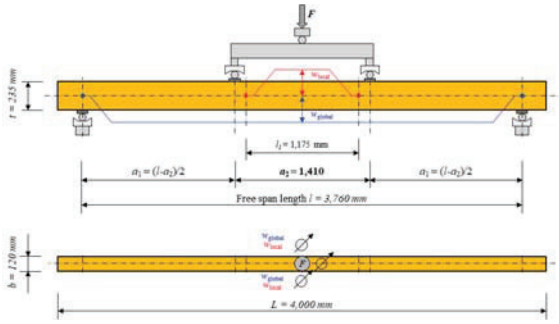

Figure 6: *Test setup for bending tests of GLT made from Strip Lamellas*

5.2 RESULTS

The results of the bending tests in Table 7 show the enormous potential of GLT out of birch Strip Lamellas. With a characteristic bending strength of almost 58 N/mm², this product exceeds the properties of solid birch GLT [8] by 80 % coming close to the values of BauBuche by Pollmeier.

Table 7: *Results of bending tests on GLT made from birch Strip Lamella*

Bending tests on GLT made from Strip Lamella		
width: 120 mm | height: 235 mm		15 specimen
Bending strength	$f_{m,g,mean}$	86.8 N/mm²
	$f_{m,g,k}$	57.8 N/mm²
Coefficient of variation	COV	8.6 %
MOE	$E_{0,g,mean}$	17,813 N/mm²
Coefficient of variation	COV	4.2 %
Density	$\rho_{g,mean}$	616 kg/m³
	$\rho_{g,k}$	557 kg/m³
Coefficient of variation	COV	1.4 %

The MOE on the other hand exceeds not just the solid birch GLT, with 17,800 N/mm² it is the highest value currently available in timber construction products.

6 CONCLUSION AND OUTLOOK

This paper shows the potential modern timber construction products have, when using birch. While current processes are sufficient to achieve very good mechanical properties in the product compared to spruce, new technologies have the chance to further increase them.

To further asses the mechanical properties of the Strip Lamella, more tests will be performed on the lamellas themselves, but also on products like GLT or CLT made from them. There will also be further investigation on connections in these new products to be able to use the in large timber buildings properly.

This will all finally lead to the application for an European Technical Assessment (ETA), to be able to have approved timber construction products.

ACKNOWLEDGEMENT

This project is funded by the Austrian Research Promotion Agency (FFG) via the program "Industrial PhD". The Dissertation is carried out at the Institute of Timber Engineering and Wood Technology at Graz University of Technology and is supervised by Univ.-Prof. Dipl.-Ing. Dr. Gerhard Schickhofer and co-supervised by Univ.-Prof. Dipl.-Ing. Dr. Johannes Konnerth from the Institute of Wood Technology and Renewable Materials at the University of Natural Resources and Life Sciences in Vienna.

INVESTIGATIONS ON MULTIFUNCTIONAL TIMBER ELEMENTS IMPREGNATED WITH PARAFFINIC PHASE CHANGE MATERIALS

Jens U. Hartig[1], Peer Haller[2]

ABSTRACT: In this contribution, investigations on multifunctional timber elements impregnated with phase change materials (PCM) are presented. The purpose of the PCM impregnation is a passive air-conditioning by structural timber elements like beams, walls or ceilings. PCM have the ability to take up substantial thermal energy within a narrow, latent temperature range without increasing their temperature. The high specific heat capacity combined with low additional mass can improve the room climate in timber buildings, which have often especially in the summer unpleasant temperature amplitudes without air-conditioning due to low thermal mass.

In order to produce large size PCM-impregnated timber elements several investigations are performed. Besides fundamental impregnation and leakage tests for several wood species, also construction related investigations are carried out. Glue-lamination is important for producing large size structural elements. Thus, different adhesives like, epoxy resin, polyurethane and phenol-based resins are tested for suitability of gluing PCM-impregnated wood. This is also a key aspect for supressing leakage on the surface of the structural element by arranging there a thin layer of not impregnated wood. Other investigations are related to the experimental determination of the mechanical behaviour of PCM-impregnated wood and the combustion behaviour.

KEYWORDS: phase change materials, glue lamination, mechanical properties, combustion behaviour, reaction to fire

1 INTRODUCTION

The use of fossil energy for thermal conditioning of buildings contributes significantly to the global warming by CO_2 emissions. There are several techniques established to reduce the energy consumption of a building for thermal conditioning like thermal insulation, shading, orientation of the building or positioning of the windows etc.

An aspect, which is often not specifically designed is thermal mass or heat capacity, although it is well known that wood buildings have especially in the summer drawbacks compared to heavy buildings made, e.g., of concrete or brick due to low thermal mass. This often results in the necessity of active air-conditioning.

Heat capacity is defined as the product of mass by specific heat capacity of the material. Thus, in order to increase the heat capacity of a building either the amount of material can be increased or a material with higher specific heat capacity can be used. With regard to limited resources, increasing mass just for the purpose of improving thermal conditions seems not to be desirable as it increases the CO_2 footprint and is usually also associated with decreasing usable space or increasing the volume of the building. On the other hand, modifying the specific thermal mass of a material is not easily possible.

However, wood has a cellular structure, which can be used for impregnation to increase the mass and depending on the specific heat capacity of the impregnation materials also the heat capacity of the building element. A special class of materials, so-called phase change materials (PCM), possess a very high specific heat capacity in a narrow temperature range and might be good candidates for impregnation of wood. Especially paraffinic PCM seem to be suitable as they are inert and do not react with the chemicals of the wood. Thus, a long endurance of the PCM is expected. Literature reviews on the impregnation of wood with PCM are given in [1],[2].

By applying PCM, a low amount of additional mass leads to a high increase of heat capacity of a timber element. Previous investigations [1],[3] showed that it is realistic to deposit about 200 kg of PCM per m³ of wood. Thus, depending on the applied wood species the mass is increased by about 30 to 50 %. At the same time, the storable thermal energy is increased in the phase transition range of the PCM by 400 to 600 % (assuming a sensible enthalpy of wood of about 20 J/g and a latent enthalpy of PCM of about 200 J/g in the range of +/- 5°C around the phase transition temperature). By placing PCM in wood elements, temperature amplitudes are passively reduced inside a room over the day by energy uptake of the PCM. By natural ventilation, the room temperature can be decreased over the night below the phase change temperature of the PCM and the stored thermal energy is released.

Most of the previous investigations from literature concentrate on the application of PCM-impregnated wood for interior elements without structural functions like

[1] Jens U. Hartig, Technische Universität Dresden, Germany, jens.hartig@tu-dresden.de
[2] Peer Haller, Technische Universität Dresden, Germany, peer.haller@tu-dresden.de

https://doi.org/10.52202/069179-0085

flooring [10], etc. In the current investigations, elements like beams, walls or ceilings, bearing structural loads are intended. For practical applications, several aspects need to be investigated. A selection will be addressed in this contribution and is briefly summarized in the following.

2 MATERIAL AND METHODS

2.1 IMPREGNATION OF TIMBER

Results on the impregnation of solid wood were already presented in [1]. Pressure impregnation processes in an autoclave with a maximum pressure of 0.8 MPa were carried out. In this contribution, an update is given. The used PCM is the commercially available paraffin-based PCM RT35HC produced by the company Rubitherm, Germany. Four wood species (spruce, beech, poplar and oak) were applied for the investigations. The effectiveness of the impregnation is described by the PCM uptake, which is the mass of PCM within a certain volume of wood.

2.2 LEAKAGE AND ITS SUPPRESSION

Significant leakage was observed for some wood species, which can be substantially suppressed with increasing the viscosity of the PCM [1]. As a new development, the addition of mineral particles (cement Mikrodur R-X by the company Dyckerhoff, Germany) was tested to reduce leakage with promising results. However, for improving serviceability of timber elements, leakage on the surface needs to be securely suppressed. Therefore, a not impregnated timber layer on the surface is applied, which is able to seal the surface.

2.3 HEAT CAPACITY

The specific heat capacity of the impregnated wood is measured with dynamic differential scanning calorimetry (DSC) using a device Netzsch DSC 204 F1 Phoenix. For calibration, the sapphire standard was used. By integration of the specific heat capacity over a temperature range, the enthalpy can be determined, which is a measure for the storable heat of the material in the temperature range. A detailed description of the test procedure is given in [1].

2.4 MECHANICAL BEHAVIOUR

For structural purposes, the mechanical behaviour of the impregnated timber is important. As the PCM might be available in the solid and the liquid state, the mechanical behaviour is determined for both states. As a first indicator of structural performance, three point bending tests (span 420 mm) were carried out according to DIN 52186 [4]. The dimensions of the samples were 450 mm by 20 mm by 25 mm (length by width by height). Both, clear and impregnated samples of beech, spruce and poplar were tested. The impregnated samples of beech and spruce had a PCM uptake of about 200 kg/m³. Poplar had with about 250 kg/m³ a higher PCM uptake. The tests were performed at room temperature with the PCM either in the solid state or after a conditioning of the respective samples at 50°C (60% r. h.) in the liquid state. For each parametric combination 10 samples, thus, in total 120 samples, were tested.

2.5 GLUE-LAMINATION

For producing large size structural elements of timber, glue-lamination is important. Moreover, smaller dimensions of timber pieces support impregnation and reduce the treatment time. As gluing of paraffin impregnated wood is not standardised, investigations are performed to determine effective lamination techniques. Besides the option of producing large timber elements, a high-quality glue-line also supports the sealing of the impregnated timber parts and the suppression of leakage as pointed out previously.

In order to produce engineered timber elements, the gluability of PCM-impregnated wood was investigated. As a first indicator, the shear strength of the glue line was tested corresponding to EN 205 [5], which is a lap joint tension shear test, with different commercial adhesives: an epoxy resin (Vosschemie Epoxy-BK), a phenol resol resin (Bakelite PF 0283 HL) and a one-component polyurethane adhesive (Collano Semparoc I 12 NV). Impregnated and not impregnated reference samples of beech, spruce, poplar and oak were tested. Each four impregnated and two reference samples were tested. The tests were performed at room temperature, when the PCM was in its solid state. The small sized specimens had a glued area of 10 by 20 mm² (length by width).

2.6 COMBUSTION BEHAVIOUR

The combustion behaviour of materials can be tested with a so-called cone calorimeter according to ISO 5660-1 [6]. In this test, a quadratic board shaped sample is heated at the top side. The sample is wrapped with aluminium foil to avoid the loss of leached PCM during the test, while the top side remains open. Afterwards, the sample is placed on the sample holder, which is attached to a weighing cell continuously measuring the mass of the sample during the test. Above the sample an electrical radiant heater is placed, which heats the sample continuously with 50 kW/m².

For the ignition, a spark plug is additionally placed on top of the sample. It is removed as soon as the samples starts burning. The time for ignition t_{ig} is documented for later evaluation. After ignition, the radiant heater is heating the sample for 30 minutes. Besides the continuous measuring of the weight of the sample, the oxygen content of the air, which is collected via the conical head above the sample, is determined. Based on the oxygen content of the air, the heat release by the sample is calculated. Moreover, the smoke production is determined with a photocell.

Each two samples were prepared for the wood species beech, spruce, poplar and oak, which were either impregnated with clear PCM or a PCM-cement mixture. As a reference, also clear wood samples were tested. The samples had dimensions of 100 mm by 100 mm by 30 mm (length by width by thickness). While the longitudinal material orientation was parallel to the length

https://doi.org/10.52202/069179-0085

direction, there was no special alignment of radial and tangential direction.

The PCM uptake of the samples was different depending on the wood species: the beech samples possessed an uptake of about 130-180 kg/m³, the spruce samples of about 140-180 kg/m³, the poplar samples of about 260-280 kg/m³ and the oak samples of 120-150 kg/m³. The samples were conditioned before the testing at 23°C and 50 % relative humidity.

In a second test, the combustion behaviour of a construction element was tested in a setup according to EN ISO 9239-1 [7]. The element was a three-layer wood flooring with a PCM-impregnated middle layer of 8 mm thickness. The PCM uptake was about 200 kg of PCM per m³ of wood. The PCM contained cement particles. The top layer as well as the counteracting lower layer were not impregnated and had a thickness of 3 mm and 2 mm, respectively. The middle layer and the lower layer were made of spruce. The top layer, which was coated with a commercial lacquer, was made of oak. As a reference, elements without PCM were tested. The reference elements are commercially available.

The specimens had a length of 1050 mm and a width of 230 mm. Since the flooring elements are connected mechanically in practice, these joints have to be considered also in the tests. Thus, for the PCM-impregnated and the reference elements one test with a connection in longitudinal direction and one test with joints in transverse direction were performed. During the tests, the samples were placed on a fibre cement board of 8 mm thickness.

The detailed testing procedure is given in EN ISO 9239-1 [7]. Essentially, the sample is heated for the first 10 minutes with a gas burner at one end of the sample over the entire width. After 10 minutes, the burner is turned off. The flame propagation is observed for another 20 minutes. The flame propagation at the sample is recorded over the entire testing time (1800 s).

Moreover, the smoke development is recorded. For achieving a certain fire class according to EN 13501-1 [8], a certain limit of the critical heat flux *CHF* as well as the smoke density integral $\int R$ needs to be complied. The limits for the fire classes according to EN 13501-1 [8] are summarized in Table 1.

Table 1: *Limits for fire classes according to EN 13501-1*

	Fire class			
	B_{fl}	C_{fl}	D_{fl}	E_{fl}
CHF [kW/m²]	≥ 8.0	≥ 4.5	≥ 3.0	Test acc. to EN ISO 11925-2 [9] necessary
	Smoke development			
	s_1	s_2		
$\int R$ [min·%]	≤ 750	> 750		s1, s2 only for B_{fl}, C_{fl}, D_{fl},

3 RESULTS AND DISCUSSION

3.1 IMPREGNATION AND LEAKAGE

Investigations on the impregnation of wood with PCM RT35HC and leakage of PCM out of the wood were already presented in [1],[3]. Thus, these results are only summarised here briefly. It was shown that a high PCM uptake of up to 400 kg of PCM per m³ of wood, which is close to the theoretical maximum corresponding to the available lumen, could be achieved for poplar with pressure processes. For beech, the achieved uptake is with about 250 kg of PCM per m³ of wood less, which is associated with the smaller lumen. The impregnation of beech can be carried out, in principle, by soaking. Pressure processes only decrease the necessary treatment time. Although the impregnability of spruce is worse, a PCM uptake of about 200 kg of PCM per m³ of wood was achieved with pressure processes. However, there is considerable variation in the results of spruce. Oak is very hard to impregnate and even with the applied pressure of 0.8 MPa only an uptake of about 100 kg of PCM per m³ of wood was achieved. It shall be noted that in the respective investigations, the end grain of the samples was sealed in order to simulate the behaviour for big timber elements in the industry. For smaller elements and with open end grain, higher PCM uptake can be achieved.

The addition of thermoplastic additives for increasing the viscosity and, thus, reducing leakage resulted in reduced PCM uptake. For beech and poplar, still high PCM uptake was achieved. As a new development, cement particles with a diameter of less than 5 µm were added to the PCM for reducing leakage by closing the tips of the wood cells. The achieved PCM uptake is comparable with the values when thermoplastic additives are added. Specific values are given related to the description of the other investigations.

Since the wood has a more or less open porous structure, PCM can leach out of the wood volume, which is undesirable for the practical application. The proneness to leakage depends on the wood species. Poplar shows a maximum leakage of about 10 % of the initial amount of PCM. Leakage depends on the PCM uptake, which means that with lower PCM uptake also less leakage occurs, both absolute and relative. For oak, the observed leakage was less than 10 % and, supposedly, limited to PCM in the outermost cell layers. While leakage can be reduced for both wood species by increasing the viscosity of the PCM or by addition of cement particles, a post-treatment at a temperature above the phase transition temperature allowing excessive PCM to leach is advisable and sufficient.

For spruce and beech, leakage of more than 60 % of the initial volume was observed, especially with high amounts of PCM uptake. The addition of thermoplastic or cement particles can reduce leakage significantly to less than 20 % of the initial amount of PCM in the wood. Thus, a post-treatment for leaching excessive PCM is advisable but additionally a careful sealing is necessary to avoid leakage permanently.

https://doi.org/10.52202/069179-0085

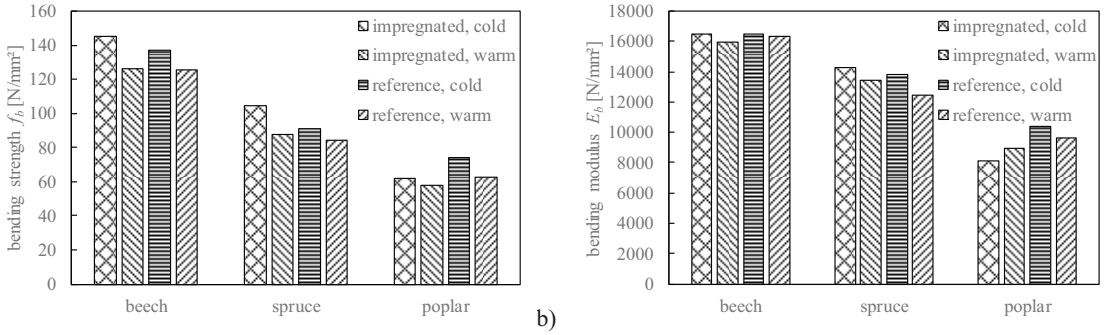

Figure 1: *Results of the bending tests; a) Bending strength, b) Bending modulus*

3.2 HEAT CAPACITY

Results regarding the determination of the heat capacity of the PCM-containing wood were already presented in detail in [1]. Thus, only a summary is given here. The determination of the specific heat capacity of PCM around the phase transition temperature is associated with some challenges due to a dependency on the applied temperature gradient and the amount of the tested material in the DSC. However, the enthalpy, which is the integral of the specific heat capacity over a temperature range, in this case the phase transition range, is independent of the temperature gradient and the amount of material.

Moreover, the enthalpy might be more useful for evaluation of the influence of the PCM on the thermal mass since it gives the total amount of storable heat around the phase transition temperature. In contrast, the specific heat capacity of PCM shows only a peak at the phase transition temperature and has before and after a value in the magnitude of the respective value of wood. Thus, the peak value is not representative for the entire temperature range in service. The results of the investigations presented in [1] show that the phase transition enthalpy of the impregnated wood is proportional to the PCM uptake.

Thus, the enthalpy of fusion or solidification of about 200 J/g of the applied PCM RT35HC and the amount of PCM in the element, i.e. the PCM uptake, can be directly used for estimating the influence on the room temperature e.g. in climatic simulations.

3.3 MECHANICAL BEHAVIOUR

Figure 1 shows the evaluation of the results of the bending tests in terms of bending strength f_b and bending modulus E_b. It can be seen that, as well known, the three wood species have different strength and elasticity values.

Moreover, the known effect of a reduction of f_b and E_b with increasing temperature is observable. In the solid state, the impregnation with PCM results in increasing f_b compared to clear wood for beech and spruce. To lower extent, this is also observable for spruce for E_b. In the liquid state of the PCM, the increase of f_b and E_b vanishes. For poplar, both f_b and E_b were smaller for the impregnated samples than the clear samples. This was also associated with a significantly more brittle failure behaviour.

For the practical application, it can be assumed that at least for the common species for construction purposes spruce and beech, the mechanical properties are not significantly influenced by the impregnation with PCM. This corresponds also to findings in [11]. For poplar, a reduced PCM uptake might result in more favourable mechanical properties and less brittleness.

3.4 COMBUSTION BEHAVIOUR

The combustion behaviour of PCM-containing wood was investigated with two different tests. Figure 2 shows the results of the cone calorimetry for the different wood species and impregnations. It can be seen that the mass of the samples decreases quasi-linearly during the combustion process. Only short before the end of the combustion an increasing mass loss rate is observable. This can be explained by a bending deformation of the samples, which results in a better access of oxygen to the bottom of the sample and an increasing burning surface.

The mass loss rate during the undisturbed combustion before bulging of the sample is approx. the same for the impregnated and the clear reference samples. Except of beech, the mass loss rate is also similar for all the wood species. Nevertheless, it can be seen that the combustion time is longer for the PCM-containing samples due to the higher total mass and has for some samples not ended at the end of the test after 1800 s. The heat release is larger for the PCM-impregnated samples than for the clear reference samples. While the heat release rate *HRR* during undisturbed combustion is except for beech approx. the same for the clear samples of the different wood species, it depends for the impregnated samples on the PCM uptake. Corresponding to the PCM uptake, *HRR* of the PCM-impregnated samples is the lowest for oak and the highest for poplar. There is no significant difference due to the addition of cement observable. The somewhat higher *HRR* for the cement-containing samples of beech can be explained by a higher PCM uptake compared to impregnated samples without cement.

Based on the measured quantities, indicators characterizing the fire ignition hazard and the provided energy for fire propagation can be calculated [12].

https://doi.org/10.52202/069179-0085

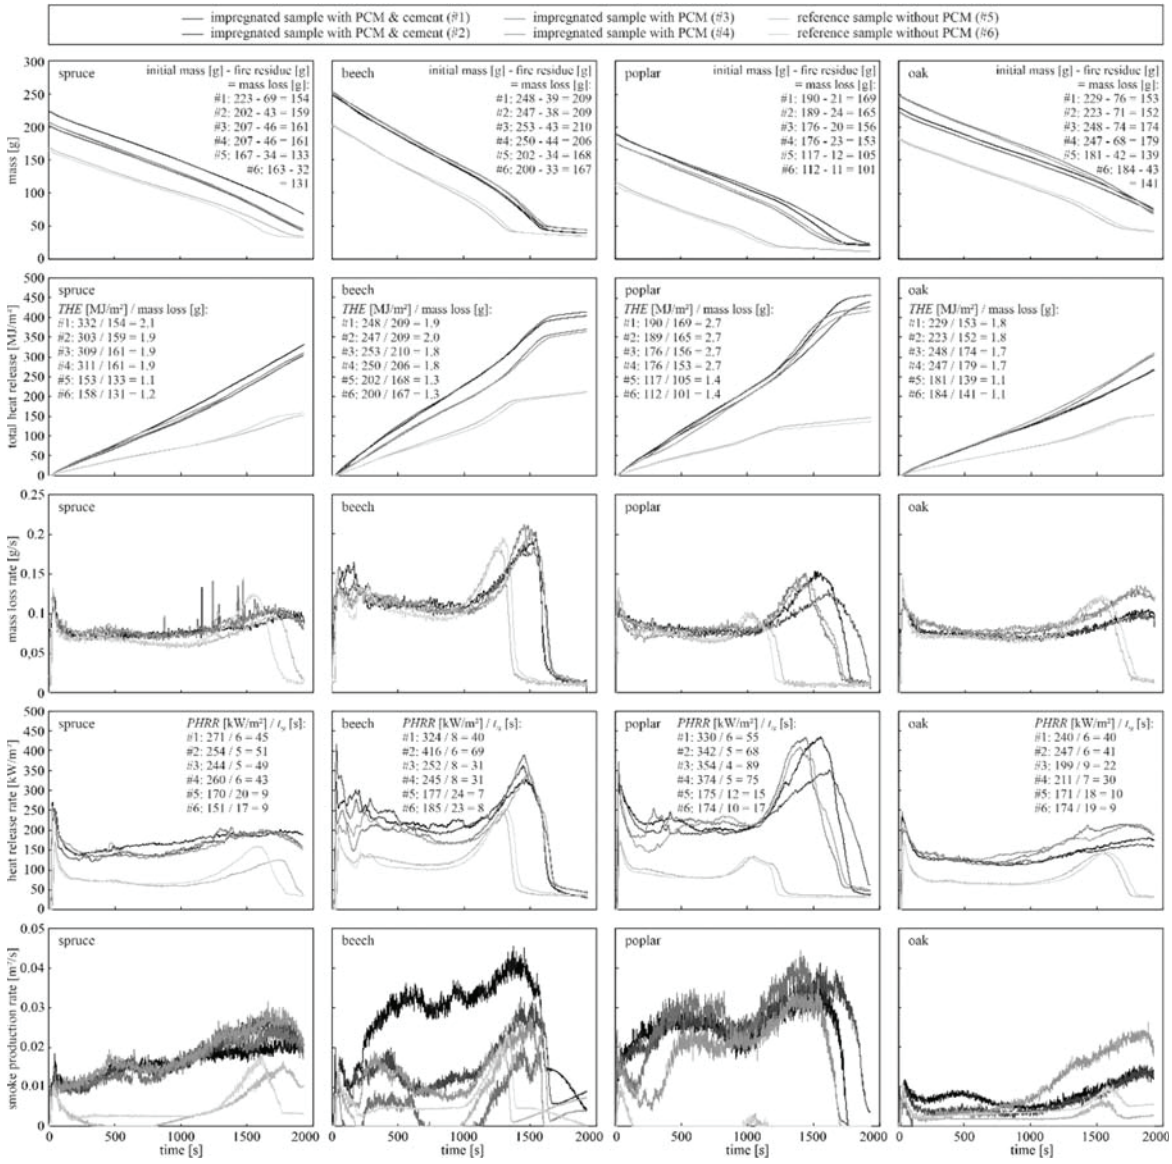

Figure 2: *Results of the cone calorimetry tests*

A first indicator is the ratio of the peak heat release rate *PHRR* and the time to ignition t_{ig}. Both values as well as the ratio are given in Figure 2 in the diagrams of the heat release rate versus time. It can be seen that t_{ig} is substantially smaller for the impregnated samples compared to clear reference samples while the PHRR values are considerably larger. The ratio PHRR / t_{ig} is approx. four to five times larger for the impregnated samples, which means that the PCM acts as fire accelerant.

A second indicator is the ratio of the total heat release at the end of the test *THE* and the mass loss of the sample. This ratio is for the impregnated samples less than twice as large as for the clear reference samples. Thus, for the propagating fire the PCM has a less significant influence than for ignition.

As a conclusion, it can be stated that unprotected PCM-containing wood ignites faster and provides more heat during combustion for fire propagation than clear wood. However, the results of the cone calorimeter tests cannot directly be transferred to real fire events due to a large dependency on length scale [12]. Thus, further tests are necessary.

As described in Section 2.6 also fire tests according to EN ISO 9239-1 [7] on wood flooring containing PCM were performed. Table 2 shows the achieved values of the fire tests with the flooring samples. Besides the *CHF* and $\int R$ values, also the maximum flame spread L_{max} and the

https://doi.org/10.52202/069179-0085

maximum light absorption R_{max} are given. The flame spread propagated in all samples until the end of the test after 1800 s.

Figure 3 shows diagrams of the flame spread vs. time and the characteristic relation for determining *CHF*. From Table 2 and Figure 3, it can be seen that *CHF* of the samples containing PCM has a higher value than the reference samples without PCM. Thus, the flooring containing PCM has with C_{fl} a more favourable fire class than the reference flooring, which achieves only D_{fl}. This probably unexpected result can be explained with the higher heat capacity of the PCM-containing elements, which initially absorb the heat and cool the flamed top layer. This is possible because the PCM is not directly flamed but protected by the not impregnated top layer. Thus, the flash point of the PCM at 177°C is not instantaneously reached like in the tests with the cone calorimeter previously described.

It should be considered that the PCM was in its solid state at the beginning of the test and, thus, a significant additional heat uptake was possible. It remains to be tested, how the behaviour is when the PCM is in its liquid state right from the beginning of the test and, thus, the cooling effect is not existing. It can be assumed that in this case also the PCM-containing elements achieve only fire class D_{fl}.

The second characteristic for the definition of the fire class is the smoke development. As Table 2 shows, the PCM-containing elements behave less favourable with stronger smoke development in terms of $\int R$ and R_{max} compared to the reference samples. Still, the values are considerably below the acceptable values as given in Table 1 for classification s_1, which, thus, both the PCM-containing samples and the reference samples reach.

As a conclusion, it can be stated that a protection of the PCM-containing wood improves the fire behaviour significantly and can compensate the fire accelerating properties of the PCM when directly flamed.

Table 2: *Results of the reaction to fire test according to EN ISO 9239-1 on wood flooring with PCM*

Value	Sample without PCM (long. joint)	Sample without PCM (trans. joints)	Sample with PCM (long. joint)	Sample without PCM (trans. joints)
CHF [kW/m²]	3.98 (D_{fl})	3.71 (D_{fl})	4.58 (C_{fl})	4.67 (C_{fl})
$\int R$ [min·%]	42.1 (s_1)	50.4 (s_1)	175.7 (s_1)	110.7 (s_1)
L_{max} [mm]	480	498	440	434
R_{max} [%]	8.7	11.1	20.7	15.8

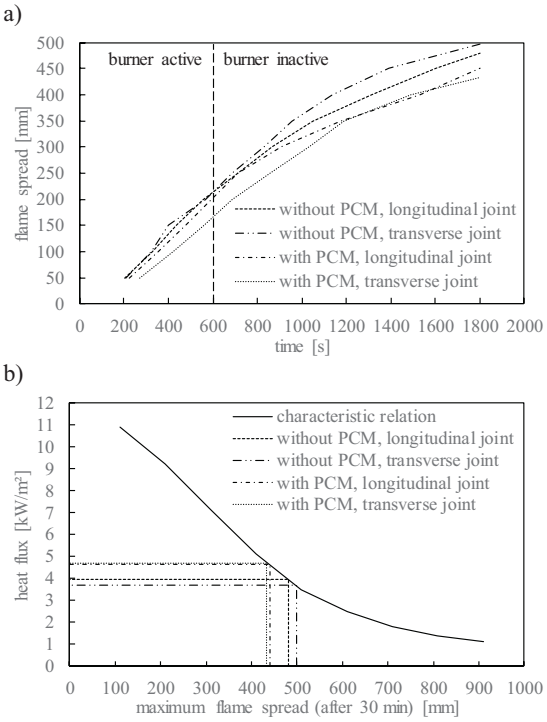

Figure 3: *Results of the fire tests acc. to DIN EN ISO 9239-1 on flooring elements; a) Flame spread vs. time, b) heat flux vs. flame spread (characteristic relation)*

3.5 GLUABILITY

The previously shown results regarding leakage and combustion behaviour indicate that it is advantageous to place the PCM-containing wood not at the surface of the building element. One technique for this purpose is glue lamination.

Figure 4 shows the results of the gluing tests as described in Section 2.5 in terms of the shear strength. It can be seen that the results depend on the wood species and the adhesive. The lowest strength of the glue line was observed for the epoxy resin. Except of beech, the PCM impregnated samples showed higher strength of the glue line compared to the reference samples. This somewhat unexpected behaviour might be explained by the cell lumen filled with PCM preventing a deeper intrusion of the resin, which is associated in the reference case with an insufficient amount of adhesive at the glue line.

The strength of the glue line is larger for the phenol-resol adhesive than for the epoxy resin. However, no clear tendency can be seen whether the performance is impaired by the PCM or not. It depends on the wood species. While for poplar and beech, the strength of the glue line is clearly impaired by the PCM, it is improved for spruce and seems to be not influenced for oak. A similar result can be seen for the PUR adhesive.

Although for poplar and beech the highest values of the reference samples are not achieved for the PCM-impregnated samples, a high-quality glue line can be

https://doi.org/10.52202/069179-0085

produced. The gluability of oak, which has a comparatively low PCM uptake, was not significantly changed by the PCM. For spruce, the PCM resulted in an improved performance of the glue line for the tested adhesives.
Besides these promising results, it shall be noted that tests with the PCM in the liquid state need to be performed. Moreover, long term and cyclic loading tests should be performed for a final evaluation.

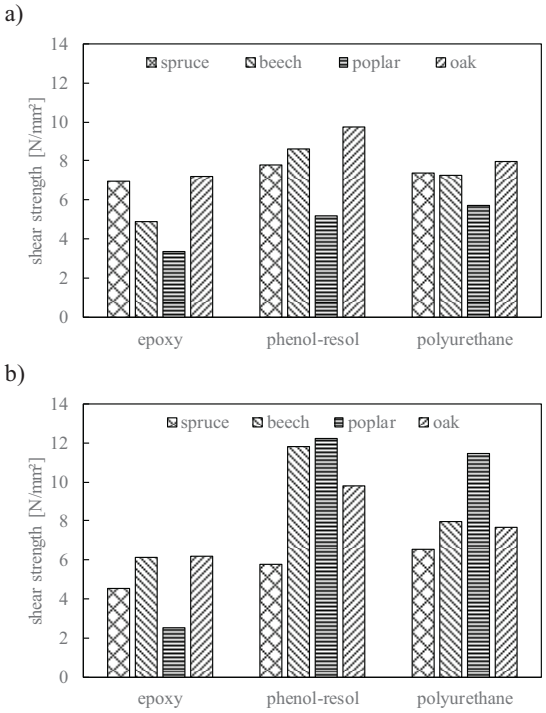

Figure 4: *Results of the gluing tests; a) PCM impregnated samples, b) not impregnated reference samples*

4 SUMMARY AND CONCLUSIONS

In this contribution, different investigations with regard to an application of PCM-containing wood in load-bearing timber elements were presented. A key aspect is the mechanical properties. The results of the bending tests showed that the PCM impregnation does not impair the strength and the modulus for commonly used wood like spruce and beech. In order to produce large sized timber elements from small sized pieces, the gluability is a key aspect. The investigations showed that high-quality glue lines could be achieved for PCM-containing wood. Although further investigations might be necessary, glue lamination is possible for PCM-containing wood. With this regard, using smaller timber pieces also facilitates the impregnation with PCM.
An exemplary glue-laminated timber element is shown in Figure 5. The element takes the aforementioned findings into account. The element consists of a core of clear glue-laminated spruce. The core remains without PCM since the heat penetration over the day is assumed to be limited and the PCM would not be activated at this position. On the side and the bottom faces of the core, PCM-impregnated spruce boards are laminated for locally increased heat capacity. In the case that the side faces are not ventilated in the room, the PCM-containing layer could be also placed only at the bottom face. As top and PCM-free, sealing layer, a thin board, which could be also a veneer, of oak is glue-laminated. Oak is hard to impregnate and serves as a barrier against leakage of the PCM. On the other hand, it has also decorative value. If the latter is not intended or necessary, other wood species, which possess a bad impregnability, like spruce could be used. However, it should be considered that knots and cracks could impair the barrier against leakage.
The PCM-free top layer also improves the fire behaviour. As the respective investigations showed, the direct flaming of the PCM-containing pieces should be prevented. Then, the PCM can even have advantageous properties regarding the fire behaviour by absorbing heat and, thus, cooling the flamed surface of the element, which delay the fire propagation.
The general concept might be applied also to other engineered timber elements like cross-laminated timber.

ADDITIVE MANUFACTURING OF WOOD COMPOSITE PARTS BY INDIVIDUAL LAYER FABRICATION-THE PRODUCTION PROCESS AND RESPECTIVE MACHINERY

Birger Buschmann[1], Daniel Talke[2], Klaudius Henke[3], Carsten Asshoff[4], Frauke Bunzel[5], Bettina Saile[6],

ABSTRACT: Additive manufacturing processes that are using wood particles as feedstock material either require large amounts of binder or have relatively poor mechanical properties. This paper details the novel Individual Layer Fabrication (ILF) process and the respective machinery which allow for the additive manufacturing of objects with a low binder content and high strength values. With flexural properties exceeding those of conventional particle boards, an application of objects produced via ILF in the construction industry is possible.

KEYWORDS: additive manufacturing, 3D-printing, binder jetting, sheet lamination, wood composites, wood adhesive processing

1 INTRODUCTION

1.1 CHALLENGES IN THE CONSTRUCTION INDUSTRY

The construction industry is currently facing a multitude of challenges. A deficit in skilled labor inhibits growth and delays or even prevents building projects and the demographic change will most likely worsen this issue in the coming years [1]. Digitalization and automation could offer a solution to this problem, where robots or other machinery fill gaps in the work force, especially for labor intensive and hazardous tasks [2]. A further challenge for the construction industry is to reduce its high environmental impact. According to the 2020 Global Status Report for Buildings and Construction [3] the construction industry as a whole is responsible for around 38 % of the global CO_2-emissions. The report recommends using digital solutions, like automated prefabrication or additive manufacturing (AM - colloquially called "3D-printing") to minimize waste and improve logistics during building construction. Another benefit of digital methods is the possibility to optimize buildings concerning their energy demand during use, which is an even larger contribution to emissions than the construction itself [3]. Employing additive manufacturing processes in the construction industry offers a multitude of opportunities such as improving workplace conditions, reducing construction time and minimizing waste material [4].

Another way of reducing the environmental impact of the construction industry is the usage of wood and other bio-based materials. These can serve as carbon sinks and thus offset CO_2-emissions that were created during construction [3, 5]. However, an increased usage of wood as building material also leads to an increased amount of logging, which can damage and even destroy whole ecosystems [6]. At the same time the waste from the wood industry (during harvest, during processing and at the end of life) is increasing continuously [7]. Hence, using this waste is essential to employ the full sustainability potential of the wood industry. If this is then coupled with additive manufacturing processes, the overall construction industry gains a powerful tool to become more environmentally friendly.

1.2 ADDITIVE MANUFACTURING OF WOOD COMPOSITES

While for example the AM process of concrete extrusion is on its way to commercial success [8], large scale processes that use wood as feedstock material have not yet moved past the experimental or laboratory status [9].

Using wood particles incorporated into a thermoplastic matrix in the fused filament fabrication process for small-scale objects is well established. Here the mixture is

molten and then extruded in strands on top of each other thereby creating objects layer by layer. The respective material is commercially available for example from [10]. Also, a large number of projects have investigated the properties of wood particles mixed into various polymeric materials like PLA [11] or ABS [12]. However, comparatively few projects used this method to build large-scale objects. Gardner et al. [13], for example, used PLA and 20 wt% of wood particles to create a boat roof tooling mould. A Finnish Company, UPM, 3d-printed a small pedestrian bridge using an undisclosed thermoplastic material with 20 wt% wood particles [14]. In the United States, in a collaboration between the University of Maine and the Oak Ridge National Laboratory, researchers printed a fully bio-based house out of an also undisclosed polymer containing wood particles [15]. The disadvantage of mixing wood particles into a polymer matrix for the fused filament fabrication process is that higher contents of wood particles (above 40 wt%) drastically reduce the mechanical properties of the composite [16]. Hence, wood is limited to the role of filler material with this process.

Significantly higher contents of wood can be achieved with the so-called liquid deposition modeling process. As in concrete extrusion, a paste of wood particles, binder and water is extruded in strands. Here, a wood content of up to 89 wt% is possible [17]. Various binders were investigated so far, ranging from synthetic urea formaldehyde binders [18] to fully biodegradable mycelia [19]. As the paste liquefier water evaporates during hardening, significant shrinkage makes the process challenging to control [20] and only comparatively low mechanical strength values are achieved [18, 20].

Kromoser et al. [21] propose a different extrusion process to create degradable “3DP Biowalls”. A mixture of wood particles, starch and lignosulfonate is extruded in a strand, activated by water and then pressed under heightened temperature to create a rigid wall, layer by layer.

Already in 2012 Henke & Treml [22] investigated the possibility to additively create objects through selective binding of wood particles with mineral and biodegradable binders for the use in construction. The binder (cement, gypsum or starch) was dry mixed with wood particles and spread thinly over a vertically movable build plate. Then one layer of the object was created by locally applying water to activate the binder. This spreading and selective activation was repeated until the desired object was finished (see Figure 1: Truncated cone generated by 3D printing with chips of spruce and gypsum as binder (Credit: [22])Figure 1).

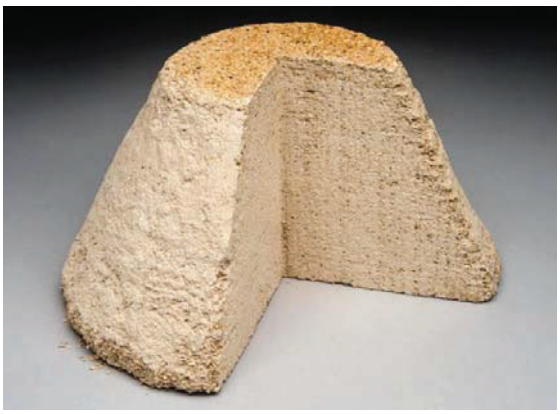

Figure 1: *Truncated cone generated by 3D printing with chips of spruce and gypsum as binder (Credit: [22])*

2 THE ILF PROCESS

2.1 GENERAL PRINCIPLE

The approach of the project presented in the following differs from the previously described ones. The main goal is to develop a process to additively manufacture large-scale, wood composite objects with a high content of wood material and strength values suited for applications in construction. This is accomplished by additively manufacturing thin, individually contoured panels that are stacked and laminated onto one another, thus forming the desired object. [23]

In the course of the project multiple process variants are explored and the necessary machinery is developed in iterative steps. Evaluation of these variants is done by investigating the mechanical properties of the resulting objects as well as the geometric capacity of the processes. Additionally, multiple demonstrators are fabricated for showcase purposes (see Figure 2).

Figure 2: *An Enneper minimal surface demonstrator made via the ILF process.*

The general principle of the ILF process, depicted in Figure 3, can be divided into the following steps. A thin layer of wood particles is scattered (a) and bound by selectively dispensing adhesive according to the target geometry of the object (b). After dispensing the adhesive, the wood particle layer is pressed under heat, curing the adhesive (c). By pressing the amount of required adhesive is drastically reduced while, at the same time, the mechanical properties of the wood composite are increased. Finally, the unbound material is removed and the contoured panel of bound material is laminated onto the stack of previously produced panels (d). [24]

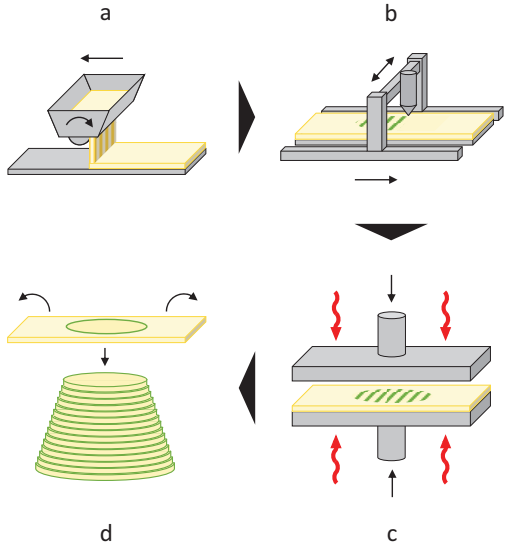

Figure 3: *The basic principle of the ILF process (Credit: [24])*

2.2 MACHINERY

Each step of the ILF process requires specialized machinery. It is either developed or acquired and modified if necessary. In the course of the overall project, multiple process variants and machines are tested and evaluated. The currently used process variant and machinery, with which the object in Figure 2 was created, will be presented in the following chapter.

Initially, a layer of wood particles is scattered on a horizontal moving transportation plate with a size of 500 mm by 500 mm. This is accomplished identically as described in [24], where the particles are picked up out of a material hopper by the needles (length: 10 mm) of a scatter roller. A brush roller (bristle length: 25 mm) rotating faster than the scatter roller brushes out the particles from the needles onto the moving plate below (see Figure 4).

Figure 4: *The particle scattering station*

The plate with the scattered particles then moves to the adhesive dispensing station, displayed in Figure 5, where the pattern of one slice of the final desired object is applied. This is done line by line similar to [24], where one line of adhesive consisted of multiple droplets. However, now the adhesive is not dispensed dropwise but in a continuous stream, thereby drastically increasing the life expectancy of the valve. An increase of temperature, and thus a significantly decrease in adhesive viscosity, allows for this method.

https://doi.org/10.52202/069179-0086

Figure 5: *The adhesive dispensing station*

After dispensing of the pattern, a second layer of wood particles is scattered onto the plate, forming a sandwich structure with the adhesive between two particle layers. This sandwich structure is then pressed under heat (up to 40 bar and 200°C), distributing and solidifying the adhesive and creating a panel with bound and unbound wood particles. The two scattered layers of particles are always of such a thickness that no adhesive can intrude them down- or upwards and preventing the panel from sticking to the press plates. The panel production is done fully automatic by the Panel Printer displayed in Figure 6.

Figure 6: *Panel Printer consisting of the scattering station in the middle, the dispensing station in the front with the transportation plate and the heat press in the back.*

In the following process steps, the unbound particles are removed and the individually contoured panels are laminated onto one another to form the final object. First automated methods and prototypes have been developed for these tasks. However, as these prototypes are not yet reliable, especially for more complex geometries, manual labor is still involved. All demonstrators displayed in this paper were cleaned and laminated by hand. However, all test specimens were processed with the automated machines to ensure reproducible results.

3 MATERIAL TESTS

3.1 MATERIAL PROPERTIES OF INDIVIDUAL PANELS

Already in [24] multiple flexural test specimens were fabricated from the processes intermediate product, the panels, and investigated according to DIN EN 310: 1993-08 [25]. In doing so, a comparison to conventionally fabricated particle boards is possible. As wood particles spruce particles produced by Fraunhofer WKI with a sieve retention mesh size between 0.6 mm and 1.25 mm were used. As adhesive a polymeric methylene diphenyl diisocyanate (pMDI) called I-BOND PB PM 4350 from Huntsman LLC was used. The results are displayed in Figure 7 where the modulus of rupture (MOR) is displayed in megapascal (MPa) and the modulus of elasticity (MOE) is displayed in gigapascal (GPa). Through an alteration of processing parameters, the adhesive content and connected with that the density of the specimens was varied.

The specimens had an average flexural strength of 25.95 to 52.45 MPa and an average stiffness of 3.04 to 5.34 GPa. With these values they all fulfill and largely surpass the flexural requirements of particle boards according to DIN EN 312: 2010-12 [26]. Similarly, also the investigation of tensile properties showed strength and stiffness values exceeding those of conventional particle boards.

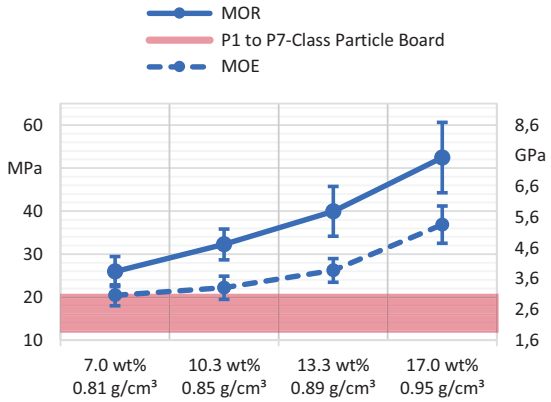

Figure 7: *Flexural properties of individual panels. MOR (left) and MOE (right) as a result of adhesive content (upper) and density (lower). The red area contains bending requirements for P1 to P7 particle boards.*

3.2 PROCESS PARAMETER STUDY

Further investigations regarding the influence of process parameters on flexural strength (MOR in MPa) and density (in g/cm³) of the panels were done. As these flexural test specimens were directly printed and not cut or milled, they deviated from the geometry required according to DIN EN 310: 2010-12. On average they had a thickness of 3 mm, a width of 55 mm and a length of 160 mm. Furthermore, they were stored at room temperature and humidity and not at a precisely defined climate. Because of this the values displayed in Figures 8

https://doi.org/10.52202/069179-0086

to 10 cannot be seen as absolute but rather their change is important. All test specimens were produced in the same way with the parameters displayed in Table 1 kept constant, except for the one that was varied. The results of varying the adhesive content is displayed in Figure 8, the result of varying the pressing force in Figure 9 and the results of varying the pressing duration in Figure 10. Cubic wood particles with the name of Lignocel 9 from J. Rettenmaier & Söhne GmbH were used with a moisture content of 7 wt%. These wood particles have an average diameter of 0.8 mm to 1.1 mm. As adhesive the same type of pMDI as in [24] was used.

Table 1: *Constant production parameters for the parameter variation study*

Parameter	Value
Adhesive Content	12.5 wt%
Pressing Force	31.25 bar
Pressing Duration	180 seconds

Generally, the test specimens behaved as expected from conventional engineered wood. An increase in adhesive content and an increase in pressing force increased the density of the panels, which in turn increased the mechanical properties [27].

When comparing the flexural strength values in Figure 7 with the ones in Figure 8, the significantly lower values of the latter become apparent. Partly this is due to the lower density values of the test specimen in Figure 8. However, the factor of particle morphology also has to be taken into consideration. The test specimens of Figure 7 were fabricated with wood particles specifically produced for particle boards with a relatively high length to width ratio [27]. For the specimens in Figure 8 commercially available wood particles for smoking of foods or horse bedding were used. The two kinds of particles are displayed in Figure 11. A high length to width ratio significantly improves the mechanical properties of the final composite.

A comparison of Figure 8 and 9 indicates that while an increase of density certainly increases mechanical properties, the process parameter of pressing force has only a limited influence. An increase of adhesive content, and a consecutive slight increase in density, leads to a significant increase in mechanical properties in Figure 8. Whereas a very large variation of density through pressing force only marginally varies the mechanical properties in Figure 9. These results seem to contradict the findings of [28] where the main factor of increased flexural strength was panel density and not adhesive content.

The graphs of Figure 10 suggest only a minor influence of pressing duration on flexural strength if a certain time has passed. In this case the minimal necessary pressing time for maximal mechanical properties lies between 30 and 60 seconds or 10 and 20 mm/s (at 3 mm thickness). This is in accordance with literature [29] where a pressing duration of 12 seconds per mm thickness of material is given as necessary for full curing of the adhesive.

https://doi.org/10.52202/069179-0086

3.3 ANISOTROPIC PROPERTIES OF ILF-OBJECTS

With the same materials as in the parameter study (Lignocel 9 as wood particles and I-BOND PB PM 4350 as adhesive), square panels with the process parameters displayed in Table 2 were fabricated. 50 of these single panels were laminated onto one another with the polyurethane adhesive Jowapur 686.60 from JOWAT Swiss AG. After adhesive application they were pressed. The lamination's adhesive application and pressing parameters are also displayed in Table 2. From the resulting blocks two kinds of flexural test specimen were cut out to the dimensions of 150 mm length, 50 mm width and 10 mm thickness as given in DIN EN 310: 1993-08 [25]. Eight test specimens were cut in a way so that the orientation parallel to the stacked panels could be tested. Another eight were cut in a way so that the orientation perpendicular to the panels could be tested. This made it possible to analyse the anisotropic behaviour of the overall material properties.

Table 2: *Production parameters for anisotropic flexural test specimens*

Parameter	Value
Panel Adhesive Content	8.9 wt%
Panel Pressing Force	31.25 bar
Panel Pressing Duration	180 seconds
Lamination Adhesive Content	9.4 wt%
Lamination Pressing Force	7.50 bar
Lamination Pressing Duration	24 hours

The results of the density and flexural investigation are shown in Table 3 with the average (AVG) values of the eight specimen and the respective standard deviation (SD). Similar to the 25.0 wt% adhesive content specimens from Figure 8, which have a MOR of 29.92 MPa, the parallel oriented specimens, with a total adhesive content of 18.3 wt%, have a MOR of 29.86 MPa. However, as two different materials are compared, such a comparison must be considered with care.

A significant difference in MOR and MOE can be observed between the parallel and perpendicular oriented specimen. The MOR of the parallel oriented specimen is greater than the ones of the perpendicular oriented by a factor of 20. The MOE is greater by a factor of 10. This behaviour is well known from conventional engineered wood materials, where the tensile strength perpendicular to the fibres is only a fraction of the one parallel to the fibres [27]. Also in [28] the transverse tensile strength of the panels was identified to be in the same order of magnitude as the one observed for the perpendicular oriented flexural specimens. In the investigations of single panels some form of arithmetic average of mechanical properties is calculated. Whereas, in a stack of laminated panels only the weakest panel is decisive for the overall mechanical properties.

Table 3: *Results of the anisotropic to panel orientation done flexural and density investigations.*

Parallel oriented	AVG	SD
Density	0.88 g/cm³	0.04 g/cm³
MOR	29.86 MPa	4.73 MPa
MOE	3.31 GPa	0.23 GPa

Perpendicular oriented	AVG	SD
Density	0.88 g/cm³	0.02 g/cm³
MOR	1.44 MPa	0.26 MPa
MOE	0.31 GPa	0.05 GPa

4 APPLICATION

In the course of the overall project multiple demonstrators are fabricated. Next to purely geometric demonstrators, like the Enneper minimal surface in Figure 2 that demonstrate the capabilities of the ILF process, also functional demonstrators are produced. One example is shown in Figure 12. Here a Helmholtz resonator is displayed. A Helmholtz resonator is a bottle like unit made of an airtight material that has a defined cavity. Additionally, the resonator has a neck with an opening that connects the cavity with the surrounding air. This geometry can absorb a certain sound frequency from the surrounding atmosphere. By changing the size of the cavity volume and the length and width of the neck, the sound frequency that is absorbed is changed as well [30]. One possible application for the ILF process is to create wall or ceiling elements that contain a multitude of different sized Helmholtz resonators. With these elements it would be possible to change the sound or filter unwanted acoustic frequencies in e.g. concert halls or lecture rooms.

Another possible application of the ILF-process is to use it as a tool to fabricate optimized parts. This optimization can be in regard to e.g. weight reduction, thermal insulation, fire safety or even combinations thereof. As designs that are created this way are oftentimes geometrically complex their fabrication using conventional methods can become challenging. However, with additive manufacturing methods, like the ILF-process, where the required effort and cost are largely independent of the design's complexity, creating optimized parts is easily feasible. This makes optimization and additive manufacturing an ideal match. Accordingly, optimization tools, like topology or shape optimization, have already been applied to additively manufactured construction elements [31].

Figure 12: *Bottle like Helmholtz resonator (Credit: Korbinian Schwab & Birger Buschmann)*

An example of combining structural optimization with the ILF process is shown in Figure 13. Here, a ceiling element was designed with topology optimization. This was done in such a way that the total volume was reduced by around 75 % in comparison to a massive block. At the same time the original stiffness in regard to an even distributed force from the top was maintained. One corner of this design was selected and printed. The result is shown in Figure 13 (bottom) while the original design can be seen in Figure 13 (top). With conventional fabrication this object would have resulted in a large amount of waste material, whereas with the ILF-process it can be created out of waste material.

5 CONCLUSION

In this paper a new process was presented that enables the additive manufacturing of large-scale wood composite objects. The process was detailed and the respective machinery presented. At more than 80 wt% wood content the objects produced with the process showcased comparatively high mechanical properties at a flexural strength of 29.86 MPa and a stiffness of 3.31 GPa. The overall material properties were identified to be anisotropic in regard to panel orientation with a difference in flexural strength by a factor of 20 and in flexural stiffness by a factor of 10. As relevant production parameters the particle morphology, the adhesive content and the pressing force were identified.
Furthermore, first examples of possible application fields were presented. These include functionalized objects that can e.g. be used for building acoustics or structural elements, designed with the aid of digital optimization tools. Hence, the ILF-process allows for the production of individualized, free-formed structures made primarily of renewable material and with mechanical properties suited for applications in construction.

ELASTOMECHANICAL PROPERTIES OF GLUED LAMINATED TIMBER MADE OF STRENGTH GRADED OIL PALM LUMBER

Katja Fruehwald-Koenig[1]

ABSTRACT: The wood from oil palm trunks exhibits significant variations in distribution of structural tissue, density and elastomechanical properties across and along the trunk. Its reliable, safe, and economic usage for load-bearing purposes, such as glued laminated timber (GLT), requires a precise definition of its elastomechanical properties through appropriate strength grading procedures. Oil palm lumber is strength graded according to its density using an X-ray technique in which 50 % of the lamellas are ripped, graded, edge glued and therefore density homogenized, and 50 % are cut only according to their geometry. Lamellas are tested in tension parallel to the vascular bundles; combined GLT is produced from strength-graded lamellas and tested in bending parallel and compression parallel and perpendicular to the vascular bundles. The characteristic strength values for C10 and C14 according to EN 338 are achieved. A correlation between density and elastomechanical properties is established. GLT from density-homogenized lamellas achieve higher bending properties than from lamellas with a "natural" density gradient across the width.

KEYWORDS: Oil palm lumber, glue laminated timber, GLT, strength grading, elastomechanical properties

1 INTRODUCTION

Oil palm trees (*Elaeis guineensis* JACQ.) are mainly cultivated in large plantations for palm oil production to be used for food, chemicals, pharmaceuticals and bioenergy. The palms' oil productivity decreases after 20 years of age. Therefore, plantations are renewed after 25 to 30 years. Each year, there is a large supply of oil palm trunks (approximately 200 Mio. m³ per year, of which over 80 % are in SE-Asia) traditionally considered as waste. Recent research, however, has explored the potential commercial uses of oil palm wood [1]. In many cases, the wood can substitute tropical hardwoods, e.g. as panels (blockboards, flash doors multi-layer solid wood panels) and softwoods in construction timber (glued laminated timber, GLT; cross laminated timber, CLT). In the past 35 years, the macro-mechanical properties of oil palm trunk wood have been widely studied. Because of the property gradients within the cross-section and within the height of the trunk [2,3], all investigations on elastomechanical properties of oil palm wood were performed using small, defect-free test specimens (e.g. [4]) and describe strength and stiffness variations over the cross-section and the trunk height and/or depending on the density, the number or the share of vascular bundles. Only a few investigations focus on oil palm wood in construction size. Jumaat et al. [5] tested trussed rafters from oil palm wood, Srivaro [6] and Srivaro et al. [7] tested sandwich panels with oil palm wood core and rubberwood veneer faces in bending, compression and indentation. Srivaro et al. [8] investigated finger-jointed oil palm wood products in bending and compression parallel to the vascular bundles. Srivaro et al. [9] tested cross laminated timber (CLT) in compression, the hygroscopic properties and the rolling shear. Hoffmann [10] dealt with hybrid CLT from bamboo (surface layer) and oil palm wood (core layer) in bending and compression.

The anatomic wood structure of monocotyledonous palms differs from deciduous and coniferous trees. Palms have no secondary thickness growth, due to the absence of a peripheral cambium. Palm wood consists of high density, rather long vascular bundles embedded in soft (low density) parenchymatous ground tissue. Knots, probably the most important grading criteria for common tree species, are not present in palm lumber. Hence, on the macroscopic level, palm wood is in some aspects homogeneous compared to dicotyledonous wood.

Within the context of a research project [11,12], combined GLT from density graded oil palm wood is tested in bending (f_m, E_m) as well as compression parallel ($f_{c,0}$, $E_{c,0}$) and perpendicular ($f_{c,90}$, $E_{c,90}$) to the vascular bundles and glulam lamellas are tested in tension parallel to the vascular bundles ($f_{t,0}$, $E_{t,0}$). Strength, respectively Young's modulus are related to the density and the performance indices for minimum weight design according to Ashby et al. [13] are calculated. The results are compared with those of

https://doi.org/10.52202/069179-0087

small, defect-free specimens of oil palm wood [4] and with building components from palm wood and common wood species found in the literature.

2 MATERIAL

2.1 LAMELLAS FROM OIL PALM WOOD

The material is taken from 30-year-old oil palms (*Elaeis guineensis* JACQ.) grown near Kluang/Johor, Malaysia. The denser material from the periphery is cut to 30 mm (fresh) and has a thickness after kiln drying of 27 mm, the lower dense material from the centre is cut into 55 mm (fresh) resp. 50 mm (kiln-dried) boards. The kiln-dried material is shipped to Germany. For the GLT production, 70 boards of 27 mm thickness from 20 different logs and two different trunk heights (1 – 4 m and 4 – 7 m above ground) are taken. The mean length of the boards is 2.8 m and mean width 0.22 m.

Due to the anatomical structure of monocotyledons (rotationally symmetrical around the stem axis), it is assumed that opposite boards have comparable elastomechanical properties. For the pairwise comparison in this investigation, two outer and two inner 27 mm boards placed opposite to each other are selected by visual inspection. Boards with cracks or cell collapse are not used. The edges of the boards are trimmed along the cortex using a table saw. Due to the natural taper of the oil palm trunks (some 0.8 cm per meter trunk length), the boards have different widths at each end (approx. 2–3 cm difference). The rough-cut lamellas are calibrated using a two-side planer with HeliPlan tools from Leitz, Germany, one board of each pair to a thickness of 20 mm, the other to 17 mm. Details on the material preparation are given in Heister and Fruehwald-Koenig [11]. Some of the 17 mm lamellas are used for the tension test parallel to the vascular bundles (Table 1).

2.2 CALCULATION OF LAMELLA STRENGTH CLASS LIMITS

No strength grading standard exists for oil palm wood. Because of the small dimensions of the GLT specimens produced within this investigation, the strength grading of the oil palm lumber is based on the European strength class system for coniferous lumber (C-classes) according to EN 338 [14] and EN 14081-2 [15]. Fruehwald-Koenig and Heister [4] showed that most elastomechanical properties of oil palm wood depend on the density. Therefore, the statistic calculation model of EN 14081-2 attachment B [15] is used in modified form to calculate the density limits for the strength classes. The calculations are based on the relationships between density (indicating property (IP)) and tensile strength ($f_{t,0}$) resp. compression strength ($f_{c,0}$) parallel to the vascular bundles for MOR determined in preliminary investigations on small test specimens, published in Fruehwald-Koenig and Heister [4] and linearized by the natural logarithm. Details on the calculation of lamella strength class limits are described in Heister and Fruehwald-Koenig [11].

For strength class C14, the characteristic tensile strength value parallel to the vascular bundles ($f_{t,0,k}$ = 7.2 MPa) leads to a density limit value of >427 kg/m^3 and the characteristic compression strength ($f_{c,0,k}$ = 16 MPa) to a density range of 363 – 427 kg/m^3. Because of the high share of oil palm wood material with densities below 350 kg/m^3, property values for an assumed strength class C10 are extrapolated with 290 – 335 kg/m^3 for the compression lamellas and 335 – 363 kg/m^3 for the tension lamellas. The density limit value for the shear lamellas is <290 kg/m^3 for both beam setups.

2.3 STRENGTH GRADING OF THE BOARDS

When grading oil palm boards according to their density, the average density of the board must not be assumed because of the density gradient over the trunk's cross-section (which is higher than the gradient along the trunk height) [3]. Figure 1 shows the density profile across the 140 mm width of a board from the outer area of the trunk.

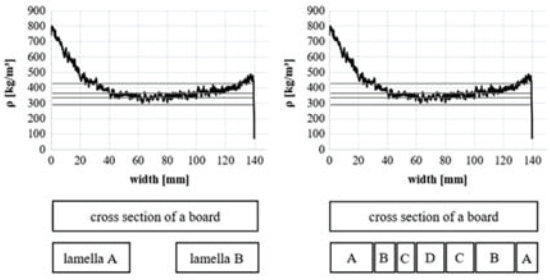

Figure 1: *Density profile of a board from the outer area of an oil palm trunk with a high density gradient over the board width. Cutting of "full size" lamellas according to their geometry with inhomogeneous density (left) and cutting strips with individual width and homogeneous density (right)*

The 17 mm thick board of each pair is used to "conventionally" cut the boards according to their geometry in two 55 mm wide and 2200 mm long lamellas from each side of the board, which results in "full size" cross-section (= non-ripped) lamellas (Figure 1, left) with a density gradient over the cross-section from approximately 800 – 350 kg/m^3. The mean density of each non-ripped lamella is determined from mass and volume.

The 20 mm thick board of each pair is density measured over the board width using X-ray. Therefore, 5 cm long specimens are cut from both ends of the boards. The specimens are planed, rectangular cut and conditioned at a standard climate of 20 °C/65% rh [16]. The X-ray measurements are performed using DENSE-LAB X from Electronic Wood Systems (EWS), Hameln. Measurements are taken at every 0.1 mm of the specimen. Based on the measured density profile from the end with the lower density (according to Koelli [3], it is assumed that this is the upper end), the cutting positions of each board are calculated from the smoothed density profile with a specially developed software. The minimum strip width is 10 mm. The boards are ripped lengthwise from the upper end to strips with individual width (Figure 1, right). The grade assigned to each strip is verified by determining the mean density of each strip from mass and volume. Due to the longitudinal density distribution, the density is higher at

https://doi.org/10.52202/069179-0087

the lower end of the board. This leads to a deviation between the calculated X-ray density class and the measured mean density of the strip. The strips are grouped according to their grade and randomly (within the grading class) edge-glued into boards. Two to six strips are required to achieve a board width of 175 mm. A fibre-reinforced, one-component polyurethane adhesive (Jowapur® 686.60) is used for the edge-gluing. After curing and conditioning, the edge-glued timber boards are calibrated to the final thickness of 17 mm. Three ripped lamellas are cut in width (55 mm) and length (2200 mm) from each edge-glued board. After lamella preparation, the average density is determined from mass and volume. Ultimately, the ripped lamellas show a more uniform density over their width compared to the non-ripped lamellas.

2.4 PRODUCTION OF GLT FOR BENDING AND COMPRESSION TESTS PARALLEL

Six strength-graded lamellas are arranged within the combined GLT beam according to Figure 2. Due to the low number of ripped and non-ripped lamellas of grading class <290 kg/m³, additional non-ripped lamellas are produced from the low density boards from the center of the same trunk sections. The boards are processed in accordance with the manufacturing steps of the non-ripped lamellas described in Sect. 2.3.

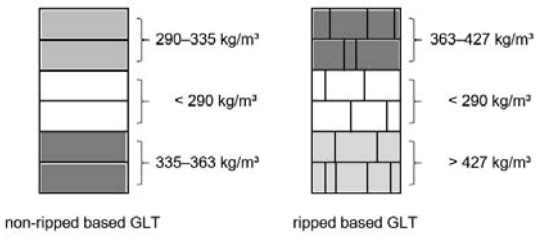

Figure 2: *Examples for lamella arrangement in the 6-lamella GLT test specimens for bending and compression test parallel produced from non-ripped (left) and ripped (right) lamellas, dimensions cf. table 1*

The same resin is used for gluing the GLT as for the edge-gluing (Jowapur® 686.60). The mean adhesive application rate is approx. 350 g/m². Pressing the GLT is done with a specific pressure of 0.75 MPa for a minimum of 240 min on a modified press, TimberPress X 300, commonly used to produce CLT at MINDA Industrieanlagen in Minden, Germany. After storing the beams in a standard climate [16], they are calibrated to the final width of 50 mm and stored again in the standard climate until testing. In summary, 20 beams with different beam setups and from different lamella strength classes are produced, which are used for the bending tests (cf. Sect. 3.2). After the bending test, two specimen sizes are cut from ends of the bending specimens for the compression tests parallel to the vascular bundles. Large specimens are taken over the entire cross-section of the GLT beams with a dimension of 100 x 50 x 300 mm³ (height x width x length) according to EN 408+A1 [17] (= 6 lamellas). Small specimens are taken from the compression and tension zones with a dimension of 34 x 50 x 205 mm³ (= 2 lamellas) (table 1).

2.5 PRODUCTION OF GLT FOR COMPRESSION TESTS PERPENDICULAR

For the compression tests perpendicular to the vascular bundles, test specimens with dimensions of 250 x 204 x 100 mm³ (length x height x width) according to EN 408+A1 [17] are produced out of twelve lamellas each. The arrangement of the lamellas over the cross-section of the specimens is comparable to that of the test specimens for the bending and compression test parallel to the vascular bundles. Figure 3 shows the arrangement of six lamellas as taken for the GLT beams, which are arranged mirror inverted. The two outer lamellas (top and bottom) have the highest densities, the four core lamellas medium density and the two intermediate lamellas are of low density. For the high and medium density lamellas, the 17 mm material described in Sect. 2.1 and 2.3 is used. The low density lamellas are produced from oil palm wood scantlings with dimensions of approximately 1300 x 75 x 45 mm³ (length x width x height), treated with about 2 % of boron by using the vacuum-pressure method. The scantlings are imported to Germany in dry state and visually graded. Due to the width of the scantlings (75 mm), two scantlings are edge-glued together after planning and trimming. For gluing one-component PUR adhesive (Jowapur® 686.60) is used.

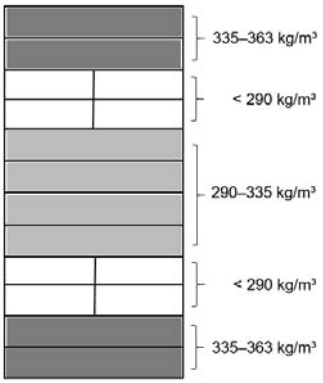

Figure 3: *Compression test specimen perpendicular to the vascular bundles, dimensions cf. table 1*

2.6 OVERVIEW TEST SPECIMENS

Before testing all specimens are stored in a climate chamber at a climate of 20 °C and 65 % relative humidity according to DIN 50014 [16]. An overview on all test specimens is given in Table 1.

Table 1: *Number and dimensions of test specimens, 2l = 2 lamellas, 6 l = 6 lamellas*

test	# specimens	dimension (length x height x width) [mm³]
f_m E_m	20	2,200 x 102 x 50
$f_{c,0,2l}$ $E_{c,0,2l}$	150 48	205 x 50 x 34
$f_{c,0,6l}$ $E_{c,0,6l}$	41	300 x 102 x 50
$f_{c,90}$ $E_{c,90}$	15 22	250 x 204 x 100
$f_{t,0}$ $E_{t,0}$	88	610 x 17 x 50

3 METHODS

3.1 DETERMINATION OF DENSITY

Contrary to EN 408+A1 [17], for all test specimens the density is not determined on a section from the immediate vicinity of the fracture after destructive testing, but as an average from the mass and volume of the entire specimen before testing.

3.2 BENDING TEST

Modulus of rupture (MOR) and local and global modulus of elasticity (MOE) are determined in a four-point bending test according to EN 408+A1 [17]. A 20 kN testing machine is used for the C10 and a 100 kN testing machine for the C14 beams. For measuring the local and global MOE of the C10 beams, three inductive displacement transducers are used (two of type WA50 and one of type WA100; Hottinger Baldwin Messtechnik (HBM), Germany). Plywood and oil palm wood supports of various dimensions are used to protect against support roller imprints when testing the C10 beams, plywood supports are used for the C14 beams (length of all supports three times the specimen width). Specimen geometry and test setup are corrected with k_h and k_l according to EN 384 [18] and the calculation of the characteristic values is done according to EN 14358 [19] (parametric approach for calculation of characteristic density (ρ_k) and strength ($f_{m,k}$) values). Instead of the reduction factor k_s (n), which depends on the number of specimens, the value of the 5 % quantile for a standard normal distribution (p0.05=1.645) is used in all calculations of the characteristic values in addition to the calculation according to the normalized reduction value for k_s (n). Details on the bending test and the calculation of the results are described in Heister and Fruehwald-Koenig [11].

3.3 COMPRESSION TEST

The compression tests parallel and perpendicular to the vascular bundles are carried out according to EN 408+A1 [17] using a 200 kN universal testing machine (FORM+TEST Seidner&Co. GmbH). In deviation to EN 408+A1 [17], the force used to calculate the compression strength perpendicular ($f_{c,90}$) is determined at 1 % plastic strain of the specimen height and the strain measurement for the Young's modulus is carried out by means of digital image correlation (DIC) with a camera system (type GOM Aramis 5M, Carl Zeiss GOM Metrology GmbH). The strain measurements are evaluated with GOM Correlate 2019 (Carl Zeiss GOM Metrology GmbH). Details on the compression test and the DIC strain measurement are described in Fruehwald-Koenig and Heister [12].

3.4 TENSION TEST

The tension test on glulam lamellas parallel to the vascular bundles is carried out according to EN 408+A1 [17] on the FORM + TEST universal testing machine with a clamping length of 80 mm (resulting in a free test length of 9 x width = 450 mm). The elongation is measured with a long-travel extensometer up to approximately 50 % of the tensile strength ($f_{t,0}$) of small, defect-free specimens according to Fruehwald-Koenig and Heister [4]. In deviation to EN 408+A1 [17], the measuring distance of the sensors is 200 mm. To avoid compression failure in the clamping area, the specimens are reinforced with birch plywood on both face sides.

4 RESULTS AND DISCUSSION

4.1 INFLUENCE OF THE DENSITY ON THE PROPERTIES

Figure 4 shows the tensile properties parallel, compressive properties parallel and perpendicular and bending properties of oil palm wood as a function of density for full-size and small, defect-free test specimens. Independent of the specimen size, they show a higher correlation to the density compared to dicotyledons. This is caused by the much larger density range of the oil palm wood and the resulting large range of property values. All strength and stiffness values of the full-size specimens parallel to the vascular bundles increase with the density by power law relationship with similar exponents, except the higher exponent for the bending properties ($f_{m,0}$ and $E_{m,0,global}$), which might be due to the lower number of test specimens in a much lower density range. Properties from compression test perpendicular to the vascular bundles ($f_{c,90}$ and $E_{c,90}$) on full-size test specimen are constant, which might be due to the low number of test specimen and the very low density range. The exponents correspond to the results for oil palm wood on small test specimens according to Fruehwald-Koenig and Heister [4], Srivaro et al. [20] and Srivaro et al. [21] and for other palm species according to Rich [22]. But the determined exponents are very different from those of softwood and hardwood species from modelling [23-25] or from experimental results [26-28], which might be due to the different anatomical structures. The concentration of vascular bundles, as well as the concentration of fibers within the bundles, is greater in the periphery of the trunk than in the central tissue [2,29]. Cell wall thickening is more pronounced in the peripheral tissue than in the central tissue and more in the bottom of the trunk than in the top of the trunk [30], because the bending stresses on the arborescent palm are greatest on the bottom at the periphery of the trunk. Furthermore, the cell wall properties themselves are not constant. Cell wall thickening means that as the palm tissue (vascular bundles and parenchymatous ground tissue)

https://doi.org/10.52202/069179-0087

ages, more cell wall layers are added on the cell wall towards the lumen of the cells resulting in smaller lumina diameters and thicker cell walls with a higher cellulose content [29]. The density in the peripheral zone at the bottom of the trunk rises over time because the trunk volume increase is lower than the mass increase by added volume of additional cell wall layers. But, the density increase due to cell wall thickening is lower than the increase of the elastomechanical properties, which leads to exponents > 1 of the power law relationship.

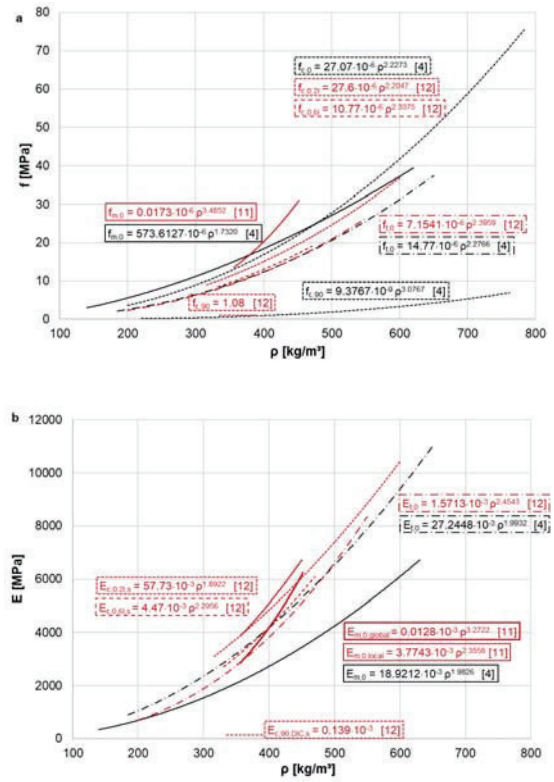

Figure 4: *Elastomechanical properties in relationship to the density (ρ), a strength properties, b stiffness properties (full-size specimens in red, small-size specimens in black)*

4.2 INFLUENCE OF THE TEST SPECIMEN SIZE ON THE PROPERTIES

In contrast to common wood species, the strength of the full-size test specimens is above ($f_{c,90}$), in the same range ($f_{t,0}$, f_m) or only slightly below ($f_{c,0}$) that of small, defect-free test specimens, cf. Figure 4a. Therefore, for oil palm wood specimen size does not influence the strength values.

When testing common wood species a clear distinction must be made between

- "material testing" of small, defect-free specimens that fail on a microscopic level as a result of many small, randomly distributed structural defects in the specimen, and
- "(building) component testing" with macroscopic structural defects due to natural growth characteristics, which mostly fail as a result of these structural defects (especially knots and fiber deviation). For most strength types, the properties of the defect-free wood between the structural defects have no influence on the properties of the building component respectively it´s influence is superimposed by the structural defects.

Both, material and component testing show different failure modes depending on the type and direction of loading and results in significantly different property values.

In contrast to the dicotyledonous common wood species, monocotyledonous palm tissue consists of vascular bundles (having honeycomb-like prismatic cells and dense fibers aligned along the stem) surrounded by parenchymatous ground tissue (made up of thin-walled polyhedral parenchyma like close cell foam-like structure) [31]. From a structural mechanics perspective, if the vascular bundles are considered as reinforcements (fibers) and the ground tissue as the matrix, oil palm wood can be seen as a unidirectional long-fiber-reinforced biocomposite. Therefore, on the microscopic level, palms as monocotyledons have a more heterogeneous structure in comparison to dicotyledons. Since monocotyledons only grow at the top part of the trunk where the apical meristem is located; no radial growth occurs and therefore, palms do not possess radial oriented ray cells or an annual ring structure. The tissue does not contain the typical macroscopic structural defects due to natural growth characteristics (e.g. knots) like dicotyledones. The elastomechanical properties of oil palm wood depend on the anatomical structure at the microscopic level and are therefore not influenced by the specimen size. Main influencing factors on the elastomechanical properties are the density, but also the age of the palm, the location within the trunk (height and cross section) and probably also the oil palm subspecies, differences between individual palms and the plantation sites.

4.3 RELATIONS OF THE PROPERTIES

For the full-size test specimens, the compressive strength parallel to the vascular bundles ($f_{c,0}$) is only approx. 1.2 times the tensile strength parallel (($f_{t,0}$) Figure 4a), whereas it is much higher for low grade softwood (e.g. 2.2 for C14 $f_{c,0,k}/f_{t,0,k}$ according to EN 338 [14]). The ratio of bending and tensile strength parallel to the vascular bundles (Figure 4a) rises with the density from 0.8…1.7…2.6 : 1 within the relevant density range of ρ = 200…400…600 kg/m³ and is in the range of low grade softwood (e.g. 1.9 for C14 $f_{m,k}/f_{t,0,k}$ according to EN 338 [14]). Similarly, the ratio of compression strength parallel and perpendicular to the vascular bundles (Figure 4a) rises with the density from 2.7…13.0…32.6 : 1 for ρ = 200…400…600 kg/m³ and is therefore for most densities above that for low grade softwood (e.g. 8.0 for C14 $f_{c,0,k}/f_{c,90,k}$ according to EN 338 [14]). Figure 4b shows that for oil palm wood $E_{m,0,local} : E_{c,0} : E_{t,0}$ = 1.3 : 1.2 : 1 for ρ = 400 kg/m³. This is in contrast to common wood species according to Egner [32], who stated that $E_m < E_{t,0}$. and according to Kretschmann [27], who stated that E_m includes an effect of shear deflection and therefore can be increased by 10 %.

4.4 PERFORMANCE INDICES FOR MINIMUM WEIGHT DESIGN

Because of the power law relationship between strength respectively stiffness and density, the performance indices for minimum weight design by Ashby et al. [13] calculated for oil palm wood rise with the density and are shown in Table 2. They are comparable to that of small size oil palm, coconut palm and date palm wood test specimens. The strength-density performance index M_4 (strength of a tie under uniaxial load) of oil palm wood is comparable to that of structural size softwood, M_5 (strength of a beam in flexure) and M_6 (strength of a plate in flexure) are only slightly lower than that of structural size softwood. However, the modulus-density performance indices ($M_1 – M_3$) of oil palm wood are much lower than that for structural size softwood. The performance index for elastic design M_8 to allow large, recoverable deformation based on tensile tests is above and that based on compression tests in the range of structural size softwood lamellas.

Table 2: *Performance indices for minimum weight design as proposed by Ashby et al. [13] for ρ = 200…600 kg/m³*

4.5 INFLUENCE OF RIPPED LAMELLAS ON BENDING PROPERTIES

Figure 5 shows the positive trend between density (ρ) and bending strength ($f_{m,0,rf}$) after taking the reduction factors k_h and k_l into account. The bending strength of the ripped beams ($f_{m,0,rf,r}$) is higher than that of the non-ripped beams at the same density and ranges between 22…27 MPa for the ripped C14 and 17…24.5 MPa for the ripped C10 beams. At a density of 400 kg/m³, the ripped C10 and C14 beams show almost the same bending strength of 22.5…24 MPa. The characteristic bending strength ($f_{m,k}^{0.05}$) of the ripped C14 beams is 21 MPa and comparable to that of the ripped C10 beams with 20 MPa (Table 3). The difference between the characteristic bending strength of the non-ripped C10 (11 MPa) and C14 (16 MPa) beams is higher. The characteristic values $f_{m,k}^{k(s)}$ according to EN 14358 [19] are 2…3 MPa lower than the $f_{m,k}^{0.05}$ values. The coefficient of variation ranges between 9…13 % for the C14 and 7…8 % for the C10 beams. The oil palm wood GLT C10 and C14 achieves the target MOR ($f_{m,k}$) according to EN 338 [14]. Applying the reduction factor for coniferous wood according to EN 14358 [19], the target $f_{m,k}$ is not fulfilled by the non-ripped C10 beams. Therefore, the calculated density limits for achieving a target characteristic strength and the calculation method are reasonable.

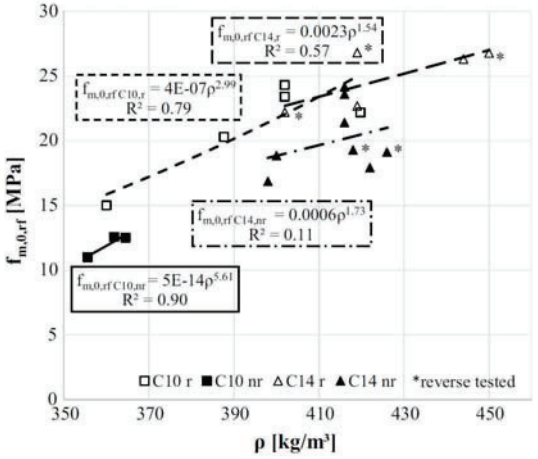

Figure 5: *Relationship between bending strength ($f_{m,0,rf}$) after considering the reduction factors k_h and k_l [18] and the GLT density*

Figure 6 shows the local MOE ($E_{m,0,l}$) for the different beam setups and strength classes. The range of the local MOE ($E_{m,0,l}$) of C14, especially the ripped beams, is the highest for all setups and strength classes. The lower values of the C14 are similar to the higher values of C10. The statistical values for the local MOE are shown in Table 3. The ripped beams show a higher mean local MOE ($E_{m,0,l,\bar{x}}$) than the non-ripped beams and the C14 are higher than the C10. $E_{m,0,mean,l}^{0.05}$ of the non-ripped C14 beams is higher (4.32 GPa) than that of the ripped C14 beams (3.99 GPa) (due to one very low MOE value in the C14r group, cf. Figure 5). In contrast, $E_{m,0,mean,l}^{0.05}$ of the ripped C10 beams is higher (4.00 GPa) than that of the non-ripped

https://doi.org/10.52202/069179-0087

C10 beams (3.28 GPa). $E_{m,0,mean,l}^{0.05}$ for ripped beams of both strength classes is almost similar (3.99 GPa for C14 and 4.00 GPa for C10). The target MOE for C14 according to EN 338 [14] ($E_{m,0,mean}$ = 7 GPa) is far from achieved. In contrast, the target density (ρ_k = 290 kg/m³) of C14 according to EN 338 [14] is achieved by all oil palm wood beams.

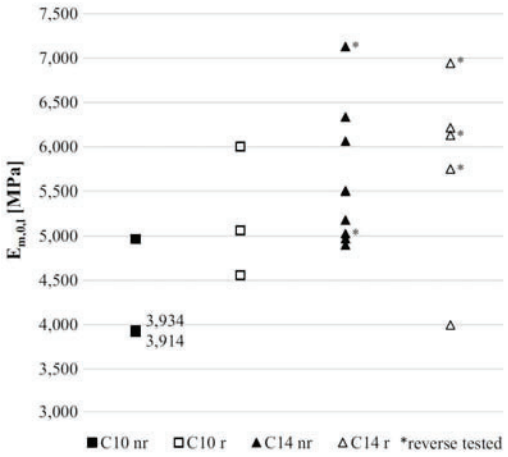

Figure 6: *Local MOE ($E_{m,0,l}$) of the different beam setups and strength classes*

4.6 LOCAL VS. GLOBAL MOE

Figure 7 shows the relationship between the local MOE ($E_{m,0,l}$) and global MOE ($E_{m,0,g}$) for oil palm wood beams with different setups and strength classes and the linear relationship for coniferous wood species according to EN 384 [18]. For all specimens, the local MOE ($E_{m,0,l}$) is above the global MOE ($E_{m,0,g}$). All oil palm wood beams tested showed a positive linear correlation between the global and local MOE, but the linear relationship for softwoods according to EN 384 [18] does not apply to oil palm wood.

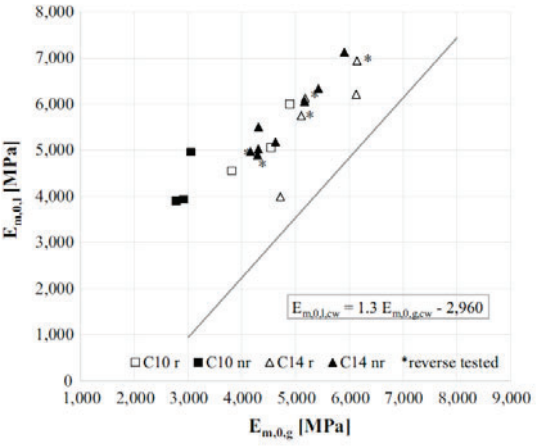

Figure 7: *Relationship between global MOE ($E_{m,0,g}$) and local MOE ($E_{m,0,l}$) for oil palm wood GLT and the linear relationship for coniferous wood species according to EN 384 [18]*

5 CONCLUSIONS

Oil palm wood availability provides good opportunities for supplementing respectively substituting common tropical timber species especially in Asia and timber from pine plantations. Due to its elastomechanical properties, medium and high-density oil palm wood can be used for load bearing products like GLT, but the elastomechanical properties are slightly lower compared to common wood species. The challenge with regard to load-bearing construction products such as GLT and CLT from oil palm wood lies in the comparatively low stiffness of oil palm wood compared to common wood species. The high variation of oil palm wood´s properties compared to common wood species requires grading the oil palm wood, e.g., according to density, because most design values are based on 5th percentiles and high variations result in low product performance. The strength grading according to density and the defined density limits used in this study appear to be reasonable in principle, the targeted strength classes of EN 338 [14] are achieved. Designing beams with lamella positions according to their density has a significant influence on the properties. Ripping boards according to their density into stripes and edge-gluing the stripes to density homogeneous lamellas results in higher MOR and MOE values (no difference is shown for compression properties parallel to the vascular bundles).

As the oil palm wood (similar to other palms) differs in its structure and properties compared to common wood species, special product development (including material respectively product modelling) and process development is necessary to achieve market competitiveness. Hackel [33] modelled the bending properties described in this paper using the finite element method (FEM). For load bearing products, grading and trimming of the lumber, long term durability under load (and wet climate) and design values as well as standardization (matching with building codes) are significant challenges. Standards for common wood species do not automatically fit for oil palm wood. For example, the effect of test specimen size, especially the difference between small-size and construction-size test specimens, is much smaller compared to common wood species; for some properties, the full-size test specimens show higher values than small-size test specimens at the same density (which is likely caused by the complex macroscopic structure of the oil palm wood). The equation between local and global MOE for solid construction timber from softwoods according to EN 384 [18] does not apply for oil palm wood GLT. The relationship between the characteristic values for strength and density of coniferous timber according to EN 338 [14] fits for GLT from oil palm, but not the relationship between the mean MOE and density. The MOE is – in relation to strength and density – much lower for oil palm wood. The correlations between lamella and GLT quality (“GLT model”) and the various properties among themselves, which are well-known for common wood species, do not apply to oil palm wood. Therefore, the building codes need to be adapted for oil palm wood.

ACKNOWLEDGEMENT

The project was funded by the German Federal Ministry of Education and Research through the "Bioökonomie International 2017" project "Oilpalmsugar (031B0767A)". The procurement of the oil palm material was supported by the Malaysian Timber Industry Board (MTIB) and the Fibre and Biocomposite Development Centre (FIDEC) represented by Dr. Loh Yueh Feng as well as Profina Plywood Sdn Bhd. Sawmilling of some of the material was provided by the Forest Research Institute Malaysia (FRIM). Leitz GmbH & Co. KG provided the wood processing tools, Electronic Wood Systems, Hameln the X-ray measurement devices, Jowat SE the adhesives and MINDA Industrieanlagen GmbH the press. Dipl.-Ing. Claus Deis, M.Sc. Lena Heister. M.Sc. Nico Ferlemann and M.Sc. Martin Hackel did the laboratory work.

FLEXURAL PROPERTIES OF OIL PALM WOOD (*ELAEIS GUINEENSIS* JACQ.) BASED GLUED LAMINATED TIMBER (GLT) USING FINITE ELEMENT METHOD (FEM)

Martin Hackel[1]

ABSTRACT: The anatomical structure of oil palm wood is only to a limited extent comparable to common wood species used in construction. Typical for monocotyledons, the material is composed of high density vascular bundles and a parenchymatous tissue of lower density. In three experiment sets, the local and global moduli of elasticity (MOE) and the flexural strength of oil palm wood based GLT are determined using FEM and various influencing parameters are investigated in a sensitivity analysis. Furthermore, the application of densified tension lamellas is studied. The results of the modelling are compared with the results from mechanical tests. Significant differences, mainly attributed to the specific parameters of the selected material, are observed. The results of this preliminary study serve as a starting point for computer-aided optimisation and modelling of other oil palm-based products.

KEYWORDS: Oil palm wood, finite element method (FEM), GLT, modulus of elasticity, flexural strength

1 INTRODUCTION

The rising population in recent decades has led to increased demand for raw materials, especially in the food, chemical and pharmaceutical industries as well as the construction and energy sectors. Oil palms *(Elaeis guineensis* JACQ.) are a versatile raw material producing crop. Oil palm provides raw materials in the form of palm and palm kernel oil, for all industry sectors mentioned. As a result, the global oil palm cultivation area, concentrated in Southeast Asia, increased between 1996 and 2021 by 328 % to 28.9 million hectares [1]. Declining crop yields limit the economic lifespan of oil palms to about 25 to 30 years [2]. The clearing of plantation areas after the end of the economic lifespan results in up to 180 million m³ of usable oil palm wood per year [3]. Its actual use, however, is limited by a lack of knowledge regarding the wood's material properties. Possible substitution potentials of the material are also unrecognised and accordingly not utilised. Influenced by the shortage of building products caused by various factors, such as the conflict in Ukraine, droughts and bark beetle calamities in Europe and North America as well as the effects of the Covid pandemic, building products have been identified as a possible field for substitution approaches.

The development of construction materials from renewable raw materials (e. g. wood or wood like materials) is economically intensive. These raw materials are characterized by inherent variations of their material properties and naturally occurring inhomogeneity. Common building materials such as glued laminated timber (GLT) use layer-based approaches to reduce the property variations respectively the inhomogeneity. The application, production and properties of GLT are specified by e.g. European standards [4, 5]. Before oil palm based GLT can be introduced to the market, it is necessary to create a lamella grading [6] and develop various beam structures in regard to the requirements in the standards. Therefore, expensive material tests need to be performed. A way to reduce costs is through digitalisation. Larger series of experiments can be performed using the finite element method (FEM) without material expense and in a comparatively short investigation period. The quality of FEM-modelling depends on the quality of the material parameters used as input parameters. But suitable material parameters of oil palm wood are only published to a limited extent in the literature. Currently, no modelling of oil palm wood based products has been published.

The aim of the work is to evaluate the suitability of FEM for determining the flexural properties of oil palm GLT by comparing the modelling results with the results of Heister and Fruehwald-Koenig [7] (static tests). Furthermore, possible relationships of the flexural properties with other material properties, primarily density, are evaluated. In the form of a sensitivity analysis, possible influences of different material properties on the flexural strength are examined. Furthermore, the influence of densified tension lamellae on the flexural strength is evaluated.

The objectives of the work are achieved through a multi-stage process. Based on a literature research, suitable relationships between the density and elastomechanical material properties are determined. Missing relationships are established by own investigations or approximation. The beams tested by Heister and Fruehwald-Koenig [7] are implemented in the modelling software RFEM 6.02. Using suitable statistical methods, the results of the different experiments are compared and evaluated.

[1] Martin Hackel, OWL University of Applied Sciences and Arts, Lemgo, Germany, martin.hackel@th-owl.de

https://doi.org/10.52202/069179-0088

Subsequently, correlations of the modelling results with different specimen properties are investigated. Following this, the results of the modelling are compared with the results of the experiments by Heister and Fruehwald-Koenig [7]. Finally, the results are discussed and placed in the context of existing literature.

2 STATE OF THE ART

2.1 ANATOMICAL FEATURES OF OIL PALM WOOD

Oil palms (*Elaeis guineensis* JACQ.) are monocotyledons and show differences in the anatomical structure to dicotyledons (deciduous and coniferous trees). Monocotyledons have no cambium, which results in a lack of annual rings (no secondary thickness growth). Furthermore, oil palms have no wood rays, no differentiation between heartwood and sapwood and no knots. Oil palm wood is composed of vascular bundles of high density and parenchymatous ground tissue of low density. The vascular bundles are mainly parallel to the mantle, but also helical orientations are widespread [8]. Deviations from the stem axis occur due to direct contact with the palm fronds and are therefore also referred to as leaf trace bundle [9].

Lim and Khoo [2] define three zones within the oil palm stem. The “outer” or “peripheral” zone of the stem includes about 20 % of the stem volume, irregular vascular bundles and a low parenchyma content characterise this zone [10]. The “inner” zone (about 40 % of the stem volume) has a high parenchyma content and widely distributed vascular bundles. The “central” zone (approx. 40 % stem volume) forms a transition between the peripheral and inner zone. Lim and Khoo [2] report densities of 170 kg/m³ from the “inner” zone to 700 kg/m³ in the “outer” zone. Kölli [11] confirms this density range (180 kg/m³ - 561 kg/m³). With increasing trunk height, the density of oil palm wood decreases. Kölli [11] shows exponential relationships between the position in the trunk and the density (horizontal and vertical). The “wood” tissue of oil palms is anisotropic, but only small property differences between radial and tangential directions are reported [2, 10]. Nevertheless, orthotropic material behaviour is assumed in the context of this work.

2.2 ELASTOMECHANICAL PROPERTIES OF OIL PALM WOOD

In compression tests (longitudinal), Fathi [12] determines Young's moduli of 1856 to 8238 MPa with a linear relationship ($R^2 = 0.99$) to the density. Srivaro et al. [13] determine values for the Young's modulus (longitudinal) of 114 to 996 MPa and an exponential relationship with the density ($R^2 = 0.64$, exponent 2.67). In the tensile test in fibre direction, Fruehwald-Koenig and Heister [14] determine a Young's modulus of 488 to 13102 MPa and report an exponential relationship to the density ($R^2 = 0.53$, exponent 2.41). A determination of the Young's modulus along all anatomical axes is performed by Fruehwald-Koenig and Faust [15] using ultrasonic measurements. Values of 4368 to 11695 MPa and a linear correlation with the density ($R^2 = 0.75$) are determined for the longitudinal Young's modulus. The values of the radial Young's modulus range from 100 to 501 MPa. The correlation to the density is low ($R^2 = 0.04$). The tangential Young's modulus is determined with values from 91 to 743 MPa and a linear relationship with density is shown ($R^2 = 0.26$).

G_{TL} and G_{RL}, respectively, are determined by Koelli [16] in static shear tests. The reported relationships are determined using linear or exponential regression models and provide coefficients of determination of $R^2 = 0.39$ (linear) or $R^2 = 0.43$ (exponential). Fruehwald-Koenig and Faust [15] determine the G-moduli in all three planes by dynamic ultrasound measurements. The results for G_{LR} range from 189 to 472 MPa, for G_{TL} from 196 to 555 MPa and for G_{RT} from 167 to 345 MPa. For all G-moduli, linear relationships with density are evident ($R^2 = 0.69$ - 0.85).

The Poisson's constants are determined by Fruehwald-Koenig and Faust [15] by dynamic ultrasonic measurements. The mean values of the individual constants are given as follows: $\mu_{LR} = 0.389$, $\mu_{RL} = 0.026$, $\mu_{LT} = 0.911$, $\mu_{TL} = 0.044$, $\mu_{RT} = 0.647$ and $\mu_{TR} = 0.707$. Fruehwald-Koenig et al. [17] determine Poisson's constants on specimens in service dimensions. The measurements do not distinguish between radial and tangential directions. Mean values for $\mu_{L/RT}$ from 0.379 to 0.523 and μ_{RT} of 0.117 are reported. Relationships between density and Poisson`s constants are not pronounced ($R^2 = 0.0024$).

For oil palm wood, no data on hardening moduli are available at the time of writing. Fruehwald-Koenig and Heister [14] determine the tensile strength (longitudinal) with values from 1.9 to 47 MPa and show an exponential relationship to the density ($R^2 = 0.76$, exponent 2.24). Furthermore, tensile strength (radial/tangential) with values of 0.4 to 2.3 MPa and an exponential relationship ($R^2 = 0.5$, exponent 1.4) are reported.

Fathi [12] determines compressive strengths (longitudinal) with values from 4.4 to 27.6 MPa and shows a linear relationship with density ($R^2 = 0.6$). Fruehwald-Koenig and Heister [14] demonstrate an exponential relationship ($R^2 = 0.76$, exponent 2.24) and reported values from 3.1 to 64.6 MPa. For the compressive strength (radial/tangential) an exponential relationship ($R^2 = 0.73$, exponent 3.08) and values from 0.1 to 12.2 MPa are reported.

Investigations by Fathi [12] regarding the shear strength in RL-plane with longitudinal load provide results of approximately 2 to 4 MPa and a linear relationship with density ($R^2 = 0.998$). Fruehwald-Koenig et al. [17] determine an exponential relationship with density ($R^2 = 0.52$, exponent 1.36) for the shear strength in RL plane under longitudinal load and report values from 0.2 to 7.8 MPa. In addition, rolling shear strengths with values from 0.1 to 3.1 MPa and a moderate exponential relationship with density ($R^2 = 0.17$, exponent 1.05) are determined.

2.3 FEM FOR LAYER BASED WOODEN PRODUCTS

FEM is used to model the material behaviour of GLT beams and other layer-based wooden materials. Ehlbeck et al. [18] use FEM to predict the load-bearing capacity of glulam beams made of spruce. The material behaviour is assumed to be linearly elastic. The load is increased

stepwise. Within each stage, all elements are tested against reaching the tensile or compressive strength. When the tensile strength is reached, a case distinction is made. If the applied load is greater than in the previous load level, the material properties of the element are set to zero and the load is increased further. If the load is less than in the previous load level, the load-bearing capacity is reached. When the compressive strength is reached, the properties of the element are changed so that no further load absorption is possible [18]. Blaß et al. [19] and Frese [20] transfer the approach of Ehlbeck et al. [18] to beech wood. Orthotropic linear elastic material behaviour is assigned to the tension zone. The failure of the beam is defined by reaching the tensile strength in one element of the tension lamella. The elements of the compression zone are assigned an ideal elastic-plastic material model [19–20]. If the compressive strength is exceeded, ideal plastic material behaviour is assumed. The deviations between modelling and laboratory tests are between -6.9 % and +2.5 % (flexural strength) and -8.1 % and +1.9 % (global MOE) [20]. Gao et al. [21] transfer the aforementioned approach to Cathay poplar. Deviating from Blaß et al. [19], a three-dimensional model and steel intermediate layers (riders) are used in the load application points. In addition, the adhesive bond is investigated. Isotropic material properties are assigned to the adhesive layers. The bond between adhesive and timber layers is assumed to be rigid. The assignment of the material models in tension and compression zone is realised analogous to Frese [20]. Modelling underestimates the flexural strength by 3.9 % and overestimates the global MOE by 2.8 %.

3 MATERIAL

3.1 MATERIAL ORIGIN

The material used in the laboratory tests [7] originates from two cultivation regions in Malaysia. The material of the specimens with the identifiers ZA and ZN is obtained from approximately 30-year-old oil palms from the Kedah region. The material is transported to Germany in frozen state. Further processing takes place in Germany. Information on processing and drying can be found in Heister and Fruehwald-Koenig [7]. The material of specimen identifiers A and N originates from the Johor region. The cutting of the palms (approximately 30 years old) as well as the drying are carried out within the framework of a research project of the Forest Research Institute of Malaysia (FRIM). Further information on the processing of the material is provided by Heister and Fruehwald-Koenig [7].

3.2 BEAM STRUCTURES

Within the scope of this work, combined GLT beams are investigated. The beams have the dimension 2200 mm x 50 mm x 102 mm and consist of six lamellas each (2200 mm x 50 mm x 17 mm, L x W x H). The chosen beam design aims to achieve strength classes C14 and C 10 (definition by [7]) with density graded lamellas for the compression, shear and tension zones The lamellas of the highest density class are assigned to the tension zone 335…363 kg/m³ for C 10, respectively >427 kg/m³ for C 14. Medium density lamellas are in the compression zone (289…335 kg/m³ for C 10 respectively 363…427 kg/m³ for C 14). Low density lamellas are in the shear zone (<289 kg/m³ for C10 and C14).

For the production of the beams, the two lamella types "natural lamellae" (specimen identification N, cut according to geometry from wider boards and therefore show high density and property gradients) and "assembled lamellas" (specimen identification A, edge-glued of narrow, density graded strips and therefore show more homogeneous density and properties over the width) are used.

3.3 DENSIFIED MATERIAL

To investigate the influence of the densification of lamellas on the GLT properties, material properties of densified oil palm wood are used as input parameters for tension lamellas (only in FEM modelling, no laboratory test). The material is mechanically dewatered and thermo-hydro-mechanically densified using two densification rates (40 % and 60 %). Further information on the process and elastomechanical properties are given in Fruehwald-Koenig et al. [22] and Koelli and Fruehwald-Koenig [23].

3.4 ELASTIC MATERIAL PARAMETERS

Modelling is carried out using two sets of material constants from ultrasonic testing and static testing. The Young´s moduli and shear moduli are taken from Fruehwald-Koenig and Faust [16], who described them related on density from ultrasonic tests. Equations (1) - (3) provide the relationships for the Young´s moduli and (4) – (6) for the shear moduli [15].

$$E_L(\rho) = 22.345\,\rho + 204.89 \quad (1)$$

$$E_R(\rho) = 0.318\,\rho + 223.38 \quad (2)$$

$$E_T(\rho) = 1.37\,\rho - 42.164 \quad (3)$$

$$G_{RT}(\rho) = 0.6917\,\rho - 16.657 \quad (4)$$

$$G_{TL}(\rho) = 1.3857\,\rho - 91.621 \quad (5)$$

$$G_{LR}(\rho) = 1.0738\,\rho - 37.963 \quad (6)$$

where $E_{L,R,T}$ = Young´s moduli along the anatomical axes (ultrasonic test), $G_{RT,TL,LR}$ = Shear moduli in symmetry planes (ultrasonic test), ρ = density

Equation (7) provides the relationship between Young´s modulus in longitudinal direction and density from static test [14].

$$E_{t,0}(\rho) = 0.0021\,\rho^{2.41} \quad (7)$$

where $E_{t,0}$ = Young´s modulus longitudinal (static test), ρ = density.

Equation (8) shows the relationship between shear modulus in the longitudinal direction and density from static test [16].

https://doi.org/10.52202/069179-0088

$$G_{RL,stat}(\rho) = 0.2812\,\rho - 1.7586 \quad (8)$$

where $G_{RL,static}$ = Shear modulus TL-plane (static test), ρ = density.
Due to limited data on static tests, the dynamically determined elastic constants are converted in "reduced" (static) properties using the Equations (9) and (10).

$$E_{R,T\,reduced}(\rho) = \left(\frac{E_L(\rho)}{E_{t,0}(\rho)}\right) E_{R,T}(\rho) \quad (9)$$

$$G_{RT,LR\,reduced}(\rho) = \left(\frac{G_{TL}(\rho)}{G_{RL,stat}(\rho)}\right) G_{RT,LR}(\rho) \quad (10)$$

where $E_{R,T,reduced}$ = reduced Young´s moduli along R and T axis, $E_{L,R,T}$ = Young´s moduli along the anatomical axes (ultrasonic test) (Equations (1) – (3)), $E_{t,0}$ = Young´s modulus longitudinal (static test) (Equation (7)), $G_{RT,LR,reduced}$ = reduced shear moduli in RT, LR plane, $G_{RT,TL,LR}$ = Shear moduli in symmetry planes (ultrasonic test) (Equations (4) – (6)), $G_{RL,static}$ = Shear modulus TL-plane (static test) (Equation (8)), ρ = density.
According to Fruehwald-Koenig et al. [17], Poisson's ratios are not density dependent. Therefore, the mean values μ_{LT} = 0.497, μ_{LR} = 0.497 and μ_{RT} = 0.117 are used. For the densified lamellas, the E- and G-values given in Table 1 are used. They are determined using Equations stated in Koelli and Fruehwald-Koenig [23] estimating a density of 550 kg/m³ and adjustments as described above. As Poisson's ratios, the ratios for undensified material as stated above are used.

Table 1: *Material parameters densified tension lamellas*

	E_L [MPa]	E_R [MPa]	E_T [MPa]	G_{RT} [MPa]	G_{LT} [MPa]	G_{LR} [MPa]
40 %	6301.4	212.3	125.4	43	139.6	148.6
60 %	3741.3	211.6	36.7	43	139.6	157.5

3.5 PLASTIC MATERIAL PARAMETERS

The compressive yield strength is defined as the strength of a material at the transition from elastic to plastic material behaviour. The determination of the compressive yield strength is realised using [4] and [24] and based on the stress-strain diagrams of the compression tests of oil palm wood in service dimensions carried out by Heister and Fruehwald-Koenig [25].
Starting the determination, a straight line is formed through the linear area of the stress-strain diagram. Subsequent this line is shifted parallel by a plastic strain of 0.02 %. The intersection of the shifted line and the test curve defines the elastic limit. The stress in the intersection point corresponds to the compressive yield strength.
The compressive yield strength longitudinal (L) ranges from 5.3 to 34 MPa (mean 15 MPa). An exponential relationship with density is observed (R^2 = 0.76, see Equation (11)).

$$f_{c,L}(\rho) = 1.6115\,e^{0.0052\rho} \quad (11)$$

where $f_{c,L}$ = compressive Yield-strength longitudinal, ρ = density.
The compressive yield strength radial/tangential (R/T) ranges from 0.42 to 0.60 MPa. No relationship with density (R^2 = 0.08) can be proven. The mean value of 0.499 MPa is used as input parameter.
Due to the brittle material behaviour of oil palm wood under tensile load, the tensile yield strength is assumed to be equal to the tensile strength. Equation (12) and (13) show the relationship between density and tensile strength (L) $f_{t,L}$ and tensile strength (R/T) $f_{t,RT}$ [14].

$$f_{t,L}(\rho) = 0.00004\,\rho^{2.12} \quad (12)$$

$$f_{t,RT}(\rho) = 0.0002\,\rho^{1.4} \quad (13)$$

where $f_{t,L}$ = tensile strength (longitudinal), $f_{t,RT}$ = tensile strength (radial / tangential), ρ = density.
Due to limited data on the plastic behaviour of oil palm wood under shear stress, shear yield strengths are assumed to be equal to shear strengths.
Equations (14) and (15) show relationships between density and rolling shear strength and shear strength in the R/T plane (longitudinal loading) [14].

$$f_{v,RT}(\rho) = 0{,}001\,\rho^{1{,}0539} \quad (14)$$

$$f_{v,RL}(\rho) = 0{,}0004\,\rho^{1{,}3573} \quad (15)$$

where $f_{v,RT}$ = rolling shear strength, $f_{v,RL}$ =shear strength (tangential plane, longitudinal load), ρ = density.
For shear strengths in the transverse plane, no correlations are available in the literature. To approximate the shear strengths in the transverse plane, ratios of shear strengths in different plane-load combinations of beech wood according to Kollmann [26] are used to adjust the rolling shear strength and shear strength in the radial/tangential plane (L).
The hardening modulus is defined as the slope between the compressive yield strength and the compressive strength. The hardening modulus (L) reaches values of 526 to 3193 MPa (mean value 1486 MPa). An relationship with density is observed (R^2 = 0.50, see Equation (16)).

$$E_{p,L}(\rho) = 254.14\,e^{0.004\rho} \quad (16)$$

where $E_{p,L}$ = hardening modulus (L), ρ = density.
The hardening modulus (R/T) reaches values from 33.79 to 47.61 MPa. No relationship with density (R^2 = 0.00) can be proven. The mean value of the hardening modulus (R/T) (41.86 MPa) is used as input parameter.

4 METHODS

4.1 DETERMINATION OF FLEXURAL PROPERTIES

The flexural properties of glued laminated timber are determined in accordance with [4] using a four-point bending test. The support points are spaced 18 times the height of the beam (h) corresponding to 1836 mm. Load application points are required to be spaced 6 h (612 mm) apart. In the laboratory tests [7] partially deviating distances of 646 mm, 612 mm and 595 mm are used. Deviating from the requirements of the aforementioned standard solid wood (pine, oil palm) and plywood (beech, birch) riders instead of steel are used [7]. Local and global MOE as well as flexural strength are determined according to [4].

4.2 DETERMINATION OF MODELLING PARAMETERS AND EXPERIMENTS

The effects of varying parameters on the results of the modelling of GLT beams are investigated. The effects are tested in three experiment sets. In the first experiment set (I), the influences of the parameters geometry (2D / 3D), material model (isotropic, orthotropic), material parameter determination (non-destructive, destructive) implementation of riders and element size (8.5 mm, 5.66 mm) on the elastic flexural properties are investigated. Between each experiment one parameter is changed at a time, this enables the observation of the parameter effect. In each individual experiment, 23 beams are investigated and six experiments are carried out.

In the second experiment set (II), the general suitability of FEM for determining the flexural strength of oil palm-based GLT is investigated. Furthermore, the influence of the implementation of riders is again investigated. In addition, densified tension lamellas (cf. section 3.3) are examined separately in two individual experiments. Four different experiments are carried out on 22 GLT beams.

In the third experiment set (III), the influence of variations in the material parameters hardening moduli ($E_{p,L}$, $E_{p,R}$, $E_{p,T}$), compressive yield strengths (R/T) ($f_{c,R}$, $f_{c,T}$), material model (orthotropic plastic: compression zone / total specimen), tensile yield strength (L) ($f_{t,L}$) and shear yield strengths ($f_{v,RT}$, $f_{v,LT}$, $f_{v,LR}$) are investigated on a homogeneous beam model with lamellas of the same density. The total sum of the individual experiments of the third experiment set is 17.

4.3 EXPERIMENT IMPLEMENTATION IN MODELLING SOFTWARE

The modelling is realised using RFEM 6.02 (Dlubal Software GmbH). The beams are represented as two- or three-dimensional geometric models. The lamellas are represented by planes or volume elements. A solid bond is assumed between the lamellas. Modelling of the adhesive joints is omitted in this work, as no failure of the adhesive joints is reported in the laboratory tests.

Isotropic linear and orthotropic linear elastic material models are used to model the local and global MOE. For modelling the flexural strength orthotropic plastic material behaviour is assigned to the compression zone, tension and shear zone are described by orthotropic linear elastic material behaviour. For the description of the material behaviour, nine (orthotropic linear elastic) respectively 21 (orthotropic plastic) material parameters are necessary. The material parameters are determined as described in sections 3.4 and 3.5.

The support is realised as nodal supports or line supports. Displacements along the Y- and Z-axes are omitted. Along the X-axis displacements are possible. The bearings in the X-direction are described by a spring (k = 0.1 kN/m).

The lamellas are modelled with the help of two- and three-dimensional, rectangular plate or cubic volume elements. The element size is set to 5.66 mm or 8.5 mm, which corresponds to two respectively three elements over the height of one lamella. Depending on the settings the models are formed out of 3108 – 366019 elements with 3380 - 110802 nodes.

Loads are applied as nodal or line loads. Half of the total load is applied at each of the two load application points. For the determination of the elastic flexural properties, the loads are applied in two steps representing 10 % and 40 % of the estimated maximum load. The application of the orthotropic plastic material model requires stepwise calculations. Within each load step, equilibrium is determined using the Newton-Raphson method with a maximum of 100 iterations. The load is increased in steps of 50 N as a compromise between accuracy and calculation time.

Four nodal supports are used to determine the deflection necessary to calculate the elastic flexural properties. The supports are arranged according to [4]. To determine the maximum load required to calculate the flexural strength, the longitudinal stresses at raster points on the tensile lamellas are compared to the tensile strength of the corresponding lamella. Failure occurs when the recorded stress exceeds the tensile strength. Tensile strengths and stresses are compared at each load level. Load and stress of the failure load level and the previous load level are used to determine the maximum load by interpolation.

The deformation and stresses are calculated using the solver implemented in RFEM 6.02 and according to first-order theory. The results are presented in the form of graphical representations of the result gradients and tabular output of results in nodes and at grid points (10 mm spacing, total 7120 grid points) on the boundary surfaces of the tension lamellas.

5 RESULTS AND DISCUSSION

5.1 RESULTS FOR LOCAL MOE

Table 2 shows statistical variation parameters of the first experiment set regarding the local MOE. The mean values reach from 4050 MPa to 9625 MPa (laboratory tests 5422 MPa).

Normal distribution can be assumed for all experiments and laboratory tests acc. to an Anderson-Darling test. A one-factor ANOVA and a posterior pairwise t-test with alpha error correction according to Bonferroni shows significant differences of the mean values.

https://doi.org/10.52202/069179-0088

Table 2: *Statistical variation parameters local MOE*

	Parameter	Min [MPa]	Max [MPa]	Mean [MPa]	Sd [MPa]	COV [%]
Exp. I.1	2D, iso, nr, nd, 8.5	7934	10848	9347	838	8.97
Exp. I.2	3D, iso, nr, nd, 8.5	8238	11078	9625	832	8.64

Figure 1 shows the relationships between density and local MOE (experiments and laboratory test). The results of the local MOE show linear correlations with the density in all individual experiments with R^2 between 0.52 and 0.55. The slopes of the linear relationships are lower than that of the laboratory test. Differences between the equations of the regression lines are limited to the ordinate intercept. The regression lines are parallel shifted.

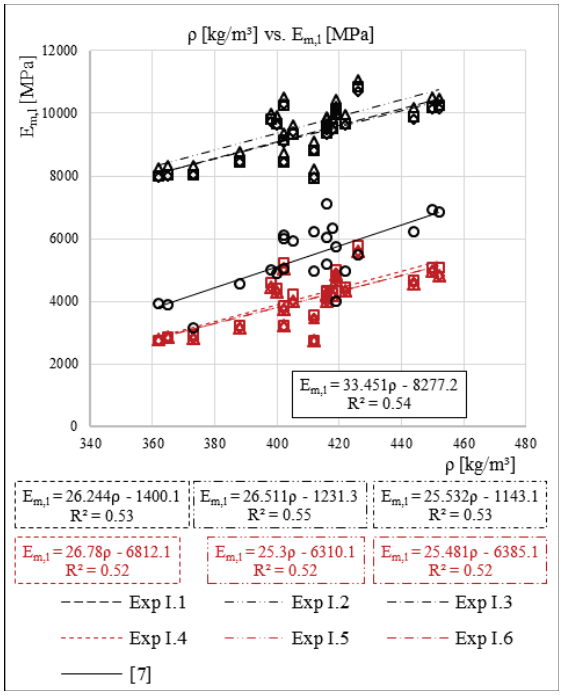

Figure 1: *Relationship between density and local MOE (statistical variation parameters see Table 2)*

5.2 RESULTS FOR GLOBAL MOE

Table 2 shows statistical variation parameters of the first experiment set regarding the global MOE. The mean values reach from 7447 MPa to 18513 MPa (laboratory tests 4562 MPa). Normal distribution can be assumed for all experiments and laboratory tests acc. to an Anderson-Darling test.

A one-factor ANOVA and a posterior pairwise t-test with alpha error correction according to Bonferroni shows significant differences of the mean values.

Table 3: *Statistical variation parameters global MOE*

	Parameter	Min [MPa]	Max [MPa]	Mean [MPa]	Sd [MPa]	COV [%]
Exp. I.1	2D, iso, nr, nd, 8.5	15806	21414	18513	1666	9.00
Exp. I.2	3D, iso, nr, nd, 8.5	15475	20500	18053	1544	8.55

Figure 2 shows the relationships between density and global MOE (experiments and laboratory test). The results of the global MOE show linear correlations with the density in all individual experiments with R^2 between 0.53 and 0.57. The slopes of the linear relationships are higher than that of the laboratory test differences between the equations of the regression lines are limited to the ordinate intercept. The regression lines are parallel shifted.

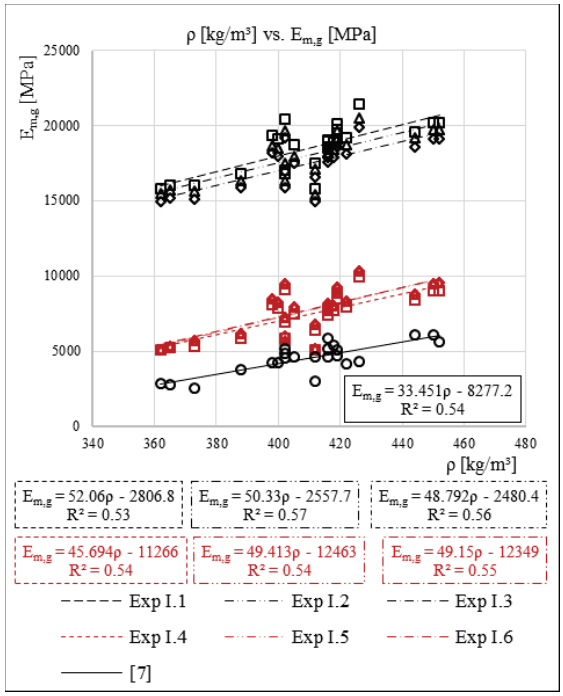

Figure 2: *Relationship between density and global MOE (statistical variation parameters see Table 3)*

5.3 DISCUSSION LOCAL AND GLOBAL MOE

The differences between the experiments can be attributed to varying factors. The difference between experiment I.1 and I.2 is the geometrical dimension (2D, 3D). Only minor effects for components homogeneous across the width occur. The small difference between experiment I.2 and I.3 after changing the material model is attributed to the load case. In four-point bending tests, stresses primarily occur in fibre direction. According to Ehlbeck et al. [18], the Young´s modulus in the fibre direction is the dominating factor for the flexural properties of GLT beams. The Young´s modulus in fibre direction is not varied between experiment I.2 and I.3. The implementation of riders according to [4] in experiments I.5 and I.6 shows no significant effect. The modelling is carried out in the elastic range of the material behaviour of the oil palm wood (no plastic deformations occur). The riders serve to distribute and transmit the load. Minimising the element size (experiment I.6) shows no significant effect in this study. Discretisation by using two or three elements over the lamella thickness is considered sufficient [28]. The significant differences between experiment groups I.1 – I.3 and I.4 – I.6 are attributed to the choice of material parameters. The difference of the Young´s modulus in the fibre direction as one of the main influencing parameters corresponds to 55.4 %. The differences for local MOE (56.7 %) and global MOE (57.5 %) between the experiment groups show similar percentages.

Comparison of the local and global MOE shows that the global MOE exceeds the local MOE in all experiments. Heister and Fruehwald-Koenig [7] report an opposite relationship for the laboratory tests (local MOE > global MOE). The ratio of the mean values of local to global MOE ranges from 0.505 to 0.558. The laboratory tests provide a ratio of 1.189 (0.99 spruce [29]). Thus, the modelled values are below the comparative literature values. Boström [30] reports for spruce, that the local MOE > global MOE if the global MOE is > 10 GPa and local MOE < global MOE if the global is < 10 GPa. Boström [29] attributes the differences between local and global MOE to shear deformations and the influence of timber defects in small cross-sections. The effects described are consistent with the results of experiments I.4 – I.6. Applying one density the whole lamella, leads to a reduction of the natural property gradients (artificial homogenisation). The absence of these natural property variations and defects results in comparably higher values for the global MOE, the influence on the local MOE is less pronounced.

5.4 RESULTS FOR FLEXURAL STRENGTH

Table 4 shows statistical variation parameters of the second experiment set regarding the flexural strength. The mean values are 13.3 MPa and 13.9 MPa (laboratory tests 22.1 MPa). Normal distribution cannot be proven for all experiments. Only the laboratory test shows normal distribution according to an Anderson-Darling test. A Friedman-Test and a posterior pairwise, paired Wilcoxon-Test with alpha error correction according to Bonferroni shows significant differences between the experiments and the laboratory test.

Table 4: *Statistical variation parameters flexural strength*

	Parameter	Min [MPa]	Max [MPa]	Mean [MPa]	Sd [MPa]	COV [%]
Exp. II.1	nr	9.5	15.7	13.3	2.2	16.5
Exp. II.2	r	9.7	16.5	13.9	2.4	17.5
laboratory test [7]		11.7	29.7	22.14	5.57	25.16

r/n.r.: rider, no rider

Figure 3 shows the relationships between density and flexural strength divided for specimen groups A (assembled) and N (natural). R^2 ranges from 0.53 to 0.55. The slope of the laboratory test is steeper than the experimental slopes for specimen group N. The regression lines of the laboratory results from Heister and Fruehwald-Koenig [7] lie above the regression lines of the experiments. Specimen group A (assembled) shows similar slopes for experiments and laboratory tests. The regression lines of specimen group N (natural) agree for the experiments, but differ to that from laboratory testing. This leads to the conclusion, that inhomogeneity and variations in material properties influence the results of the flexural test. Further tests are recommended to enable reliable statements about the stochastic behaviour of the flexural properties of oil palm based GLT.

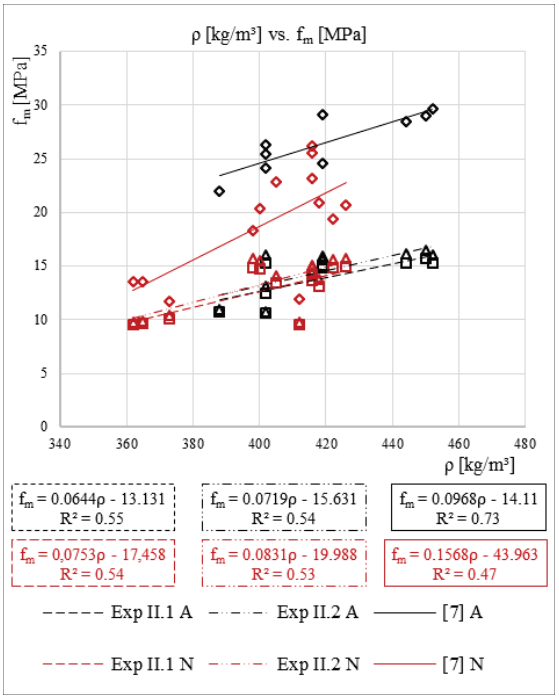

Figure 3: *Relationship between density and flexural strength divided by specimen group A (assembled) and N (natural)*

https://doi.org/10.52202/069179-0088

The comparison with the results of Heister and Fruehwald-Koenig [7] shows mean percentage deviations of -38.6 %. These deviations tend to correspond to the deviations of the local MOE (-25.5 %). Increasing the values of the elastic constants leads to stiffer material behaviour. This in turn results in loads being transferred with a certain delay and thus the critical tensile strengths in the tensile zone are reached later. The flexural strength increases. Further, the choice of the material model influences the flexural strength. Blaß et al. [19] point out that the use of the linear elastic material model in the tensile zone leads to an underestimation of the flexural strength. Plastic material behaviour in the tensile zone results in stress redistributions and thus a delayed attainment of the critical tensile stress. The sensitivity analysis (see section 5.8) shows that the application of the orthotropic plastic material model in the tensile zone results in an increase of the flexural strength of about 3.8 %.

Figure 4 shows the relationships between the density of the tensile lamellas and the flexural strength. Linear relationships are observed (R^2 = 0.83 Exp. II.1, R^2 = 0.84 Exp. II.2). R^2 (0.39) for the laboratory is lower compared to the experiments. Deviation from the behaviour observed for specimen group N (natural) in Figure 3, the regression line of the data from Heister and Fruehwald-Koenig [7] runs roughly parallel above the regression lines of the experiments. It can be observed that the density of the tension lamellas shows better correlations to the flexural strength than the overall density of the GLT beams.

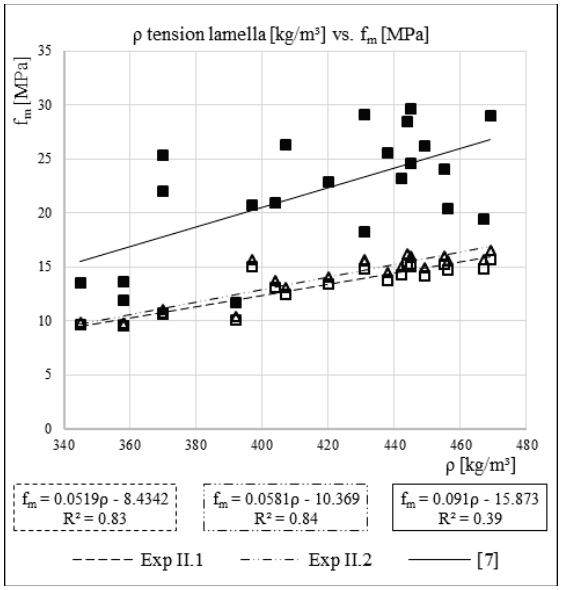

Figure 4: *Relationship between density tension lamella and flexural strength*

The differences between experiment II.1 and experiment II.2 are due to the change in the supports and load application points. Two effects can be observed due to the introduction of riders. The first effect is that plastic deformations are initiated later due to the load distribution over a larger area. Frese [20] confirms this effect by modelling homogeneous comparison beams. The second effect is the change in the stress profile within the tension lamella. As described by Frese [20], a rounding of the stress profile can be observed, which leads to the critical tensile stress being reached later. The mean percentage deviation between the experiments of 4.6 % exceeds the value of 1 % reported by Frese [20] for beech. The effect of load distribution by the riders therefore is higher for oil palm wood. The observed behaviour might be explained by the comparably low compressive strength (R/T) of oil palm wood.

5.5 INFLUENCE OF DENISFIED TENSION LAMELLAS

The use of tension lamellas of uniform density (550 kg/m³) in all test specimens results in a reduction of the observed variations. These variations represent the influence of the remaining test specimen structure. The flexural strength is increased compared to the comparison experiment (Exp. II.2) up to a density of 398 kg/m³ (40 % dens.) and 434 kg/m³ (60 % dens.). Surpassing those aforementioned thresholds, the flexural strength is decreased. This reflects the results of Koelli and Fruehwald-Koenig [23], who report that at the same density, undensified specimens show higher flexural strengths than densified specimens. This explains why despite the higher density of the densified tensile lamellas (550 kg/m³), no improvement in flexural strength can be achieved when the thresholds are exceeded. Densified tension lamellas are therefore particularly suitable for improving the flexural properties of low-density beam structures.

5.6 SENSITIVITY ANALYSIS

Within the sensitivity analysis, influences of the factors listed in section 4.2 on the flexural strength are investigated on the basis of percentage deviations from the comparison experiments III.C1 and III.C2 (Table 5).

Reducing the hardening modulus (R/T) from 41.9 MPa to 4.4 MPa in experiment III.1.1 reduces the flexural strength to 12.0 MPa (-3.6 %). A further reduction of the hardening modulus (R/T) to 0.2 MPa in experiment II.1.2 results in a further reduction of the flexural strength to 10.8 MPa (-13.7 %).

Variation of the compressive yield strength (R/T) shows little influence on the modelling results. Increasing the compressive yield strength (R/T) to 1 MPa (100 % increase) in experiment III.2.1 results in an increase in flexural strength of 0.005 MPa (+0.03 %). Increasing the compressive yield strength (R/T) to 4 MPa (700 % increase) in experiment III.2.2 results in an increase in flexural strength of 0.1 MPa (+0.3 %).

In experiment III.C2, the orthotropic plastic material model is assigned to all lamellas of the comparative specimen. Due to this change, the flexural strength of the reference specimen is increased to 13.0 MPa (+3.8 %). The change of the material model, reduces the compressive stresses in the support area. As described by Blaß et al. [19], stress redistributions in the tensile zone are possible using orthotropic plastic material behaviour, which lead to the critical tensile stress being reached later.

Experiments III.3 and III.4 evaluate the effects of a combination of the change of the material model and increased tensile yield strength (L). When changing the tensile yield strength (L), two separate considerations are to be carried out depending on the chosen comparative tensile strength (L) of the tensile lamellas (cf. section 4.3). Not increasing the critical tensile strength (L) and keeping it at 13.1 MPa (Exp. III.3.2 and III.4.2), results in flexural strengths of 13.0 MPa (-0.1 %, Exp. III.3.2 and Exp. III.4.2). Increasing the critical tensile strength (L) according to the increased tensile yield strength (L), results in flexural strengths of 19.6 MPa (+50.9 %, Exp. III.3.1) and 28.9 MPa (+123.3 %, Exp. III.4.1). The recorded percentage increases of flexural strengths are equal to the percentage increases of the applied tensile yield strengths (L) of 52.32 % and 128.48 %.

The increase of the shear yield strengths (Exp. III.5) shows only little influence on the flexural strength of the comparative specimen, (increase of 0.02 %) because of the choice of test arrangement. In four-point bending tests, only low shear stresses occur.

The sensitivity analysis shows that variations in the hardening moduli have a large influence on the flexural bending strength and needs further investigations. Variations of tensile yield strengths (L) with simultaneous adjustment of the critical tensile strength shows strong effects and needs further investigations. Variations in compressive yield strength and shear yield strength have small influence on the flexural strength. The parameters are applicable in the chosen form.

Table 5: *Sensitivity analysis result and percentage deviations*

	III.C1	III.1.1	III.1.2	III.2.1	III.2.2	
f_m [MPa]	12.5	12.0	10.8	12.5	12.5	
Deviation [%]		3.6	13.7	0.03	0.3	
	III.C2	III.3.1	III.3.2	III.4.1	III.4.2	III.5
f_m [MPa]	13.0	19.6	13.0	28.9	13.0	13.0
Deviation [%]		50.9	0.06	123.3	0.07	0.04

Exp. III.1: reduction hardening moduli (R/T), Exp. III.2: increase compressive yield strength, Exp. III.3: change material model, increase tensile yield strength (L), Exp. III.4: change material model, increase tensile yield strength (L), Exp. III.5: change material model, increase shear yield strength

6 CONCLUSION AND OUTLOOK

The results of the modelling confirm the applicability of the finite element method for modelling oil palm wood-based GLT. The selected geometric models as volume and plane models based on individual layers with varying material properties as well as the chosen support and load application implementation are suitable for a realistic representation of the comparative tests.

Geometric representation, material model, riders as well as element size show no significant influence on the results of the modelling of the local and global MOE, whereas the material parameter determination has a significant influence on the modelled MOE. Deviating from this, the implementation of riders shows a significant influence on the modelling results of the flexural strength. In further investigations, an implementation of riders is strongly recommended.

The comparison of the flexural properties (MOE and flexural strength) with the results of the laboratory tests by Heister and Fruehwald-Koenig [7] shows significant differences due to the material constants used (elastic constants and tensile strength) and the material model used in the tensile zone. The effects of material constants and material model adjustments have to be investigated in experiments on a larger scale.

The relationships between density and local and global MOE proven in this work show comparable forms to Heister and Fruehwald-Koenig [7], whose differences lie primarily in the ordinate intercepts determined. Comparable behaviour is shown by the relationships between density of the specimens and flexural strength (for specimen group A (assembled lamella)) and between tensile lamella density and flexural strength (overall collective). The overall collective as well as specimen group N (natural lamella) show uniform shapes within the modelling for the relationship between density and flexural strength but deviate strongly from the results of Heister and Fruehwald-Koenig [7]. An adjustment of the ordinate intercept is not expedient. The observed behaviour offers a starting point for further investigations regarding the optimisation of the modelling results. The use of densified tension lamellas results in a homogenisation of the flexural strength. Especially the performance of lower density specimens can be improved by using densified tension lamellas. The level of improvement is higher for higher densification rates.

The local and global MOE of the modelling show a different behaviour compared to the literature. The global MOE exceeds the local MOE in all experiments. Further investigations on the global MOE are recommended. An effect of the artificial homogenisation, by applying only one density for one lamella and reducing the natural property gradients, on the results of the global MOE can be demonstrated for specimen group N (natural).

The sensitivity analysis identifies the hardening modulus, the tensile yield strength (L) and the choice of material model in the tensile zone as parameters that strongly influence the results of the flexural strength. The parameters compressive yield strength (R/T) and shear yield strength show much lower influence. The sensitivity analysis is suitable for determining parameter influences.

The results of this work offer starting points for further investigations, in particular the consideration of the influencing factors identified in this work, the modelling of oil palm-based cross laminated timber as well as the application of statistically varying material constants for the representation of larger specimen collectives and the improved representation of natural property variations within the lamellas.

ACKNOWLEDGEMENTS

The laboratory tests referred to in this study were carried out by Prof.'in Dipl.-Holzwirtin Katja Fruehwald-Koenig (creation of a grading system for oil palms, lamella grading and determination of the GLT structure) and Lena Heister M.Sc. (production and testing of the GLT beams).

BENDING PROPERTIES OF 100 NARROW CLT-BASED BOARDS – STATIC AND DYNAMIC TESTS AND DIC ANALYSIS

Mikael Perstorper[1], Johan Vessby[2], Emil Lockner[3]

ABSTRACT: Production of CLT-panels typically results in 5-10% cut-offs due to window and door openings. CLT-boards can be made by slicing these cut-offs and finger-jointing them. This paper presents bending properties of 100 narrow CLT-boards (45x95x1800) made from 5-ply CLT panels made of Norway spruce. A limited variation in E-modulus (CV=9%) and bending strength (CV=20%) was found with gross section values not far from typical structural C24-timber. The tests indicate that narrow CLT-boards have sufficient bending properties for being used as structural components, also where the bending capacity is formally utilized. However, the variation was slightly higher than for typical tests on larger CLT-elements (CV=8-16%), probably due to the smaller homogenization effect when fewer sub-parts carry the load. The rolling shear modulus was estimated to be G_r= 65 MPa, which is to be expected due to the distance from the pith of the cross layer boards. The surprisingly high net flatwise bending strength ($f_{m,05}$=49 MPa) can likely be attributed, for the most part, to the reinforcing effect from the cross layers that limit the slope of grain cracking near knots in the longitudinal layers. DIC-tests revealed an indication of a non-plane normal strain distribution over the beam depth in the shear-free zone between the inner loading points. This might lead to an underestimation of the shear-free local E-modulus according to EN 408.

KEYWORDS: CLT, bending strength, E-modulus, rolling shear modulus, strain distribution, DIC-analysis

1 INTRODUCTION

The background of this study is the urge to find smart use of cut-offs from production of Cross Laminated Timber (CLT), see Figure 1. Due to window and door openings, 5-10% of all CLT material is typically chipped up to become biofuel. The idea here is to slice these cut-offs and finger-joint them to CLT-boards with sizes similar to structural timber. It has been verified that this kind of boards can successfully be finger-jointed.

The cross-layers weaken the bending properties compared with solid wood, but give the CLT-boards superior properties when loaded in the perpendicular direction as with horizontal rails in a wall frame. An up to fivefold increase in capacity has been found, see Vessby et al. [1]. However, in this paper the focus is on the bending properties of this kind of narrow CLT-based boards to verify that they have properties that allow for typical handling in the production of timber frame elements. Tests are also warranted in view of applications of the CLT-boards where the bending properties are critical also for formal load-bearing.

It has been shown in many studies that the variation in bending strength is much smaller in CLT, thanks to the fact that many boards carry the load together. One severe defect in an individual is not critical for the strength as neighboring boards carry the load. The coefficient of variation is typically CV=8-16%. Structural timber has a greater variation, especially if the classification is done to only one low grade like C24 and reject: (CV=30-35%). However, most studies on CLT has been done on quite large elements, typically 600 mm wide, which contain several boards. It is not clear how much narrower CLT-boards behave in bending where defects in single boards potentially are more critical for the overall behavior.

In the standardization work in Europe, the size limitations for the applicability of the CLT-standard for small sizes are discussed [2]. This study may contribute to the discussion about such limits. Furthermore, few studies have been done on the in-plane bending strength, especially with small sizes. One of few studies of small size CLT is the one reported by Flaig and Blaß. (2014). [3]. They studied the in-plane bending properties of smaller specimens down to 100x150 mm^2 with a focus on the lamination (system) effect. Their results are encouraging and indicated a substantial positive effect of the cross layers on the in-plane bending strength. However, the narrow CLT-boards focused on here are much smaller and only 45 mm deep for the in-plane bending mode (flatwise in this case).

The objective of this study was to investigate not only the edgewise properties but also the flatwise bending properties as the latter is of importance for practical handling at the construction site and/or at the pre-fabrication factory.

2 MATERIAL AND METHODS

2.1 MATERIAL

The material for the study came from the normal CLT-production at the Stora Enso mill in Gruvön, Sweden. A so called C5s panel with the intended use as a wall element was chosen. This 100 mm thick 5-ply CLT consisted of 20 mm thick layers of Norway spruce boards, strength graded as a single grade to T15. In this case it is comparable to C24, which for Nordic material gives a grading yield of about 99%. The boards were side-glued.
A total of 100 CLT-boards (slices) were produced and planed to the desired standard size (45x95x1800 mm^3) according to Figure 2. The thickness of the layers were: 17.25+20.3+20.3+20.3+17.25 mm resulting in an actual width of 95.4 mm. The boards were in this case cut from one full-size CLT-panel and not from cut-offs. Therefore, there was no need for finger-jointing of board parts from cut-offs. However, it should be noted that the individual boards in the CLT-panel were finger-jointed as usual. The layers were made of 100 mm wide, flat sawn side boards with an average distance from the board center to the pith of approximately 120 mm, see Figure 2. It can also be noted that some longitudinal layers were laminated and contained material from two different side-glued boards. Approximately 80% of the boards had one or more laminated layers.
The average moisture content of the boards was 9.4% and all reported elastic properties were adjusted to the reference moisture content 12%.

Figure 2: *Flatwise view and section of CLT-board where layer 3 and 5 is laminated (consists of two side-glued boards).*

2.2 STATIC TESTS AND DIC MEASUREMENTS

The CLT-boards were tested to determine the edgewise (50 pcs) and flatwise (50 pcs) static bending properties following the EN 408 standard [4]. One deviation was that the flatwise tests were done using the same test set-up as for the edgewise test with a span of 18 times the width (1710 mm), see Figure 3. Unfortunately, the measurement of the local E-modulus between the loading points using a yoke on the tension edge did not give reliable results and is not reported here. The global E-modulus E_{gl} is based on the overall mid-span deflection and the value presented here is not corrected for shear deformations, which are considerable due to the weak cross layers. Properties for the gross and net section were calculated. In the latter case the transverse E-modulus of the cross layers was assumed to be zero, E_{90}=0 MPa. The net E-modulus, without shear deformation influence, was calculated from the global value using the gamma method [5], assuming E_{90}=0 MPa and a rolling shear modulus of G_{90}=65 GPa based on dynamic test analysis.
Strain and displacement data from a Digital Image Correlation (DIC) system was gathered for 5 edgewise boards for the area between the loading points, see Figure 3.

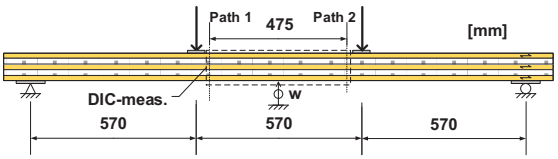

Figure 3: *Bending test set-up according to EN 408 [4] and zone for DIC strain measurement.*

2.3 DYNAMIC TESTS

The 50 boards that were tested in edgewise bending were also subjected to dynamic tests whereby the specimens were suspended in springs to simulate free-free boundary conditions, see Figure 4. Based on geometry, density and resonance frequencies for different vibration modes, E-moduli and shear moduli were determined. The first 3-4 modes of vibrations were analyzed for axial ($E_{d,ax}$), flatwise and edgewise bending ($E_{d,bf}$ + $E_{d,be}$) and torsion ($G_{d,t}$). For the bending vibrations, evaluation was made using beam theory according to both Euler-Bernoulli (Eu) and Timoshenko (Ti). In the latter case the influence of shear deformations and rotatory inertia is taken into account and the approximate solution suggested by Goens [6] was used. See also Hearmon [7] and Perstorper [8] for details on the evaluation of dynamic elastic properties. Since knowledge of the shear modulus G and the ratio E/G is needed for the evaluation, an iterative procedure was used for each board individually until the E-moduli for the first 3 modes of bending vibration coincided as much as possible. This shear-free E-modulus is denoted $E_{d,bf,Ti}$ and $E_{d,be,Ti}$ for flatwise and edgewise bending. As a result of the iteration, a gross shear modulus associated with bending was determined ($G_{d,be}$).

https://doi.org/10.52202/069179-0089

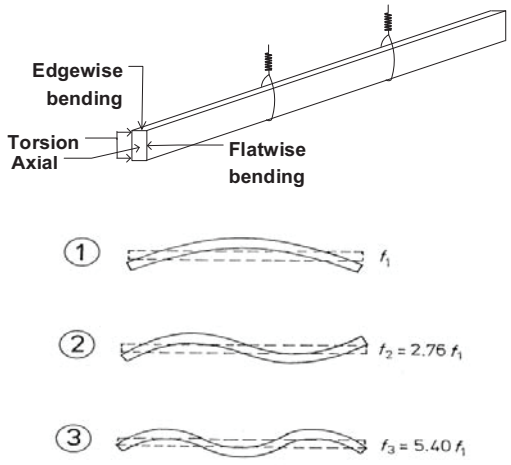

Figure 4: *Dynamic test set-up with indication of excitation directions and accelerometer positions. Visualisation of the mode shape of the first three bending modes.*

A shear mode was observed in the axial tests, for which the outermost layers slide on the weak cross layers, see Figure 5. This vibration mode is governed by the shear stiffness of the cross layers and an attempt was made to establish a model that allowed for an estimation of the rolling shear modulus G_r. In this simplified SDOF-model, the outer layer was modelled as a mass with infinite stiffness and the cross layer below as a shear spring with zero mass.

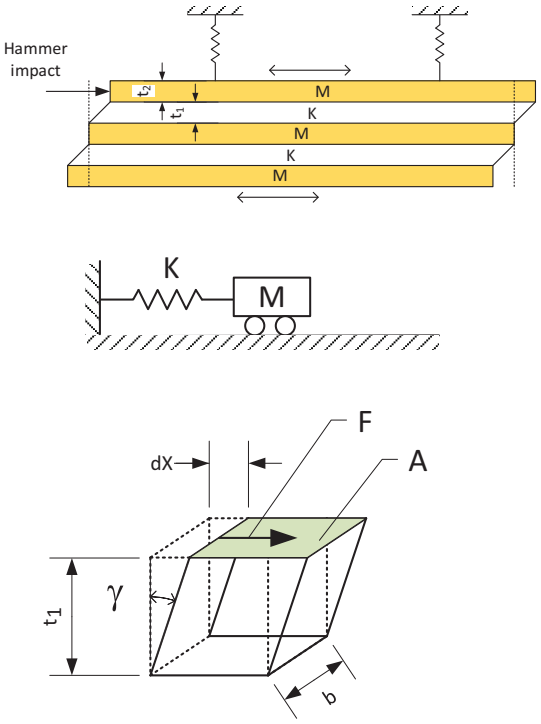

Figure 5: *Shear mode model.*

$$K = \frac{G \cdot A}{t_1} \tag{1}$$

$$f = \frac{1}{2\pi} \times \sqrt{\frac{K}{M}} = \frac{1}{2\pi} \times \sqrt{\frac{G}{\rho \cdot t_1 \cdot t_2}} \tag{2}$$

$$G_{d,r,sh} = (f \cdot 2 \cdot \pi)^2 \cdot \rho \cdot t_1 \cdot t_2 \tag{3}$$

The evaluated mode was the one where layer 3 was a node that did not move. The resulting Equation (3) for the rolling shear modulus $G_{d,r,sh}$ included the thickness (t_2) and density (ρ) of the outer layer, the thickness of the transverse layer (t_1) and the resonance frequency f.

3 RESULTS

3.1 STATIC PROPERTIES

3.1.1 Gross section analysis and overall product performance

The results from the static tests are presented in Table 1 for both the net section and the gross section. The reason for presenting the gross values is that it is easier to compare the overall practical performance of the CLT-boards to solid structural timber. In this sense, the CLT-boards had an edgewise and flatwise bending stiffness that were approximately 30% lower than C24 timber. On the other hand, and as expected, the variation was much smaller for the CLT-boards with a coefficient of variation (CV) of only 9% compared to the usual level for C24 of CV=20-25% for the E-modulus, see Figure 6 and Table 1. At the 5%-percentile level the gross stiffness of the CLT-boards was only 12% lower than the nominal level for C24 ($E_{0,05}$=7.4 GPa).

A similar pattern was found for the gross bending strength, where the bending capacity of the CLT-boards were lower on average but with a smaller variation compared with C24, see Table 1 and Figure 7. The gross average capacity was about 30% (edgewise) and 15% (flatwise) lower for the CLT-boards compared to typical values for single grade C24 ($f_{m,avg}$=45 MPa). The coefficient of variation was 22% and 19% for edgewise and flatwise capacity compared to the typical 30-35% for C24. Thanks to the limited variation, the 5%-percentile value for the gross bending capacity was only 16% lower for the edgewise tests, compared with the nominal value for C24 ($f_{m,05}$=24 MPa). For the gross flatwise bending capacity, the 5%-percentile was actually 19% higher than the C24-value.

In summary, one can conclude that the narrow CLT-boards have gross average bending properties that are not so far from typical structural timber (15-30% lower than C24). Thanks to the limited property variation, the gross 5%-percentile values of the CLT-boards are almost on a par with solid timber. The tests indicate that narrow CLT-boards have sufficient bending properties for being used as structural components, not only as rails but also for situations where the bending capacity is formally utilized.

3.1.2 Detailed evaluation and net section analysis

The net section properties presented here are based on an assumption that the E-modulus of the cross layers is zero (E_{90}=0). Furthermore, the effective rolling shear modulus of the cross layers is assumed to be G_r= 65 MPa, based on the dynamic tests, see below (section 3.2).

Based on the edgewise global E-modulus, and using the gamma method [5], the net local E-modulus is calculated to be $E_{net,be}$=12.2 GPa, which is higher than the nominal level of C24 of 11 GPa.

The corresponding net E-modulus for the flatwise tests was much higher: $E_{net,bf}$=13.6 GPa, indicating that the material in these boards might have been of a higher structural quality, despite the fact that the boards for the edgewise and flatwise tests were produced at the same time and came from the same batch. The higher net bending strength of the flatwise tests supports this idea, but the almost equal density does not, see Table 1.

However, side boards cut far from the pith as here has been found to have higher E-modulus and strength in many studies, e.g. Oscarsson et al. [9]

One might argue that a too high rolling shear modulus was assumed for the edgewise gamma evaluation, but it would require a value of G_r=44 MPa to get the edgewise net E-modulus $E_{net,be}$ to 13.6 GPa, which is not likely.

A third possible explanation would be a systematically higher E-modulus of the middle lamella (#3) compared to the outer lamellas (#1 and #5). The dynamic tests of the edgewise boards indicate such a tendency, since the edgewise net E-modulus $E_{d,be,Ti,net}$=12.9 was lower than the flatwise $E_{d,bf,Ti,net}$=13.5 MPa and axial E-modulus $E_{d,ax,net}$=13.8 MPa, see Table 3.

A fourth possible explanation would be if there is a lamination effect that is enhancing the E-modulus of the flatwise tests in another way compared with the edgewise direction. It can be noted that the 36 boards with laminated layers had a higher flatwise E-modulus than the 14 boards without laminations: $E_{net,bf}$ = 13.9 GPa vs 12.6 GPa, see Figure 11. For edgewise tests the effect was smaller: $E_{net,be}$ = 12.2 for the 37 boards with lamination vs. $E_{net,be}$ = 11.8 GPa for the 13 boards without laminations. This might indicate that there is a lamination effect for the E-modulus that possibly work differently in flatwise loading (in-plane) compared with edgewise loading (out-of-plane).

https://doi.org/10.52202/069179-0089

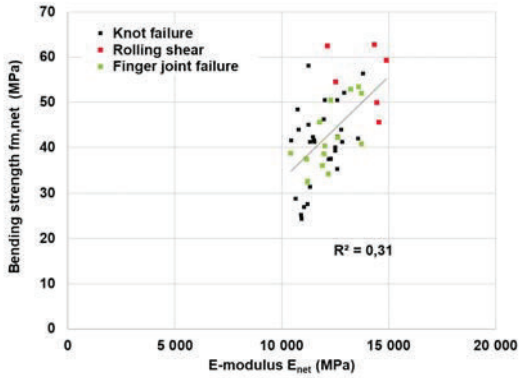

Figure 8: *Correlation between net static edgewise global E-modulus and net bending strength and indication of boards which capacity was limited by rolling shear failure.*

Most boards tested on edge, failed in bending due to knots or finger joints at the tension (predominantly) or compression edge, see Table 2 and Figure 8. However, six boards showed a rolling shear failure outside the loading points. This is quite common for bending tests of CLT with a span of 18 times the beam depth but does not influence the 5%-percentile value. These boards had a higher average failure load and E-modulus compared with the boards that failed in bending, see Figure 8 and Table 2.

The estimated shear stress in the cross layers at failure for the six boards was on average 1.36 MPa, with a range from 1.11 – 1.53 MPa. This is slightly lower than the rolling shear strength reported for Norway spruce by Ehrhart et al [10] but close to the tabled value for C24 for which the characteristic 5%-percentile value is $f_{v,90,k}$=1.1 MPa. It should be noted that there were drying cracks in the cross layers prior to testing, which may have had an influence, see Figure 2. Such cracks are common in CLT when the moisture content in service is lower than it was at the time of production.

It can be noted that the boards with finger joint failure had an average bending strength and E-modulus on a par with boards that failed due to knots. At the lower end of the strength distribution, there were only knot failures. Finger joints seem not to introduce weaknesses that lower the bending strength distribution, see Figure 9.

Table 2: *E-modulus and bending strength for different failure modes for edgewise tests, net section: Rolling shear failure in cross layers and tension/compression failure in outer layers due to knots or finger joints.*

Failure mode	No.	E-modulus	Bending strength
		E_{net} (GPa)	$f_{m,net}$ (MPa)
Rolling shear	6	13.8	55.7
Finger joint (tension or compression)	12	12.2	41.6
Knot (tension or compression)	32	11.9	40.6
All	50	12.2	42.9

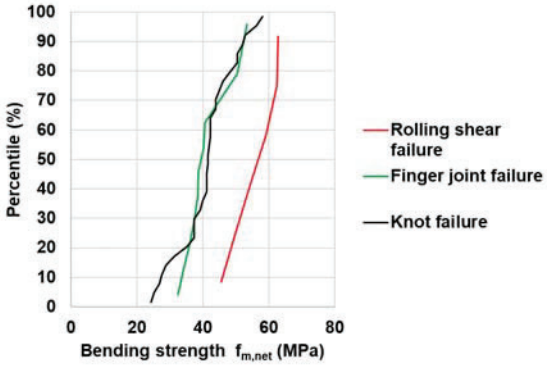

Figure 9: *Percentile plot of net edgewise bending strength for different failure modes.*

Figure 10a: *Examples of failure modes in edgewise bending. Rolling shear (top), knot in tension zone (mid), finger joint in tension zone (bottom).*

https://doi.org/10.52202/069179-0089

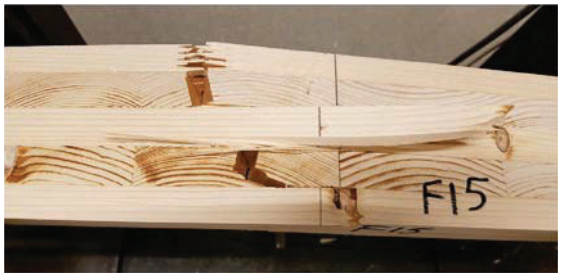

Figure 10b: *Example of bending failure in flatwise bending.*

The net edgewise bending strength was on average $f_{m,net}$=42.9 MPa, which is close to the typical value for Nordic Norway spruce graded to C24 (single grade). The lower variation thanks to the homogenization in CLT led to a 5%-percentile value of $f_{m,05,net}$ = 27 MPa which exceeds the nominal C24-value by 12%, see Table 1. This indicates a lamination effect of 12%, which is stronger than expected for these narrow boards.

However, it shall be noted that 80% of the boards had one or more laminated layers, see Figure 2. The boards without any laminated layers had a 5%-percentile edgewise bending strength of 24 MPa, indicating no difference to the board strength, see Figure 11.

For the flatwise tests, the net bending strength was surprisingly high with an average of $f_{m,net}$=66.7 MPa; almost 50% above the typical value for C24. The 5%-percentile of $f_{m,05,net}$=49.1 MPa was more than double the value for C24.

The net E-modulus was also high (13.6 GPa) for the flatwise tests, supporting the idea of a quality difference. However, it is not likely that a quality difference is the sole reason, since an average E-modulus of 13.6 GPa corresponds to an average bending strength of approximately 50 MPa and a 5%-percentile of 30 MPa, using a database for Nordic Norway spruce from approval tests of grading machines.

Other contributing factors might be that the middle layer (#3) were stronger than the outer layers (#1 and #5), see discussion above for the E-modulus. This would lead to a higher flatwise net strength than edgewise.

An important influencing factor is likely the lamination effect (homogenization). It is plausible that the lamination effect is stronger for flatwise loading, where three layers carry the load in parallel, see Figure CC. In edgewise loading a single defect in the outer lamellas is more critical for these narrow boards.

In the study by Flaig and Blass [3] the lamination effect for in-plane bending was estimated to 8-9% for a lay-up with 3 longitudinal layers in parallel, which would indicate a 5%-percentile bending strength of a single board to 49.1/1.085=45 MPa.

Furthermore, the same study showed a substantial effect of the cross layers on the bending strength. A 5 mm thin cross layer on the side of a board, tested in edgewise bending, increased the average bending strength by 18% (34.0 vs 40.3 MPa). Based on estimations from a graph in the report, the difference at the 5%-percentile level could be more than 60% (13.4 vs 22.2 MPa). Apparently, the cross layers, with a high cross stiffness, strengthened the weak sections by limiting cracking associated with grain deviations around knots.

If one assumes a cross layer enhancement effect of 50% on the 5%-percentile bending strength, and a lamination effect of 8.5%, the 5%-percentile bending strength of the individual layers would be 30 MPa to fit the strength of the CLT-board. This is in fact close to the strength corresponding to the measured flatwise net E-modulus of 13.6 GPa.

If one or more layers were laminated (two side-glued boards), the bending strength was higher compared to CLT-boards where each layer consisted of only one board, see Figure 2 and 11. Out of the 50 CLT-boards tested edgewise, 13 pcs had no laminations and the corresponding number for the flatwise tests was 14 CLT-boards.

The influence of laminations was more pronounced for the boards tested in flatwise bending compared to the edgewise tests at the median level, but the opposite at the 5%-percentile level.

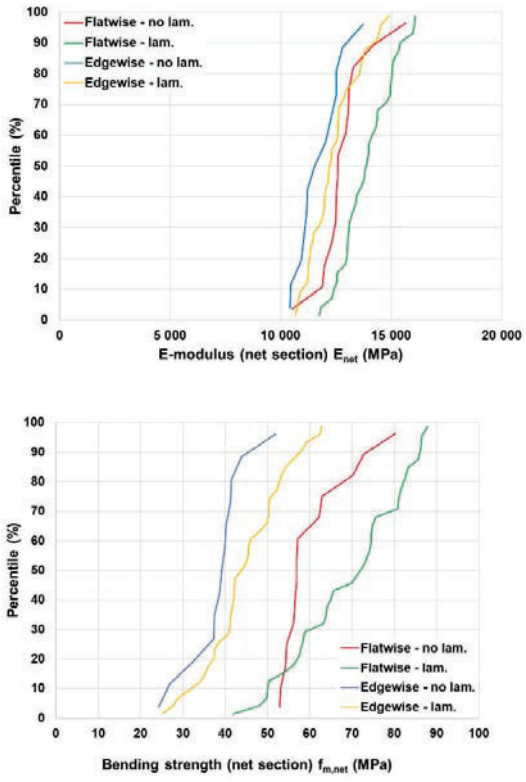

Figure 11: *Percentile plots of net E-modulus and net bending strength for boards that had no laminated layers compared with boards that had one or more layers with lamination (layer with two side-glued boards, see Figure 2).*

https://doi.org/10.52202/069179-0089

3.2 DYNAMIC PROPERTIES AND COMPARISON WITH STATIC RESULTS

A very strong correlation (R^2=0.96) was found between gross dynamic edgewise E-modulus (Euler) $E_{d,be,Eu.gross}$ and gross static global E-modulus $E_{gl,be,gross}$ see Figure 12. Both moduli are influenced by shear deformations more or less in the same way. The dynamic E-modulus was 5,5% higher than the static one, which is found in most studies and is attributed to the large difference in loading speed and the viscoelastic nature of wood.

It can be noted that the shear-free net dynamic E-modulus $E_{d,be,Ti,net}$ = 12.9 GPa coincide very well with the corresponding static E-modulus E_{net} = 12.2 GPa, when taking into account the typical static-dynamic difference.

The average shear-free (Timoshenko beam theory) net E-modulus from edgewise bending vibration was $E_{d,be,Ti,net}$ = 12.9 GPa, see Table 3.

In order to match the gross global E-modulus $E_{d,be,Eu,gross}$ =7.96 GPa the rolling shear modulus of the cross layers must be $G_{d,r,gm}$= 69 MPa using the gamma method [5]. Assuming the usual 5.5% difference, the static rolling shear value would be G_r = 65 MPa, which was used when estimating the shear-free static E-modulus in Table 1.

A rolling shear modulus of G_r = 65 MPa is not far from other studies on Norway spruce for boards cut far from the pith: Erhart et al [10] reported an average value of G_r=56 MPa for boards cut 100 mm from the pith.

Görlacher [11] studied the influence of annual ring geometry on the rolling shear modulus of Norway spruce. For the material in the present study, the angle between the tangential ring direction and rolling shear loading was on average 13 degrees, which points at a rolling shear modulus of 60-65 MPa according to the results of Görlacher.

It can be noted that the nominal value for C24 is 50 MPa, which is considered to be a conservative value for typical CLT-boards. However, it is likely a rather good estimate of the constitutive material parameter G_{RT} for Norway spruce to be used in FE-modelling (valid for boards with zero annual ring curvature and purely tangential or radial ring orientation in relation to board geometry).

The analysis of the shear mode, see Figure 5, resulted in a slightly lower rolling shear modulus of $G_{d,r,sh}$ =55 MPa. One reason for the difference is likely that one needs to account for parts of the mass of the cross layers in the model and this would increase the evaluated shear modulus.

The dynamic shear modulus from analysis of three edgewise bending modes was $G_{d,r,be}$ = 132 MPa. This is a weighted gross average over the cross section including influence of both lengthwise and cross layers. A common way of calculating the effective gross shear modulus for a layered material is given in Eq. 4 where V_{cross} and $V_{lengthwise}$ is the volume fractions of the layers; 43% and 57% in this case.

$$\frac{1}{G_{gross}} = \frac{V_{cross}}{G_{cross}} + \frac{V_{lengtwise}}{G_{lengtwise}} \quad (4)$$

Based on the experimental gross shear modulus of $G_{d,r,be}$=132 MPa and by assuming a shear modulus of G_l = 650 MPa for the lengthwise layers, the rolling shear modulus of the cross layers is $G_{d,r}$= 64 MPa, which is quite close to other estimates in this study.

The gross section shear modulus from torsional vibration was $G_{d,t}$ = 266 MPa, which is less than half of the level for solid timber, but not alarming with respect to practical handling at production. It can be noted that in torsion, the cross layers are not subjected to purely rolling shear stresses as in bending. Furthermore, the shear stresses have a more pronounced maximum in the middle layer (#3) in torsion. Both these factors increase the gross section shear modulus for torsion compared to gross shear modulus related to edgewise bending ($G_{d,r,be}$ =132 MPa).

Table 3: *Results from dynamic tests of the 50 boards that were tested in static edgewise bending. Average values and standard deviation within brackets. The stiffness properties are adjusted to the reference moisture content 12%.*

Property and vibration mode		Gross section	Net section
Dynamic E-modulus (GPa)			
Axial	$E_{d,ax}$	7.91 (0.69)	13.8 (1.2)
Flatwise bending, Timoshenko theory	$E_{d,bf,Ti}$	7.77 (0.66)	13.5 (1.1)
Edgewise bending, Euler theory	$E_{d,be,Eu}$	7.96 (0.74)	-
Edgewise bending, Timoshenko theory	$E_{d,be,Ti}$	9.65 (1.1)	12.9 (1.5)
Dynamic shear modulus (MPa)			
Torsion	$G_{d,t}$	266 (13)	-
Edgewise bending Timoshenko theory	$G_{d,r,be}$	132 (8.7)	64
Rolling shear mode Cross layer value	$G_{d,r,sh}$	-	55 (4.4)
Estimate using gamma method, Cross layer est.	$G_{d,r,gm}$	-	69

The dynamic edgewise E-modulus was correlated to the bending strength. Due to the limited property variation of the multi-ply CLT-board, the coefficient of determination was only R^2= 0.38 but the standard error was quite small: SEE=5.6 MPa, see Figure 13. The results indicate a possibility to use dynamic methods to grade the CLT-boards to a bending strength quality comparable to C24. The average E-modulus of C24 will obviously be harder to achieve.

3.3 NON-PLANE STRAIN DISTRIBUTION BETWEEN LOADING POINTS - INFLUENCE ON LOCAL E-MODULUS

A DIC-analysis of 5 CLT-boards was done regarding the bending deflections and normal strains in the area between the inner loading points. The bending deflections at the neutral layer were determined over a length of 475 mm (5h), corresponding to the method of determining the local shear-free E-modulus according to EN408 [4]. A deviation was that the measurements were only done on one of the faces, whereas the standard prescribes measurements on both sides to account for twisting.

The average net local E-modulus $E_{loc,DIC}$ for the 5 boards was 10.8 GPa which is lower than expected. Based on the gross static global E-modulus E_{gl} = 7.42 GPa for these boards, a rolling shear modulus of 65 MPa and using the gamma method, the net local E-modulus should be 11.9 MPa. Furthermore, the gross dynamic edgewise E-modulus using Timoshenko beam theory (shear-free) for the 5 boards was 12.4 GPa, which translates to a comparable static value of 11.8 GPa (5.5% reduction). Thus, both static and dynamic data supports that the static local E-modulus seems to be underestimated by approximately 10%.

A possible reason for the underestimation is that the assumption of plane normal strain in the shear-free zone between the loading points is not valid. In order to check this an analysis was made for a load step of 2.5 kN. The strains were calculated based on the normal deformations (x-direction) in path 1 and 2, at each mm of the beam depth, see Figure 3. The idea was to get a strain distribution that represents an average for the measurement zone and thereby minimize local effects that blur the picture. This revealed a non-plane strain distribution over the beam depth with a steeper strain gradient in layer 1, 3 and 5 compared with the overall inclination, see Figure 14. The degree of deviation from a plane strain varied between the boards, possibly depending on local defects close to the paths chosen. The strain gradient was on average 10% steeper in layer 1,3 and 5 compared to a plane strain situation. It is quite possible that this non-plane strain distribution explains the underestimation of the local shear-free E-modulus. Similar strain distributions have been presented in other studies on models for CLT [12].

Although this part of the beam is not subjected to vertical force causing shear stresses, the beam layers are subjected to the non-plane stress distribution from the beam parts outside the loading points, where the shear-weak cross layers influence the normal stress distribution in the manner seen in Figure 14. The general implication of this is that an evaluation of the local shear free E-modulus according to EN 408 [4] might lead to an underestimation if the beam to be tested has a low shear stiffness, like in this case with very shear-weak cross layers. The increased span-to-depth ratio typically used in CLT-tests to avoid rolling shear failure is beneficial in this respect as the shear deformations are diminished.

However, due to the small amount of boards analysed and the variation, one cannot draw any firm conclusions. Further tests and analysis will be done to see if this effect can be verified.

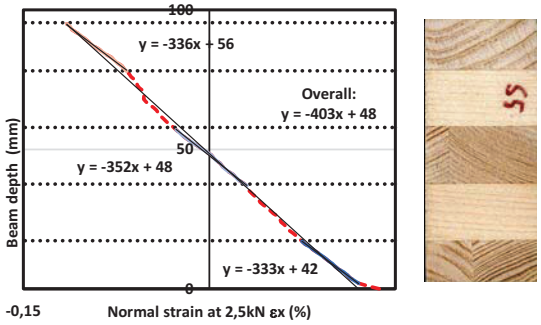

Figure 14: *Non-linear normal strain distribution for board E5, in the shear free portion of the beam between the inner loading points.*

https://doi.org/10.52202/069179-0089

4 CONCLUSIONS

1. The narrow CLT-boards (45x95 mm^2) in this study show gross average bending properties that are not so far from typical structural timber (15-30% lower than C24). Thanks to the limited property variation, the gross 5%-percentile values of the CLT-boards are almost on a par with solid timber. The tests indicate that narrow CLT-boards have sufficient bending properties for being used as structural components, not only with regards to handling but also for situations where the bending capacity is formally utilized.
2. The dominating failure mode in edgewise bending tests was knot failure at the tension edge. The 12 boards that failed at a finger joint had strength on a par with the boards that failed at a knot.
3. Six boards out of 50 exhibited a rolling shear failure. The estimated rolling shear strength was 1.36 MPa, with a range from 1.11 to 1.53 MPa, which is slightly lower than comparable studies on Norway spruce. However, the failure load for these boards were on average 35% higher than the boards that failed in bending.
4. The coefficient of variation for the bending strength was about 20% for both edgewise and flatwise loading, which is in between typical values for CLT (8-16%) and C24 (30-35%, single grade). The small size compared to other CLT-tests seems to reduce the homogenization effect (many sub-parts share the load).
5. The surprisingly high net flatwise bending strength ($f_{m,05}$=49 MPa) can likely, to a high degree, be attributed to the reinforcing effect from the cross layers that limit slope of grain cracking near knots in the longitudinal layers.
6. The rolling shear modulus of the cross layers was estimated to G_r = 65 MPa. This is in line with other studies of flat-sawn Norway spruce side-boards cut far away from the pith.
7. Dynamic E-modulus from edgewise vibration was very well correlated to the global static E-modulus with R^2=0.96. The correlation to bending strength was less strong (R^2=0.38) but with a low standard error (SEE=5.6 MPa).This indicates a possibility for non-destructive testing and grading of CLT-boards to achieve a superior quality for specialty applications.
8. Analysis of the local E-modulus between the loading points of 5 boards based on DIC-measurements indicated a 10% lower level than expected. The analysis also revealed a non-plane normal strain distribution that is likely linked to the low local E-modulus. Further studies are warranted to see if the “shear-free” local E-modulus determined according to EN408 might be underestimated for very shear-weak beams where the non-plane stress distribution outside the loading points have an influence.

DENSIFIED WOODEN NAIL FOR ADHESIVE- AND METAL-FREE TIMBER ASSEMBLES

Lei Han[1], Dusan Pauliny[2], Anna Sandak[3], Mariapaola Riggio[4], Andreja Kutnar[5], Dick Sandberg[6] and Jakub Sandak[7]

ABSTRACT: The widespread utilisation of adhesives to assemble engineered wood products may lead to environment and recycle concerns. To improve materials sustainability and recovery at the end-of-life, it is preferable to replace adhesive with mechanical lock-in fasteners such as wood-based connectors. Nowadays, the development of robotic fabrication technologies and wood modification technologies brings the opportunity to rejuvenate traditional wood-joining methods. In this study, thermo-hydro-mechanical densified wooden nail were proposed as an adhesive- and metal-free connector for timber assembles. The densification ratio varied between 40 to 68%. Research has been performed in order to determine the effect of densification on the compression behaviour of wood in the form of nails. The result showed that densification with high compression ratio can successfully increase the density and modulus of rupture of wood, while its influence on modulus of elasticity is not obvious. A set of prototype nails made of densified wood was manufactured. In addition, preliminary insertion tests into wood samples were carried out and served for insertion process understanding. The results obtained reveal a potential for using the densified wooden nail connectors for substitution of adhesive or metal connectors. However, the "success ratio" for proper inserting of wooden nails was not satisfactory. It was observed that the excessive dynamical loading induced buckling failure of the nail during hand-operated insertion.

KEYWORDS: Nail laminated timber; Thermo-hydro-mechanical densification; Compression behaviour

1 INTRODUCTION

Climate change and its dramatic consequences are stimulating a transformation towards sustainable development. The long-term solution of slowing down climate change is to close carbon cycles and reduce greenhouse gas (GHG). In Europe, buildings sectors account for 40% of total energy consumption and 36% of total carbon dioxide emission [1], and it is therefore a key sector for improvements. Compared with other materials used in construction, wood products have much better ecological and environmental performance [2]. In the past decade, the demand to use wood for applications in both residential and non-residential building construction has been increasing. This development has partially result out from the emergence of new engineered wood products (EWPs) and the potential economic benefits of prefabrication and rapid on-site construction [3].

However, EWPs are in majority of cases assembled by adhesives or metal fasteners, which reduce their machinability, sustainability, and limit recyclability. Furthermore, the use of adhesives in EWPs may affect the environment and human health by emitting non-healthy volatile organic compounds (VOC) such as formaldehyde, that increase during use-periods under the high-temperature and varying relative humidity conditions. Therefore, there is a need in the modern timber construction sector for an ecofriendly and recyclable technologies substituting or replacing adhesive and/or metal fasteners [4].

Assembling timber by hardwood connectors like dowels, nails, wedges, and tenon-mortise joints has been invented and applied in furniture making and timber construction from the ancient time [5]. Among these methods, nail connection represent the easiest and fastest method to assemble timber members [6], as metal nails could be successfully inserted into wood and make connection without pre-drilling holes. However, the high thermal conductivity of metal nails affects the overall energetic performance and energy requirements of structures during its service life. The machinability of components joined with metal nails is limited during both, construction and end-of-life transformation. Other problems may occur due to interaction of metal fasteners with tannic acids causing black colored spots on the surface of wooden elements. Therefore, Hasan et al. [7] suggested that wooden nails could be an alternative for renewable fastener used in a robotic fabrication process of nailed laminated timber.

Hand-operated hammer and pneumatic nailing guns are usually used to drive nails into wood. When inserting by pneumatic nailing guns, the friction between the nail and the surrounding surfaces heats the interface to the glass-transition temperature and softens the cell-wall lignin. The following solidification of the softened lignin when the joint's temperature drops results in additional chemical-physical bonding the wood members [8]. Moreover, wooden nails ensure a firm fixing of the elements as they expand when exposed to moisture, that corresponds to same mechanism as observer in the case of wood dowels [9].

The wooden-nail assembling technology was combined recently with other wood modification technologies such as resin impregnation and/or THM wood densification [10–13]. THM densification involves heating the wood above its glass-transition temperature in the presence of moisture. A compression force can be applied in the transverse direction to make the wood cells collapse without fracturing their cell walls. It leads to the reduction in the lumen volume and in the increase of cell density. It is known that there is a strong relationship between wood density and its mechanical properties. Therefore, THM densification is frequently used to improve the mechanical performance of wood, including advanced use of wood in load-bearing timber construction [14,15].

An important research aspect that has received less attention in the context of wooden nails is the compression behaviour in the longitudinal direction of the elongated beams of densified wood forming the nail. Better understanding of densified wood behaviour under compression stress is extremely important for ensuring appropriate quality of the nailing connection. The nail damage occurring during insertion may disqualify the joint as well as may affect the further behaviour of the connection in the service conditions. A proper use of this knowledge may lead to designing nails with high slenderness ratio useable to assemble thicker panels. It would be a greatly appreciated functionality resulting in expansion of wooden nails usage in construction. The goal of this report if to present a set of preliminary results describing the compression behavior of densified wood in the form of nails made from three different species and various compression ratios.

2 MATERIAL AND METHOD

2.1 MATERIAL

Industrial kiln-dried beech (*Fagus sylvatica* L.), poplar (*Populus tremula* L.), and spruce (*Picea abies* L.) were used to produce the densified wood specimens for compression tests. The boards selected for test were detects-free and conditioned at 20°C and 65% RH to achieve an equilibrium moisture content. Standard metal fasteners (nails) were tested for comparison.

2.2 WOOD DENSIFICATION

The densified wood specimens were manufactured by carrying out the THM densification in the radial direction in an open-system hydraulic hot press. The densification cycle was composed of 10 minutes pre-heating (plasticization), 10 minutes densification, 5 minutes post treatment and 5 minutes cooling (Figure 1). The final cooling of the densified samples was performed out of the press, assuring limitation of the sample flatness changes, by applying clamping. The achieved compression ratio (CR) after densification is calculated as in equation 1:

$$\text{Compression ratio (CR)} = \frac{T_0 - T_d}{T_0} * 100\% \quad [1]$$

Where T_0 is the initial thickness and T_d is the thickness after densification

The densified specimens with different CR were conditioned at 20 °C and 65% RH then sawn to final dimensions of 55 mm (longitudinal) × 3 mm (radial) × 3 mm (tangential) before the compression tests.

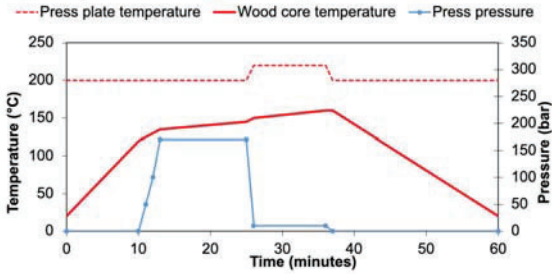

Figure 1: *Schedule of thermo-hydro-mechanical (THM) densification.*

2.3 COMPRESSION TEST

Compression tests were carried out to evaluate the influence of densification on the mechanical behavior of the wooden nails during insertion (Figure 2). Tests were done with the intention to notice the maximum force to be applied during nail insertion, including analysis of the buckling behavior of the nail. For these reasons, the slenderness ratio (which is defined as the ratio of the column length over its diameter) is higher than that recommended for the standard compression tests according to the EN 408 [16]. The ratio of the maximum force to the specimen cross-sectional area was computed here instead of modulus of rapture (MOR) as defined in EN 408. A custom-made mechanical testing machine equipped with a load cell (5 kN) was adopted to conduct the compression load experiments.

https://doi.org/10.52202/069179-0090

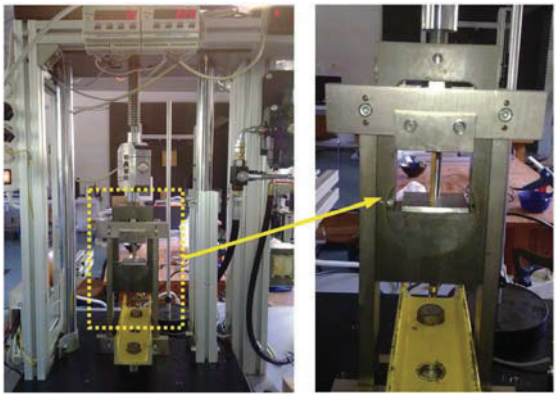

Figure 2: *Compression test setup*

3 RESULTS AND DISCUSSION

3.1 PHYSICAL AND COMPRESSION PROPERTIES

Figure 3 and Figure 4 presnts the density and mechanical properties of the wood densified with different CR. It can be noticed that there is a strong positive correlation between CR and densified wood density as well as modulus of rapture (MOR). However, it is also evident that after certain level of CR the MOR is reduced (for example densified poplar wood with 68% CR). It might result from excessive damage of the cellular structure of wood induced by densification. By contrast, there is no clear correlation between the CR and modulus of elastic (MOE). Majority of the samples have been damaged during test by excessive buckling. Only few of compressed samples were damaged by typical collapse of wood cells. The compression tests have been also performed on the standard metal nails with dimension as densified wooden nails. As expected, the performance of the metal nail was superior compared to wooden nail. Both MOR and MOE under compression of metal nails were more than four times higher than the highest value achieved by wooden nails.

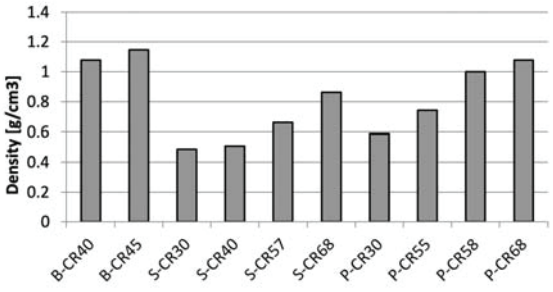

Figure 3: *Density of densified specimens*

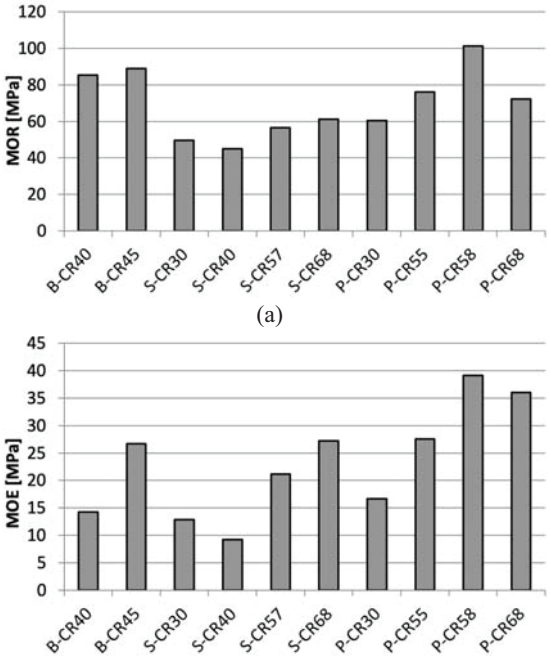

Figure 4: *Mechanical properties of densified specimens measured during compression test (a), modulus of rapture (MOR)(b), modulus of elasticity (MOE)*

3.2 DENSIFIED WOODEN NAIL PROTORTYPE AND PRELIMIARY NAILING TEST

Based on the above observations, it was possible to design a prototype of densified wooden nails. The image of the proposed nail is presented in Figure 5. The slenderness ratio (L/d) depends on the integrity of densified wood. As a rule of thumb, the insertion force is suggested nu exceed the critical buckling load of the nail. The nail's tip geometry depends strongly on the joined material hardness and its anatomical structure. The tip shall never be too sharp. The recommended tip angle (α) is ~30°.

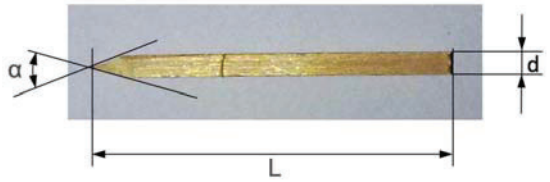

Figure 5: *Image of the developed wooden nail and recommendations for its design.*

The example of the wood pieces joined by densified wooden nails with hand-operated hammer is presented in Figure 6. It should be mentioned here that the ability of the wooden nail to join the other wood pieces is limited by the hardness and anatomical structure of the joined material. Simplifying, the technology developed can be only applied to join wood species of rather low densities. Up to data experiences show acceptable performance if

https://doi.org/10.52202/069179-0090

spruce, fir or poplar to be joined together. Any trials to join higher density species or pieces having certain defects (such as knots) have not been successful.

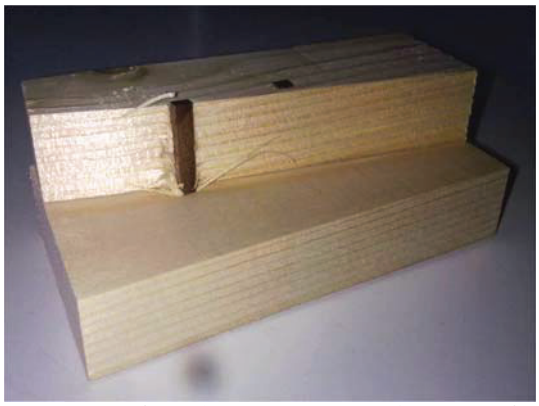

Figure 6. *Wooden nails joining two pieces of spruce wood.*

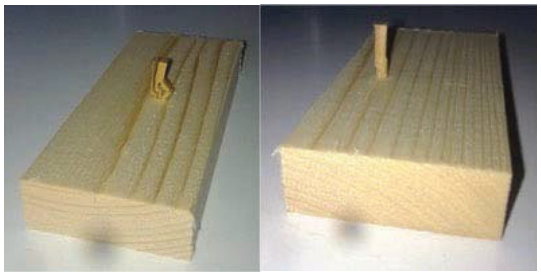
The "success ratio" of the insertion wooden nails was not exceptionally high. The most typical failures of the nails are presented in Figure 7. Splitting the nail over the surface of joined wood (Figure 7a) occurs if the force direction is not parallel to the nail axis direction. On the other hand, the overload of wood nail (effect in the collapse of wood fibers within the nail structure (Figure 7b). Anyway, the final effect is not satisfactory joint and usually the broken nail protruded over the joined surface.



(a) (b)

Figure 7: *Typical damages to the wooden nail occurring during insertion; (a) splitting of the nail, (b) collapse of the wood fibre due to excessive compression stress.*

4 CONCLUSIONS AND FUTURE WORK

The research was dedicated for development of the novel technology of wood assembling by means of densified wooden nails. The results obtained shows a potential of such joins as an alternative to adhesive and traditional metal nails. However, it should be pointed, in general the "success ratio" for proper inserting of wooden nails was much lower that corresponding to metal joints because of excessive dynamical loading, especially when nailing with hand-operated hammer. The necessary loading to insert a wooden nail result in extensive buckling of the nail column, and this may lead to fracture during nail insertion. Another damaging factor was a compressive stress concentration at the tip of the nail limiting the penetration into the wood components to be joined.

The buckling failure of the nail under compression could be influence by many factors. For example, loading type (either dynamical or static loading), nail tip geometry, slenderness ratio, MOE, tribological properties of the wooden nail etc. Therefore, the future work will be focused on studying how those factors affects the buckling behavior of densified wood. An assist tool will also be designed and test to avoid buckling failure during nailing (Figure 8).

Figure 8. *Concept for the assist tool for avoid buckling during nailing.*

EXPERIMENTAL INVESTIGATION OF FINGER JOINTS UNDER TENSILE AND BENDING LOADS

Farid Vafadar[1], Steven Collins[2], Gerhard Fink[3]

ABSTRACT: Finger joints are commonly used to fabricate endless lamella for engineered wood products such as glued laminated timber beams. The finger joints' properties are important for the mechanical characteristics of glued laminated timber beams, particularly those fabricated from higher-strength-graded lamellas. In the present study, 120 spruce timber boards were used to fabricate finger joints. Each timber board was assessed for quality by measuring the eigenfrequency and the density before the finger joint fabrication. The timber boards were cut in half, and both sets were arranged in the same order and afterward fabricated to endless lamellas, such that the finger joints were fabricated from the same timber boards in both sets. On one set, the tensile strength and on the other one, the flatwise bending strength and stiffness were investigated. This paper presents a statistical summary of the finger joint tensile and bending test results and correlation analyses between the mechanical properties and the relevant quality assessment indicators. A significant relationship between the finger joint tensile and bending strength is observed. Furthermore, the dynamic modulus of elasticity is identified to be a useful indicator of finger joint strength and stiffness.

KEYWORDS: Spruce, finger joint, tensile experiments, bending experiments, correlation analysis

1 INTRODUCTION

A finger joint (FJ) is the longitudinal interlocked connection between two timber boards. It is broadly used in the wood industry to fabricate endless lamella, mainly to produce engineered wood products such as glued laminated timber (GLT) or cross-laminated timber. Particularly for GLT beams fabricated from higher strength graded timber boards, which are typically characterized by fewer and smaller knots, the mechanical properties of the beams are influenced by the properties of the FJs [1].

The mechanical properties of FJs were investigated in several studies. In [2], the relationship between tensile strength and flexural modulus of elasticity in the bending of FJs from spruce timber was investigated. In [3], experiments were reported on the bending and tensile strength of finger-jointed pine lamellas from ten GLT factories. The aim was to compare bending and tensile strengths. As a result, a relatively constant ratio between the mean values of the tensile and bending strengths was found, such that the tensile strength was about 60% of the bending strength. In [4], bending and tensile experiments were performed on 700 FJs to investigate the ratio between the characteristic value (5^{th} percentile-Guassian distribution) of finger joints' tensile and bending strength. Overall, a ratio between the characteristic values of the tensile and bending strength of approx. 0.65 was identified. However, it should be noted that in [4], a reduced testing length was used, and specimens with failures outside the FJ were not considered for analysis.

The importance of FJ is also considered in the respective standard for GLT beam mechanical behavior (EN 14080 [5]), where the mechanical properties of FJs are addressed. According to [5], the strength class of a GLT beam is estimated based on the tensile properties of the used timber boards and the flat-wise-bending properties of the FJ. In this case, the required value of the characteristic strength for FJs tested in tension is $f_{t,0,j,k} = f_{m,j,k}/1.4$.

A few studies have also been carried out to identify the correlation between various strength and stiffness-related indicators and the FJ properties. For instance, in [6], the mechanical performance of structural finger joints was investigated in four-point bending. The results indicated a positive relationship between the density and the bending strength. In [7], the results of 40 FJ tensile experiments were used to develop a model to predict the tensile strength of FJ based on the dynamic modulus of elasticity (E_{dyn}) of the connected timber boards. Nonetheless, the literature in this direction is lacking, particularly for studies investigating the influence of indicators on the FJ mechanical properties.

In the present study, the relationships between the FJ tensile and bending properties on paired specimens and the influences of timber board indicators (stiffness and density) on the FJ mechanical properties are investigated.

2 MATERIAL AND METHOD

2.1 SPECIMEN

Spruce timber boards (w x t = 125 x 50 mm with a length between 3800 mm and 4700 mm) were used to study the FJ tensile and bending mechanical properties. All timber boards were investigated for quality with a commercial grading device (Precigrader), which grades based on the timber board's E_{dyn} and measures the density. Based on the grader information, the boards were classified into R (rejected), T14, and T22 classes. The descriptive statistics of E_{dyn} for each class are mentioned in Table 1.

The timber boards were cut in half and finger-jointed into two equivalent sets of endless lamellas, according to Figure 1. Thus, the timber boards were arranged in the same order in both sets so that paired (tension and bending) FJs were fabricated. The two endless lamellas were cut into 8 m long segments to transport to the Aalto University testing laboratory. Then the FJs were cut out of each segment. Due to the cutting procedure (for transporting), some FJs could not be used for further testing. In total, 227 finger-jointed specimens (110 FJs for tension and 117 for bending test) were investigated, of which 98 were paired. The order of the timber boards was random, i.e., they were not grouped according to the strength grades[1]. The finger-jointed specimen groups were determined based on the class of the two connected timber boards (see Tables 2 and 3).

For the tensile and bending tests, the specimens were planed to the final dimensions of w x t x l = 115 x 45 x 1300 mm and w x t x l = 115 x 45 x 1000 mm, respectively. In the bending tests, eight specimens had a shorter span (distance between the supports) of 700 mm. All specimens were conditioned in a climate chamber at 20°C, with a relative humidity of 65%.

2.2 TENSILE TEST

The specimens were tested in tension according to EN 408 [8]. The test setup with failure at the FJ is shown in Figure 2. The test length clear of grips was 560 mm (> 9 x 45 mm) with 370 mm clamping length on each side. To secure the specimens in the grips while testing, lateral pressure was applied. However, 14 specimens slipped from the grips. Ten of these were re-clamped and tested for a second time to achieve failure, although it was not possible to test four FJs again because of damage at the clamping region. An actuator with a tensile capacity of 500 kN applied the force. A force control testing protocol with a 30 kN/min loading rate was used.

[1]Initially the study was planned to be performed with graded timber boards, although due to a technical error the boards were not sorted.

Table 1: *Descriptive statistics of E_{dyn} for the used timber boards*

Class	Mean value [MPa]	COV [-]	Range [MPa]
R	8795	0.06	< 9600
T14	10966	0.07	9600-12300
T22	13625	0.08	> 12300

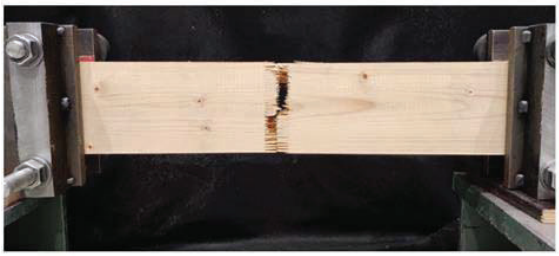

Figure 2: *FJ after failure in a tensile test*

2.3 BENDING TEST

The bending experiments were performed according to EN 408 [8]. The test setup and a specimen during the test are shown in Figure 3. A universal testing machine with a capacity of 200 kN was used. The testing protocol was force control with a 2.5 kN/min loading rate. One linear variable differential transformer (LVDT) in the center of the specimen, at the bottom surface, was installed for global stiffness. For local deflection measurement, two LVDTs were installed on both side faces at the neutral axis and the FJ location. The average value of deflection was considered for local stiffness calculation. The LVDTs were removed from the specimens at an estimated 40% of the maximum force to prevent damage during failure.

2.4 VISUAL INSPECTION

After testing, the specimens were visually inspected. Following the approach presented in [9], the specimens were categorized into four groups according to their fracture pattern: Finger joint failure (FF), wood failure (WF), mixed failure (MF), and the slip of the grip without failure (S) which happened only in tensile tests.

The four specimens that slipped from the grips were considered slipped specimens (S). Conditions for classification are such that if at least two-thirds of the failed cross-section was within the finger joint (failure in adhesion and joint failure at fusion or net section), the specimen was categorized as finger joint failure (FF).

https://doi.org/10.52202/069179-0091

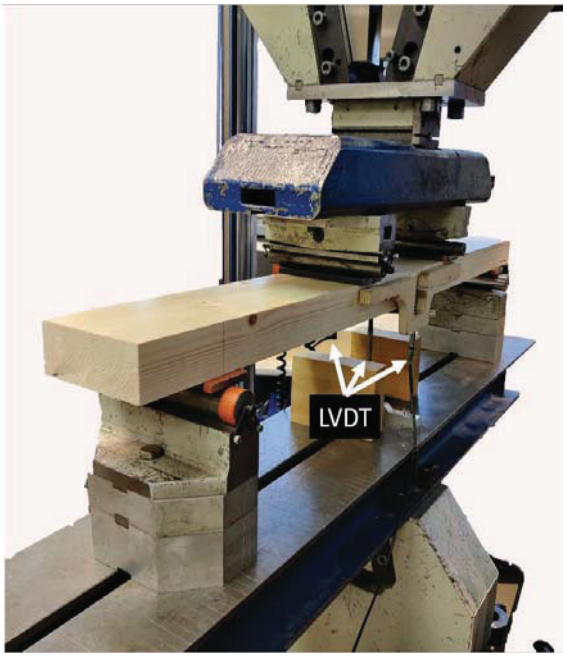

Figure 3: *Flatwise four-point bending test setup and location of the linear variable differential transformer (LVDT)*

Likewise, if two-thirds of the failed cross section was within a wood section, the specimen was considered with a wood failure (WF). All other specimens were defined as mixed failure (MF).

In addition to the failure type, the timber board in which the failure occurred was identified. It was targeted only for specimens where the failure could be allocated to a specific timber board. From the tensile and bending experiments, specimens are considered where at least two-thirds of the failed cross section was within one timber board. For the bending tests, the tension zone of the specimens was investigated. All other specimens, meaning specimens where the failure could not be directly allocated to one specific timber board, are not considered for related investigations.

3 RESULTS

The tensile and bending test results are summarised in Tables 2 and 3, respectively. Descriptive statistics of strength values are given for specimens with the same failure type and all FJs within each FJ group. In the latter case, the specimens with WF, MF, and S failures are considered censored from the perspective of FJ strength since the exact strength of the FJ is unknown, and only a lower bound is known; see [7] for more information. As a result, the tensile and bending strength of the FJs were calculated using equality data (FF) and censored data (WF, MF, S).

In this paper, it is distinguished between (a) the tensile and bending strength of tested specimens denoted with $f_{t,s}$ and $f_{m,s}$ and (b) the tensile and bending strength of FJ denoted with $f_{t,j}$ and $f_{m,j}$.

Table 2: *Expected values and coefficient of variations of tensile strength of FJ (calculated for all specimens considering censored data) and tensile strength of the specimens (categorized according to the failure type).*

FJ group (Based on the quality of the timber boards)	Failure type	n [-]	Tensile strength E(·) [Mpa]	COV [-]
R-T14	FF	4	20.9	0.10
	MF	3	22.8	0.23
	WF	7	18.3	0.29
All finger joints $f_{t,j}$	**-**	**14**	**25.3**	**0.18**
R-T22	FF	4	29.2	0.17
	MF	1	25.0	-
	WF	6	23.2	0.17
All finger joints $f_{t,j}$	**-**	**11**	**30.4**	**0.12**
T14-T14	FF	11	27.9	0.20
	MF	4	25.3	0.07
	WF	9	24.2	0.25
All finger joints $f_{t,j}$	**-**	**24**	**30.4**	**0.18**
T14-T22	FF	24	31.5	0.19
	MF	6	32.4	0.16
	WF	10	26.6	0.31
	S	1	36.3	-
All finger joints $f_{t,j}$	**-**	**41**	**34.2**	**0.20**
T22-T22	FF	14	33.1	0.14
	MF	2	32.4	0.16
	WF	1	38.5	-
	S	3	43.9	0.09
All finger joints $f_{t,j}$	**-**	**20**	**36.6**	**0.20**

About half of the specimens in the tensile experiments failed in the FJ (type FF). Slipped specimens have the highest mean tensile strength value. About 75% of the specimens in bending tests failed in the FJ (type FF).

The mean value of local and global bending stiffness increases with the quality of the timber boards. The global stiffness mean values are lower than the local stiffness. In addition, it is noted that the local deflection data in four specimens and the global deflection of one specimen are missing due to measurement errors of the LVDTs.

General results concerning the tensile and bending tests indicate that the relative frequency of the specimens with FF failure type increases with the quality of the timber boards, particularly for tensile-loaded specimens. This is expected since, in higher-quality timber boards, there are (in general) fewer natural defects that may cause failure outside of the FJs.

4 CORRELATION ANALYSIS

4.1 MECHANICAL PROPERTIES

A scatter plot of the tensile and bending strength for all the paired specimens is shown in Figure 4. In total, 41 pairs failed within FJ in both the bending and the tensile tests. This case is classified as FF-FF. For illustrative reasons, the "Other" specimens are illustrated together, representing specimens in which a failure occurred outside the FJ in tension and/or bending. According to the scatter plot, the relationship is associated with a rather large scatter.

https://doi.org/10.52202/069179-0091

Table 3 *Expected values and coefficient of variations of bending strength and stiffness (local and global). Bending strength of FJ (calculated for all specimens considering censored data) and bending strength of the specimens (categorized according to the failure type).*

FJ group (Based on the quality of the timber boards)	Failure type	Bending strength n [-]	E(·) [Mpa]	COV [-]	Local bending stiffness E_L n [-]	E(E_L) [Mpa]	COV [-]	Global bending stiffness E_G n [-]	E(E_G) [Mpa]	COV [-]
R-T14	FF	11	38.4	0.11						
	MF	3	40.7	0.11						
	WF	2	35.2	0.26						
All finger joints $f_{m,j}$	**-**	**16**	**40.2**	**0.12**	**15**	**9496**	**0.13**	**16**	**8524**	**0.15**
R-T22	FF	8	39.2	0.20						
	MF	2	30.4	0.06						
	WF	3	33.6	0.34						
All finger joints $f_{m,j}$	**-**	**13**	**41.0**	**0.18**	**13**	**9812**	**0.17**	**12**	**9294**	**0.14**
T14-T14	FF	23	42.4	0.18						
	MF	5	43.7	0.15						
	WF	3	44.8	0.17						
All finger joints $f_{m,j}$	**-**	**31**	**44.7**	**0.18**	**31**	**10147**	**0.16**	**31**	**9532**	**0.14**
T14-T22	FF	36	46.5	0.17						
	MF	5	46.9	0.19						
	WF	1	45.5	-						
All finger joints $f_{m,j}$	**-**	**42**	**47.6**	**0.17**	**40**	**11408**	**0.12**	**42**	**10666**	**0.12**
T22-T22	FF	11	53.5	0.11						
	MF	1	44.2	-						
	WF	3	54.1	0.08						
All finger joints $f_{m,j}$	**-**	**15**	**54.8**	**0.10**	**14**	**12348**	**0.19**	**15**	**12009**	**0.16**

Significant relationships are observed between the specimens' tensile and bending strength. The corresponding correlation coefficient for all paired specimens is $r(f_{t,s}, f_{m,s}) = 0.50$, and for the FF-FF case, the correlation is $r(f_{t,j}, f_{m,j}) = 0.48$.

Regarding the relationships between strength and stiffness, notable correlations are found between the bending strengths ($f_{m,s}$ and $f_{m,j}$) and local and global bending stiffness (E_L and E_G), with correlations of $r \approx 0.70$ for all relationships. However, the correlations between tensile strengths and local bending stiffness are lower: for all paired specimens, $r(f_{t,s}, E_L) = 0.44$, and for specimens with FF, $r(f_{t,j}, E_L) = 0.34$. Similar trends for the relationship between tensile strength and global bending stiffness are identified with $r(f_{t,s}, E_G) = 0.51$ (all paired specimens) and $r(f_{t,j}, E_G) = 0.33$ (specimens with FF).

4.2 MECHANICAL PROPERTIES VS. INDICATORS

Correlation analyses are made between the mechanical properties and selected strength and stiffness-related indicators. For the strength properties, the lower quality timber board of the connected timber boards is expected to influence the strength predominantly. Accordingly, the investigated parameters are the minimum characteristics: $E_{dyn,min}$, and ρ_{min}. Based on visual inspection, the timber board in which the failure occurred was identified for each specimen with FF. Of all the specimens tested in tension and bending with FF (57 tensile specimens and 89 bending specimens), 63% and 78% of specimens failed in the timber board with lower E_{dyn}, respectively.

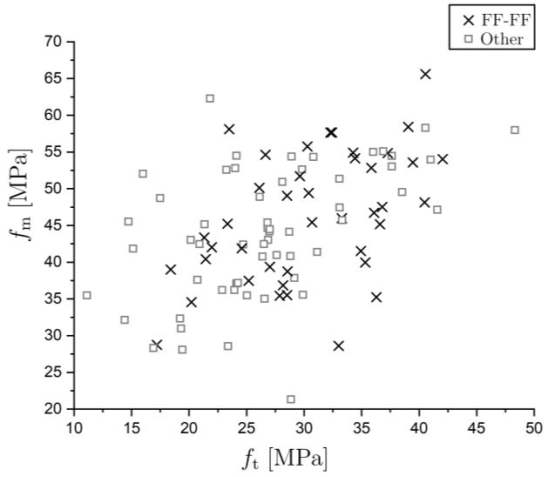

Figure 4: *Scatter plot of all the paired FJs' bending strength versus tensile strength. FF-FF represents FJ failures in both paired bending and tension specimens.*

Further investigation showed that most failures within the stiffer boards were characterized by natural defects, such as knot clusters close to or within the FJs. Since the ρ_{min} and $E_{dyn,min}$ are highly correlated, similar results are expected when considering the minimum density. Therefore, results suggest that FJs fail more frequently within a lower-quality timber board.

A scatter plot of FJ tensile strength and $E_{dyn,min}$, and ρ_{min} are shown in Figure 5. For $E_{dyn,min}$, when all failure types are considered together, the correlation is apparent, and a significant correlation coefficient of $r(f_{t,s}, E_{dyn,min}) = 0.59$ is obtained.

https://doi.org/10.52202/069179-0091

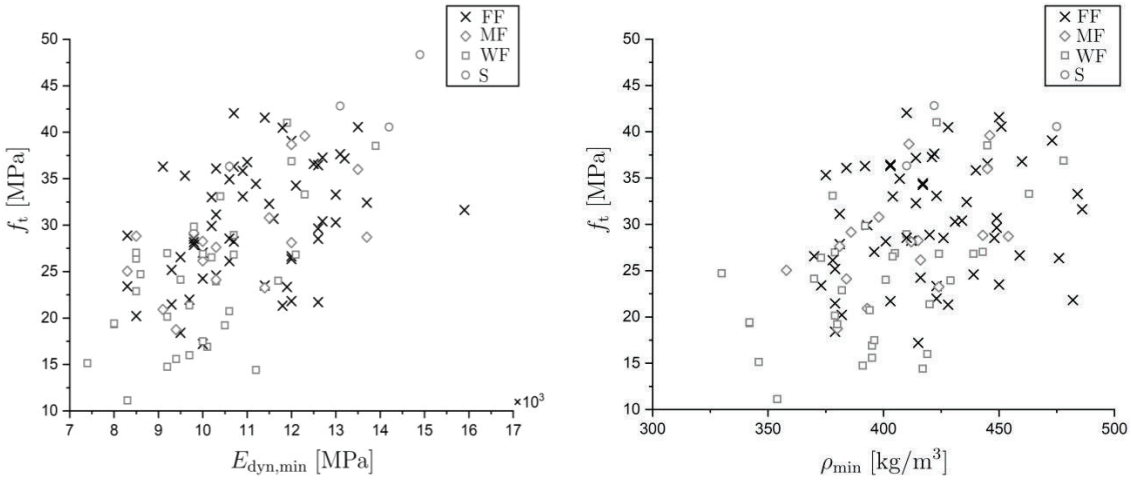

Figure 5: *Scatter plot of FJ tensile strength versus (left) $E_{dyn,min}$ (right) $\boldsymbol{\rho}_{min}$ of the connected boards.*

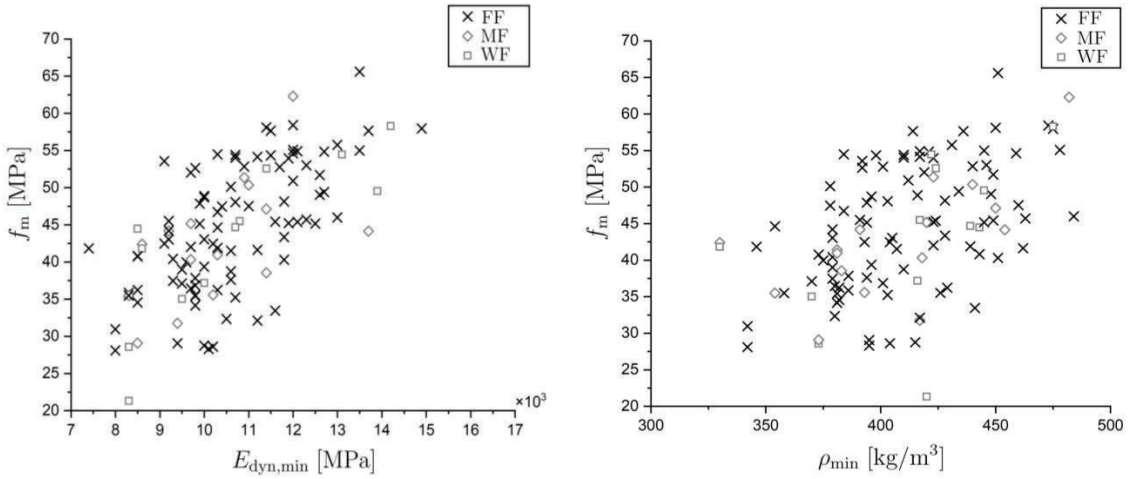

Figure 6: *Scatter plot of FJ bending strength versus (left) $E_{dyn,min}$ (right) $\boldsymbol{\rho}_{min}$ of the connected boards.*

However, for specimens with FF, the relationship between tensile strength and $E_{dyn,min}$ is comparatively lower: $r(f_{t,j}, E_{dyn,min}) = 0.36$. The reason for this difference may be related to the failure types: some of the strongest and stiffest specimens slipped from the testing grips (type S), and some of the weakest specimens failed outside the FJ (e.g., WF); both are not accounted for in the FF group. Therefore, the overall effect is a stronger correlation when all failure types are considered and a lower correlation when FF failure is considered individually. From the scatter plot, the influence of ρ_{min} on the tensile strength for specimens with FF is not unambiguous and associated with a rather large scatter. Overall, the influence of density on the tensile strength is minor. The correlation coefficient is $r(f_{t,s}, \rho_{min}) = 0.47$ and $r(f_{t,j}, \rho_{min}) = 0.20$. It is noted that a few specimens significantly influence this correlation coefficient, with WF having some very low values.

The scatter plot of the FJs bending strength versus the $E_{dyn,min,}$ and ρ_{min} are shown in Figure 6. Overall, the relationship between bending strength and $E_{dyn,min}$ is more significant than the tensile strength. The correlation coefficients are $r(f_{m,s}, E_{dyn,min}) = 0.64$ and for specimens with FF, $r(f_{m,j}, E_{dyn,min}) = 0.62$. In addition, an apparent influence of density on the bending strength is observed, although the scatter is relatively large. The correlation coefficients are $r(f_{m,s}, \rho_{min}) = 0.50$ and $r(f_{m,j}, \rho_{min}) = 0.48$.

The relationships between the local bending stiffness (considered more relevant to FJ, compared to global stiffness) and the indicators are presented in Figure 7. The mean values of the indicators ($E_{dyn,mean,}$ ρ_{mean}) are, in this case, considered to be the relevant characteristics. The corresponding correlation coefficient between E_L and $E_{dyn,mean}$ is $r = 0.59$. However, E_G and $E_{dyn,mean}$ has a higher correlation with $r = 0.67$. The correlation between E_L and ρ_{mean} is $r = 0.42$. A similar correlation is found between E_G and ρ_{mean} ($r = 0.43$). These results suggest that the $E_{dyn,mean,}$ and ρ_{mean} are related to FJ bending stiffness, with $E_{dyn,mean}$ being an important indicator.

https://doi.org/10.52202/069179-0091

5 CONCLUSION AND OUTLOOK

The tensile and bending mechanical properties of finger joints are investigated. Overall, 227 finger-jointed specimens in five quality groups were tested in tension and bending. The statistical properties of the test results are presented along with a correlation analysis for the relationships between FJ tensile and bending mechanical properties and their relationship to non-destructive indicators. Results indicate:

- On average, the bending strength of finger joints is stronger than tensile strength.
- A significant relationship is identified between the FJ tensile and bending strength with a correlation coefficient of approximately 0.5.
- The mean value of the FJ tensile and bending mechanical properties increases with the quality of the joined timber boards.
- The connected boards' minimum dynamic modulus of elasticity significantly correlates with the FJ tensile and bending strength. The minimum density is also correlated, although to a lesser extent due to a rather large scatter.
- The mean value of the dynamic modulus of elasticity of the jointed boards correlates with the FJ bending stiffness properties.

This research contributes knowledge on the mechanical properties and behavior of finger joints. In addition, it will serve as the base for the development of material models, incorporating the relationship between FJ bending and tensile properties and relevant non-destructive strength and stiffness indicators.

POTENTIAL OF REUSING SALVAGED WOODEN MATERIALS IN FABRICATING STRUCTURAL DOWEL LAMINATED TIMBER

Mohammad Derikvand[1], Gerhard Fink[2]

ABSTRACT: Reusing salvaged wooden materials in new structural products offers a promising approach towards a circular economy. In this paper, the potentials and challenges related to reusing salvaged wooden materials in mass laminated timber are explored. Furthermore, the research activities at the group for Wooden Structures (Aalto University) related to the reuse of salvaged timber materials in fabricating dowel laminated timber (DLT) are discussed and the outlook of the subject and the future research needs are summarized. Among others, the research group focuses on the use of DLT in structural applications both as a beam-type element and as a slab-type element. The results show that salvaged plywood plates, which are e.g., used in the construction sector as concrete formwork, can be used effectively to produce tenon connectors for DLT fabrication. In addition, the combination of salvaged timber and new full-scale timber boards in alternate layers have shown to be a promising alternative. In this method, short, salvaged timber elements can be used without any end-to-end joining or gluing. Minimizing the required processing procedures can make salvaged timber more profitable and more attractive to the timber products manufacturing sector.

KEYWORDS: salvaged timber, dowel-laminated timber, wooden connectors, circular economy, climate change, reuse, low processing

1 INTRODUCTION

Over the past years, interest in biobased materials such as timber has increased in different sectors, e.g., due to the challenges related to the climate change. Accordingly, several studies have expected difficulties in meeting the demands for timber in the near future [e.g., 1]. In the case of the construction sector, the cascade use of timber has shown promising potentials for addressing the anticipated demands for timber solutions [1]. In addition, reusing wooden materials could be an effective approach in battling the climate change, and therefore, this subject has been the focus of numerous studies in the recent years [e.g., 2-8].

In this paper, the case of reusing salvaged wooden materials in mass laminated structural elements made with wooden connectors is discussed. A description of the related research and development works at the group for Wooden Structures (Aalto University, Finland) on this topic is also provided. The focus here is on the reuse of salvaged wooden materials in fabricating dowel laminated timber (DLT), both as a beam-type element and as a slab-type element. Finally, the outlook and research needs for breakthrough innovation in the subject area are summarized.

2 POTENTIALS AND CHALLANGES

The concept of reusing salvaged wooden materials is related not only to meeting the future demands for timber solutions, but also to addressing the climate change. Reusing wooden materials offers a potential to reduce the need for new materials, and therefore, preserve the natural resources. Furthermore, salvaged wooden materials are theoretically cheaper than new materials; therefore, if processed economically, they can be used to produce more affordable products. Here, salvaged wooden materials refer to both salvaged timber and salvaged engineered wood products that are often obtained either from a primary application or as waste from a timber production process. Figure 1 shows two examples: cut-offs from a regional housing company and falsework for a concrete bridge. Depending on the material type, several approaches exist in the literature to reuse salvaged wooden materials in new products and applications. Most of the approaches require additional processing on the salvaged wooden materials, e.g., particleboard production or cross laminated timber (CLT) production.

Figure 1: *Examples of salvaged wooden materials; cut-offs from a housing company (top) and falsework for a concrete bridge (bottom).*

Despite the existence of some methods for the case of reuse, it should be acknowledged that no single method can be effective for all types of salvaged wooden materials, considering the variabilities in e.g., type, shape, dimensions, irregularities, and material characteristics. Some salvaged wooden materials may be only good enough to be used for energy. However, for others a fit-for-purpose approach might be best in order to develop certain types of wooden products.

In terms of new products development, the interest in reusing salvaged timber in fabricating mass laminated timber products for structural applications has increased in recent years. Some research works have also already been conducted on this topic (examples of those studies are summarized in Table 1), most of them focused on non-finger jointed CLT.

Nevertheless, the concept of reusing salvaged timber has several challenges that need to be acknowledged, some of which are described in the following:

- Unknown material source: salvaged timber materials come from different sources and usually their original strength class and or their species are unknown. Assigning the correct species for salvaged timber could be quite difficult [13,14] and this creates further obstacles in the segregation and grading of the salvaged timber materials.

Table 1: *Examples of mass laminated timber products developed from salvaged timber materials in the literature. CLT (cross laminated timber), GLT (glued laminated timber), NLT (nail laminated timber).*

Materials used	Product	Ref.
Salvaged timber and new timber	CLT	[4]
	CLT	[7]
	GLT	[9]
Salvaged timber	CLT	[6]
	CLT	[8]
	CLT	[10]
	NLT*	[11]
	NLT	[12]

*Using wooden nails

- Unknown load history: the previous load history of salvaged timber is typically unknown, especially when the source of the materials is not identified. This makes it more difficult to account for issues such as the duration of load effect on the material properties [15].

- Uncertainties related to the mechanical properties: as the initial grade and the previous load history are usually unknown, the salvaged timber materials that are obtained from different sites might have a wide range of mechanical characteristics. In addition, previous research works [e.g., 5] have demonstrated that it is often quite difficult to identify any clear trend on how much some of the mechanical properties of timber may change over time.

- Grading rules: the classification of the material properties is essential for reusing salvaged timber in structural applications; however, the existing grading rules are in general valid only for new timber. One exception is the Australian interim industry standard for recycled timber [16], however, for most regions a strength grading regulation still does not exist.

- Distortions and damages: distortion and other shape irregularities are usually common in salvaged timber. The presence of damages such as fastener holes, slots, or cracks are also common and can affect the performance of salvaged timber [see, e.g., 17].

- Length limitation: another common challenge for reusing salvaged timber is the length limitation. Usually, the usable part of a salvaged timber board could be relatively small and the additional costs for end-to-end joining can affect the profitability of reusing salvaged timber.

- Presence of metallic fasteners: salvaged timber may contain metallic fasters such as nails or screws from the previous applications. This can make the

processing of salvaged timber more challenging and time-consuming. In this regard, automated systems have been recently developed for processing salvaged timber, including nail and screw removals; see e.g. [18]. Nevertheless, until such technologies become widely available, post processing of salvaged timber can be difficult and costly.

- Contamination: salvaged timber could be also sometimes contaminated due to exposure to chemicals e.g., wood preservatives or other substances such as wet concrete in falseworks.

- Limited availability and supply: although a large volume of salvaged timber is produced every year, currently the number of companies that are involved in sourcing and distributing salvaged timber is quite limited compared to those for new timber. Therefore, access to continued supply of usable salvaged timber can be difficult for manufacturers of timber products and or builders who may want to use salvaged timber in their projects.

The existence of such challenges warrants in-depth research in order to establish effective approaches to achieve the full extent of advantages that can arise from reusing salvaged wooden materials. This could include e.g., establishing an assessment scheme and or grading criteria that could quantify the mechanical properties of salvaged timber as well as implementing design for deconstruction concepts that could ease the end-of-life disassembly processes and streamline the reuse of salvaged timber.

3 EXPERIMENTAL RESEARCH ON DLT

Given the environmental benefits, the full sustainability potential of reusing salvaged wooden materials in new applications can be achieved if, preferably, no synthetic glues or metallic fasteners are utilized. In this regard, wooden connectors have received particular attention as an alternative solution. In this section, two related projects recently carried out by the authors of this paper are summarized.

3.1 DLT FABRICATED WITH CONNECTORS FROM SALVAGED ENGINEERED WOOD PRODUCTS

The use of wooden connectors in fabricating DLT has been studied intensively [e.g., 19-24]. DLT has been used as a slab-type element by the construction industry in several projects worldwide and a design guide is already available for its application as well, see: [25]. Nevertheless, wooden connectors result in flexible connections; therefore, the composite action of DLT is a challenge to be met when it is used as a beam-type element.

In [26], we aimed to reuse salvaged engineered wood products in fabricating connectors for DLT beams. One of the assumptions was that the superior mechanical properties of connectors from engineered wood products can improve the composite action and, at the same time, enhance the sustainability aspects of DLT beams. The project involved push-out shear tests on dowel and tenon connectors made from Oak, salvaged laminated veneer lumber (LVL), and salvaged plywood. Based on the findings, we then performed four-point bending tests on DLT beams made with the selected connectors (i.e., salvaged plywood tenons, Oak tenons, and conventional Oak dowels as a reference).

The project demonstrated that the DLT beams fabricated with salvaged plywood tenons were efficient and led to approximately 40% higher bending stiffness compared to the conventional DLT beams made with Oak dowels. This approach not only improves the bending stiffness of the DLT beams, but also has the potential to contribute to the circular economy by offering a method for reusing salvaged plywood materials.

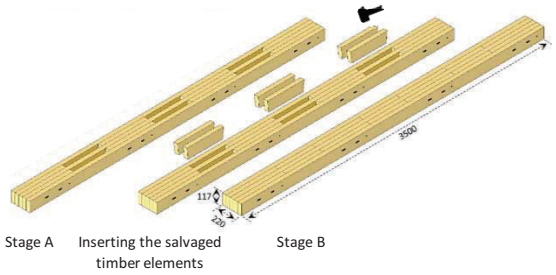
3.2 DLT FABRICATED WITH SALVAGED TIMBER LAMELLAE AND SALVAGED PLYWOOD TENONS

Length limitation was identified earlier as a challenge for reusing salvaged timber. Reusing short, salvaged timber elements in mass laminated timber products normally requires significant processing, including gluing and end-to-end joining. However, the associated costs of the additional processing and gluing can make salvaged timber less profitable, and therefore, less attractive to the timber products manufacturing sector. On the other hand, without end-to-end joining and gluing the existing methods of mass laminated timber production may not lead to a product that could meet the structural performance requirements.

A recent project conducted at our group aimed to address this issue by developing DLT floor slabs with a mixture of new (full-scale) timber boards and short salvaged timber elements [27]. The idea was to reuse the salvaged timber elements in every other layer of the DLT slab without end-to-end joining or gluing to reduce the cost associated with reusing the short, salvaged timber elements and to reduce the volume of the full-scale boards that would normally be needed in the conventional DLT.

The concept was evaluated on large-scale DLT specimens. The specimens were composed of three layers of new timber boards (l = 3.5 m) and two layers of salvaged timber elements. The specimens were fabricated with six voids located along the two layers of salvaged timber elements (Stage A in Figure 2). The voids were filled by inserting short, salvaged timber elements with about 2 mm larger lengths (Stage B in Figure 2). The specimens were laminated using salvaged plywood tenons.

https://doi.org/10.52202/069179-0092



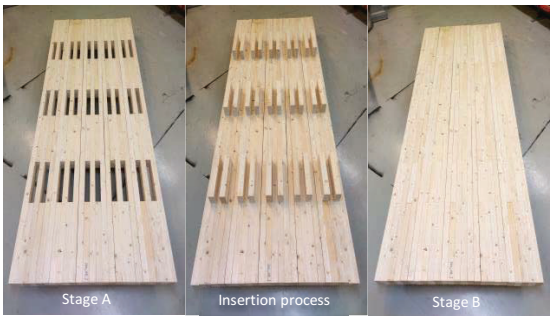


Figure 4: *The fabrication process of the large-scale DLT specimens (top), the actual specimens placed side-by-side to resemble a wider panel (middle), recreated based on [27].*

The vibration characteristics and the bending properties of the specimens were examined in both stages. The results exhibited substantial increase in the bending stiffness and relatively improved vibration characteristics. Overall, the average bending stiffness of the Stage B specimens was about 84% of the expected average bending stiffness of a conventional DLT made with five full-scale timber boards.

Another important finding was that the bending failures occurred almost exclusively in the full-scale timber boards, suggesting that the proposed system may not be so much dependent on the bending strength of the salvaged timber elements. This was due to the fact that the salvaged timber elements were used without end-to-end joining. Therefore, the tension stress caused by the bending loads is resisted predominantly by the full-scale boards.

4 OUTLOOK

Given the current research trends, a promising outlook could be anticipated for the subject of reusing salvaged wooden materials in structural laminated products. In this context, DLT represents a great potential, as it is a cost-effective alternative that does not require gluing. This can directly improve the profitability of salvaged timber materials which may promote their further application in the timber sector. In addition, DLT could be a good option for the construction of affordable housing in less developed areas around the world where access to advanced mass timber production technologies may not be available.

Nevertheless, as highlighted in this paper, there are also important challenges that need to be investigated in order to enable breakthrough innovation in the subject area. Therefore, future research can focus on evaluating ways in which the challenges related to the reuse of salvaged wooden materials can be addressed. Furthermore, when a mixture of new timber and salvaged timber boards are used to fabricate laminated timber products with wooden connectors, different lay ups of the salvaged timber layers could be investigated to identify an efficient lamination system. Investigating the long-term performance under variable service conditions as well as establishing analytical models to predict the mechanical performance are also other vital areas that require further development.

Finally, to better realize the future potentials of salvaged timber, some regulations need to be implemented that can ensure proper ways of sourcing and handling of salvaged timber as well as certifications that can verify its quality. Furthermore, education and awareness about salvaged timber need to be increased in order to improve the consumers perception, create demand, and make products from salvaged timber more available on the market.

ACKNOWLEDGEMENT

The authors would like to thank Serveh Hosseinzadeh (from Tarbiat Modares University) and Lorenzo Giordano (formerly from Aalto University) for their involvement in the experimental research works that were introduced in this paper.

STRUCTURAL SAWN WOOD PRODUCTION IN THE CHILIEAN SAWMILL INDUSTRY, DATA ANALYSIS FROM SURVEYS CARRIED OUT FOR 4 YEARS

Pamela Poblete[1], Janina Gysling[2], Carlos Kahler[3], Wilson Mejías[4], Daniel Soto[5], Verónica álvarez[6], Evaristo Pardo[7].

ABSTRACT

The sawmill industry produce around of 8 million cubic meters annually, setting Chile as the tenth world producer of sawn wood. Since Chile is a foretry country, the current sectoral policy has among its strategic axis the promotion of quality wood construction. From here it emerges the necesity of reinforce graded structural sawn wood supply, boosting this product demand by the construction industry.

In this context, INFOR began to generates specific statistics on structural sawn wood (MAE), this activity accumulates four years of measurments. In the present research, it is presented the main results of the analysis of data obtained from these measurments, through surveying in the sawmill industry. To carry out the survey on MAE (structural sawn wood), sawmills with production higher than 10,000 cubic meters annually were selected, gathering information from a sample of 100 sawmills per year, from 2018 to 2021; these sawmills represents near of 80% of the sawn wood national production.

Results indicate that the knowledge about MAE concept has just slightly increased during four years of measurments; while the interest of sawmill in participating in MAE production it is determined by the greater access to higher pirces, a more stable demand, and a greater reliability in logs availiability.

KEYWORDS: Structural lumber market; classified structural lumber, structural lumber production

1 INTRODUCTION

In 2021, the sawmill industry in Chile had 1,233 sawmills, from which 922 were in operation. The industry consumed 16.7 million cubic meters of wood in logs, resulting in a production of 8.7 million cubic meters of sawn wood, from which 97.7% corresponds to *Pinus radiata.* From the national total production, 24.8% it is destined to exports, while 75.2% stays in the internal market [1]. According to FAO, these levels of production place Chile in the eleventh position at world level as a sawn wood producer [2].

Regarding the sawmills production range, historically plants with production lower than 5,000 m³/year have been the most numerous, representing 80% of the total number of sawmills in operation in 2021 [3].

In terms of mobility, sawmills are divided in permanent, and mobile. The number of permanent sawmills reaches a share of 48.6% in a historical growing trend, and a decrease of mobile sawmills. This is mainly due to a significant decrease in native sawn wood production, where mobile sawmills dominated [1].

In 2021, La Araucanía region concentrated the greater number of sawmills in operation with 202 units (21.9%), followed by Biobío region, and Los Lagos region with 144 units each, and Maule region with 135 units. These four regions concentrate 67.8% of the total in-operation sawmills in the country [3].

Since Chile is a forestry country, with a highlighted roll as a wood producer, the supply of sawn wood for structural use in construction, graded as such, and in accordance with requirements demanded by the norm in force, is very low. On the other hand, from building statistics it is deduced that 60.7% of predominant materiality in walls was concrete, far surpassing wood as a structural material, which reached 10.6% of the total housing, and non-housing authorized area of new works in 2020 (13.1 million m²) [1]. These figures differ a lot when compared with other wood-producer countries, where the structural use of this material in housing construction exceeds 85% as in case of United States, and Canada, and above 60% in case of Australia, and New Zealand [4].

The promotion of wood construction is a challenge that has been considered as a strategic axis in the current forestry policy. State agencies, companies, and private associations related to the forestry, and construction sectors, as well as the academies, and I+D centers, are developing several initiatives focused on promoting wood as a construction material.

In this regard, INFOR has surveyed during four year a representative statistical sample of sawmills in the country, in order to gather information that allows to know the wood supply for construction. From this information, in the present research, a characterization, and an analysis of the structural sawn wood production is provided.

1.1 DEFINITIONS

1.1.1 Sawn wood for structural use

The sawn wood refers to solid pieces of wood obtained from a sawmill, with different features, and dimensions, which are used in construction with structural ends, mainly in roofing, and walls, but without being subjected to a formal classification process.

1.1.2 Graded structural sawn wood and its requirements

In order for radiata pine sawn wood to meet the structural requirements in construction, there are certain essential specifications that allow to ensure its good performance inside the structure. These are: structural grade, dimensions, moisture content, and preservation. [5].

a) Structural grade

The structural grade corresponds to a category of pieces of sawn wood having the same capacity to resist loads, and stress, that can be measured through the visual grading technique (NCh1207 [5], and NCh1198 [6]), which assign a structural grade to the sawn wood in terms of size, and knots location, pith, missing edges, wrapping, among others; The visual grading results in the following classifications: GS, G1, and G2; or also through a mechanical grading, based on a set of non-destructive tests, which allows to determinate the stiffness, and to be classified in a structural grade, which are: C16, C14, MGP10, and MGP12. (NCh3028 [7] part 1, and part 2, and NCh1198).

In table 1 [5], the different types of structural classifications that the sawn wood can be graded into are presented.

Table 1: *Structural grades for Radiata pine sawn wood, and its mechanical features*

Allowable stress for radiata pine wood							
Grading system	Structural grade	Bending (Mpa)	Parallel compression (Mpa)	Parallel traction (Mpa)	Normal compression (Mpa)	Shearing (Mpa)	Modulus of elasticity in bending (Mpa)
Visual	GS	11	8.5	6	2.5	1.1	10,500
	G1	7.5	7.5	5	2.5	1.1	10,000
	G2	5.4	6.5	4	2.5	1.1	8,900
Mechanical	C24	9.3	8	4.7	2.5	1.1	10,200
	C16	5.2	7.5	3.5	2.5	1.1	7,900
	MGP12	13.5	15.5	6	2.5	1.1	12,700
	MGP10	8.4	10	4	2.5	1.1	10,000

b) Dimensions

In compliance with the 1207 Chilean norm regarding the visual grading, it is stipulated that the allowed dimension tolerance in sawn wood must be in compliance with the 2824 Chilean norm [8]. This stipulates the nominal thickness, and width of the sawn and planed radiata pine wood, establishing a dimensional tolerance for the use of sawn wood of +3 mm thickness, and +5 mm wide. The length of the pieces permits a maximum tolerance of 0.1m.

c) Moisture content

Each piece of radiata pine sawn, or planed wood destined for structural use must be dry, with a moisture content lower or equal to 19%, as stated in the norm NCh 2150 [6].

d) Preservation

In compliance with the *Odenanza General de Urbanismo y Construcciones*, the different species of wood used more frequently are classified in 5 categories according to its durability: very durable, durable, moderately durable, low durability, and non-durable. The radiata pine wood is located in the category of non-durable, consequently, as the *Ordenanza* stipulates, must be preserved in compliance with the NCh 819 [10].

2 MATERIALS AND METHODS

INFOR carry out a sampling of the sawmill industry each year, where information is gathered from around a thousand sawmills from Coquimbo region, to Magallanes region. Since 2019, sawmills are selected to an additional survey on structural sawn wood. The selection requirements are: a production higher than 10,000 cubic meters annually, with a facility with minimum

https://doi.org/10.52202/069179-0093

infrastructure to produce graded sawn wood, as in case of wood drying chambers, or the access to them.
The number of sawmills selected in each year of measurement is: 116 sawmills in 2018, 119 sawmills in 2019, 134 sawmills in 2020, and 136 sawmills in 2021. From the second year, the selection is in accordance with the follow-up of productive units surveyed last year.

The sawmills in the sample were classified in 8 ranges of annual production: lower or equal to 5 thousand m³; 5 thousand to 10 thousand m³; 10 thousand to 20 thousand m³; 20 thousand to 50 thousand m³; 50 thousand to 100 thousand m³; 100 thousand to 200 thousand m³; 200 thousand to 300 thousand m³; and higher than 300 thousand m³.

The quantitative, and qualitative information collected on structural sawn wood consist in: the knowledge on the concept of graded structural sawn wood, and the requirements for its production; annual amount produced; sales orders received, and business done; number of trained operators in wood grading; available equipment to produce structural wood, interest in producing it, and main factors in making the decision to enter the business.

Through the Forestry Statistics Platform from INFOR, the data was stored, and processed to its following analysis.

The information obtained was subjected to a correlation analysis to search for relations between the MAE volume produced, and other variables collected through surveys. The Spearman's rank correlation coefficient was used, since this is a non-parametric measure of statistical dependency between two variables [11]. The statistical significance of correlation between two variables was evaluated with a 95% confidence level.

3 RESULTS

The selected sample to characterize MAE production represents 28.3% average of the period from active permanent sawmills in the country, and around of 13% of the total of sawmills. The 2021 production of sawmills in the sample represents 88.3% of the national sawn wood production.

Table 2: *Number of surveyed sawmills, permanent, and in total in the 2018-2021 period.*

Year	2018	2019	2020	2021
Sawmills Sample MAE	116	119	134	136
Permanent sawmills	448	448	440	448
Active sawmills in the country	984	957	938	922

The surveyed sawmills are concentrated in the southern-central zone of the country, being Maule, Biobío, and La Araucanía regions the ones concentrating approximately 80% of the surveyed sawmills in average during four years of analysis.

In regard of sawmills size in the sample, more than half is concentrated in a production range of 10,000 to 50,000 cubic meters annually.

The sawmills were consulted about their knowledge on the concept MAE (Structural sawn wood), which indicated a positive result, going from 75.0% in 2018, to 86.8% in 2021. This represent a broad knowledge of the concept, which could be helpful in generating classified wood supply.

It is important to mention that, in all production ranges, the knowledge is superior to 66.7%, reaching near to 100% in higher production ranges sawmills, slightly decreasing in lower production ranges.

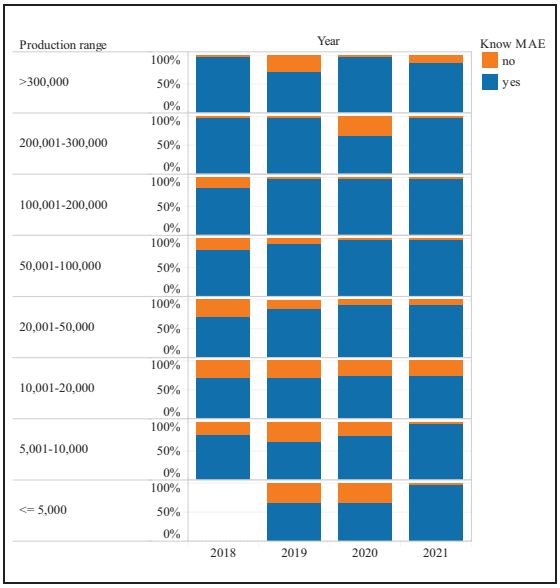

Figure 1: *Knowledge on MAE by production range, and year.*

In case of geographical location, Biobío region is the one with the greater knowledge on the concept, while Los Rios region is the one with lowest levels of knowledge on the concept.

It should be noted that when consulting about MAE concept, it was not mentioned the requirements this product must fulfil. At the period's beginning, 34.5% of the sample declared they produce structural wood, while in 2021, 45.6% of sawmills in the sample declared they produce it, they being located in production ranges of 10,000 to 20,000 m³.

The knowledge of the requirements has also had a slight variation, but negative, from 51.7% of sawmills in 2018 that indeed knew the requirements, to 47.8% in 2021.

https://doi.org/10.52202/069179-0093

In practice, structural sawn wood is identified in a lot of sawmills by its use in construction, however, in few opportunities this wood is subjected to a formal classification process. As a consequence of this, there is no certainty in meeting the structural requirements.

In regard of MAE orders, in the first measurement in 2018, 15 units claimed they had received orders to produce MAE, it was not different in 2021, confirming the orders by 15 sawmills; in average during the period's study, 11.6% of sawmills in the sample received MAE production orders. It should be highlighted that MAE production orders are concentrated in ranges of 10,000 to 20,000 m³, and 20,000 to 50,000 m³.

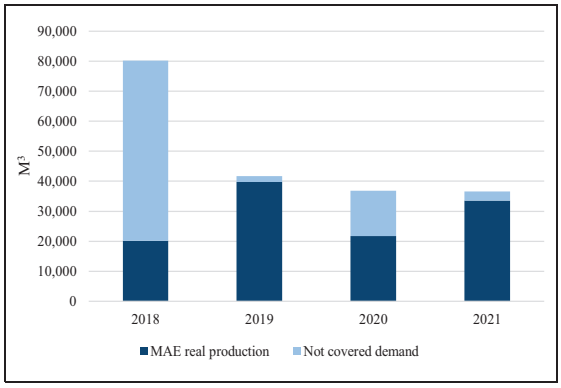

Figure 2: *Structural Sawn Wood demand, and production in 2018-2021 period.*

The volume of MAE requested has had a negative evolution, dropping from 80,120 m³ in 2018, to 36,607 m³ in 2021. On the other hand, the MAE's effective volume produced, and sold presents an increase of 66.1% since 2018 to 2021, amounting a total of 115,109 m³ during the period, meeting 59.9% of the demand in the period.

The demand unmet by sawmills, that is to say, the volume of MAE requested minus the effective produced volume has decreased (See Figure 2), representing in 2021 near of 3 thousand m³, this great variation can be explained by the increase in MAE knowledge y the real capacity of sawmills to produce this product, it is observed that requests in last three years have been adjusting to the real production.

The trained operators to carry out classification tasks have increased from 66 workers in 2018, to 92 in 2021, showing a certain interest by the sawmills in MAE production, promoting external training over internal training.

The main decision factors considered by sawmills during the period to produce, and sell MAE are: obtaining better prices for the product, reach a more stable demand, and reliability in log supply.

Another interesting way of examining the variables was though the correlation analysis, in Figure 3 are presented the main variables, those with a greater correlation with each other, excluding other variables less like-minded with the elements of the survey.

In figure 3, when the variables are closer to 1 (blue), it means a greater correlation. In case of "x", these indicates correlations without statistical significance.

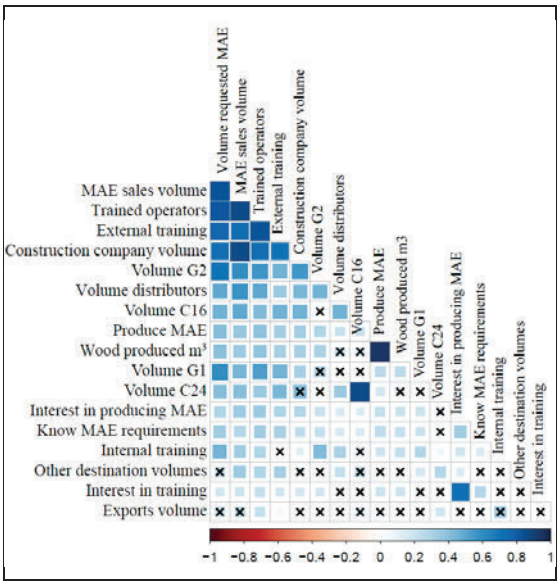

Figure 3: *Outline of main variables correlation of MAE survey*

It is observed that exist a high correlation between MAE requested volume, and actual MAE sales, in addition to trained operators, a key factor in visual grading. It also emerges that MAE requests come from construction companies, which prefer wood graded as G2, followed by G1.

To address the question if sawmills are interested in producing MAE, it is observed that this is linked to the interest in training operators, followed by the knowledge of requirements to produce MAE.

4 CONCLUSIONS

Four years of analyzed samples shows the following:

- Slight increase in knowledge of the graded structural sawn wood concept.
- In average only 5.7% of the wood for structural use marketed in construction corresponds to MAE.
- 59.0% of MAE demand was met by sawmills, of a total of 195,000 cubic meters requested during the research period.
- From the selected sawmills total production, 0.4% corresponds to MAE sales.
- Approximately, per year 10 sawmills participates actively in MAE sales, however, around of 40 are interested in production.

https://doi.org/10.52202/069179-0093

- The main decision factors observed by sawmills in order to produce, and sell MAE during the research period were: higher prices, more stable demand, and reliability in logs availability.

- While there is an interest in producing MAE, the industry recognizes the importance of training their operators externally in order for them to be able to carry out a proper wood grading.

After 4 years of measurements on MAE production, and its features, it is observed that there have been no fundamental changes in supply nor in demand of the product, thus sawmills are still under observations, since MAE production is still not an attractive business in which they can rely on a certain level of demand, and prices.

For this reason, it is necessary to implement policies, and public instruments with biding effect, wood labeling or promoting instruments like subsidies in grading training, to trigger production, supply, and demand to massive level.

The current forestry industry development, new technologies in construction, in addition to sawn wood, and logs prices, it emerges the necessity of making a difference, and to add value to production in sawmills, creating opportunities to exploit graded structural sawn wood production destined to construction.

ACKNOWLEDGEMENT

The present research have been carry out under the framework of the project entitled: *"Fortalecimiento de las Capacidades Tecnológicas del Instituto Forestal (INFOR), para el desarrollo de la Industria Secundaria de la Madera, a través de bienes públicos, orientados al sector de la construcción"*. The project was funded by *Corporación de Fomento a la Producción* (CORFO) and INFOR.

ROTATIONAL STIFFNESS OF NEWLY DEVELOPED LVL-BASED COLUMN-HEAD REINFORCEMENT FOR POINT-SUPPORTED SLAB-COLUMN BUILDING SYSTEMS

Cristóbal Tapia[1], Felix Amtsberg[2], Aaron Münzer[3], Simon Aicher[4], Achim Menges[5]

ABSTRACT: The paper presents a recently developed concept for the transmission of vertical loads between columns in point-supported timber slab systems. The concept consists of a specially milled beech LVL element inserted into the end of a GLT column, thus allowing to receive concentrated loads from an also specially milled LVL pin element. Under axial compression the LVL insert proved being able to redistribute the compression stresses effectively before transferring the stresses to the lower GLT column. This paper investigates the rotational stiffness of this concept, both numerically and experimentally with two manufactured specimens. For the studied geometry the obtained rotational stiffness was 3.4×10^2 kNm/rad, being in good agreement with the finite element simulations. Relevant aspects of the robotic manufacturing relating to the tight tolerances needed are discussed.

KEYWORDS: multi-storey timber buildings, GLT, beech LVL, rotational stiffness, robotic manufacturing, point-supports

1 INTRODUCTION

The construction of high-rise buildings based on modern wood engineered products has been a reality for the past decade, with the number of new projects steadily rising worldwide (see e.g. [2, 11]). This development has been fostered by a variety of interacting factors, associated with mechanical, environmental, architectonic and social aspects. Timber, having an excellent weight/strength ratio and enabling a high degree of prefabrication for rapid on-site assembly, fits perfectly the needs of multi-storey building construction. Furthermore, the increasing urge to transit to more CO_2-neutral building technologies has lead to an increasing interest in timber—a natural CO_2 container—as a viable option for high-rise buildings, up until now almost exclusively dominated by reinforced concrete and steel.

This relatively new field of multi-storey timber buildings has not come free of challenges, mostly represented by the need for new performant, bespoken connection solutions for the different components. Examples of problematic joints are found especially in column-slab type of structures, typically consisting of glued laminated timber (GLT) columns and cross-laminated timber (CLT) plates with an additional lateral bracing system. Here, the point-support situation leads to highly demanding requirements for the connection system. In such a situation two main problems arise: firstly, the point-support condition of the plate induces high shear and bending stresses in the immediate region of the CLT surrounding the column. This poses a problem for the CLT plate due to its relative low rolling strength values, normally about three times lower than the shear strength of timber parallel to the fiber. Secondly, the vertical load originating from the upper floors and carried by the upper column needs to be transferred to the bottom column supporting the CLT plate. Owed to the low compressive strength perpendicular to the grain of timber, $f_{c,90}$, the column cannot be supported directly on the CLT plate, and therefore the column force is normally transferred through a hole in the CLT plate (e.g. [10, 11]). This further worsens the stress situation in the CLT in the column region, as tensile stress concentrations will develop in the vicinity of the hole on the bending tension side [13]. Solutions for the reinforcement of CLT plates under these loading conditions are implemented or have been proposed in [10, 13, 18].

The transfer of the vertical loads has been addressed by Fast et al. [11] for columns at the edges of the CLT plate and in [10] for columns placed at the inner field of the CLT plate. In both cases the concept applied to transfer the vertical loads is very similar, consisting on a cylindrical steel profile used to transfer the loads through the reduced cross-section of the column. This steel profile has attached at both ends steel plates, which are fixed to the columns.

The efficacy of these solutions has been verified by means of full-sized experimental campaigns, for example in [4], where also two additional concepts were tested. Nevertheless, as mentioned in [4], the inclusion of the special steel connectors is costly and alternatives should be explored that require less steel.

Within the context of Research Project 3 of the Cluster of Excellence "Integrative Computational Design and Construction for Architecture" (IntCDC), at the University of Stuttgart, the problem of timber connections for multi-storey timber buildings was addressed. One of the specific objectives was to develop an almost pure timber column-to-column connection. The concept leverages modern digital fabrication methods to combine and glue different timber products with the required tolerances ($\approx$ 1 mm), enabling complex geometries for an efficient use of material and transfer of loads. This paper presents first experimental and finite element results on the newly developed connection concept. Especially, the behavior under vertical and lateral load situations is analyzed, and manufacturing aspects will be discussed.

2 DESCRIPTION OF THE CONNECTION CONCEPT

2.1 GEOMETRY

The newly developed connection consists of an assemblage of three specially milled timber components as illustrated in Fig. 1. The load coming from the top GLT column is first transferred to a stepped, pyramid-shaped beech laminated veneer lumber (LVL) element embedded in an equal negatively shaped pyramid cavity in the column. Then the load is transferred to a hardwood pin element with a similar stepped geometry. From there, the load travels to the bottom column through the same, but inverted, beech LVL component.

The number and dimensions of the steps of each component is variable. The radius, r, of the milled corners (see Fig. 2) is bound to the diameter of the used milling tool, which for the studied case was $r = 8$ mm.

The idea behind the chosen geometry for the beech LVL insert is to enable a gradual transfer of stresses from the smaller cross-section of the pin element to the GLT column. In other words, the stronger LVL insert serves as transition zone for the spreading of the compressive stresses, which are then transferred to the column. The same principle applies to the geometry of the hardwood pin element.

2.2 MATERIALS

In terms of used materials, it is evident that the pin element, owed to its reduced cross-section, is subjected to higher compression stresses as the GLT column. Thus, a strong material is required. For the present study, unidirectional, CE-marked beech LVL according to EN 14374 [7] was used for this component. According to the producer's Declaration of Performance [14] the characteristic compressive strength parallel to grain can be assumed as $57.5 \times 1.2 = 69$ MPa for use in service class 1. However, it should be noted that the performed experiments suggest that an even stronger material—e.g. from tropical hardwoods or densified veneer wood—is required to fully utilize the connection. Similarly, the transition pyramid-shaped insert element is also subjected to rather high stresses, reason for which beech LVL was used as well. The LVL blocks from which the pyramid insert elements were milled consisted of block-glued LVL plates.

Each component is glued into the next one by means of a two-component polyurethane adhesive. For a proper functioning of the connection, the different elements must fit precisely into each other. Otherwise, the loads would concentrate on a subset of the contact surfaces, leading to premature local damage and reducing the capacity of the connection. Small gaps can be effectively bridged by the used gap-filling adhesive, however only to a certain degree. Therefore, it is essential to achieve very small tolerances ($<$ 1 mm) during the manufacturing process. The components can easily be pre-assembled, leaving only one last on-site bonding step per connection during the construction phase.

Due to the geometry of the LVL pyramid insert, stresses perpendicular to the grain are expected in the column. In order to avoid an early failure due to splitting, the GLT column can be reinforced by means of self-tapping screws. The effect of this reinforcement measure was experimentally studied in [17], where a Weibull-based design approach is presented, and will not be further addressed in this paper.

2.3 BEHAVIOR UNDER AXIAL COMPRESSION LOADING

The column was previously investigated numerically and experimentally under axial compression in [17]. In

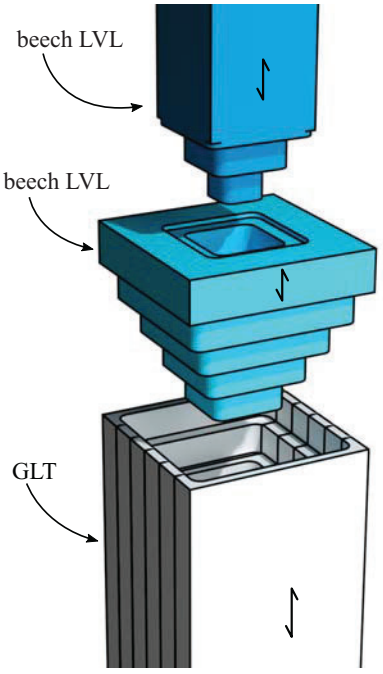

Figure 1: *Concept for the proposed connection for the vertical transfer of loads from upper columns*

https://doi.org/10.52202/069179-0094

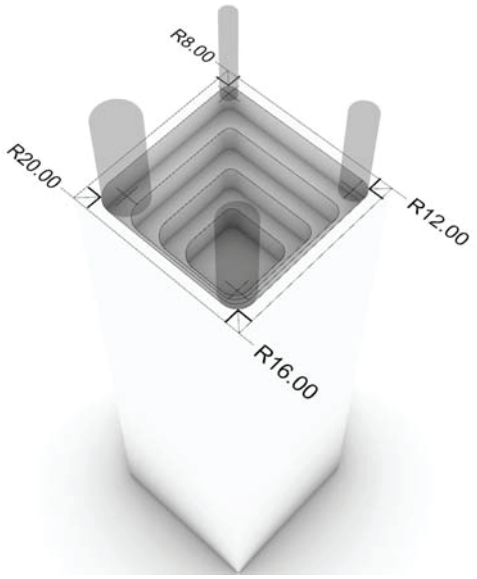

Figure 2: *Example of an automatically generated column detail based on 4 different milling tool diameters*

that study, a series of five specimens was manufactured and tested in order to obtain maximum capacities and to understand the failure mode under axial compression, where the load was introduced exclusively through the LVL pin element. The specimens had identical dimensions as those presented in this paper. The general concept of the connection can be understood by looking at Fig. 3a, where the stresses in the z-direction obtained by a 3D finite element (FE) model are shown.

The rather concentrated load coming from the LVL pin on the top induces a region of high stresses directly below the pin element. However, by placing a strong material in this region—in this case beech LVL aligned vertically—, the stresses can be taken and spread downwards. By using the special stepped geometry, the high stresses can be kept inside the LVL insert, roughly following the stress-isolines as shown in Fig. 3a. The σ_z stresses at the interface between LVL insert and GLT column can be accurately estimated by an analytical model, making this a suitable tool for the design of the connection, without requiring a full 3D FE model [17].

A further analyzed issue was the formation of a region of tensile stresses perpendicular to the fiber, directly below the LVL insert, as illustrated in Fig. 3b. The experiments showed that these stresses were responsible for the failure of the specimens, as splitting triggered the maximum capacity of all tested specimens. The consideration of these stresses was tackled in a first approximation by a Weibull-based design approach, similar as done in [3]. However, local crushing in the GLT, directly underneath the LVL insert was also observed. Therefore, the exact failure model is owed most likely to a more complex combination of compression and splitting stresses.

A further analysis was also made to assess the influence of the application of loads directly on the top surface of the LVL insert, simulating a CLT plate being supported by

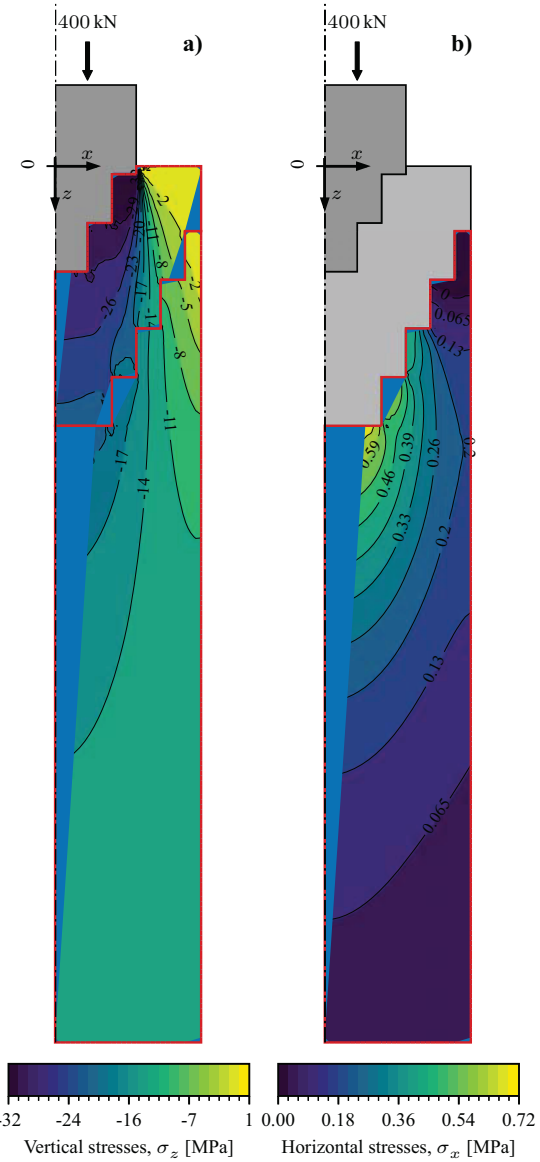

Figure 3: *Contour plots of vertical stresses σ_z (a) and horizontal stresses σ_x (b) for a load of* 400 kN *applied on top of the LVL pin element*

the column. The numerical results showed that the vertical stresses, σ_z, were rather evenly distributed and that the splitting stresses, σ_x, decreased by a factor of two to three.

2.4 MANUFACTURING CONSIDERATIONS

In the digital process chain, parametric models were developed specifically to produce the design details of the outlined column-to-column connections. These allowed an effortless generation of the geometry and resulting milling paths to produce and test various configurations of, for example, the column cross-section steps. Other parameters that were automatically generated include the infeed and path planning according to the selected cutter geometry and blank, feed rate and speed. Rhinoceros 6 [12] and Grasshopper were used as the development environment

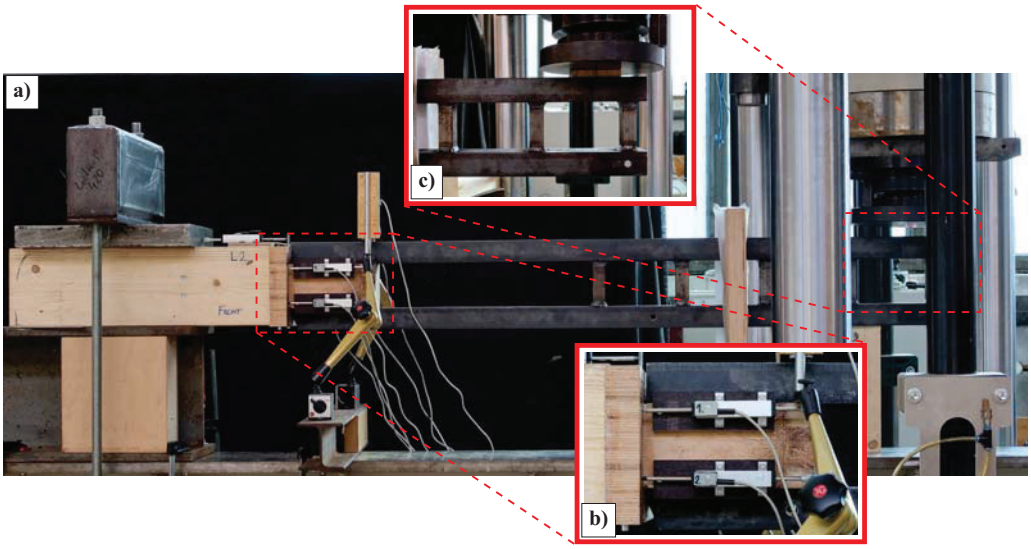

Figure 4: *Example of the realized experimental set-up for the lateral loading testing of the connection concept*

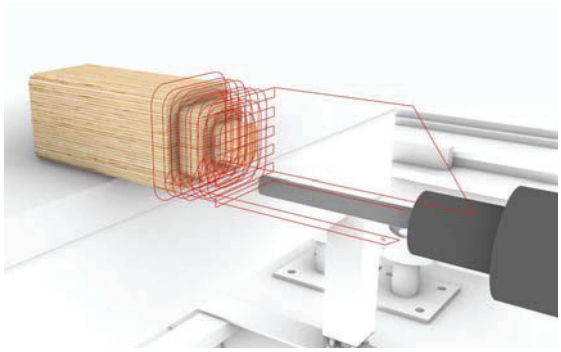

Figure 5: *Rhino Model of the geometry and automatically generated toolpath (red)*

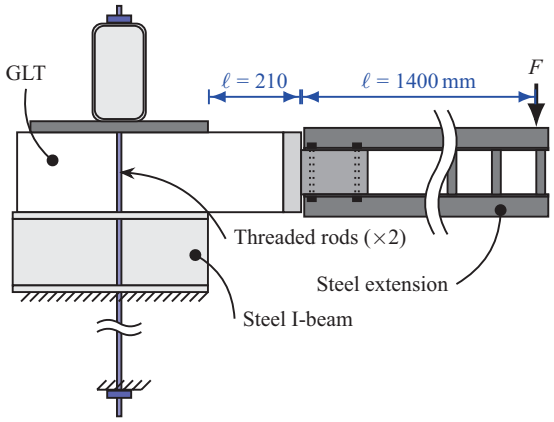

Figure 6: *Experimental setup for the lateral loading configuration*

for tool path, NC code generation and simulation. The data were then transferred to KUKA-CNC and implemented (see Fig. 5).

3 EXPERIMENTAL INVESTIGATIONS

3.1 STUDIED CONFIGURATIONS

The reported connection was studied under lateral loading in order to obtain the moment capacity, as well as the rotational stiffness. The specimens are composed of a softwood GLT column with a cross-section of 180 mm × 180 mm and a length of 600 mm; the dimensions of the LVL insert and the pin elements are described in [17]. The specimens of both configurations were tested at the Division of Timber Constructions of the Materials Testing Institute, University of Stuttgart, with a servo-hydraulic machine with a maximum loading capacity of 1.6 MN. The load was applied in displacement-controlled manner with a stroke rate of 1.5 mm/sec until failure occurred. Since the achieved loads were rather small compared to the maximum capacity of the machine (about 2 kN compared to 1.6 MN), the data recording was accompanied by a significant amount of electronic noise. Future experiments will use an independent load measuring cell, appropriate for the expected load range.

The experimental set-up with its relevant dimensions is illustrated in Fig. 6. Here, an extension made from two steel profiles welded together was attached to the LVL pin element by means of threaded rods. This increases the lever arm, thus increasing the moment to shear force ratio on the connection. The steel extension had a total weight of 14.2 kg. The specimens were clamped to a large steel profile, to achieve a cantilever situation, as presented in Fig. 4.

In both configurations the specimens were reinforced by means of full-threaded self-tapping screws. This was done in order to delay splitting due to stresses perpendicular to the grain. The position of the used screws can be seen in Fig. 7.

https://doi.org/10.52202/069179-0094

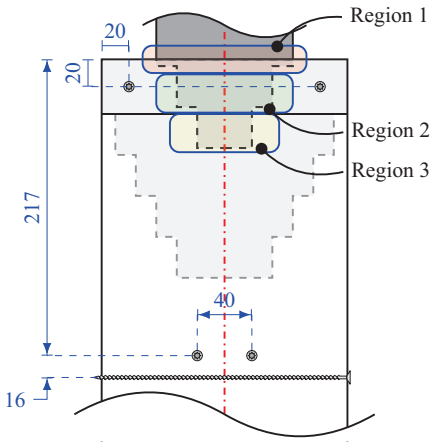

Figure 7: *Position of screws used to reinforce the connection during the lateral loading experiments and definition of regions in the interface between LVL-insert and LVL-pin elements (dimensions in millimeter)*

3.2 MANUFACTURE OF PROTOTYPES

The fabrication setup used to produce the joints from softwood GLT and beech LVL consists of a KUKA 420 R3031 industrial robot mounted on a KUKA KL 4000 linear axis with a travel distance of 11 m. The system is designed and tested for a machining accuracy of $\leq$ 0.4 mm. An air-cooled HSD 929L spindle with a power of 14.40 kW was used for subtractive machining. The column-to-column connection was produced using a coated spiral roughing/finishing cutter with a useful length of 30 mm, a total length of 205 mm and a diameter of 16 mm. After three tests with varying step geometries a total of 12 assemblies were fabricated for experimental testing. The GLT column and LVL pin were machined horizontally (see Fig. 8), while the LVL pocket element was manufactured vertically (see Fig. 9). These were also reclamped to be machined on both sides. Other parameters are feed rate (3000 mm/min GLT, 600 mm/min LVL), speed (12 000 rpm), final infeed (0.25 mm) and offset (0.25 mm). The bond line thickness resulting from this milling set-up was analyzed on a parallel milled sample using an electronic stereo microscope [5]. Predominantly thin (<1 mm) bond line thicknesses were observed. The mean glue joint thickness and the corresponding coefficient of variation were 0.14 mm and 40 % respectively (see Fig. 10). This indicates a high accuracy of the milling process and that, if necessary, the programmed tolerances could be further reduced.

3.3 RESULTS

3.3.1 General observed behavior and failure mode

Figure 11 shows the global moment-displacement curve of specimens L1 and L2 (displacement as machine piston displacement). Both specimens presented a linear behavior until about 1.5 kNm, where first audible failure noise could be heard. This is clearly shown in Fig. 11 for specimen L2, but not for specimen L1. The reason for this is that for the case of specimen L1 this initial failure occurred during the first attempt of testing this specimen, which had to be

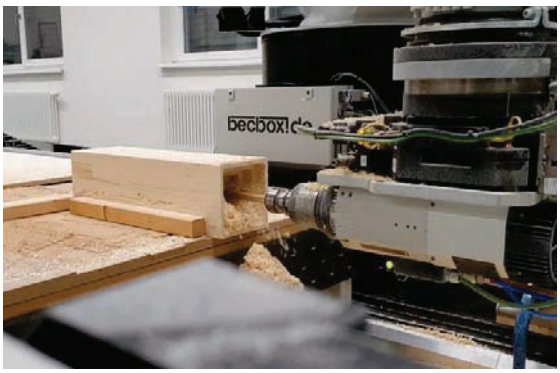

Figure 8: *Horizontal milling of the GLT column*

Figure 9: *Vertical milling of the LVL pocket*

interrupted, as the used steel extension proved to have a far too low shear stiffness—initially both steel profiles were held together exclusively by threaded rods, which were then welded together to increase the shear stiffness.

After the first load drop-down a second failure took place. A further increase in the load triggered the global failure at about M_1 = 2.57 kNm and M_2 = 2.46 kNm for specimens L1 and L2, respectively. Beyond this point the upper part of the pin element began to visibly to be pulled out from the cavity of the LVL insert (see Fig 12). A summary of the achieved maximum loads and corresponding moments is presented in Table 1.

The first can most probably be attributed to the failure of the interface between LVL-pin and LVL-insert elements

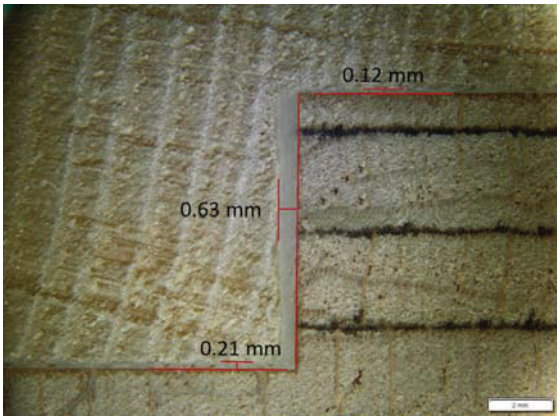

Figure 10: *Adhesive joint thickness of a milled sample*

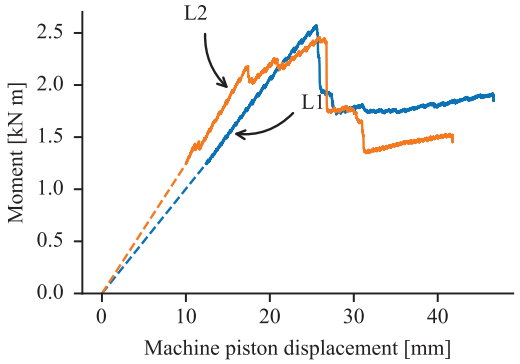

Figure 11: *Load-displacement curves of both tested specimens.*

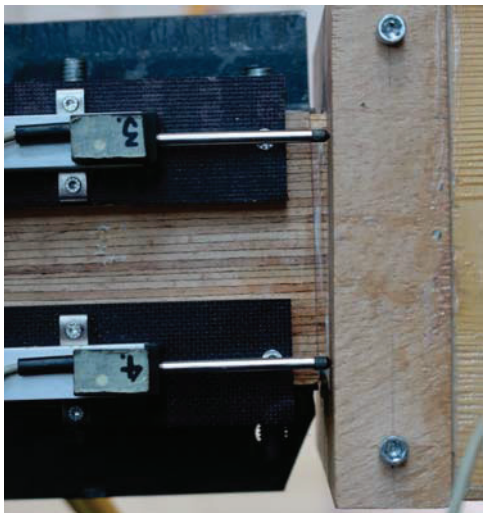

Figure 12: *Pin element of specimen L1 being pulled-out of the LVL insert after reaching maximum load.*

in the vertical surfaces of region 1 shown in Fig. 7. As the damage progressed, the horizontal faces in region 1 failed, causing the second load drop. Finally, the vertical and horizontal bond faces of region 2 failed, causing the global failure of the connection. The bond faces of region 3 probably failed together with those of region 2, as they show a smaller total area to transfer the loads and the lever arm is smaller compared to region 2, thus increasing the bending stresses. Figure 13 shows the failed vertical surface of region 2 for Specimen L1, where a rather low percentage of fiber breakage can be observed.

Table 1: *Maximum loads and moments achieved by specimens L1 and L2, and estimated rotational stiffness*

Specimen	Maximum Load [kN]	Maximum Moment [kN m]	Rotational Stiffness [kNm/rad]
L1	1.84	2.57	3.4×10^2
L2	1.76	2.46	–

Figure 13: *Shear failure on the vertical surface of region 2, corresponding to the vertical surface of the second step of the LVL-pin element*

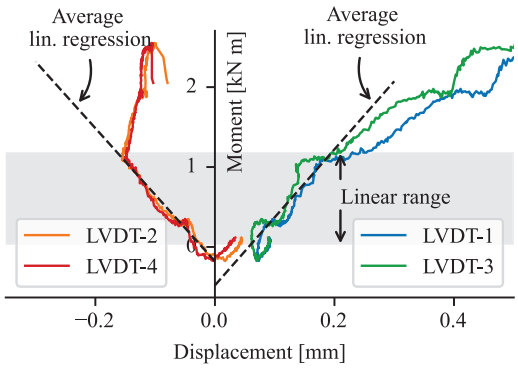

Figure 14: *Measured relative displacement between pin element and LVL insert of specimen L1. LVDT's 1 and 3: tension side; LVDT's 2 and 4: compression side. Grey region marks the load limits used to compute the average linear regression on both sides.*

3.3.2 LVDT measurements

Figure 14 presents the moment-displacement curves for the LVDT's which measure the displacements in the tension (1 and 3) and compression (2 and 4) regions of specimen L1. Although the data is rather noisy, the expected behavior of positive and negative displacements in the tension and compression regions, respectively, can be clearly observed. The dashed lines in Fig. 14 represent the linear regression of the averaged curves from LVDT's in tension and compression within the linear range denoted by the shaded region.

The corresponding measurements from Specimen L2 are not presented here, as problems with the fixation of the steel extension lever arm caused a relative shift between steel and pin-element, resulting in erroneous data. Future experiments will consider a more robust concept for the clamping of the steel extension to the LVL-pin element.

3.3.3 Rotational stiffness

The rotational stiffness of the connection can be obtained from the LVDT measurements at positions 1 and 3 (bending tension side), and 2 and 4 (bending compression side), as shown in Fig 14. To estimate the rotational stiffness, k_θ, the rotation angle between the LVL-insert and the LVL-pin

https://doi.org/10.52202/069179-0094

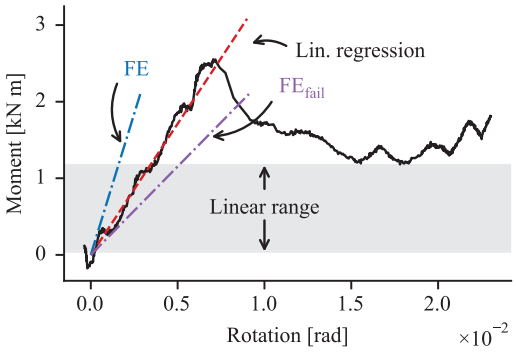

Figure 15: *Moment-rotation-rotation curve computed for specimen L1. The rotation was computed from the averaged results of the front and rear LVDT's*

elements was computed as

$$\theta = \arctan\left(\frac{\bar{u}_t - \bar{u}_c}{d}\right), \tag{1}$$

where $\bar{u}_t$ and $\bar{u}_c$ are the averages of the displacements measured in tension and compression, respectively, and d is the vertical distance between the LVDT's, in this case $d = 80$ mm.

Figure 15 shows the moment-rotation curve obtained for Specimen L1, from which the rotational stiffness can be estimated by means of a linear regression. The linear regression was computed for the data within the linear range defined in Fig. 14. Finally, a rotational stiffness $k_\theta = 3.43 \times 10^2$ kNm/rad was obtained for Specimen L1.

4 NUMERICAL ANALYSIS

4.1 DESCRIPTION OF FE MODEL

A parametric 3D finite element model was programmed in Abaqus V2022 [1] with the available Python API. The model consists of three parts (GLT column, LVL insert and LVL pin) bonded by means of cohesive interactions on the respective vertical faces and contact behavior for the horizontal surfaces (i.e. end grain can take up compressive loading but not tension). This can be seen in Fig. 16, where the different cohesive and contact regions, as well as the used mesh is shown. Symmetry along the YZ-plane was used to reduce the total number of elements. The boundary conditions corresponding to the clamping where applied on the side surfaces according to Fig. 6, by restraining all degrees of freedom. The load was applied as a shear force-moment pair on a reference point placed at the center of the top face of the LVL pin part. This reference point controls a rigid surface, which is "tied" to the top face of the pin.

The geometry was meshed with linear 3D brick elements with incompatible modes of type C3D8I, with an approximate size of 3 mm. The elastic material properties used are shown in Table 2, while the cohesive interaction was defined with stiffness parameters $k_{nn} = k_{tt} = 1000$ N/mm^3, with finite sliding. A failure of the bond line of the vertical surfaces of region 1 (see Fig. 7), in the bending tension side of the connection, was simulated by deactivating the cohesive behavior in this region. The full model is available in [16]. For the post-processing and visualization the results were saved in the ASCII format *.fil and were then analyzed with the Python library Pybaqus [15].

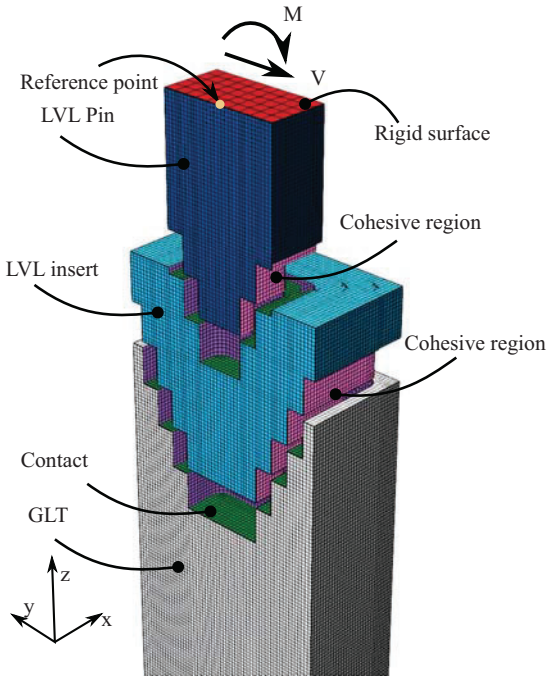

Figure 16: *Illustration of the FE mesh, together with the definition of cohesive regions and load application*

4.2 ROTATIONAL STIFFNESS

The numerical results for the moment-rotation behavior are shown in Fig. 15, where both models—with and without simulated failure in region 1—are shown along with the experimental curve. It can be seen that the experimental results yield values in-between the two models, which most probably means that in reality the horizontal faces are not fully unused. The rotational stiffness for the model with and without simulated failure is 7.4×10^2 kNm/rad and 2.3 kNm/rad, respectively. The experimentally measured stiffness is 3.4×10^2 kNm/rad.

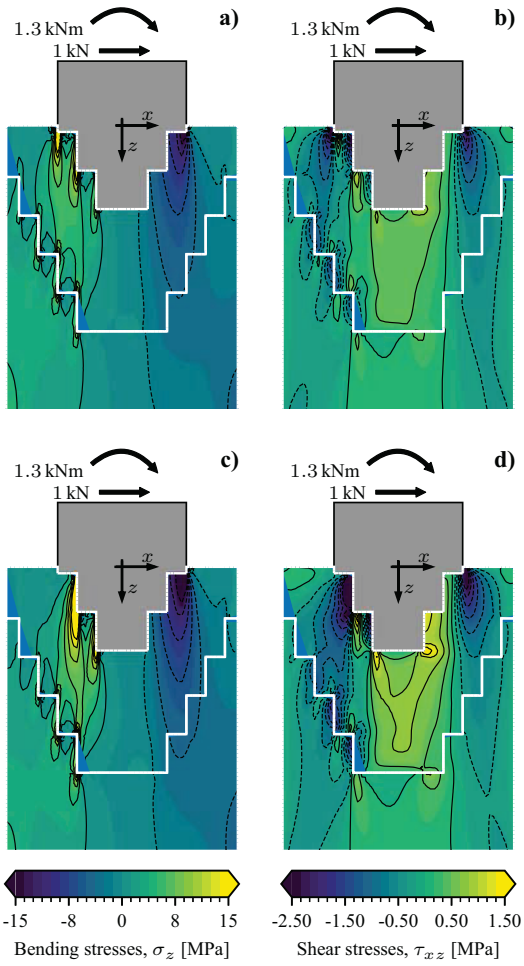

Figure 17: *Stresses in the region of the column-head for the intact connection and with the simulated failure of bonded faces of region 1; (a) Stresses parallel to column axis, σ_z ans (b) shear stresses τ_{xz} for intact connection; (c) Stresses parallel to column axis σ_z and (d) shear stresses τ_{xz} for simulated damaged connection.*

The current analysis did not consider any form of fracture mechanics based softening in the bonded surface, assuming a very simple mixture of cohesive and contact behavior. It can be expected that a much better agreement with the experiments can be obtained, if a more realistic mechanical behavior for the bonded region is used. This could be done by considering softening or by simply adjusting the stiffness properties of the cohesive region.

4.3 STRESSES IN THE COLUMN-HEAD REGION

Figure 17a presents the stresses parallel to the fiber and column axis for the intact model (no failure), where regions of high tensile and compressive stresses are seen at the interface between LVL pin and LVL insert element. The observed asymmetry in the stress distribution is due to the assumption that tensile stresses are not transferred through the horizontally bonded surfaces (endgrain bonding). Figure 17b shows the shear stresses, τ_{xz}, in the same region, where high stressed regions are evidenced on the vertical bond faces on the left side (bending tension side).

Figures 17c,d present the analog results for the model with the simulated failure in region 1. It is evident that the stresses increase significantly due to the reduced cross-section. These high stresses remain mostly in the LVL insert element. From Fig. 17d it can be seen that the shear stresses on the bonded surface are above 2.5 MPa with a moment of 1.4 kN m directly on the top face of the insert element. The characteristic shear strength of the used beech material is 4.5 MPa, which explains the observed failure during the experiments (at about 2.5 kN m).

5 DISCUSSION

5.1 GEOMETRY OF THE CONNECTION

The initial development of the presented connection considered only the effects of vertical loads, as the horizontal loads were assumed to be taken by a stiffening element, such as a reinforced concrete core. However, unless a pin joint is used, some amount of moment will still be transferred to the columnhead, in which case it is important to understand the behavior under moment action, thus justifying this analysis. The most evident problem with the current geometry is the small depth of the vertical step of region 1, which leads to a rather early failure due to the small available shear surface to transfer the stresses. A simple solution for an improvement is to make the first step deeper, hence, increasing the shear surface and resulting in a more robust concept.

5.2 UTILIZED ADHESIVE

Although the bonding of the different components worked very good—as can be judged from the observed axial compression experiments from [17]—, the aspect of the shear failure from Fig. 13 hints a possible limitation of the chosen two-component PUR adhesive. This is due to the rather low percentage of fiber breakage observed. However, it must be stated that the used beech LVL cannot be judged by the same parameters as e.g. softwoods, due to the marked differences in strengths of both materials. Further studies with different gap-filling adhesives should be performed in order to better assess the here presented results.

6 CONCLUSIONS AND OUTLOOK

The current state of a new column-to-column connection was presented. Following one of the project's objective of only using wooden materials if possible, a concept based on softwood GLT and beech LVL was conceived, where the GLT column head is reinforced by embedding a stepped beech LVL insert. Relevant aspects of the mechanical behavior as well as of the manufacture process were presented and discussed, from which the following conclusions can be distilled:

1. The robotic-based manufacturing process proved to be suitable for the precise milling of components with tight tolerances of about 1 mm, enabling the experimental testing of the concept.

https://doi.org/10.52202/069179-0094

2. The rotational stiffness was shown to lay within the range predicted by finite element simulations if damage in region 1 (top most level) is assumed. An improved agreement with the experiments could be achieved by using more realistic material behavior such as softening.

3. The data acquisition during the experiment was problematic due to the rather low fracture load level (about 2 kN) as compared to the maximum load of the machine (1.6 MN). Further experiments will consider a separate load measuring cell, appropriate for the expected load range.

4. The observed failure mode on the shear surface indicates possible limitations with the chosen two-component PUR, which needs to be further assessed experimentally.

5. Finally, although the current geometry is rather weak under bending induced by lateral loading, simple modifications to the geometry can be introduced to improve this if needed.

ACKNOWLEDGEMENTS

The presented ongoing research is partially supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – EXC 2120/1 – 390831618. The authors owe many thanks to the company Pollmeier (Creuzburg, Germany) for generously sponsoring the beech LVL plates (Baubuche) for the presented tests. Further gratitude is owed to the Company Henkel AG & Co. KGaA, Düsseldorf, Germany for supporting the project with tailor-made adhesives.

DATA AVAILABILITY

Some or all data, models, or code generated or used during the study are available in a repository or online in accordance with funder data retention policies. (doi: 10.18419/darus-3388, Ref. [16])

MECHANICAL PROPERTIES TESTS OF DELIGNIFIED AND DENSIFIED WOOD

Jörg Wehsener[1], Martina Bremer[2], Peer Haller[1]

ABSTRACT: Wood modification has a long tradition. The target is in many case to improve the mechanical properties, durability or other properties. In this study was investigated a combination of delignification and densification to enhance bending strength and ASE. Both wood treatments change properties in different ways depending on the conditions and the wood species. The primary objective of this treatment combination was the improvement of mechanical properties by partly extraction of lignin components. The treated structure retains cellulose and hemicellulose chains aligned. The densification perpendicular to the grain will reduce the cell lumina and compress the wood structure more than 70% together, afterwards. As a result, the cell walls become entangled and hydrogen bonds between adjacent cellulose nanofibers according [1].
The combined processes were applied to the green and dried poplar (*Populus nigra* L.). Firstly: delignification procedure was done with small samples in NaOH and Na_2SO_3 solution by more than 100°C, 130°C and 150°C for 7h. After washing and analyse wood components second step followed: densification. The wood was compressed perpendicular to the grain in different temperature levels (100°C, 130°C, 160°C) and holding times up to 80% of the original thickness. After the treatment, ASE, MoR and MoE were determined. The bending strength was meanly depending on the solution temperature and compression time and temperature. Bending strength has the optimum by around 90% lignin removal and 130°C pressing time over 24h. The bending strength will increase up to 450MPa compare to the densified reference of 250MPa and the untreated polar app. 65MPa. ASE was reduced by strong delignification and increase temperature.
.

KEYWORDS: tension, bending strength, recovery set, delignification, densification

1 INTRODUCTION

Investigations on modification processes have been done since the last decades. All types of processes (chemical, physical or biological) improve the material behavior in different ways. Thus, better material properties must be achieved. Samples of wood modification – like thermo hydro mechanical densification - was produced as LIGNOSTONE, STAYPAK or LIGNIFOL [8, 20]. Inoue et al. [6] and other authors tried to solve the recovery problem by superheated steam, [12] and [9] by heated oil, [10] in combination by both. Other treatment with chemical components and different types of resin impregnation (DMDHEU, melamine, phenol, furfuryl) were investigated by e.g. [19, 13, 21, 14, 11, 17] and many more. Beside of the published study from [4] using alkaline, densification and partial extraction of wood polymers will attract attention. The dependency of densification time and temperature to improve the dimensional stability of are well known: first, decrease in the very hydrophilic hemicelluloses means a decrease in the water affinity. Second, the resulting furfurals bind to the lignin and provide additional crosslinking through this adhesion. In this way, the stresses that arose during compaction can be relieved by re-crosslinking the microfibrils of the cellulose. According to [10], these stresses are the main cause of recovery. Also the moisture influence reduced the glass transition temperature of lignin. It appears less tensions during densification process caused by wood plasticizing. Moisture also contributes to further hydrolysis of the polysaccharides, which supports hydrophobicity, but also leads to a shortening of cellulose chain length and an associated loss of strength. Results of those treatments show significant increase of mechanical properties and dimensional stability. In this point of view, success appear, but modification processes are dealing with small and thin wood samples.

Poplar, as fast growing wood species has the potential to become high strength properties by chemical and mechanical modification. It is well-known that densification transverse to grain will improve the mechanical properties [18, 22, 15]. Delignification influence wood structure, dimensional stability and bond strength of cellulose [23, 25]. By using both, there is stronger increase of mechanical properties caused by breaking and reformation new hydrogen bonds [1, 16, 26]. A new approach is a partial delignification combined with a compression of the wood was described by [2, 3]. As a structure-forming polymer, lignin plays an important role in plants. It penetrates the cellulose fibers and stick them together whereby it contributes significantly to the strength properties. With partial removal of the lignin, a higher compression of the cellulose fibers is possible [24]. In addition, fewer cracks form in the cell wall during densification and the density and associated strength increase. According to [5] and [4] new intermolecular interactions between the cellulose chains are formed during compression, which further increases the strength. In addition, the dimensional stability is improved due to reduced water accessibility and other solvents. Another positive benefit of this material is the improved surface hardness [7]. These modified properties result in new applications potentials such as parts of music instruments, timber joints like wood nails or connection plats, machine parts or others.

2 MATERIAL AND PROCESS

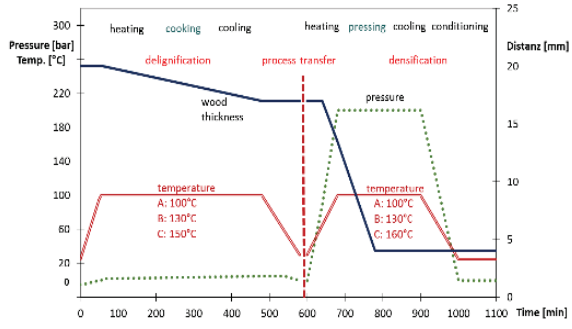

***Figure 1**: Process parameters during thermal delignification and thermo-mechanical densification (schematically)*

2.1 MATERIAL

Green sawn and dried poplar wood (*Populus nigra* L.) was used for the investigations. The wood samples, with the dimensions of 200 mm (longitudinal) x 100 mm (tangential) and 20 mm (radial), were cut from green log with initial oven dry density of 0.44 g/cm³). The same log-material were used for all treatments, respectively, were used as untreated reference specimens. The initial moisture content (mc) of green specimens was 90%, 124% and 162% at the beginning of delignification process (temperature of 100°C, 130 °C and 150°C). The dried one were treated at 9% moisture. Green and dried specimens were delignified in digester, washed and conditioned (20°C/65%RH) for two weeks. Afterwards, densification was applied in heating press. In each case, twin specimens were produced in order to be able to determine the changes in chemical composition caused by the delignification and to be able to proof hornification effects on delignification. In total, 12 specimens were modified by each process. Figure 1 shows both modification processes schematically:

2.2 DELIGNIFICATION

Delignification takes place in a 20 Litre autoclave with circulation pump (Figure 2). The delignification liquor contained sodium hydroxide (2.5 molar) and sodium bisulfite (0.4 molar). Wood specimens were placed in the digester with the help of a grid to ensure even circulation of the cooking liquor around all specimens. The temperature during delignification was varied whereby the delignification time was counted from reaching 100°C. Digestion time was seven hours for each.

For removing the chemicals and dissolved wood components, several washing steps were carried out after the cooking process. At first, the specimens were washed inside the autoclave with hot water (80°C) two times. In the next step, the samples were placed in green water for at least 18h hours. This was followed by two short rinsing cycles with cold water. Finally, the samples were stored again in water for 2 days.

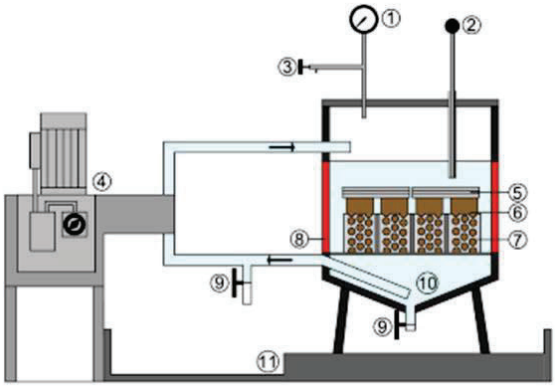

***Figure 2:** Digester equipment for delignification (1 pressure gauge with pressure relief valve, 2 temperature sensors, 3 valve, 4 circulation pump, 5 stainless steel perforated plates, 6 specimens, 7 stainless steel perforated grilles, 8 wall heating, 9 drain valve, 10 solution, 11 drip tray)*

2.3 CHEMICAL CARACTERIZATION

The delignified as well as the twin specimens were characterized for their chemical composition. For that, the specimens were dried at 103°C and milled by a cross beater mill using a 4 mm sieve. All contents relate to the dry matter of the specimens. Content of extracts were estimated by Soxhlet extraction with a mixture of ethanol and toluene (1:1 v/v) for 6 h. Since there is a mass loss

https://doi.org/10.52202/069179-0095

during delignification, the reference mass for the chemical analysis of the contents of the individual wood components changes. Therefore, the wet-chemically determined contents were corrected on the basis of the mass loss.

2.3.1 Cellulose

For determination of cellulose content about 1 g of the specimens were cooked three times under reflux in 25 % nitric acid in ethanol for a half hour each. After that the cellulose was separated by filtration using glass filter crucible of pore size 40 – 100 µm. The separated cellulose was cooked again in water for 1 h and washed acid free with water. Masses of cellulose were determined after drying at 103°C.

2.3.2 Holocellulose

About 0.3 g of specimens were used for estimation of holocellulose by delignification with sodium chlorite. For this, the specimens were shacked in a solution of 60 µL glacial acetic acid and 0.3 g sodium chlorite in 45 mL deionized water five times for 1 h at 70°C. After each hour glacial acetic acid as well as sodium chlorite was added again in the same amounts. Then the holocellulose was separated by filtration using glass filter crucible of pore size 16 – 40 µm and washed acid free with water. Masses of holocellulose were determined after drying at 103°C.

2.3.3 Hemicelluloses

Content of hemicelluloses results from the difference between holocellulose and cellulose.

2.3.4 Klason lignin

Content of Klason lignin was determined by dissolving of the Polysaccharides. About 0.5 g of specimens were mixed with 15 mL of 72 % sulphuric acid. This mixture was hold at room temperature for 2 h with occasional stirring. After that, the mixture was diluted with 560 mL of deionized water and cooked for 4 h under reflux. The resulting Klason lignin was separated by filtration using glass filter crucible of pore size < 16 µm and washed acid free with hot water. Masses of lignin were determined after drying at 103°C.

2.4 DENSIFICATION

The specimens were conditioned in a climate chamber at 20°C and 90 % *RH*. At a wood moisture content (*MC*) of approx. 20 %, 12 boards of each species were thermo-mechanically densified transverse to the grain to a thickness of 4 mm. It was carried out as a thermo-mechanical pressure deformation in an open system (Figure 3). The process was applied in three steps: 1) heating for 60 min by using temperature of 100,130 and 160°C, 2) densifying during next 120 min by maximum pressure of 40 N/mm² followed by a second phase of thermosetting for 4 h, 20 h or 24 h, and 3) cooling to 40°C within 60 min.

During the densification process, *MC* was reduced. Metal spacers were used to limit the degree of densification but there was no limitation in width. Volumetric density measurements were performed subsequently on densified specimens. After conditioning, specimens were cut parallel to fibre in original thickness for mechanical tests. Compression set *C* was evaluated as.

$$C = \frac{R_0 - R_c}{R_0} \quad (1)$$

were R_0 is the initial thickness and R_C is the thickness of compressed specimens. The compression set was 80 % caused by inhomogeneous cross section of delignified specimens.

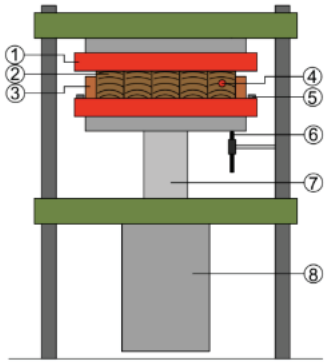

***Figure 3**: Hot press (1 hot plate, 2 specimens, 3 fixer, 4 temperature sensors, 5 metal spacer, 6 transducers, 7 plunger, 8 hydraulic cylinder)*

2.4.1 Three-point bending test

The modulus of rupture (*MoR*) was determined in a three-point bending test according to DIN 52186 (1978) with a span of 120 mm parallel to the grain and 3 replicate (n) specimens of 140 mm (longitudinal) x 10 mm x 4 mm (radial) for each test modification parameter. The direction of densification was equal to the direction of loading. Test speed was 6 mm per minute.

2.4.2 Determination of dimensional stability (ASE)

Based on the DIN 52184 modified material was stored in normal conditions for 10 days. Specimens of 10 mm (longitudinal) x 20 mm x 4 mm (n = 3) were tested with five cycles of oven drying at 103 ± 2°C for 18 h. This was followed by a soaking phase by means of water vacuum-pressure impregnation (50 kPa and 15 min followed by 800 kPa and 20 min) with subsequent water storage for 24 h to determine the change of volume due to the treatment. *ASE* was calculated as

$$ASE = \frac{a_{untreated} - a_{treated}}{a_{untrated}} \quad (2)$$

where $a_{\text{untreated}}$ is the maximal swelling before and a_{treated} is the maximal swelling after treatment.

Additional were determined compression-set-recovery C_R according Equation (3), which

express permanent thickness after swelling. It was calculated as

$$C_R = \frac{R_{C,wet} - R_c}{R_0 - R_c} \quad (3)$$

where $R_{C,\,wet}$ is the thickness of dried compressed specimens after swelling.

3 RESULTS AND DISCUSSION

3.1 PROCESSES

Washing was done two times 15 min and repeated after 18 h water storage. Depending on treatment temperature, surface colour changed from white to dark brown. This may be explained by contact of black liquid, caused by lignin. Green and dried specimens were soft after processing and distorted after drying. Particularly with regard to the dried poplar specimens showed drying cracks and loose fibers (reduced bonds due to removed lignin). After conditioning, densification, the determination of chemical components took place. Mean density of green and dried specimens after treatment are shown in Table 1. As expected, the poplar density was multiplied by densification and once again more by delignification.

In generally, on dried specimens were measured higher density than on the green one, significantly. The density of green sawn specimens was slightly affected at delignification temperature of 100°C and 130°C, but degreased of 150°C significantly. Higher process temperatures result in more defibration and degradation of the cell composite.

Table 1: *Oven-dry density of poplar (reference=0.44g/cm³), only densified poplar (1.22g/cm³) specimens after delignification and densification (treatment temperature/ treatment time)*

Delignification temperature (°C)		Densified, delignified 100°C/4h (g/cm³)	Densified, delignified 130°C/4h (g/cm³)	Densified, delignified 160°C/4h (g/cm³)
100	green	1.46	1.39	1.41
	dried	1.50	1.51	1.49
130	green	1.44	1.36	1.44
	dried	1.55	1.51	1.53
150	green	1.09	0.93	0.98
	dried	1.38	1.41	1.34

3.2 CHEMICAL COMPOSITION

It can already be seen from the measured loss of mass due to delignification that there is a significant difference between the green and pre-dried wood. While the mass loss of the green specimens is independent of the temperature, in the dry specimens the mass loss increases with rising delignification temperature. A comparison of mass loss with the summarized changes in the contents of the wood components, which were determined by wet-chemical methods, shows the same trends. In the case of green specimens the absolute value of measured loss is significantly smaller than the summarized changes in contents of wood components. This suggests that depolymerizations occur. The resulting low molecular weight (oligomeric) products cannot be determined with the wet chemical methods. For the technical-dried specimens, the values of the measured mass losses and the sum of changes of wood components are closer together. Beside this, the mass loss at delignification temperature of 150°C is much higher for the dried specimens.

If one considers the change in the individual wood components (Table 2), the different behaviour of the green compared to the technical dried specimens can also be seen here. With the exception of cellulose, in the dried specimens the proportion of all components decreases with increasing temperature. The lignin is then completely removed. Extracts and hemicelluloses are only about 80% present after delignification at 150°C. The change in the cellulose content shows a minimum at 130°C, which is caused by the binding of reactive degradation products of lignin or hemicelluloses to cellulose. At 150°C, the degradation of hemicelluloses and lignin leads to less reactive substances with condensed structures and low content of functional groups.

Table 2: *Changes in contents of wood components*

Sample	$T_{Delignification}$ (°C)	Change in contents (% (w/w)) EXTRACTIVES	LIGNIN	CELLULOSE	HEMICELLULOSE	ASH
green	100	15	-19	6	-68	169
	130	1	-44	13	-62	87
	150	-14	-91	47	-68	202
dry	100	-21	-5	-15	-42	1265
	130	-42	-54	-7	-52	372
	150	-81	-99	-20	-77	287

For green specimens the change of lignin content correlates also with the temperature. In contrast, the degradation of hemicelluloses seems to be almost independent of temperature. The increase of cellulose content can be explained with the binding of reactive degradation products. Change in extractive content varies with temperature. Indeed, the content of extractives in green specimens is in general less. Digestion chemicals that have not been removed completely cause the sharp increase in the ash content for all specimens. These results show that the accessibility of the digestion chemicals is better in technical dried wood than in green wood.

3.3 DENSIFIED WOOD

Delignified specimens were app. 4 mm thick after densification. The average density after the treatment varied from 0.9 g/cm³ to 1.5 g/cm³, depending of different delignification. Deformation of cross section does not influence compression quality result in very tightly

https://doi.org/10.52202/069179-0095

packed, stiff and hard material. Only highly delignified specimens show loose fibres on the surface.

3.4 BENDING STRENGTH

Bending strength was determined by 3-point bending test. MoR of undensified poplar was according *Wehsener et al. (2018)* approx. 62 MPa by mean density of 0.36 g/cm³ and on 50 % densified specimens MoR of 107 MPa (0.69 g/cm³) was achieved. The MoR of tested only densified reference (approx 75%) increased to 234 MPa by density of 1.219 kg/m³.

Results of MoR from green cut and dried poplar (4 h and 20/24 h densification process) were summarized in Figure 4. Densification of delignified poplar lead to increased MoR depending on treatment temperature and time.

Delignified specimens by 100°C (lignin content 19%) show high MoR (440 MPa) after long densification process (24 h, 130°C), as well as after short process of 4 hours and 160°C (426 MPa). There was not remarkable influence of using green sawn or dried poplar on bending strentgh after delignification at temperatures of 100°C or 130°C.

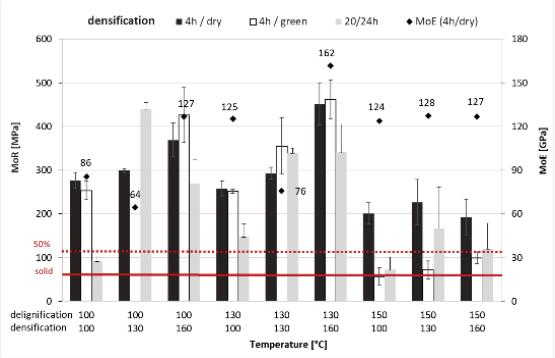

***Figure 4**: Bending strength of poplar (red), 50% densified (red dotted) and 80% densified and delignified by 100°C, 130°C and 150°C; lignin content by delignification temperature was 19% (100°C), 13% (130°C) and 2% (150°C)*

Delignification temperature of 130°C and 4 h on 160°C densified shows also high MoR of 462 MPa (dry) and 452 MPa (green). Specimens treated by 150°C, MoR degrease all about, but twice on green sawn specimens at the same time.

MoE of 150°C delignified specimens sustained at the high level close to 120 GPa, but shows also indifferent behaviour on lower temperature. In generall, it can be seen, the MoR values are higher on lower temperature and longer pressing time (130°C, 24h) even on short time and high temperature (160°C, 4h). For obtaning optimum results, the delignification temperature should be on mild temperatures (100°C or 130°C) for partial delignification (reduced lignin between 20 and 60%) and high temperatures for densification (130°C; 160°C). The treatment process achive maximal bending strength on less than 50% reduced hemicellulose and elevated densification temperature.

The delignification reduces density and hence characteristics like mechanical properties are affected. The measured bending strength are indifferent in regards to the expected results. Figure 5 shows the MoR results of the untreated, densified, and delignified and densified specimens (densification: 4 h) in relationship to the density. High delignified green sawn wood (2% lignin) show similar results close to 100 MPa, but very high density differences (0.44 to 1.4 g/cm³). Dried and high modified wood achieved MoR twice time compared to green sawn specimens. Specimens low delignified (13% and 19% lignin) tend to high density up to 1.5 g/cm³ and MoR (up to 250 MPa). All specimens show maximum MoR independent of the initial moisture content. Only 80% densified specimens double MoR nearly and density compared to 50% densification. Values of around 200 MPa were measured.

Material of 2% lignin remaining are less compact and dense than mild delignified wood. Specimens failed interlaminar and show defibration. High delignification reduced bonding of cellulose fibers, caused by lignin removing. Bending tests show MoE around 120 GPa, but low MoR on 100 MPa by green sawn specimens. In opposite to the high treated material (2% lignin) the mild delignified material (13% and 19% lignin) shows high elasticity and no brittle failure. Material has compact and dense structure across the section. Bending strength increased up to 440MPa and the specimens failed very ductile. Green sawn specimens failed by shear and on several specimens fiber splitting appeared.

Considering the densification time it can be stated that long densification time of 24 hours combined by mild delignification leads to high mechanical properties. In the tests, the MoR showed similar tendency and increased when densification time chosen for 4 hours and densification temperature was high.

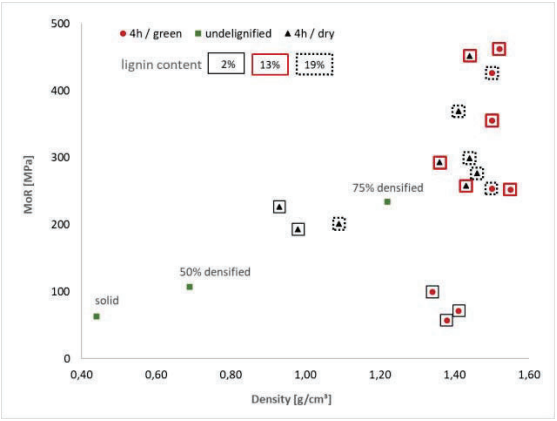

***Figure 5**: MoR in comparison to density modified on green and dried poplar with reduced lignin content and densification ratio*

3.5 ANTI-SWELLING EFFICIENCY (ASE)

During five cycles of swelling and shrinking the recovery-set of the modified material was reduced. As previously reported by [15], recovery-set of densified wood is decreasing with increasing intensity of a thermal

modification. In this study, solid, densified and densified combined with delignified modification processes were tested. Highly delignified specimens showed different layers by loose fibres. In general, swelling is reduced by increased temperature and compression time compared to only densified specimens. Influence of different lignin content was not detectable. Swelling of green sawn specimens was smaller than dried one. The results showed similar behaviour of maximum swelling and recovery, basically. Specimens (lignin 13%) densified by 100°C and 20 hours and also densified by 130°C and 4 hours, recovery decrease to 62.4% and 59.4%. The treatment (19% lignin content) reduces recovery less than 50% (Table 3). The material obtained from the combined process of thermo-mechanical densification and delignification was, thus, more dimensionally stable.

Table 3: *ASE and C_R of modified specimens (*-failed)*

Lignin (%)		Densification time (h)	Densification temperature (°C)	ASE	C_R

4 CONCLUSIONS

The results obtained in this study confirmed the potential of the combined treatment to improve material properties e.g. bending strength and ASE. It showed also the absolute requirement to determine the optimum between process temperature and time of delignification and densification. The rate of delignification depends strongly on temperature. At 100°C, lignin degradation only takes place to a small extent. At 150°C, on the other hand, lignin is almost completely degraded. The degradation of the hemicellulose does not show this strong temperature influence. Strong delignified material shows less compact structure than mild delignified. Mechanical properties increase by extended densification and high temperatures. Improved bending strength was gained by partly removed lignin and temperature of 130°C on both processes. The bending strength increase up to 450 MPa compared to the densified reference of 250 MPa and the untreated poplar of 65 MPa. The densification time had the strongest influence parameter on the dimensional stability. High delignification rate as well as decrease of polar polysaccharides reduces ASE. However, there was no clear correlation to bending strength and the density.

World Conference on Timber Engineering Oslo 2023

DEVELOPMENT OF CONSTRUCTION METHODS WITH NATURALLY GROWN TIMBER AND BENDING-RESISTANT JOINTS

Kevin Moreno Gata[1], Alex Seiter[2], Denis Grizmann[3], Martin Trautz[4].

ABSTRACT: Timber is a highly versatile material that can be used for a wide range of applications and products, including standardized construction elements such as bars, boards, and beams. However, these traditional timber constructions typically rely on straight logs, with naturally grown irregular elements like tree branches, forks, or curved logs often being discarded.

Advancements in digitization tools, such as 3D scanning and image-based processing in parametric environments, allow architects and engineers to upcycle these discarded materials innovatively. This study proposes a method integrating discarded tree parts collected from timber harvesting forests. We have developed a structural joint-free knot system using timber forks that can be employed in bar-type structures. Therefore, we analyzed the morphological possibilities of the timber forks and used an optimization system based on their length and angle variations. The proposed knot system can seamlessly integrate into architectural designs with minimal processing and rapid assembly, providing a solution to managing this intelligently grown material. This approach can expand the application of grown timber in construction by utilizing naturally irregular elements that would otherwise be discarded. We suggest that this approach can extend the application of grown timber and provide a solution to managing this intelligently grown material.

KEYWORDS: naturally grown timber, image-based modeling, bar structures, construction methodology

1 TREE PARTS AS LOAD-BEARING ELEMENTS IN CONSTRUCTION

Grown timber parts are usually irregular and discarded due to their unique geometry. However, their use is frequent in temporary constructions in agricultural areas, small industrial roofs, or structures for decorative purposes using cultivated structural round timber (SRT), see [1].

Novel digital applications, such as Photogrammetry or Laser Scanning, allow the combination of natural and digital geometries and mapping tree parts as load-bearing elements in construction. Incorporating and cataloging tree forks (bifurcations) [2] with digital standardization techniques enhances the design and manufacturing process for such a construction method [3]. Robotized manufacturing strategies allow for exploring new possibilities for augmenting the design of structures [4]. Other design explorations incorporate tree forks in a digital workflow to assist in creating reticular shells [5].

Furthermore, the study of tree growth allows us to understand its geometry to make alterations or guidance during its early age, being able to design constructive elements that grow [6]. A computational approach and geometric simplification of tree growth enable mechanical growth simulations to understand the internal geometry of the tree and study its cross-sections [7].

In this paper, we explore how to generate bar-type structure typologies based on the characteristic geometric dimensions of the timber elements, Figure 1.

Figure 1: *a) Bar-type structure with naturally grown timber elements: flat, curved bars and fork b) construction detail development. c) Tree-fork as an off-knot element.*

2 RECONSTRUCTION OF GROWN TIMBER BASED ON IMAGES

Theoretically, trees and plants grow according to L-Systems [8] growth rules. However, they adapt to the conditions of the environment generating three-dimensional structures that are difficult to simplify into axes or main growth lines. These shapes are classified into lines, curves, and forks (bifurcations). They can be simplified into three-dimensional axes, which, sectioned into parts, can be contained and approximated in two-dimensional planes. In this work, we have studied methods of simplification and automation to find the most

suitable geometries and sections to manage the grown elements for documentation.

2.1 3D SCAN AUTOMATIZATION INTO 2D AND CLASSIFICATION

The process starts with a 3D scan of the elements. We developed an automatization to contain these shapes in bounding boxes. These boxes can be positioned in 3D. Additionally, we vary the scan's position to reduce the box's volume. This box acts as a basic geometry where we contain the scan, and therefore we determine the most optimal 2D positioning for further processing, see Figure 4.

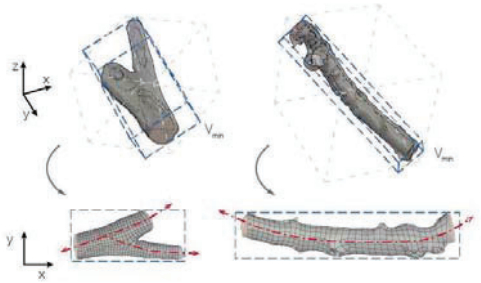

Figure 2: *Minimal volume bounding box automatization and 2D reorientation.*

2.2 GEOMETRIC PROCESSING AND CLASSIFICATION

After the previous procedure, we generate a series of additional automation in which we convert the mesh into NURBS volumes. We can automate and define the main growth line (in red) through this volume, see Figure 3. We finally geometrically process the elements and generate a library of objects with their angle and dimension classification.

Figure 3: *Image-based 3D modeling method, from 3d mesh to NURBS and growth trajectories.*

This process involved 60 elements, which were analyzed and digitized. An example can be seen in Figure 4. The studied specimens of oak, beech, and birch provide geometric variations of angles that were considered for developing constructive structures later in the methodology used in 3.2.

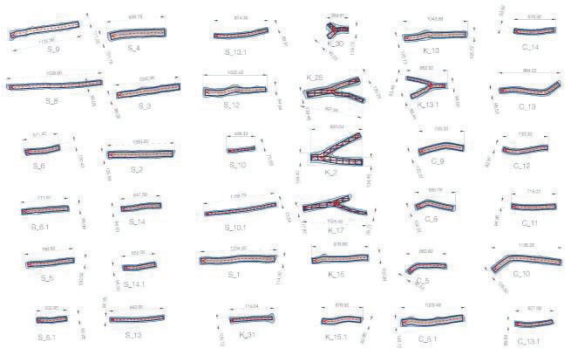

Figure 4: *Analysis of selected elements based on the image-based methodology.*

3 CONSTRUCTION METHODS

The analyzed and documented elements allow for estimating the load capacities of the analyzed elements according to their geometry. These elements can be applied in structures individually, making it necessary to explore structural typologies. Based on the examples in the literature [1-5], we carried out a constructive design approach in bar structures. These elements may be straight, curved, or forks (or bifurcations), and their structural connections (P) must be located at the ends of the growth trajectories.

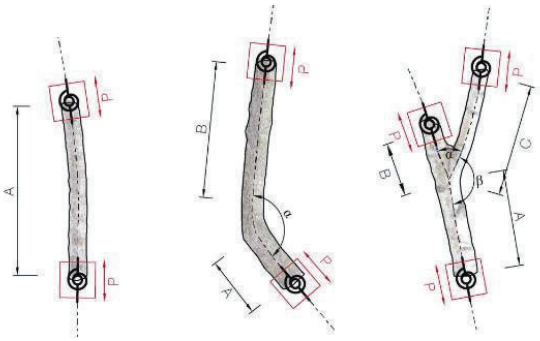

Figure 5 *Elements definition (straight, curved, and bifurcations) and main parameters end (P) as rotational springs, member axis (A, B, C), and angles (α, β)*

3.1 BAR-STRUCTURES DESIGN

Timber bar structures, generally designed as trusses, require complex connection nodes mainly executed with slotted steel plates. These connections are therefore located at the structural nodes. The present design method studies the construction of these trusses and frameworks with rigid nodes. Taking advantage of the capacity of naturally grown timber, we develop free, "off-knot" structural nodes. The moment curves in the frameworks are characteristic of Vierendeel and frame systems.

https://doi.org/10.52202/069179-0096

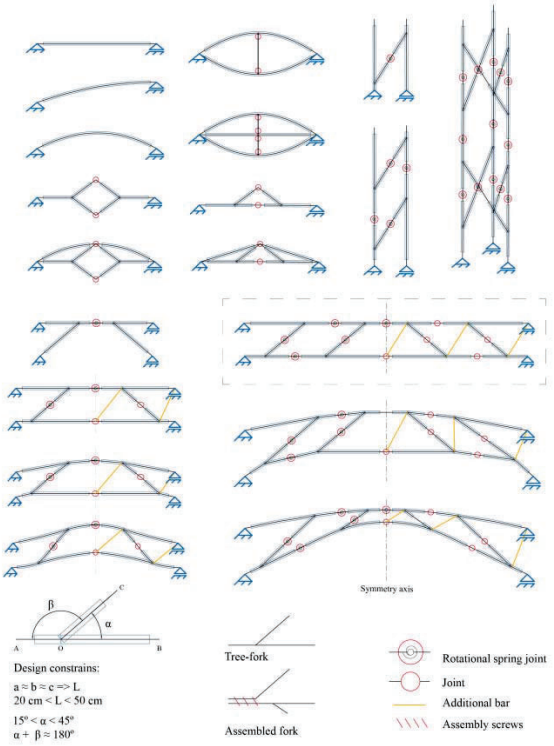

Figure 6: *Above: frameworks and bar-structures design. Below: the design constraints for a joint definition based on grown timber.*

In addition to the cross-sectional dimensions of the tree forks, the position of the joints of the "straight bars" are decisive for the structural design of the grown timber structures. While the bifurcations are optimally suited for moment loads thanks to their bending strength due to the unbent cross-section, the joints of the straight bars should be subjected to normal forces.

3.2 JOINT METHODOLOGY

In this section, we define a method for positioning the joints, and applying it to one of the simplified typologies. The proposed methodology for determining the most appropriate location of the joints utilizes multi-objective optimization. The location of the joints along the member axis ($0 < x_{joint} < L$) serve as input parameters. Joints are implemented as rotational springs. Geometric restrictions derived from databases of raw timber elements, such as maximum and minimum fork angles and lengths, can be considered (e.g., by the following condition $0.1\ L < x_{joint} < 0.9\ L$). Optimization objectives are reduction of total system deflection, maximum deflection, summed bending moments, and maximum fork moment. All load cases are considered.

The automated selection of fitting elements can thus only be done after the static analysis. Such a process see can be based on [2]. In addition to lengths and angles, minimum section dimensions derived from the determined internal forces can be specified as search criteria in the data beacons. This method is similar to the common cross-section optimizations, where only a structural element's minimum and maximum cross-sections are considered. The process integrated the modeling part in Rhino & Grasshopper [9], used MOO engine Octopus [10], [11], and used Karamba [12] for the static analysis.

3.3 OPTIMIZATION RESULTS

Figure 7 shows a Vierendeel-girder under a vertical and 45° inclined traveling load. Each of the 16-point loads (P01-P16) represents a separate load case (LC01-LC16). The joint positions were determined under the optimization objectives of a minimum sum of moments, a minimum sum of deflections, and a minimum maximal deflection of the girder.

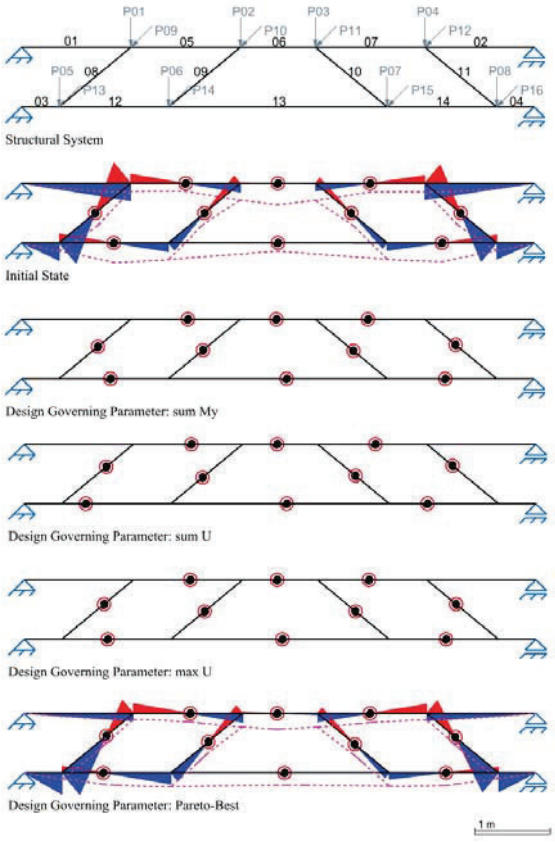

Figure 7: *Vierendeel-girder system*

Table 1 shows that optimization of the joint position results in up to 23% less total deflection (sum U) and 21% less maximum deflection (max U). The total moment summed up over the girder (sum My, magnitude sum) increases by 7% to 78%. For asymmetrical governing load cases or systems, more favorable moment distributions and lower deflection can be achieved by optimization.

https://doi.org/10.52202/069179-0096

The method is especially beneficial since the grown timber elements from the databases do not always allow joint positions in the center of the member.

4 CONSTRUCTION DETAILS

The criteria for defining the construction details were to meet the static analysis results. The result of the image processing allows us to know the stock material with its dimensions and the direction of the wood grain. In addition, the optimized bar structure shows the load-bearing trajectories. This combination defines the construction development and its joints.

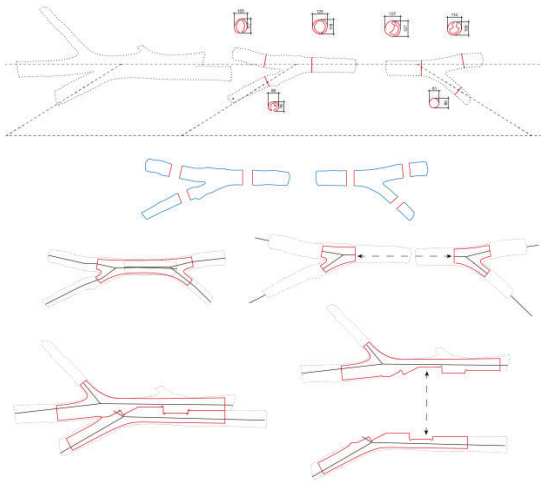

Figure 8: *Framework division in individual off-knot elements, according to their growth trajectories and cross-section.*

4.1 CONSTRUCTION DEVELOPMENT

Using natural timber allows the development of multiple construction details (Figure 1b) based on traditional Timber construction in many cases. The incorporation of robotic fabrication methods also allows to the incorporation of three-dimensional curved elements in a practical way, which also using dowel joints [13] can withstand normal forces and certain bending moments. In this project, we develop 2-dimensional elements based on the examples analyzed in 3.1.

The documented elements (Figure 4) were examined with the optimized structure to determine joining methods. In addition to incorporating interlocked joints with dowels for the connections (Figure 9), the possibility of using fully threaded screws is also experimented with. Examples from the literature [14] [15] show how using these screws enables homogenization in solid wood. This allows us to combine curved/straight elements or forks to generate solid joints as "hybrid" forks (Figure 10).

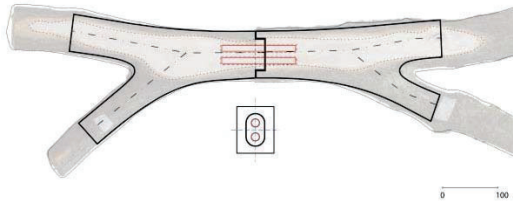

Figure 9: *Detail of a butt joint with two oak elements with inserted dowel. Scale in cm.*

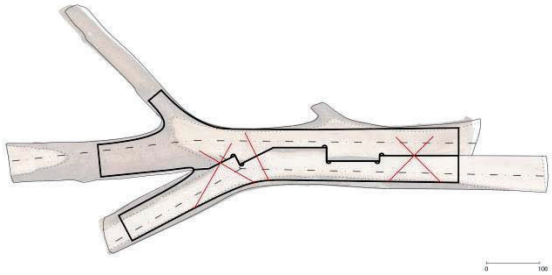

Figure 10: *Detail development of a bending-resistant connection from two elements of maple and beech in a hybrid fork using fully threaded screws. Scale in cm.*

4.2 FABRICATION METHODS

In this manufacturing method, the elements (stock material) are minimally processed with a planning machine following the positioning of the bounding box (Figure 2). As it is a 2D process based on optimization, the pre-processing is quick. After the stock is pre-processed, the construction details are adapted for 2D-CNC fabrication (Figure 8). From the automated information about the positioning of the Bounding box we reposition the cutting lines (in red). Then the stock material position is transmitted through informative sensors and the CNC programming is performed. The manufacturing of butt-joints takes place by milling in 2D the sides of the fabricated parts.

https://doi.org/10.52202/069179-0096

Figure 11: *Projection of the fabrication outlines for the CNC cutting operation.*

5 FABRICATION RESULTS

As a sample, we fabricated several elements. The first specimen was made as the central element of the structural system, manufactured with two oak elements, Figure 12. The ends were made with beech dowels, see Figure 13. Secondly, we made a joint of two parts to form a hybrid element (Figure 14 and 15). This shows that it is possible to use two different materials (beech and maple) to vary the mechanical properties of the construction element. As a last example, we experimented with three-dimensional joints (Figure 16 and 17), which were executed in an interlocking geometry in two birch specimens.

6 CONCLUSIONS

The work detailed in this study demonstrates a novel approach for automating the integration of naturally grown elements into structural design, focusing on bending-resistant joints. We propose construction methodologies to incorporate the inherent geometries of these elements into minimally processed structural components. The proposed procedures can be applied to both planar and three-dimensional structures whose constituent parts are described in two dimensions. Furthermore, we leverage image processing techniques to

https://doi.org/10.52202/069179-0096

automate the design and production processes, as evidenced by construction demonstrations.

7 FUTURE WORK

The subsequent phases of the project will prioritize evaluating the load-bearing capacity of the elements, utilizing their respective cross-sectional dimensions as a basis. The remaining tasks include numerical simulation of the scanned elements and conducting load tests. We are also investigating the feasibility of integrating the joint simulation process with tree felling operations to streamline the selection of suitable specimens within the same forest. Augmented reality tools may also be employed to enhance the integration of tree specimens with the overall structure.

ACKNOWLEDGEMENTS

The methods presented here are part of preliminary work carried out during the summer semester of 2022 in the academic project "Tree-based constructions" at the Faculty of Architecture of the RWTH-Aachen; special thanks to Mr. Viktor Wages for his bachelor thesis with the same title. This paper is part of the preliminary work of the recently started interdisciplinary research project. Special gratitude for the financial support to the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation). Project-ID: 512769030

GREEN OAK BUILDING WITH HIGH-TECH METHODS, PART 1: CHARACTERISATION OF THE RAW MATERIAL

Nicolas Hofmann[1], Franka Brüchert[2], Udo H. Sauter[3], Kay-Uwe Schober[4], Beate Hörnel-Metzger[5], Maximilian L. Müller[6]

ABSTRACT: In Germany, only half of the annual increment of oak stands is used. Especially small-diameter oaks are currently either not used or only used as firewood. This research project aims on making small-diameter oak logs available as structural timber members. For this purpose, the mechanical properties of the logs and factors influencing them must be determined.

In the experimental program, (oven-dry) wood density, moisture content, internal and external wood defects and round wood geometry properties were measured by non-destructive and destructive methods. Additionally, dynamic and static modulus of elasticity and modulus of rupture were determined for log characterisation. The test material (210 oak logs, *Quercus petraea* (Matt.) Liebl.) originated from one stand at age of 90 years in Rhineland-Palatinate which developed from stump sprouts.

The results show that the strength and stiffness of small-diameter oak logs are well sufficient for the use in load-bearing structures. Initial analysis on strength prediction of individual logs based on non-destructive methodologies reveal large heterogeneity at the small sample size and thus only restricted prediction strength. Among the investigated predictors, oven-dry wood density and log dynamic modulus of elasticity showed the best correlation with strength.

Improvement of the strength prediction, which could then allow strength grading, would be desirable for even more efficient utilization of small-diameter oak wood. This could possibly be achieved by finalizing the assessment of the internal knot features in this study and by increasing the sample size (number of oak logs) in a subsequent study.

KEYWORDS: structural timber, NDT, wood properties, wood density, external quality grading, *Quercus petraea*

1 INTRODUCTION

In Germany, only half of the annual increment is used in oak stands [1]. Especially small-diameter oaks are currently either not used or only used as firewood. The use of wood as a construction material has several advantages. On the one hand, the carbon is sequestered much longer compared to firewood, and on the other hand, energy-intensive materials such as steel or concrete are substituted. In addition, there is a higher added value for the forest owner.

In order to exploit these opportunities, our research project aims on making small-diameter oak logs available as structural timber members, e. g. for columns, frameworks and agricultural buildings, like barns. For this purpose, the mechanical properties of such logs and the factors influencing them must be determined, as these have only been insufficiently investigated so far. Most of the previous studies on strength properties have been conducted on softwoods, since softwoods have been used much more frequently for load-bearing structures than hardwoods in recent decades due to their straightness and better predictable mechanical properties. As a consequence, one goal of the project was to apply conventional NDT technology already in use for (board strength) grading, with which we can infer the strength of green oak logs.

The second part of this project deals with the implementation of log bending tests (strength and stiffness) to obtain reference values, the third part with the construction of a demonstration hall from a subset of the investigated oak logs. Part two was also presented at this conference and included in the proceedings [2].

2 MATERIAL AND METHODS

As test material, 210 oak logs (*Quercus petraea* (Matt.) Liebl.) with a length of 5 m and an average mid diameter of about 25 cm were cut from one stand at age of 90 years in Rhineland-Palatinate. The trees have developed from

stump sprouts. The logs were divided into three subsamples (n = 70, each) to facilitate the measuring process. Subsample 3 was used for the construction of the demonstration hall [2] and underwent a shorter test program without destructive measurements. In this article, we only present the results from the subsamples 1 and 2 which underwent the complete measurement programme in non-destructive and destructive testing for characterisation. From these subsamples, 80 logs were debarked, 30 logs were edged on two sides and 30 logs were edged on four sides. Debarking was executed for faster drying, edging for a simplified construction geometry (Figure 1).

Figure 1: *Oak logs from subsample 1 (n = 70). Edged on two or four sides (left) and debarked (right).*

In the experimental program, green density distribution and internal knot features of the logs were determined by computed tomography scans (MiCROTEC® CT.LOG, Figure 2).

Figure 2: *Measurement of natural frequency (Viscan), left, and of raw density and geometry (CT.LOG and DiShape), right.*

The dry wood density distribution was measured on 2 × 1 cm small clear samples, which were taken in four spatial directions from a ~2 cm thick log slice from the top end of the log (Figure 3). The samples were dried to constant weight at 103 °C, followed by immersion weighing to determine sample volume. Moisture content of the logs (MC, moisture mass fraction on dry basis) was determined by sampling of seven slices per log at the end of the trial (Figure 3). In conjunction with the mass measurement of the log at all phases of the test programme, we were able to determine the moisture content of the logs at earlier points in time as well.

External wood defects, i.e. knots, were investigated by log quality grading following the German Framework Agreement for Timber Trade (RVR) [3]. Geometry properties were measured using a 3D laser scanner (MiCROTEC® DiShape, Figure 2).

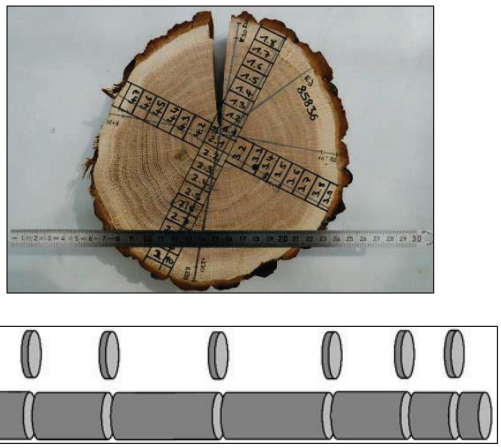

Figure 3: *Samples for determination of oven-dry density distribution (MC = 0 %) on a log slice from the top end of the log (top). Slice samples for determination of the final moisture content and dry mass of the log (bottom).*

The curvature was calculated from the DiShape data as the maximum bow height divided by the log length, excluding the 50 cm butt end of the log, according to [4] to avoid buttresses.

The dynamic modulus of elasticity (MOE_{dyn}) of the logs has been calculated from measurements of the natural frequency (MiCROTEC® Viscan, Figure 2), the green density and length of the logs. The static modulus of elasticity (MOE_{stat}) and the bending strength (MOR) have been investigated by our project partners according to DIN EN 14251 [5] (see part 2 of this project) [2].

3 RESULTS AND DISCUSSION

Round wood grading according to RVR show that most logs were graded in quality class C, which represents intermediate quality logs characterised by a large number

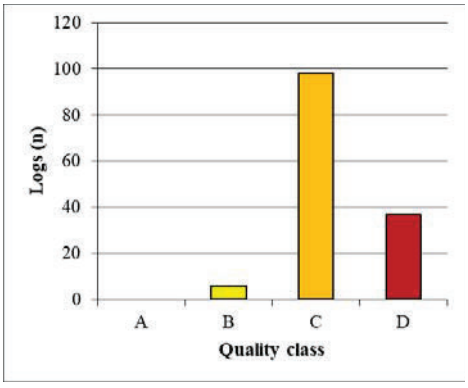

Figure 4: *Frequency distribution of the oak logs from subsample 1 and 2 (n = 140) in different quality classes (A = best quality, D = worst quality) according to the German Framework Agreement for Timber Trade [3].*

https://doi.org/10.52202/069179-0097

of small to medium sized knots, the presence of curvature and other features (Figure 4). Mean number of externally visible knots and burls per log was 24.9 (± 17.9) and mean curvature was 1.7 % (± 0.8 %), with multiple curvatures occurring frequently.

Wood density in oven-dry condition (Figure 5) was within the range found for oak in the literature [6]. Heartwood showed a slightly higher dry density than sapwood, probably due to narrower annual rings in sapwood affected by increasing competition between the trees. Incorporation of chemical substances in heartwood seems to have a minor effect on dry wood density [6].

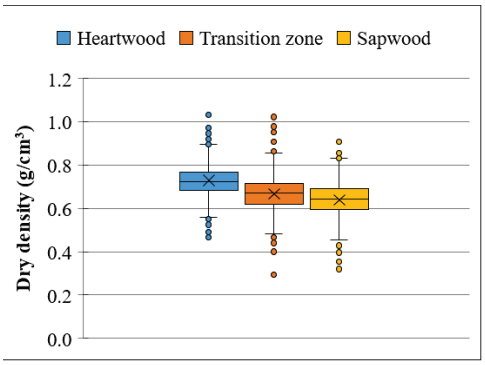

Figure 5: *Dry wood density distribution (MC = 0 %) of different wood compartments for the 140 oak logs from subsample 1 and 2, determined on 4720 wood samples.*

Moisture content in fresh condition was, compared to other studies [7], relatively low at 66.8 % (mean value for subsample 2, not measured for subsample 1), which is probably due to the very dry weather conditions over the last years. The logs dried to an average moisture content of 35.4 % within ~20 months (Figure 6) until the testing programme terminated with destructive testing. When the bending tests were performed, all but two logs from subsamples 1 & 2 were still above the fibre saturation point (FSP), which is at approx. 25 % MC for oak wood [8].

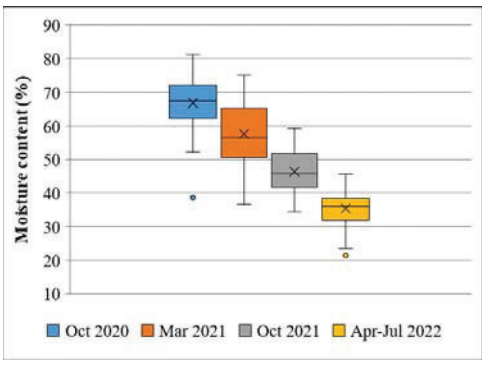

Figure 6: *Moisture content distribution of subsample 2 (n = 70 oak logs) over time, determined by regular weighing and measurement of the dry mass of the logs at the end of the trial. Felling was conducted in September 2020, bending tests from April to July 2022.*

Dynamic modulus of elasticity ranged from 5,481 MPa to 18,754 MPa (median 12,070 MPa) for all logs. Mean dynamic MOE was about 3.5 % higher than mean static MOE (see part 2 of this project [2]). Static MOE showed several extremely high values with a maximum of 32,956 MPa. Consequently, the median of MOE_{stat} was only 10,647 MPa, and therefore 13.4 % lower than the median of MOE_{dyn}, which is in accordance with other studies comparing non-destructive and destructive methodologies for mechanical characterisation of timber [9]. Modulus of rupture (MOR) ranged from 27.4 MPa to 135.0 MPa (median 66.1 MPa) for all logs [2]. Conventional classification of stiffness and strength results to standard seemed not appropriate, as dimension/geometry and moisture content of our test specimens (logs) were not in line with common test standards. Literature values were mostly determined on small clear oak specimens at a moisture content of 12 %. For such specimens, a range of 9,200-13,500 MPa for MOE_{stat} and of 78-117 MPa for MOR is given by [10] and a mean of 12,300 MPa for MOE_{stat} and of 105 MPa for MOR were reported by [11]. In green condition, a mean MOE_{stat} of 8,600 MPa and a mean MOR of 57 MPa was specified [11]. Consequently, the strength and stiffness values measured in this study appear to be within the natural range for oak, or even slightly higher if the high moisture content of the logs is taken into account.

ANOVA and bivariate linear regression analysis to clarify the influence of the external and internal log structures and characteristics on the bending strength revealed the necessity to deal with the different geometric variants separately. Hereafter, only the results for the round logs are presented. In future, round logs will probably play a more important role in the processing of small-size oak construction timber than edged logs, since less material is wasted and no sawing is required. Bending tests were performed on 71 of the 80 round logs. Three round logs were used for compression tests, the six remaining logs had either too strong curvature or too large drying cracks to perform the bending tests safely.

Oven-dry wood density and dynamic modulus of elasticity of the logs contributed most to the variation in log MOR (Figure 7). Both variables were statistically significant positively correlated with the bending strength, oven-dry density even quite closely (Pearson test, $\alpha = 0.05$ with $r = 0.61$ and $p = 0.000$ for dry density and $r = 0.51$ and $p = 0.000$ for MOE_{dyn}).

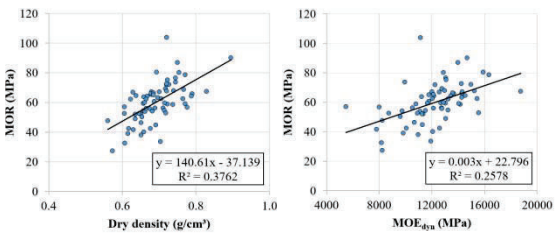

Figure 7: *Relation and linear regression between modulus of rupture and mean oven-dry wood density at MC = 0 % (left) and dynamic modulus of elasticity (right) for the debarked round wood (n = 71).*

https://doi.org/10.52202/069179-0097

In a study on a strength prediction model for pine wood, density and MOE_{dyn} were also the variables with the best explanatory power [12]. Compared to the present study, the coefficients of determination were slightly lower and the MOE_{dyn} had a slightly higher explanatory power than the wood density. In addition, study [12] did not investigate oven-dry density, but density at 12 % moisture content. However, this low and uniform MC is unlikely to have had a large effect on the strength of the correlation.

Considering a log grading procedure based on these characteristics, measurement of MOE_{dyn} can be described as non-destructive and relatively fast. The measurement of oven-dry density, on the other hand, is only possible based on destructive wood sampling. Since these samples originated from the very top end of the log, the log's subsequent use is hardly restricted. However, for an on-line work-flow, a disadvantage is the long time required for this measurement.

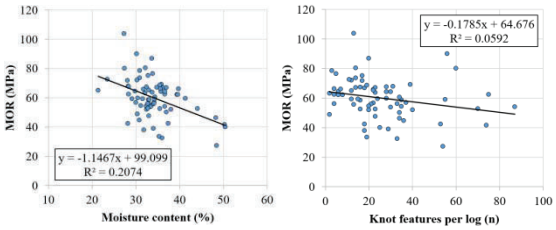

Figure 8: *Relation and linear regression between modulus of rupture and mean moisture content of the logs (left) and number of knot features per log according to [3] (right) for the debarked round wood (n = 71).*

In contrast to the literature, a statistically significant correlation (Pearson test, $\alpha = 0.05$ with $r = -0.46$ and $p = 0.000$) was also found between bending strength and moisture content of the logs (Figure 8, left). The literature states that the mechanical properties only change below the fibre saturation point (FSP) [13]. In this context, a mean log moisture measure over the whole cross section could be misleading as significantly drier areas below the FSP located in mechanical important peripheral stress zones might have a greater influence on the strength in a bending test than the core areas. An evaluation of additional moisture measurements by means of impact electrodes (resistance-based, Hydromette CH 17, GANN Mess- u. Regeltechnik GmbH) at peripheral log depths of 2 cm and 4 cm frequently showed values below the FSP, but explained the variation in strength distinctly worse instead of better. This indicates that we have a spurious negative correlation based on other, unknown causes in case of Figure 8 (left).

The number of externally visible knots and burls per log also showed a statistically significant, but very weak negative correlation (Pearson test, $\alpha = 0.05$ with $r = -0.24$ and $p = 0.045$) with bending strength (Figure 8, right). In a study on the effect of knots on the bending strength of boards from two different poplar clones, the correlation coefficients r range from -0.12 to -0.60, depending on the position and diameter ratio of the knots [14].

For a better interpretation of our results, a deeper analysis of the knot data is necessary. Above all, the internal knot structures of the logs must also be taken into account. For this purpose, all knot features in CT scans of five logs were manually annotated (over 10,000 polygons in total) and categorized (Figure 9). A machine learning algorithm was trained with these scans to develop an automated knot detection procedure for knot segmentation for further use on such CT scans (Figure 10). This process has not yet been completed, but due to the accuracy achieved so far stronger correlations between knot architecture of oak logs and their strength is expected.

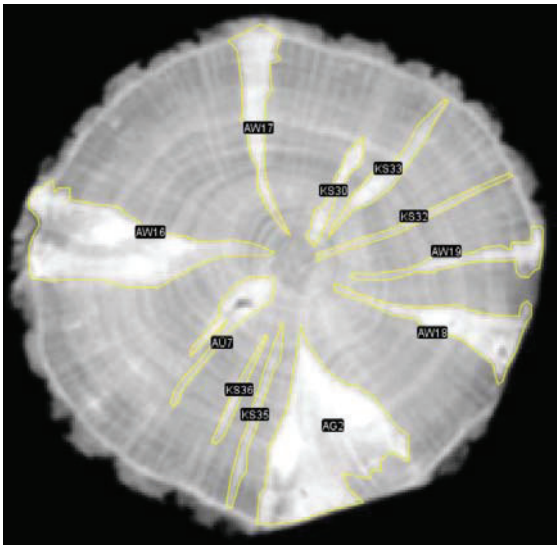

Figure 9: *Manually annotated and categorized knot features in a CT slice of an oak log. KS = bud trace, AW = burl, AG = sound knot, AÜ = overgrown knot; followed by the consecutive number of the feature within the log.*

Figure 10: *Comparison of manual (left) and machine learning based automated (right) segmentations of knot features in the same CT slice of an oak log.*

Mean curvature of the round logs was 1.9 % (± 0.8 %). Curvature showed no statistically significant correlation with bending strength. Strong stem deviation leads to stem eccentricity and severe tension wood formation in hardwoods which usually shows a lower strength. Obviously, the curvature recorded in the test material did not lead to the formation of tension wood with different mechanical properties. This assumption was visually confirmed during the sampling of numerous log slices after the bending test.

Measurement of knot features as defined in visual log grading regulations and CT scanning works non-

destructively. In contrast, measuring a precise moisture content is only possible by the collection of representative wood samples and their subsequent kiln-drying [15]. The disadvantage of this method is that it is time-consuming and destructive. Non-destructive rapid MC determination devices usually show high deviations in their measurement precision from the reference method [16].

Although small-diameter oak logs are well suited for construction purposes, grading procedures of individual logs similar to softwood board strength grading still requires further evaluation of our data. Furthermore, an increase in the sample number in additional studies could significantly improve this strength prediction.

4 CONCLUSIONS

The results of our collaborative research project indicate that small-diameter oak logs appear well suitable for load-bearing structures. This application seems to be the best option, since such logs cannot be used for the production of lumber or even veneer due to their knottiness, small diameter and strong curvature.

For even more efficient use, it would be beneficial to predict the strength of individual logs by non-destructive measurements. In this study, the best explanation for the variation in bending strength was obtained by the measurement of the oven-dry density at the top end of the logs, followed by the measurement of the global dynamic modulus of elasticity. Moisture content of the logs also showed a significant correlation with bending strength, but this relation appears to be coincidental since almost all logs were still above the fibre saturation point at the time of testing. Log curvature in the range found in the test material had no effect on bending strength, probably because it was not related to tension wood occurrence. Number of knots and burls quantified in course of external quality grading was weakly correlated with strength. However, the influence of knots is still under evaluation. In particular, innovative machine learning procedures applied to CT scans with respect to internal knot features could lead to a better strength prediction.

After completion of data evaluation, all measured parameters and log characteristics will be integrated into a strength prediction model for oak logs.

ACKNOWLEDGEMENT

This project (support code 2218WK18C3) was funded by the Federal Ministry of Food and Agriculture (BMEL) and the Federal Ministry for the Environment, Nature Conservation, Nuclear Safety and Consumer Protection (BMUV) through the Agency for Renewable Resources (FNR) from the Forest Climate Fund (WKF).

The authors would like to thank Oswald Keller, Heike Laux, Christoph Beilharz, Adrian Kölz, Elias Maurer, Jakob Fei and Nikolaj Markgrander for their great help with sampling and practical measurements, Werner Rützler for the CT/DiShape scanning and Martin Huber, Elisa Kammer, Omoyemi Edun, Hannah Staiger and Tushar Maske for the detailed processing of the CT scans.

VARIATION IN MECHANICAL PROPERTIES WITHIN AND BETWEEN PLANTATION-GROWN *GMELINA ARBOREA* TREES

Stanley Emeka Iwuoha[1], **Werner Seim**[2]

ABSTRACT: Recent studies have shown that the material properties of Gmelina - a fast-growing hardwood species, are comparable with those of European-grown softwood species and are suitable for construction purposes. Information on the variation in the material properties which could aid the end use, such as sorting the logs with respect to end user requirement, is lacking. This work is an investigation into the variation of the mechanical properties along the height and between different Gmelina trees, to aid an efficient and effective end use of the material. 10 material properties were experimentally and statistically investigated. The results showed that the material properties of Gmelina do not vary along its height as much as is observed for other timber species. Between the trees, a variation range of 11 – 14 % was determined.

KEYWORDS: ANOVA, *Gmelina arborea*, Mechanical properties, Statistical analysis, Tropical timber species, Variation

1 INTRODUCTION

Gmelina arborea is a fast-growing tropical hardwood species which is capable of reaching a mean diameter at breast height of between 60 - 80 cm in 20 years [1]. It has a low cost of establishment, is suitable for paper and pulp and for making solid wood products, and has been described as a very promising tree species [2]. It has also become one of the most important plantation species in tropical areas due to its low cost of establishment and the fact that it can be developed extensively where it has never existed before [3]. Gmelina is not a threatened species and grows across different continents of the world. Recent studies on its mechanical properties and embedment strength, show that it has great potential for use as a construction material [4]. For an optimal use of the material in the construction industry however, a proper understanding of the variation of its strength properties along its height, and between different trees is required to provide valuable information to aid decisions on how to sort the logs in accordance with end-user requirements. For Gmelina however, this information is not yet available. This study aims at determining the variation in the mechanical properties between and within (along the height of) three Gmelina trees (see Figure 2) by means of experimental and statistical investigations.

2 MATERIALS AND METHODS

2.1 MATERIALS

The material used for this study was collected from three plantation grown *Gmelina arborea* trees obtain in Akure in southwestern Nigeria (see Figure 1).

Figure 1: *Map of Nigeria, showing Akure, the location where the materials were obtained (Map was obtained from Google).*

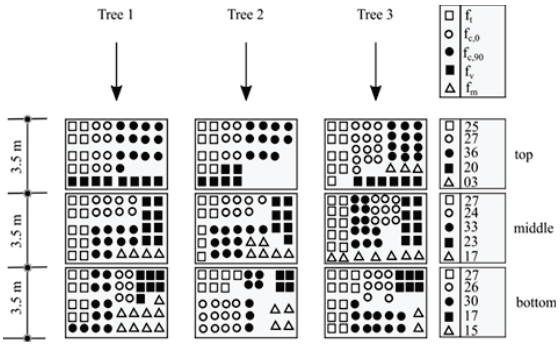

Figure 2: *Location and number of specimens tested.*

[1] Werner Seim, Timber Structures and Building Rehabilitation, University of Kassel, 34125 Kassel, Germany (wseim@uni-kassel.de)

https://doi.org/10.52202/069179-0098

2.2 METHODS

The collected specimens were prepared and tested in accordance with EN 408 [5], except for the tensile strength test, which was conducted in accordance with the German standard DIN 52188 [6]. The specimens for investigating the variation in the material properties between the trees were separated according to trees as trees 1, 2, and 3 while those for investigating the variation in the material properties along the height were separated according to location as top, middle, and bottom (see Figure 2). The number of specimens, the type of tests conducted, and the location from which the tested specimens were obtained, are all shown in Figure 2.

Details of the procedures leading to the experimental data shown in Table 1, are published in [4]. After obtaining the experimental data, statistical analyses such as the analysis of variance (ANOVA) and the Tukey HSD test were conducted on them using the R-programming language. The ANOVA was conducted to determine the variation in the various material properties along the height and between the trees, while the Tukey HSD test was conducted to determine further insights on the nature of the variations both within and between the trees.

The ANOVA, being a process of testing for the similarity or difference between two or more groups of data by testing the means of the different groups, is done under the null hypothesis H_0 that the sample means are equal, or do not have significant differences. The result of this test is generally given in terms of the F-statistic (f-value), which is then compared with critical f-values obtained from statistical tables. The null hypothesis is true if the calculated or observed f-value ($F_{observed}$) from a set of data is less than the corresponding critical f-value ($F_{critical}$) from statistical tables. Since this is a relatively complex calculation, its result from the R programming language is given both as the f-value as well as the p-value (an evidence in support of the null hypothesis). Considering a significance level (α-value) of 0.05, p-values > 0.05 would mean that there is no significant difference in the sample means of the set of data tested. P-value < 0.05 means that the means of the tested group of data are different. In such cases, the Tukey HSD test (conducted under the null hypothesis that the means of the various groups are equal) is carried out by determining the q-statistic. This is then compared with critical q-statistic values of the studentized range distribution, to uncover the source of the difference in the tested data. Using the R-programming language, the results are also given as p-values, which can be interpreted as already explained.

Ten material properties including the tensile strength ($f_{t,0}$), compressive strength parallel to the grain ($f_{c,0}$), compressive strength perpendicular to the grain ($f_{c,90}$) shear strength (f_v), bending strength (f_m), density (ρ) the elastic moduli in tension ($E_{t,0}$), bending (E_m) compression parallel ($E_{c,0}$) and the MoE in compression perpendicular to the grain ($E_{c,90}$) were all investigated in the study and the results obtained are presented and discussed in Section 3.

3 RESULTS

3.1 EXPERIMENTAL RESULTS

Results of the complete experimental investigations are shown in Table 1.

Table 1: *Experimental results*

Material property	Minimum (MPa)	Maximum (MPa)	Mean (MPa)
$f_{t,0}$	36.89	98.72	67.91
$f_{c,0}$	23.88	41.38	34.02
$f_{c,90}$	3.97	9.53	4.51
f_v	3.91	7.83	6.30
f_m	29.79	72.73	55.64
E_t	7,855	18,888	11,840
$E_{c,0}$	6,321	21,051	11,027
$E_{c,90}$	161.00	701.00	419.42
E_m	9,446	15,540	12,340
ρ (kg/m^3)	387.00	528.00	452.00

3.2 STATISTICAL ANALYSIS RESULTS: WITHIN-TREE VARIATION

The ANOVA results for the within-tree variation are shown in Table 2 and those for the between-tree variation, are shown in Table 4.

Table 2: *ANOVA results for within-tree variation*

Material Property	Within tree variation		
	$F_{observed}$	$F_{critical}$	p-value
$f_{t,0}$	2.902	3.129	0.061
$f_{c,0}$	10.02	3.131	< 0.01
$f_{c,90}$	2.428	3.102	0.093
f_v	3.316	3.102	0.044
f_m	1.595	3.302	0.219
$E_{t,0}$	0.298	3.149	0.744
$E_{c,0}$	0.146	3.130	0.865
$E_{c,90}$	1.418	3.149	0.248
E_m	0.358	3.133	0.702
ρ	3.985	3.000	0.020

The result in Table 2 shows that apart from the $f_{c,0}$, f_v, and ρ, whose p-values < 0.05, the material properties of the Gmelina trees considered in this study do not vary along the height. This findings agree with those of [7] who reported no variation in the MoE in bending, bending strength and in the compressive strength parallel to the grain of Blackwood grown in Portugal.

The variation along the height of Gmelina determined in Table 2 for $f_{c,o}$, f_v, and density also agrees with [8] who reported a variation in density and compressive strength parallel to the grain along the height of beech wood. The nature of the variation determined for these material properties along the height of Gmelina, was further investigated by comparing the mean value of one of the groups (e.g., the top) with the mean value from each of the other groups (middle and bottom respectively), using

the Tukey HSD test. The result of this is shown in Table 3. In Table 3, the results of the Tukey test are shown in the first three columns, while the mean material property values obtained from the different parts of the trees are presented and compared in the other columns.

Within-tree variation in the compressive strength parallel to the grain – $f_{c,0}$

Table 2, shows the results of comparing the strengths of one part of the trees (e.g., the top), with the other parts (middle or bottom respectively) to determine the part or parts of the tree that are different from the others. Based on the data in Table 2, one sees that there is no statistical significance in the compressive strength parallel to the grain obtained from the top and bottom parts of the trees.

A comparison between the middle and bottom parts as well as the top and the middle parts, as shown in Table 3, are seen to be statistically significant (p-values < 0.05). Furthermore, the differences of the mean strength values between the middle and bottom as well as the top and middle parts are respectively 8 % and 14 %, while that between the top and bottom part is 5 %. A look at the mean values, shows that the compressive strength parallel to the grain obtained at the middle parts of the trees, is smaller than those obtained from the top and bottom parts. This shows that the difference in the strength values detected by the ANOVA, is due to the strength obtained from the middle part of the trees. The variation in compressive strength along the height (as shown in Table 3) is thus a slight reduction in the strength from the bottom to the middle and then a slight increase from the middle to the top.

Table 3: *Within-tree Tukey HSD test results*

Material Property	Parts tested	p-values.	Mean values (MPa)			Bottom	Top	Top
			Top	Middle	Bottom	Middle	Bottom	Middle
$f_{c,0}$	Middle-Bottom	0.0008	35.88	31.60	34.23	1.08	1.05	1.14
	Top -Bottom	0.1945						
	Top-Middle	0.0219						
f_v	Middle-Bottom	0.1663	5.92	6.70	6.13	0.91	0.97	0.88
	Top-Bottom	0.7995						
	Top-Middle	0.0497						
ρ	Middle-Bottom	0.0835	448	450	458	1.02	0.98	1.00
	Top-Bottom	0.0216						
	Top-Middle	0.8476						

Within-tree variation in shear strength parallel to the grain - f_v

On the variation of the shear strength, Table 3 shows that there is no variation in the shear strength obtained from the middle and bottom parts of the trees as well as those obtained from the top and bottom parts (all having p-values > 0.05). However, comparison of results obtained between the top and middle parts is seen to be statistically significant, with a p-value of approximately 0.05. This shows that the difference detected in the ANOVA test for the shear strength tests, is due to the results obtained from the middle part of the trees, whose mean values as seen in Table 3 are relatively higher. Based on data in Table 3 however, the difference in the mean values obtained from the top and the middle parts is 12 %. The variation in shear strength is seen to increase slightly from the bottom to the middle, and then reduces slightly from the middle towards the top.

Within-tree variation in the density values

No statistical difference was determined in the density values between the top and the middle parts of the trees as well as between the middle and bottom parts of the trees. A comparison between the top and bottom parts however, showed to be statistically significant (having a p-value of 0.0216, which is < 0.05). Looking at the mean density values in Table 3, one sees that the mean density obtained from the bottom part of the trees is comparatively higher than those obtained from the middle and top parts, respectively. This shows that the difference in the density values identified by the ANOVA, is owed to the value from the bottom part of the trees. It can also be seen that the mean density value at the middle is higher than that at the top. This implies that the density values as considered in this study, fall slightly with increase in height. Although studies by different researchers as compiled in [9] show exceptions with differing along the height of different wood species, it can be understood from the formation and growth of wood in trees, as well as the influence and presence of juvenile wood up the trunk that the heaviest wood should be at the base of the tree, with a gradual decrease in density up the trunk [10]. Other density variation patterns discussed in [9] are inconsistent

https://doi.org/10.52202/069179-0098

with this rule and are not within the scope of discussion of the current study. The results (slight reduction of density with height) obtained in this study for the variation of density along the height of Gmelina, was also reported by Lamb [11] for Gmelina, as well as by other researchers [7], [8], [12] for other tree species.

3.3 STATISTICAL ANALYSIS RESULTS: BETWEEN-TREE VARIATION

Results of the between tree variation in the Gmelina trees examined in this study are shown in Table 4 and Table 5. The data in Table 4, shows that there is no variation in the shear strength, the bending strength, and the MoE in compression parallel to the grain between the Gmelina trees considered in this study, whereas the other material properties showed to vary between the trees. The nature of the variation in the mechanical properties between the trees as determined from the Tukey HSD test are detailed in Table 5 and discussed in the sections that follow.

Table 4: *ANOVA results for the between-tree variation*

Material Property	Between tree variation

Between-tree variation in the strength properties

The between tree variation in tensile strength as obtained by the Tukey HSD test and as presented in Table 5, shows no variation between the trees (p-values > 0.05 for all cases). Though different from the ANOVA results, this can be attributed to the level of sensitivity of the tests used. Considering that for all cases, the ANOVA has been proven to be very robust [13], the maximum difference detected by the ANOVA in the between-trees tensile strength (based on the mean tree values), as shown in column 7 of Table 5, is 14 %. This shows that the maximum difference was obtained by comparing the values from trees 1 and 2. Following the same procedure applied for determining the sources of differences in the material properties along the height of the trees, one sees

that the maximum difference in the compressive strength parallel to the grain between the trees is 11 %, stemming from tree 1. Considering the compressive strengths perpendicular to the grain, the maximum variation (26 %) between the trees was obtained from comparing trees 1 and tree 2. From the mean values presented in Table 5, this can easily be understood as stemming from tree 2. In general, the variation in the strength properties (both within and between the Gmelina trees species considered in this study) falls between 11 % to 14 %. The exception to this, is the compressive strength perpendicular to the grain which, although did not vary within the trees, showed a maximum variation between the trees of 26 %. It can thus, be firmly stated that for the materials considered in this study, the compressive strength perpendicular to the grain, between the trees, was the most varied.

Between-tree variation in the elastic moduli values

A comparison between trees 1 and 3 as well as trees 2 and 3 as shown in Table 5, shows that there is a significant variation in the MoE in bending between the trees. This difference however, is 17 % and agrees with the 16.9 % reported in [14] for Blackwood. The value (30 %) obtained for the MoE in compression perpendicular to the grain and for the MoE in tension, is seen to be the highest of all variations observed in this study for Gmelina.

Between-tree variation in the Density values

Considering the density variation between the trees, data in Table 5 strongly declares no between-tree density variation. This is validated by the fact that for all the cases compared, the p-values were consistently above the limits of 0.05. The maximum difference in density computed between the trees as seen in columns 8 and 9 of Table 5 is 2 % and confirms that the mean density values obtained for the different trees as presented in Table 5 are within the same range. It can thenceforth be conclusively stated that the density of Gmelina as considered in this study does not vary between the trees. Any difference between the Tukey HSD and ANOVA tests would be due to the difference in the level of sensitivity of the different tests.

4 FINDINGS

Using 10 material properties which were experimentally determined from different parts of three Gmelina trees obtained from Southwestern Nigeria, this study has shown that at 95 % confidence level:

i. There is no consideration variation in the tensile strength, compressive strength perpendicular to the grain, bending strength, MoE in tension, MoE in compression parallel to the grain, MoE in compression perpendicular to the grain, and the MoE in bending along the height of the Gmelina sample considered in this study.

ii. The compressive strength of Gmelina parallel to the grain ($f_{c,0}$) varies along the height; with mean values from the middle parts being 8 % and 14 % lower than those from the bottom and top parts, respectively.

iii. Even though the shear strength varies with height, no difference was determined for the middle and the bottom parts as well as for the top and the bottom parts, respectively. A comparison between the top and the middle parts however, showed to be statistically significant. This difference (in terms of the mean shear strength values) was observed to be 12 %.

iv. Variation in the shear and compressive strength parallel to the grain along the height of Gmelina as obtained in this study, ranged between 11 % and 14 %, and was the same as was obtained between the trees for the tensile and compressive strength parallel to the grain. The only exception was the compressive strength perpendicular to the grain whose variation between the trees was obtained to be 26 %.

v. The shear strength, bending strength, MoE in compression parallel to the grain and density did not vary between the trees considered in this study, whereas the other material properties did vary.

vi. The density variation within and between Gmelina trees is constant at 2 %. The variation along the height is a slight reduction with increase in height of the trees. No statistical significance was determined for the top and middle parts of the trees. However, a comparison between the other parts showed to be statistically significant. Considering the mean density values, the variation between the bottom and the middle parts and that between the top and the bottom parts are respectively 2 % and 3 %. This variation in the density as seen, does not influence the variation in the mechanical properties. This is because the variation pattern exhibited by the density data (slight reduction from the bottom to the top) is quite different from that exhibited by the mechanical properties (compressive strength parallel to the grain and the shear strength) which varied along the height. The variation pattern observed for the density in this study, agrees with that reported for Gmelina in [11].

vii. The variation in the MoE in bending between the trees is 17 % and agrees with 16.9 % reported in the literature for Blackwood [7].

viii. The mechanical properties of Gmelina as considered in this study (except for the shear and compressive strengths parallel to the grain which vary along its height), are not location dependent as is the case with some wood species. The

https://doi.org/10.52202/069179-0098

overall variation (combined variation both within and between the trees) of Gmelina is less than is obtainable for spruce (*Picea abies*) and pine (*Pinus sylvestri*) grown in Europe. The nature of the variation along the height of Gmelina would be useful in aiding end users on how to optimally and profitable apply Gmelina trunks for practical use.

5 CONCLUSION

This study has discussed the variation in the material properties between and within three plantation - grown *Gmelina arborea* trees obtained from Akure, in southwestern Nigeria, thus contributing to existing research efforts on the characterization and use of Gmelina as a construction material. Having elaborated on how the various material properties vary within and between the trees that were investigated, the study has presented information that would be useful in facilitating an efficient and optimal use of the material for effective applications. Further areas of research on Gmelina as a structural material are its long-term behaviour under load and temperature, determination of applicable modification and deformation factors for the timber, and similar investigations using materials from different sites to complement the results reported both in the current as well as previous studies.

IN-GRADE CLT FROM UNGRADED PINUS RADIATA BOARDS.

Paolo Lavisci [1], Marco Molinari [2] and Michele Brunetti [3]

ABSTRACT: Within the feasibility analysis for a Cross Laminated Timber (CLT) plant, the possibility to produce in-grade panels from boards that were not strength-graded according to the applicable standard was demonstrated by tests on panels produced in industrial conditions. The "cross-lamination effect" that explains this result was observed, and an innovative CLT lay-up with inner boards at 45deg angles was tested for the first time on Pinus Radiata. A set of scans and sorting feedback information, executed by Microtec on a sub-sample of the boards, provided a very useful insight and allowed significant resource optimization, particularly in the case of knotty boards. The comparison with a benchmark of C24 Spruce CLT, produced and tested in identical conditions, showed that higher in-plane shear resistance and modulus were achievable with ungraded Radiata Pine; this is a desirable performance for mid-rise construction (buildings of at least 4-storey high), which is a growing market trend, able to generate more value for the fraction of this fast-grown plantation timber which is currently not meeting the stud framing market specifications.

KEYWORDS: Ungraded boards, CLT, Radiata Pine, supply chain resilience

1 INTRODUCTION

Cross Laminated Timber (CLT) is changing the way architects and engineers look at wood construction systems as a viable alternative to concrete and steel in mid-rise construction, and beyond. Different countries have different definitions and regulations, and in Australia "mid-rise" means buildings with 25m maximum effective height (i.e. 4-9 storeys), but some projects have already successfully been built that exceed this height limit, through a specific "Performance Solution" addressing all the design specifications. Therefore, CLT is increasingly being selected by specifiers for several reasons including safer and quicker installation, lighter weight resulting in lower requirement for foundations (and/or consolidation of existing structures in vertical extensions of buildings), excellent sustainability credentials, wellness and comfort and, last but not least, cost-efficiency when the projects are well optimized for timber construction. Consistently with its mandate, Forest and Wood Products Australia (FWPA) has coordinated a number of initiatives in this field, including some R&D projects with industry stakeholders, one of which is described here.

Radiata Pine plantations are the major source of Australian structural products and therefore, when a local Company started considering the possibility to invest in a CLT plant, it was decided to run a feasibility analysis which included a research on the mechanical properties that might be obtained from their wood resources. Information is disclosed in this paper with some restrictions, consistently with the confidentiality agreements that the authors signed with the Company.

Machine-Graded Pine (MGP) was introduced in 1996 by Pine Australia (now Plantation Timber Association Australia), following an extensive, nationwide in-grade testing program of Australian Pine (radiata pine, pinaster pine, slash pine and Caribbean pine), undertaken by CSIRO and State Forests of NSW. The MGP grades are the result of a substantial research and development program by the pine industry to ensure that accurate and reliable design properties are available for structural pine timber in Australia, through standardized test methods [1]. The benefits of increased reliability for MGP products are not only based on MGP having more accurate information on the grade proper-ties, but also on the fact that all mills producing MGP are subject to stringent third-party auditing. This assesses appropriate machine grading and monitors property and other quality control procedures to ensure the validity and consistency of the MGP design properties. Therefore, MGP10 and MGP12 grades are currently the market standard for structural timber, and ungraded boards are not used by the frame & truss manufacturing industry that supplies the largest part of the low-rise construction market (detached houses, townhouses and multi-residential apartment blocks up to 3-storey). As a consequence, at the state of the art it was difficult to imagine that a structural product like CLT, which targets the mid-rise market, would not use MGP graded boards.

But to explore this possibility, which was considered potentially very significant for the optimization of the

[1] Paolo Lavisci, FWPA, Australia, paolo.lavisci@woodsolutions.com.au

[3] Michele Brunetti, CNR-IBE, Istituto per la BioEconomia; michele.brunetti@cnr.it

https://doi.org/10.52202/069179-0099

project's feasibility, we suggested to perform research with the aim to understand and quantify the potential benefits of innovative grading and/or layup strategies, possibly by using ungraded boards and deriving the characteristic values for structural engineering only from tests performed on the CLT panels. There are a few basic reasons why this scope of works was relevant for the Company:

- Even using only a fraction of their MGP10 and MGP12 boards for a new product, which is also potentially competing with frame & truss elements, would distract them from the established client base, therefore creating a major commercial risk;
- The MGP grading system is finalized to selecting boards for use as slender elements where buckling plays a significant role. Therefore, a single and isolated defect such as a knots or wane can already downgrade a whole board which, only a few centimetres away from that defect, may have very good mechanical qualities. The state-of-the-art solution to this problem (finger-jointing) is costly and may create a bottleneck in a CLT production;
- The effect of lamination, and even more of cross lamination, is known to "dilute" the influence of defects and therefore provide better performances than those measured on the single boards [2]. Bringing it within the grading and testing procedures may allow to optimize the yield from a fiber resource where knots and wane are relatively large (especially with respect to the board widths) like the fast-growing Radiata Pine plantation logs, which are currently considered having lower quality with respect to competing slow-growth logs.

In solid timber grading, the "reverse engineering" concept is sometimes used for in-grade testing to check production or to obtain the values representing the strength/stiffness distribution of available products as the basis for design, e.g. when a batch of ungraded timber needs to be used for a structural purpose. But so far, to our knowledge, this approach has not been applied to obtaining proprietary design values directly from product testing of CLT, instead of calculating them from the grades of the boards that are used to manufacture it. This is particularly strange because CLT is very similar to plywood in its mechanical behaviour: a few decades ago, before veneer grading machines were developed, plywood factories were testing samples from the pro-duction to derive the product's design strengths and stiffness values, as this was the only possibility. But when CLT was developed, producers and researchers were considering it more like solid timber or glulam, than a product with its own logic. Also, testing large amounts of panel samples being quite expensive, the use of available sawn timber grades to calculate the performances of CLT panels was preferred, and embedded into the Euro-pean Technical Approval Guidelines to become a market standard for many years. But this approach has proven to be particularly non-efficient for CLT, where the boards are used mostly in just two dominant stress modes (tensile bending or rolling shear), and cross lamination has a well demonstrated effect on the reduction of both fracture initiation and growth [3, 4].

The recent EN standard for CLT [5], whose drafting and approval took a very long time, has finally introduced the additional possibility to "recalculate" the mechanical properties of the timber layers from full-scale tests on panel samples. This acknowledgement of the applicability of the reverse engineering approach validates the scope and the methodology of this research.

2 MATERIALS AND METHODS

A container of Radiata Pine boards (Table 1), randomly sampled from the production at a sawmill in Australia, was shipped to XlamDolomiti's CLT factory in Italy. A narrow board width, also with respect to board thickness, was purposely chosen to maximize the influence of knots and wane, in a "worst case scenario" approach. The board cross section dimensions shown are net values, as used in the CLT after dressing before bonding.

Table 1: *Grades, sizes and quantities of the Radiata Pine boards used. The letter "U" means "Ungraded", while the letters "A" and "B" refer to two alternative sawing patterns.*

Grade	Width (mm)	Thickness (mm)	Length (mm)	Quantity (pcs)
MGP12	90	30	3300	128
MGP12	90	30	2400	128
MGP10	90	30	3300	256
MGP10	90	30	2400	256
U-A	90	30	3300	384
U-A	90	30	2400	384
U-B	90	30	3300	768
U-B	90	30	2400	768

As a first step, a random subsample of the rough sawn boards (4 packs = 512 boards) was sent to Microtec for a full non-destructive scanning, coding and grading with their GoldenEye 706 and Viscan equipment (which has a well-established correlation with MGP grades for plantation-grown Radiata Pine from the same area), in order to collect data enabling a subsequent, targeted panel layup optimization and the interpretation of failure modes (if needed). Then the boards were sent back to XlamDolomiti, for processing in their standard mill conditions, following the cycle described in the European Technical Approval (1-component PU adhesive, no edge bonding, top and side pressure).

A preliminary batch of 4x 90mm/3-layers panels was produced to test all the settings and perform the routine controls of bonding quality, then 14x 150mm/5-layers panels were produced for the mechanical testing, all in a 3300x2400mm size (LxW). A higher amount of rather small panels was preferred to a lower number of bigger panels to keep the boards' positions and alignment more easily under control. Table 2 describes the panel types and the tests which were planned on the resulting CLT samples.

The CLT panel layup is kept confidential, being part of the Company's intellectual property, but the "Purpose"

https://doi.org/10.52202/069179-0099

column in Table 2 clearly describes the logic that was followed in selecting the ungraded boards, based on the data provided by Microtec. The 45deg crossbands layup was inspired by the positive experiences reported for slow-growth Nordic Pine [6], therefore it was decided to replicate them with a fast-growth pine species. MGP12 boards were not used in the CLT manufacturing.
The samples in Table 2 were cut at XlamDolomiti and sent for testing at Universita' degli Studi di Trento, after the routine controls on bonding quality.

Table 2: *Grades, sizes and quantities of the Radiata Pine boards used. The letter "U" means "Ungraded", while the letters "A" and "B" refer to two alternative sawing patterns.*

Type	Purpose of the type's lay-up	BL	BG	DC	GT
Spruce	European benchmark	4	2	-	4
MGP10	Structural grade reference	4	2	4	4
U-A	Use the best ungraded boards	4	2	4	4
U-B_a	Understand the lower limit	4	2	4	4
U-B_b	Improve with respect to U-B_a	4	2	-	4
U-B_{45}	Try the 45deg crossbands	2	2	-	4

Table 3: *Explanation of the test codes used in Table 2.*

Code	Test type
BL	Four-point **Bending** tests perpendicular to the plan to failure on 450x3150x150mm CLT panels, according to EN 16351 Annex C2.1 for bending MOR and MOE (**Local**)
BG	Four-point **Bending** tests perpendicular to the plan to failure on 450x1950x150mm CLT panels, according to EN 16351 Annex C2.3 for rolling shear strength, rolling shear modulus and **Global** bending modulus
DC	In-plane shear tests with **Diagonal Compression** for in-plane shear strength and in-plane shear modulus, according to [7]
GT	Rolling shear tests, according to EN 16351 Annex C2.2 (**Guillotine Test**)

The test series is very similar to what is required for product development and/or approval of CLT panels, with just a reduced number of samples because the aim of the research was not obtaining statistically significant characteristic values for design, but just a proof of concept. Moreover, the test panels and then the samples were accurately assembled, based on the data provided by Microtec, to reflect the purposes described in Table 2 and to allow for the interpretation of any possible unclear fracture patterns.
In all the tests, the load was applied by means of an MTS 244.51 actuator with 1000kN capacity and 500mm stoke.

For the bending tests an MTS FT60 controller was used, endowed with 16 +/- 10V acquisition channels: two couples of AEP strain gage displacement transducers were installed and ac-quired directly by the controller. Two 10 mm instruments acquired the relative displacement of the central joke, whilst two 100 mm jokes acquired the global displacements in the central position. Instruments were applied at both sides of the panel, in the central point, thus allowing to correct effects of any unwanted torsion deriving by alignment errors and/or specimen asymmetry.
In-plane shear tests were carried out according to [7]. This method induces shear failure by axially loading a square CLT panel at two opposite corners, like shear tests carried out on masonry, and it is a good alternative to a four-point bending test with in-plane oriented panels, where unwanted bending failure often arises. This test can single out the actual type of shear failure, either torsional on the glued surfaces or perpendicular to the grain. The set-up was adapted to the reduced size of the specimens, therefore the size of the plates on which the loads were applied were reduced proportionally to the expected, reduced failure load, to 150mm length. The same MTS 244.51 hydraulic actuator was controlled by an MTS Test Star 2 system. The actuator was clamped at the top and hinged at the bottom edge, and the panel was resting on the 150mm long steel plates, leaving a "free" core failure area a*a equal to 240*240mm wide. To acquire the panel deformation, two couples of jokes, each supporting a displacement transducer, were hinged at the corners of the core. As for previous tests, AEP 10 mm stroke, strain gage linear displacement transducers were used. For panels with 45deg crossbands this in-plane shear test was not performed because it is meaningless: with 5-layer panels, there's always at least one layer with internal boards parallel to the load direction, therefore a very high load is reached, with local crushing in correspondence to the load and rest plates. Moreover, the boards loaded parallel to the grain are present only on one side, so there is a geometrical asymmetry leading to a lateral bending during test, which is evident and dangerous (during testing) since the specimen instability can be reached.
Rolling shear tests were carried out according to EN 16351 by removing two external layers from the original 5 layers, leaving a 90 mm thick, 3 layers panel. The 361 mm length of the panel was chosen in order to obtain the necessary inclination of the acting force resultant: arctan(90/361) = 14deg. The outer layers are aligned to the direction of the load, which was applied by two stiff steel plates 30 mm wide, i.e. as wide as the outer layers. The upper plate was centred above the lower hinge of the actuator. The controller, acquisition cards and transducers were the same used in the bending tests. The transducers were aligned in the load direction and acquired the relative displacement of the mid-planes of the outer layers.
Figures 1-3 show some of the panels and test setups:

- The panels with diagonal crossbands

3 RESULTS

The results from the board scanning are summarized in Table 4, and those from the tests on CLT panels are summarized in Table 5.
From the data in Table 4, it is quite clear that also the ungraded boards have rather good strength and stiffness properties, and in particular:

- "A" has a predicted MOR/MOE profile which falls in between MGP10 and MGP12,
- "B" is lower in density and predicted MOR/MOE, while it is higher in knottiness.

Table 4: *Values of density, knottiness, MOR and MOE of the board types. Each value is the average of 128 boards, the number between brackets is its Coefficient of Variation. The knottiness is an index developed by Microtec for their grading algorithms, the MOR is the predicted lowest 5th percentile bending strength of the board, and the 3 different MOEs are, respectively: measured by a dynamic tool (Viscan), predicted from knottiness and density, and the average of the previous two. The table is split in 2 parts, with the same left column.*

Board Type	**Density** kg/m3	**Knottiness** -	**MOR** MPa
MGP12	547 (8%)	1,930 (50%)	39.9 (16%)
MGP10	499 (10%)	2,965 (46%)	29.6 (33%)
A	504 (8%)	2,402 (50%)	34.7 (24%)
B	483 (7%)	3,484 (34%)	24.6 (33%)

Board Type	**MOE_{dyn}** MPa	**MOE_{pred}** MPa	**MOE_{avg}** MPa
MGP12	14,251 (14%)	11,036 (13%)	13,538 (14%)
MGP10	10,852 (26%)	8,552 (25%)	10,309 (26%)
A	12,788 (17%)	9,967 (16%)	12,149 (17%)
B	9,488 (18%)	7,555 (17%)	9,014 (18%)

The main result of the tests on CLT is that with ungraded Radiata Pine boards randomly selected from the current sawmill production output (which is additional to the MGP grades output) it was possible to obtain panels whose mechanical performances matched, and in some case even exceeded, those of both the reference Radiata Pine panels made with MGP10 boards, and of the Spruce panel (which provided a significant bench-mark because it was made of boards with a very good quality).
Moreover, the effect of the two different sawing patterns ("A" and "B") was clearly visible from the tests, as was the result of using crossbands layered at 45deg, consistently with previous findings [6]. The improvement sought from the U-Bb sample by optimizing the cost-effective layup adopted in U-Ba was indeed obtained, validating the underlying hypothesis and the use of the scanning results to inform the selection of the boards with criteria that differ from the MGP grading rules. The U-B boards being very knotty, they would have a low yield if graded according to MGP10 rules, therefore discouraging the use of this sawing pattern for the frame & truss market, but they can become a valuable resource when used correctly for CLT, where an optimized layup results in good panel performances.

Table 5: *Average values (MPa) of the mechanical parameters measured on the CLT panels. The table is split in 2 parts, with the same left column. Note 1 - Timber boards on the single panel used as benchmark were of very good quality, with no significant defects, much better than an average C24 grade. Note 2 - Grs is computed based on the reduced area Ars. Note 3 - Average published data, from [7].*

Test	**Spruce**	**MGP10**	**U-A**

4 DISCUSSION

When CLT panels are used as floor slabs, the bending stiffness is typically more important than the shear stiffness in reducing the structural deformability that often governs design; indeed, higher shear resistance is important for short span slabs with heavy loads, but this is rarely the case in residential design.

It is interesting to compare the estimate of the rolling shear parameters using bending or guillotine tests: the resistance is similar in both tests, but the guillotine test offers a simpler way to measure shear stiffness, and it can be easily carried out also to evaluate the bonding quality during production, therefore leading to higher number of measurements and providing a statistically more reliable information. Modelling of Radiata Pine CLT [4] have shown a 40% reduction of the critical load (associated with rolling shear failure) when edge-gluing is not considered in the manufacturing process, like in the present case. Therefore (and from some of the author's unpublished experiences), we can certainly expect that this would apply also to the use of the U-A and U-B panel types described here. Similar results were found by [8] for Pinus Taeda from Brazil and [9] for Southern Pine from the USA.

Other factors which were not addressed by this research, but will provide further optimization opportunities, are the variation of the lamella thickness and, if edge bonding is not considered, the aspect ratio of the boards (thickness divided by width). Specimens with 35mm and 20mm thick laminations were studied in [10] to evaluate the influence of this parameter on the rolling shear strength. The test results indicated that the recommended characteristic rolling shear strength values of CLT products in Europe and Canada might be over-conservative and it might be more efficient to specify different rolling shear strength values for CLT with different lamination thickness.

Lower grade lumber with a higher percentage of knots was recommended in [11] for the crossbands, which are mainly responsible for resisting shear stresses. The authors found that using the shear analogy method to interpret their results led to underestimations of rolling shear strength, especially in the case of CLT specimens containing knots. Clearly, also within this research, knottiness has proven to be a positive factor for the stiffness of crossbands, which mostly govern panel shear performances in bending, but close attention should be paid in the panel manufacturing to avoid excessive knots (and especially excessive wane) at the upper and lower layers of the panel, since the efficiency of some types of mechanical connections could be negatively affected; this certainly re-quires further research.

It is also worthwhile to mention the increased bending resistance of U-B45 panels with respect to their counterparts: simply changing the internal board inclination the rolling shear resistance increases by 50 % and – more importantly – the bending resistance and stiffness increase by 30%, thus deserving further research for a proper evaluation of the industrial feasibility.

The assessment of the mechanical properties of CLT panels based on four-point bending tests and guillotine tests, instead of the calculation based on the board grades, is a very promising opportunity for both the producers and the specifiers because it may result in getting "more from less" in terms of performances, and a higher product reliability, therefore making the whole production, design, and construction process a more sustainable one. This assessment approach, finally embedded into the European standard, can be rather easily applied in mill conditions due to the typical availability of offcuts from the CNC machining of large panels to produce the different elements in a building. Different analytical theories have been implemented and were used in [9] to estimate stiffness and strength properties under loads perpendicular or parallel to the principal plane of CLT panels from laboratory tests, predicting the associated deformation and failure mechanisms and assessing the reliability of the estimated properties with respect to the expected design values (and in terms of consistency among specimens with different layer configurations); the bending response is on average well represented in the theories currently used, for the two cases of loading, while for loads perpendicular to the plane the characteristic rolling shear strength appears to have a significant variability among the different layups, and for loads in plane a combined rolling and torsional shear failure criterion would provide more consistent results with respect to a less rigorous approach. Again, further experiences will provide better calibrations for the foreseen industrial quality control and in-grade testing routines.

5 CONCLUSIONS

The possibility to produce in-grade CLT panels from boards that were not strength-graded according to the applicable standard was demonstrated. The "cross-lamination effect" that explains this result was observed also for fast-grown Radiata Pine plantation logs, and particularly for sawing patterns that are not optimized for obtaining MGP grades and are therefore more cost efficient of MGP-specific patterns.

A set of scans and sorting feedback, executed by Microtec on a sub-sample of the boards, provided a very useful insight and suggested that significant resource optimization is possible, particularly for very knotty boards, leading to CLT panels which com-pared well also with a benchmark of C24 Spruce CLT which was produced and tested in identical conditions, showing that higher in-plane shear resistance and modulus were also achievable with ungraded Radiata Pine, a desirable performance for mid-rise which is a growing market trend.

These results will contribute to generating more value from a significant fraction of the Radiata Pine fibre resource which is currently not meeting the stud framing specifications and the MGP grading rules, therefore enhancing the resilience of the Australia supply chain.

COLLAGE QUALITY OF BRAZILIAN WOODS FOR USE IN GLUED LAMINATED TIMBER BEAMS

Julio Cesar Molina[1], Natália Andrade Bianchi[2], Felipe Dutra Lisboa [3] Nádia Barros Gomes[4]

ABSTRACT: The glued laminated timber industries in Brazil have been looking for alternatives that improve the quality of their products, by choosing the correct wood used in the composition of the structural elements, type of adhesive, as well as by monitoring the quality of the material's manufacturing process. This study evaluated the percentage of delamination and shear strength of glue lines in glulam beams constructed with Brazilian reforestation woods (pine and eucalyptus) and structural adhesives (Cascophen RS 216M and Polyurethane Jowat 686.60). For that, the Brazilian test method [1] based on the [2] was used. To qualify the percentage of failure in the gluing areas, the ImageJ software was used. Complementary microscopy analyzes were used to evaluate the gluing areas. As a result, it was observed that the best bonding quality results were obtained for pine and eucalyptus woods bonded with Cascophen RS 216M adhesive. There were no statistically significant differences between the shear strengths of the glue lines of the cross sections of the tested beams. The wood density and the adhesive viscosity had an influence on the bonding quality of glulam beams. The microscopic analyzes indicated that pine woods have an anatomical structure that allows better bonding quality.

KEYWORDS: Glulam, Delamination, Glue line strength, Image analysis, Microscopy

1 INTRODUCTION

The correct choice of the “specie/adhesive combination” in the manufacture of the glulam elements is fundamental to guarantee the structural quality of the element in service. In the manufacture of glulam elements, different polyurethane structural adhesives and resorcinol-based adhesives are used, as well as different types of Brazilian woods. The most common species of Brazilian reforestation woods are pine and eucalyptus, [9]. In addition, in Brazil there is a great availability of reforestation woods, [10]. There are several factors that can influence the wood glue quality response with structural adhesives. According [3] an important factor is the density of the wood. Denser woods tend to be more difficult for the adhesive to penetrate. The viscosity of the adhesive is another factor to be considered. Higher viscosities result in greater resistance to movement and, consequently, less ability of the adhesive to penetrate the wood. High viscosity values are undesirable due to the difficulty of uniformly distributing the adhesive over the wood. On the other hand, using low viscosity adhesives can result in a hungry glue line or excessive absorption by the wood [3].

The Brazilian test method [1] for evaluating the quality of bonding is based on the delamination and shear strength tests of the glue lines, proposed by the European standard [2] for the external environment.

This study proposed the evaluation of the bonding quality of glulam beams based on the recommendations of the Brazilian test method [1]. In the manufacture of the glulam beams were used two species of reforestation wood (Eucalyptus and Pine) glued with two different types of structural adhesives: one polyurethane and another based on resorcinol. Complementary microscopy and image analysis tests were realized in the evaluation of the bonding regions of the glulam specimens.

2 MATERIALS AND METHOD

The woods used in gluing the glulam beams (dimensions: 50 mm x 100 mm x 1200 mm) were Eucalyptus salligna (C30) and average density equal to 592 kg/m^3 and Pine elliottii (C25), average density equal 447 kg/m^3, without preservative treatment. For gluing the glulam beams, Cascophen RS 216M (bicomponent) and polyurethane Jowapur 686.60 (single component) adhesives were used. The viscosities considered for the adhesives were those indicated by their manufacturers. The viscosity value of Cascophen RS 216M adhesive varied between 500-1000 Pa.s and of Jowat 686.60 polyurethane adhesive between 10200 ± 2500 mPa.s. All tests were carried out at the Materials Properties Laboratory of UNESP in Itapeva,

State of São Paulo, Brazil, [4]. Wood characterization tests and tests to evaluate the bonding quality of the four different specie/adhesive combinations were carried out, in this research, as shown schematically in Figure 1.

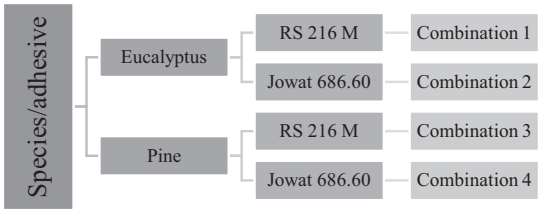

Figure 1: *Specie/adhesive combinations tested in this research*

2.1 GLUING PRESSURE FOR THE BEAMS

The bonding pressures used for the pine and eucalyptus glulam beams with different adhesives were 0.7 MPa (wood density ≤ 0,5 g/cm^3) and 1.2 MPa (wood density > 0,5 g/cm^3), respectively [5]. Pressure values were measured using a torquemeter and the gluing of the beams was made in a floor press (Figure 2). The moisture content of the wooden lamellae at the time of gluing was 12% ± 1% [5]. The glulam beams, after the pressing process, remained at rest for 72 hours for the complete curing of the adhesives and, later, they were machined to remove the specimens for the tests (delamination and shear strength of the glue lines), according to [1].

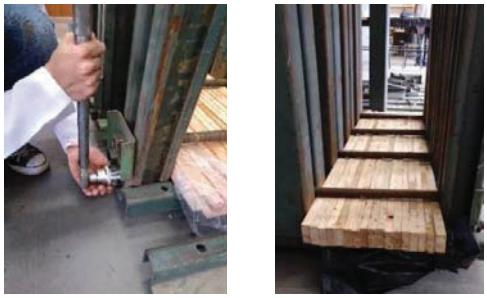

Figure 2: *Pressure control in glulam beams*

2.2 TEST SPECIMENS

All lamellae used in the glulam beams were visually and mechanically graded [5,6]. The lamellae classified in visual Class 1 were positioned at the edge of the cross section (lamellae 1, 2, 4 and 5, Figure 3) while the lamellae classified in visual Class 2 were positioned in the central part of the cross section (lamella 3). Thus, a total of four lines of glue and five lamellae were considered per beam (see Figure 3). The thickness of each lamella was 20 mm [5]. For bonding the glulam beams with the Cascophen RS 216-M adhesive (two-component), the weight considered was 240 g/m^2, applied on a single side of the lamella. A ratio of 10:2 (adhesive:catalyst) was used, i.e., 12 g of adhesive to 2.4 g of catalyst. For the Jowapur 686.60 polyurethane adhesive (one-component), a weight of 200 g/m^2 was used, with the adhesive applied to a single side of the lamella [7].

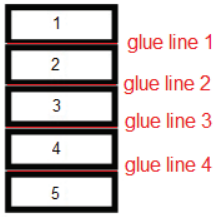

Figure 3: *Cross section of the glulam beams*

The specimens (50 mm x 100 mm x 75 mm) for the delamination and shear strength of the glue lines tests were obtained from the glulam beams, Figure 4. Six glulam beams (B1 – B6) were made for each specie/adhesive combination (total of 24 beams). From each glulam beam, 16 specimens were obtained, 7 for the delamination tests and another 7 for the glue lines shear tests. The two specimens of the edge of the beams were excluded.

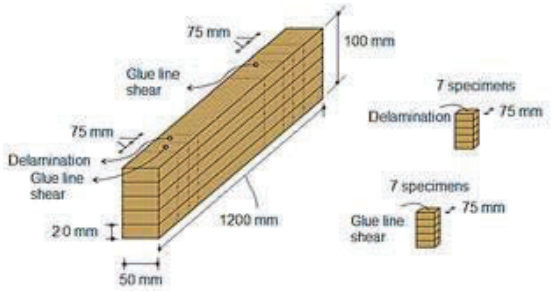

Figure 4: *Specimens for bonding quality tests*

2.3 GLUE LINE SHEAR AS A FUNCION OF POSITION IN THE CROSS SECTION

It was also analyzed whether the glue lines of the glulam beams showed differences of shear strength in relation to the height of the neutral line (LN), as lamellae arrangement shown in Figure 5. Thus, it was verified whether the two lines of glue (2 and 3) from the center of the cross section showed differences with relationship to the two other glue lines (1 and 4) at the edge of the cross section. This analysis was performed with the use of box plots for the values of the pairs of internal glue lines and external, compared to the total number of glue lines in the cross section of each analyzed combination in Figure 1.

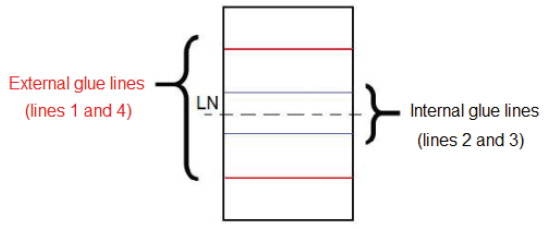

Figure 5: *Internal and external glue lines in the cross section*

https://doi.org/10.52202/069179-0100

2.4 COLLAGE QUALITY TESTS

To evaluate the bonding quality of the specie/adhesive combinations, delamination and shear of the glue lines tests were carried out on the specimens (Figure 4).

2.4.1 Delamination tests

The delamination and shear strength tests of the glue lines were carried out based on the recommendations of the Brazilian test method [1], for external environment, which is based on the European standard [2] and is recommended by the [5]. The delamination specimens initially had their masses determined. At the beginning of the test, the specimens were submerged in water, inside an autoclave, at a temperature of 20 ºC (Figure 6). Then, a vacuum of 80 kPa was applied for 30 minutes. Subsequently, the specimens were subjected to a pressure of 550 kPa for 2 hours. A metallic grid was positioned on the specimens inside the autoclave to ensure that the specimens were submerged in water during the delamination tests. After a single vacuum-pressure cycle, the specimens were placed in a drying kiln at 70 °C. Inside the drying kiln, the air flow had a velocity of 2 m/s and a relative humidity of approximately 8%. During drying, the specimens were spaced 50 mm apart, with the cut cross sections positioned parallel to the air flow. The drying of the specimens continued until the mass of the specimens reached a value between 0% and 10% above the original mass obtained before the autoclave process. The drying process of the specimens in the drying kiln lasted between 19 and 22 hours.

Figure 6: *Details of delamination tests*

The percentage of total delamination of each specimen was obtained by Equation (1) based on Figure 7.

$$D_T = \frac{L_a}{L_a} x100 \qquad (1)$$

Where:
Dt: total delamination, in %;
La: sum of the length of the opening of all glue lines on the faces of the cross section, in mm;
Lt: total length of all glue lines on the faces of the cross section, in mm.

For all delamination tests, the evaluation of the opening of the glue lines was carried out by measuring the glue lines on the front and back faces of the specimens taken from the glulam element, without considering the delamination of the lateral glue lines. The delamination limit considered for coniferous woods, according to the [1] test method was 4% and 6% for dicotyledonous woods. According to [8] the delamination lengths must be measured on the biggest face of the specimen, which generally correspond to the front and back faces of the cross section of the glulam specimen (Figure 7). In addition, according to method A of the [8] standard, the delamination limit after the third pressure and vacuum cycle is 10%.

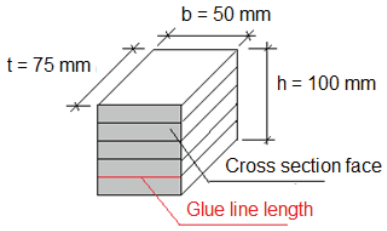

Figure 7: *Cross section of the specimen considered in the evaluation of the percentage of delamination*

2.4.2 Shear tests of glued lines

The shear strength of the glue lines and the percentage of wood failure in the sheared area were also recorded. The shear strength for the glue lines was obtained through Equation (2). The four lines of glue (Figure 3) were broken by shear for each of the specimens tested. For the shear tests, a metallic device coupled to the EMIC testing machine was used (Figure 8). The percentages of rupture, in the gluing regions, after the shear tests of the glue lines, were quantified using the ImageJ software.

$$f_v = \frac{F_{v,max}}{(b.t)} \qquad (2)$$

Where:
f_v: shear strength of the glue line, in MPa;
$F_{v,max}$: maximum shear load applied to the rupture lamella, in N;
b: width of the specimen, in mm (Figure 7);
t: height of the specimen, in mm (Figure 7).

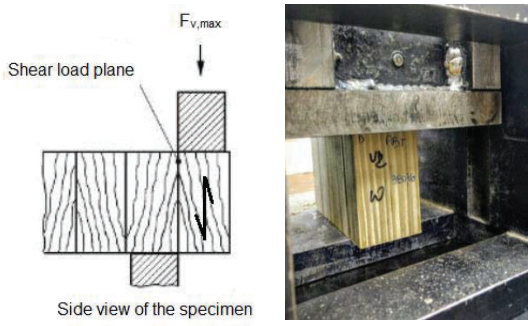

Figure 8: *Glue line shear test details*

https://doi.org/10.52202/069179-0100

2.4.3 Microscopy analysis

The surfaces of the lamellae before bonding were analyzed using optical microscopy. A LEICA M80 optical microscope with lighting was used.

From lamellas with initial dimensions of 5 x 2 x 120 cm, before gluing the glulam beams, samples with dimensions 50 x 20 x 75 mm were taken to analyze the quality of these surfaces. The variations in the thickness of the glue lines of the glulam specimens were also analyzed by microscopy.

2.5 STATISTICAL ANALYSIS OF THE RESULTS

The delamination and shear strength results of the glue lines were analyzed using the Minitab statistical analysis software. Initially, the normality of the data was verified using the Anderson-Darling test.

Subsequently, an analysis of variance was performed based on Student T test with determination of the p-value. It was verified whether there were significant differences between the means obtained for a significant level of 5%.

3 RESULTS AND DISCUSSION

3.1 DELAMINATION TESTS

Tables 1 and 2 show the delamination results of the glulam beams (eucalyptus and pine) glued with RS 216M and Jowapur 686.6 adhesives, calculated by equation (1).

Table 1: *Average delamination percentages of eucalyptus beams glued with Cascophen RS 216M and Jowapur 686.60 adhesives.*

Beams	Combination 1 (%)	Combination 2 (%)
B1	0.00	6.78
B2	0.42	7.44
B3	1.37	6.95
B4	1.23	6.70
B5	0.00	8.50
B6	0.78	6.91
Average	0.63	7.21

Note: an average of 7 specimens was considered for each glulam beam

Table 2: *Average delamination percentages of pine beams glued with Cascophen RS 216M and Jowapur 686.60 adhesives.*

Beams	Combination 3 (%)	Combination 4 (%)
B1	2.49	0.30
B2	2.40	3.84
B3	2.13	7.99
B4	2.17	1.79
B5	1.70	2.78
B6	2.12	8.97
Average	2.17	4.28

Note: an average of 7 specimens was considered for each glulam beam

The Cascophen RS 216M adhesive showed good delamination results, both for eucalyptus wood (average percentage lower than the 6% limit) and for pine woods (average percentage lower than the of 4%). The Jowapur 686.60 adhesive showed higher viscosity during application on the lamellae. Higher viscosity for the adhesive associated with higher density wood (eucalyptus) resulted in poor bonding quality.

3.2 GLUED LINE SHEAR TESTS

Tables 3 and 4 present the results of shear strength of the glue lines (Equation 2) and respective percentages of failure in the wood obtained for the glued areas (ImageJ).

Table 3: *Results of shear tests of glue lines of glulam beams with eucalyptus woods.*

Beams	Combination 1		Combination 2	
	$f_{v,m}$ (MPa)	FW (%)	$f_{v,m}$ (MPa)	FW (%)
B1	8.94	96.00	8.33	91.00
B2	8.15	95.00	7.13	92.00
B3	9.13	97.00	6.41	92.00
B4	8.51	95.00	7.51	91.00

DP	1.60	1.71	0.76	1.34
CV (%)	22.28	2.00	15.41	1.67

Notes: an average of 7 specimens was considered for each glulam beam. $f_{v,m}$= average value of shear strength of the glue lines of the beams; FW= wood failure (ImageJ); CV= coefficient of variation (DP/mean*100); DP = standard deviation; $f_{v,k}$ = characteristic value of shear strength according to [3].

For all specie/adhesive combinations (Figure 1), the failure in the collage area occurred in the wood, indicating good gluing results. The average values of the shear

strengths of the glue lines were higher for the eucalyptus beams glued with the Cascophen RS 216M adhesive (combination 1) when compared to the values obtained for the beams glued with Jowapur 686.60 adhesive (combination 2). However, from a statistical point of view these differences were not significant (p-value equal to $0.08 > \alpha = 0.05$). For the combinations of the glulam beams with pine woods (combinations 3 and 4), the average shear strengths of the glue lines were statistically significant (p-value equal to $0.03 < \alpha = 0.05$).

3.3 GLUE LINE SHEAR AS A FUNCION OF POSITION IN THE CROSS SECTION

The box-plot graphs for the values of the pairs of internal and external glue lines, compared to the number of total glue lines in the cross section of each analyzed combination are show in Figures 9 to 12.

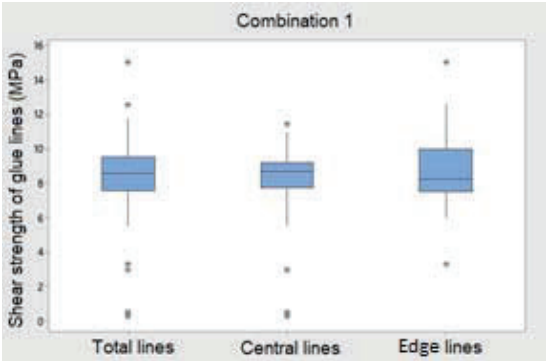

Figure 9: *Box plot of the shear strengths of the glue lines as a function of their location in the cross section (Combination 1).*

For combination 1, the central portion of the graphs showed a median (8.67 MPa) very similar to the glue lines of the extreme regions (8.26 MPa) and the total (8.30 MPa). In addition, the central value showed lower data dispersion (1.46 MPa).

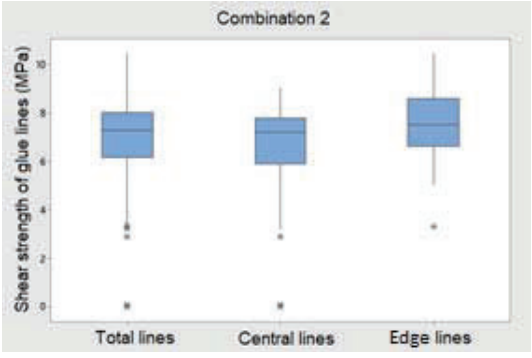

Figure 10: *Box plot of the shear strengths of the glue lines as a function of their location in the cross section. (Combination 2)*

For combination 2, the lines in the central part presented median (7.21 MPa) like the edge lines (7.52 MPa) and total (7.28 MPa). The lines in the central part showed lower data dispersion (1.88 MPa).

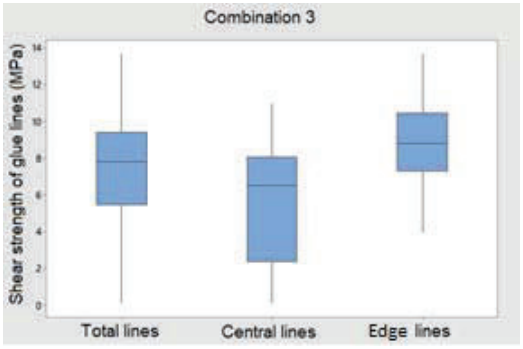

Figure 11: *Box plot of the shear strengths of the glue lines as a function of their location in the cross section. (Combination 3)*

In combination 3 (Figure 12), the median value of the center lines (6.52 MPa) was below the median of the edge lines (8.81 MPa) and total (7.81 MPa). The central lines showed the greatest dispersion (5.67 MPa).

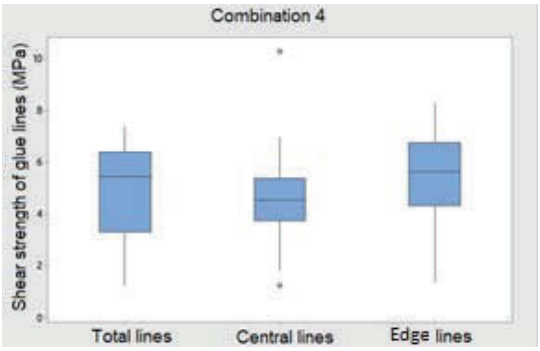

Figure 12: *Box plot of the shear strengths of the glue lines as a function of their location in the cross section. (Combination 4)*

For combination 4, the total glue lines dataset showed a median (5.45 MPa) very close to the edge glue lines (5.62 MPa). However, the central glue lines showed lower data dispersion (1.62 MPa) and median (4.52 MPa) a little lower than the others.

3.4 MICROSCOPIC ANALYSIS

Figure 13 shows the microscopy details of the surfaces of the machined lamellae before bonding.

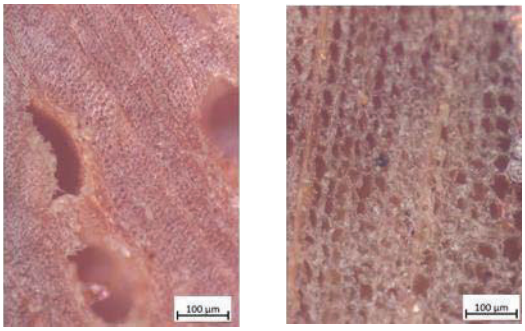

Figure 13: *Microscopy of lamellae surfaces before bonding.*

https://doi.org/10.52202/069179-0100

In the enlarged images of the lamellae surfaces, it was observed that the eucalyptus lamella presented open vessels with irregular shapes. The pine lamella exhibited a more homogeneous surface due to the presence of early and late wood tracheid's distributed throughout the lamella bonding area. The average variation of the thicknesses of the glue lines on the glulam beams are presented in Table 5.

Table 5: *Variation of glue line thickness for different specie/adhesive combinations*

Adhesives	Thickness of glue lines (μm)	
	Eucalyptus	Pinus
RS 216-M	112.8 – 119.9	69.2 – 155.0
Jowapur 686.60	225.1 – 319.0	89.6 – 211.8

When gluing pressure is applied to the glulam element, the adhesive layer acquires a narrow and continuous thickness which should obtain thicknesses between 76 and 152 μm [3]. From the analysis of Table 5, it was observed that, except for glulam elements made with eucalyptus wood and glued with Jowapur 686.60 adhesive (combination 2), all other specie/adhesive combinations (1, 3 and 4) showed variations in the thickness of the glue lines in agreement with the results of the literature [3].

4 CONCLUSIONS

The results obtained from the delamination and shear strength tests of the glue lines indicated that the wood density and the adhesive viscosity are important factors in the gluing of glulam beams.

In general, bonding the wooden lamellas with Cascophen RS 216M adhesive resulted in better bonding quality for the glulam beams. Except for combination 2 (eucalyptus glued with Jowapur 686.60 adhesive), all other combinations presented acceptable delamination limits (< 4% for gluing coniferous wood and < 6% for gluing dicotyledons) according to the Brazilian test method [1].

For all specie/adhesive combinations evaluated, the predominant failure in the specimens' bonding areas, in the shear tests of the glue lines, occurred due to failure in the wood.

In general, the shear strengths (in the glue lines of the glulam specimens made with eucalyptus wood were higher than those obtained for the specimens with pine wood.

There were no statistically significant differences between the shear strengths of the glue lines evaluated in the same cross-section of the specimens. Thus, the number of analyzes in the shear tests of the glue lines can be reduced since the test in the central region of the cross section of the specimen is prioritized, due to the higher concentration of shear stresses.

The microscopic analysis of the surfaces of the wooden lamellae indicated that the pine woods, due to their anatomy, present a greater regularity of the surface with greater porosity provided by the presence of the tracheids of the early and late wood, which facilitates the penetration of the adhesive with respect to eucalyptus woods.

The microscopy analyzes also indicated that, in general, the thickness of the glue lines for the specie/adhesive combinations analyzed agreed with the values in the literature (76 and 152 μm) except for gluing eucalyptus wood with Jowapur 686.60 adhesive.

NON-PARAMETRIC LOWER CONFIDENCE BOUNDS FOR THE FIFTH PERCENTILE – EN 14358 IN COMPARISON TO A FULLY NON-PARAMETRIC APPROACH

Andreas Weidenhiller[1], Dan Ridley-Ellis[2], Andreas Neumüller[3]

ABSTRACT: In Europe, fifth percentile values are required for the calculation of characteristic values of strength and density. The European standard EN 14358:2016 defined three ways to calculate a 75% lower confidence bound (LCB) for such fifth percentile values, based either on a lognormal parametric approach, on a normal parametric approach or on a non-parametric approach. Using simulated data with different sample sizes and with different underlying distributions, this paper studied the effects of using each of the three approaches of EN 14358. As the third approach in EN 14358 did not seem to be fully non-parametric, the simulation study included, as a fourth approach, a fully non-parametric calculation of the LCB for the fifth percentile. The simulation study confirmed that both non-parametric approaches led to acceptable results for some important distributions, although the non-parametric approach defined in EN 14358 seemed to be more conservative especially for data with a non-normal distribution. The study also confirmed that the use of an incorrect parametric assumption can lead to systematically misleading LCB values for the fifth percentile. The authors recommend replacing the non-parametric approach currently defined in EN 14358 by a fully non-parametric approach. This approach can easily be implemented in a standard.

KEYWORDS: timber strength; fifth percentile; lower confidence bound; simulation study; distribution assumptions

1 INTRODUCTION

Fifth percentile values are frequently required when assessing strength. Such values are also used for assessing the strength of timber, timber products and timber structures. In recent years, the European standard EN 14358 [1] has evolved towards encompassing a number of cases for calculating fifth percentile values.

In its original form from 2006, the standard EN 14358 [2] contained instructions for calculating 75% lower confidence bounds (LCB) for the fifth percentile assuming a lognormal distribution; the purpose was to assess test results for connections and wood-based products. Construction timber was explicitly excluded and was dealt with in a separate standard (EN 384 [3]). The calculation in EN 384 differed from the one in EN 14358 in two important aspects: it was a nonparametric fifth percentile (in contrast to the parametric lognormal distribution assumption in EN 14358), and the fifth percentile itself was reported as the result (in contrast, EN 14358 required to report the 75% LCB). With the revision of both standards in the year 2016 [1, 4], the calculation of the fifth percentiles was completely moved from EN 384 to EN 14358. In the course of this revision, EN 14358 was extended to encompass, in addition to lognormal fifth percentiles, also fifth percentiles for normally distributed quantiles, nonparametric fifth percentile calculation, and mean values of normally distributed quantities, all with a 75% LCB [1].

For the parametric quantities, the standard gives three options for calculation: using an exact formula, using a rational approximation, and using tabled coefficients. For the 75% LCB m_k of the nonparametric fifth percentile $y_{0,5}$, only an approximation formula is given [1]:

$$m_k = y_{0,5}\left(1 - \frac{k_{0,5,0,75}V}{\sqrt{n}}\right) \quad (1)$$

where n is the sample size, V is the coefficient of variation (CoV), and $k_{0,5,0,75}$ is a factor of which the standard claims that it leads to the 75% LCB [1]:

$$k_{0,5,0,75} = \frac{0.49n + 17}{0.28n + 7.1} \quad (2)$$

The authors could not trace the origins of these formulas and the underlying assumptions remained unclear. But the use of the coefficient of variation V in formula (1) makes it clear that some parametric assumptions have to be involved.

On the other hand, there is a well-known method to calculate a fully nonparametric LCB (see, for example [5]). This method is discussed in more detail in section 2.1 below.

https://doi.org/10.52202/069179-0101

How does this method perform in comparison to the approaches defined in EN 14358 [1]?
In the long run (after, say, 1000 repetitions), we would expect that, in 75% of the cases, the true fifth percentile value is above the 75% LCB. This fact was used in the present paper to compare the 75% LCB calculation approaches from EN 14358 [1] and from the fully nonparametric approach with the true fifth percentile values for simulated data with a known distribution.

2 MATERIAL AND METHODS

2.1 FULLY NONPARAMETRIC 75% LOWER CONFIDENCE BOUND FOR THE FIFTH PERCENTILE

To get a non-parametric LCB for the fifth percentile of a sample with n measurement values, we order the measurement values by increasing value, so that x_1 is the smallest value, x_2 the second smallest value, and x_n the largest value. We say that these values have rank 1, 2 and n, respectively.
The probability with which the measurement value x_i with rank i underestimates the fifth percentile can be calculated using the binomial distribution [6].
This probability is independent of the actual values x_i – it only depends on the ranks i. Therefore, one can calculate a table which tells, for each sample size n, the maximum rank i_{max} which fulfils the following condition: The probability that $x_{i_{max}}$ underestimates the fifth percentile is 75% or more. Underestimating the fifth percentile means that we get a conservative estimate of the fifth percentile.
Table 1 lists such values i_{max} (ranks) for selected values of n. Such a table could easily be incorporated in a standard. For intermediate values of n, one would have to pick the smaller rank value (e.g., for $n = 50$, still the value x_1 with rank 1 would have to be picked as the 75% LCB).

Table 1: *Lowest sample size n for which the element with a given rank (counted from the smallest to the largest value) is a nonparametric 75% lower confidence bound (LCB) for the fifth percentile.*

rank	n	rank	n	rank	n
1	28	8	193	15	347
2	53	9	215	16	368
3	78	10	237	17	390
4	102	11	259	18	412
5	125	12	281	19	433
6	148	13	303	20	455
7	170	14	325	21	476

Due to the discrete nature of the binomial distribution, for intermediate values of n, the probability that $x_{i_{max}}$ underestimates the fifth percentile can be quite a bit higher than the 75% which we aimed for – for example, the probability for $n = 40$ is 87%. However, it is also possible to determine interpolated ranks directly at the desired probability of 75%, for example, by using the R package cbinom which provides a continuous analog of the binomial distribution [7].
In the present study, we used the sample sizes $n = 40$, 80, 500, 1000 and 100000 (see 2.3) – for these, the interpolated ranks are 1.488, 3.107, 22.13, 45.77 and 4954, respectively. These ranks were used for the calculation of the fully non-parametric LCB values in the study.

2.2 INCLUDED PROBABILITY DISTRIBUTIONS

We included normal and lognormal distributions, because they are included in EN 14358. For normal distributions, the location parameter does not influence the results, so we chose 420 (required mean density in kg/m³ for C24 in EN 338 [8]) and used CoV values of 5%, 10% and 20%. For the lognormal distribution, the location parameter also changes the shape of the distribution, so we calculated mean strength values corresponding to the requirements for C16, C24 and C35 in EN 338 [8] together with CoV values of 5%, 10% and 20%. A further important class of distributions are truncated normal distributions, because these represent an extreme case of what efficient strength grading can do. Here we took the normal distributions defined above but cut off everything below 310, 350, respectively 390 (required fifth percentile of density in kg/m³ for C16, C24 respectively C35). The calculations on the truncated normal distributions were handled using the R package truncnorm [9].
Regarding normal distributions, it is important to note that those always include negative values (if maybe only with a small probability). Negative values are not realistic in the application and cause the calculation of parametric lognormal LCB values to fail. Therefore, the normal distributions are actually modelled as truncated normal distributions truncated below 1.
The parameterization of the different distributions is listed in Table 2.

2.3 SIMULATION STUDY

We simulated 1000 samples of each of the distributions given in Table 2, for each of the following sample sizes: 40, 80, 500, 1000 and 100000. 40 was chosen as the smallest sample size, because below that, the nonparametric calculation according to EN 14358 may not be used [1]. 100000 was chosen as an "almost infinite" sample size, where we expected the LCB to be almost equal to the sample fifth percentile, and we expected the sample fifth percentile to almost perfectly match the true fifth percentile according to the distribution.

2.4 STATISTICAL ANALYSIS

For each simulated sample, we calculated parametric 75% LCB values for the fifth percentile according to EN 14358 [1] assuming a normal or lognormal distribution. Further, nonparametric LCB values according to EN 14358 [1] and according to the procedure outlined in section 2.1 were calculated.

https://doi.org/10.52202/069179-0101

Table 2: *Parameters for the simulated distributions. mu and sigma describe location and spread. "lower bound" is a parameter for the truncated normal distribution that ensures that no values below the lower bound are included in the distribution. For simulation, this is implemented using accept-reject sampling (see help on rtruncnorm in [6]). Additionally, the fifth percentile of the distribution is given.*

distribution	mu	sigma	lower bound	fifth percentile
normal	420	21	1	385
	420	42	1	351
	420	84	1	282
lognormal	2,85	0,05		15,9
	2,94	0,0998		16,1
	3,1	0,198		16,0
	3,26	0,05		24,0
	3,34	0,0998		23,9
	3,5	0,198		23,9
	3,64	0,05		35,1
	3,72	0,0998		35,0
	3,88	0,198		35,0
truncated normal	420	21	310	385
	420	42	310	353
	420	84	310	329
	420	21	350	386
	420	42	350	365
	420	84	350	361
	420	21	390	396
	420	42	390	395
	420	84	390	397

For each simulated sample and each calculated LCB value, we determined the "true percentile" this LCB value corresponded to according to the distribution by which the sample was generated.
For example, the "true percentile" of 350 in a normal distribution with mean 420 and a CoV of 10% is 4.78. The "true percentile" value 4.78 in this example is lower than five. This means that 350 is a conservative estimate of the fifth percentile of the underlying distribution – in fact, the actual fifth percentile of the underlying distribution is 351.
All calculations were performed using R 4.2.1 [10].

3 RESULTS AND DISCUSSION

In Figure 1, the results of the simulation study were summarised using boxplots. On the vertical axis, for each 75% LCB value, the "true percentile" value in the respective underlying distribution was plotted. The upper end of each box corresponded to the threshold below which we found 75% of the observed values. For the 75% LCB, we would expect 75% of the observed values to be below the target value five, which is indicated by the black horizontal line.
For an optimal 75% LCB, the upper end of the box would be at the target value five, which means that 75% of the calculated values would be conservative estimates of the fifth percentile of the underlying distribution.
If the upper end of the box is above five, the calculated LCB values are too optimistic. If the upper end of the box is far below five, the calculated LCB values are very conservative. If the height of the box is large, the LCB values have a large spread. The ideal situation would be a box with low height with its upper end at or closely below five.
In Figure 1a, the true percentiles for the parametric normal calculation of 75% LCB values according to EN 14358 are shown. When the underlying distribution was normal (leftmost five boxes in Figure 1a), the height of the boxes as well as the distance of the true percentiles to the target value five decreased with increasing sample size n. For $n = 100000$, there were almost no deviations of the true percentile from the target value five. However, for the other underlying distributions in Figure 1a, the heights of the boxes and the distances from the target value five did not decrease. In particular, even for $n = 100000$, the true percentile values could be far away from the target value five. Even if the discrepancies are on the conservative side, it is clear that the parametric normal LCB calculation was misleading when the underlying distribution was not normal.
A similar pattern could be observed for the parametric lognormal calculation of 75% LCB values (Figure 1b). When the underlying distribution was lognormal (central five boxes in Figure 1b), the parametric lognormal calculation was close to optimal. For other underlying distributions, the parametric lognormal LCB calculation was misleading. When the underlying distribution was normal, the upper ends of the boxes were above the target value five, meaning that more than 25% of the LCB values were too optimistic, and this share increased with increasing n. For $n = 1000$, 75% of the LCB values were

https://doi.org/10.52202/069179-0101

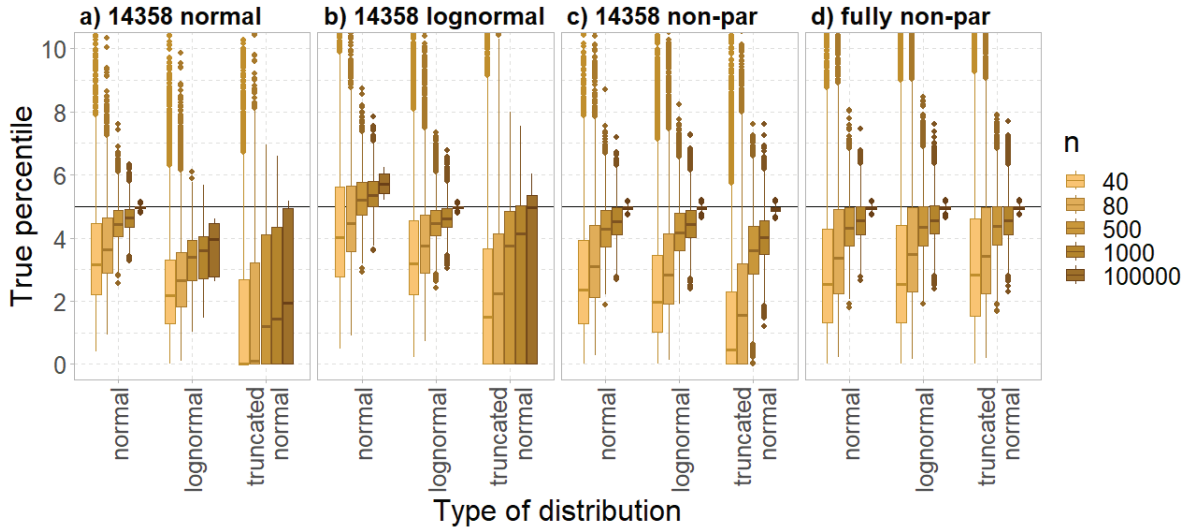

Figure 1: *Boxplots of "true percentiles" (the percentile which a calculated 75% LCB corresponds to in the true underlying distribution) separated by underlying distribution (horizontal axis), sample size n (colour scale) and mode of calculation for the 75% LCB of the sample fifth percentile. a) parametric normal LCB acc. to EN 14358, b) parametric lognormal LCB acc. to EN 14358, c) non-parametric LCB acc. to EN 14358, d) fully non-parametric LCB as outlined in section 2.1. The range of the vertical axis is optimised for the boxes – not all extreme values are included. Each box summarises 1000 runs times the number of different parameterisations for each type of distribution – see also Table 2.*

too optimistic, and for $n = 100000$, all parametric lognormal LCB values were above the target value 5.

Both nonparametric approaches to calculating 75% LCB values (Figure 1c and d) worked for all underlying distributions examined in this study. In all the cases, the height of the boxes as well as the distance of the true percentiles to the target value five decreased with increasing sample size n. For $n = 100000$, there were almost no deviations of the true percentile from the target value five.

In Figure 2, the boxes from Figure 1c and d were rearranged to facilitate comparisons between the two nonparametric approaches to calculating 75% LCB values. When the underlying distribution was normal, the two approaches behaved similarly, with the fully non-parametric LCB values being slightly closer to the target. For an underlying lognormal distribution, and even more for an underlying truncated normal distribution, the fully non-parametric LCB values were distinctly closer to the target fifth percentile.

In Figure 1, the dangers of using a parametric calculation of the 75% LCB can be observed. If the distribution assumptions are not met, there is a risk of obtaining misleading results.

The non-parametric approaches to calculating the 75% LCB seemed to work well for very different types of distributions, at the cost of a higher spread of the values (indicated by greater heights of the boxes in the plots).

To facilitate the inclusion of the fully non-parametric approach in a standard, it would be helpful to have an approximation function for the interpolated ranks which are needed to calculate the fully non-parametric LCB values (section 2.1). Using linear regression, such an approximation was calculated for all sample sizes from 40 to 10000.

The rank r can thus be calculated as

$$r = 0.422 + 0.05\,n - 0.147\,\sqrt{n} \qquad (3)$$

where n is the sample size. The relative errors of this approximation in the range from $n = 40$ to $n = 10000$ are in the range between -0.01% and +0.26%.

4 CONCLUSIONS

In this paper, different approaches to calculating 75% lower confidence bound (LCB) values for the fifth percentile of a sample were compared by means of a simulation study.

Both parametric and non-parametric approaches were included, focusing on approaches defined in the European standard EN 14358 [1]. As the non-parametric calculation of 75% LCB values defined in the standard EN 14358 [1] is not fully non-parametric, a fully non-parametric approach was also included in the study.

Samples of sizes 40, 80, 500, 1000 and 100000 were simulated for the following underlying distributions: normal, lognormal, and truncated normal. For all distributions, different coefficients of variation were included, and for the lognormal and truncated normal distributions, the mean respectively the lower bound parameter were also varied.

The study highlighted the risk of misleading results if a parametric approach to calculating 75% LCB values is used when the assumptions about the type of underlying distribution are not met.

https://doi.org/10.52202/069179-0101

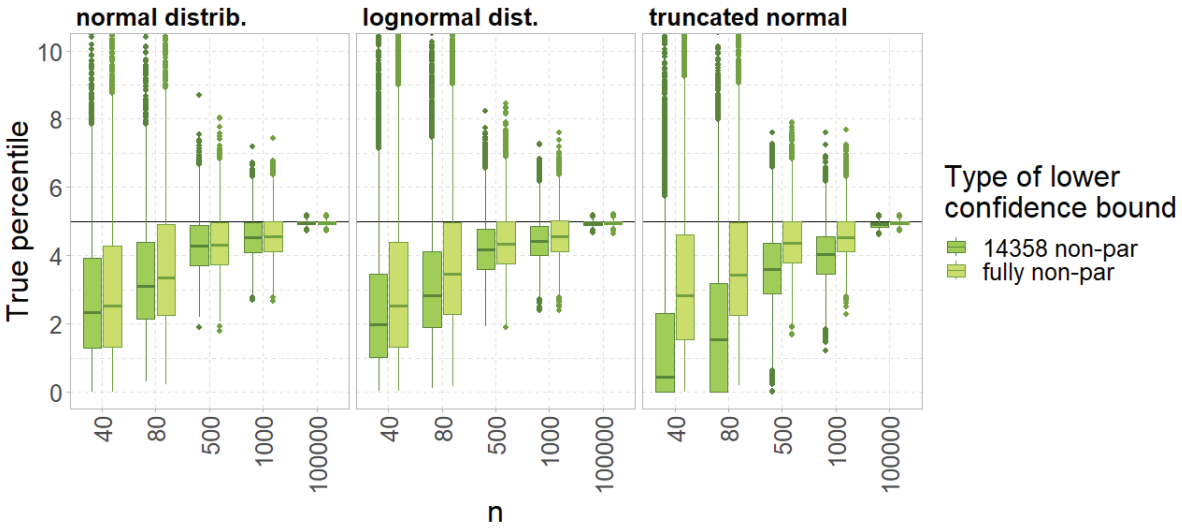

Figure 2: *Rearranged boxplots of "true percentiles" from Figure 1 for the two non-parametric approaches to calculating the 75% LCB ("14358 non-par" and "fully non-par"). For each combination of sample size n and type of distribution, the boxes for the two approaches "14358 non-par" and "fully non-par" are plotted side by side to facilitate pairwise comparison.*

Both non-parametric approaches to calculating 75% LCB values led to acceptable results. However, the non-parametric approach defined in EN 14358 [1] led to 75% LCB values which were more conservative than necessary, especially if the underlying distribution was not normal.

Therefore, the authors recommend revising the standard EN 14358 [1], replacing the current non-parametric approach to calculating 75% LCB values by a fully non-parametric approach.

The fully non-parametric approach is suitable for implementation in the standard. Implementation could be done using tabled values, an approximation formula and/or an exact formula, in a similar manner to the way in which the parametric approaches to calculating 75% LCB values are currently implemented in EN 14358 [1].

NEW CRITERIA FOR VISUAL STRENGTH GRADING OF SAWN TIMBER FROM BIRCH GROWN IN SWEDEN

Ulf Lemke[1], Marie Johansson[2], Rune Ziethén[3], Andreas Briggert[4]

ABSTRACT: Today there is no standard for strength grading and CE-marking sawn timber of Birch grown in Sweden, which makes it impossible to use this material as structural timber. Internationally, there are standards for visual grading of hardwood in several European countries. However, these standards may not be used to classify Birch timber grown in Sweden without having been tested and verified to meet the standard's requirements. In a project (BizWOOD) run by RISE, 600 pieces of sawn birch wood from Sweden is visually graded and strength tested.

The project aims to result in grading rules for birch, either by using international standards or where international standards will be used as references for the identification of defects that will be included in the grading model. This paper summarizes parts of the BizWOOD project and includes 1) description of sampling and timber origin, 2) visual grading according to international standards, 3) strength testing of the material, 4) evaluation of mechanical characteristics, 5) evaluation of grading techniques.

KEYWORDS: Birch (*Betula spp.),* density, bending strength, modulus of elasticity, MOR, MOE, strength grading.

1 INTRODUCTION

The Swedish forests consists of about 18% hardwood and this proportion is increasing as a result of environmental goals [1] and certification criteria [2]. The largest proportion of the deciduous forests are located in Southern Sweden [3], where pure stands of deciduous trees are found. However, the market for sawn timber from deciduous trees is very limited today and for several tree species the market is largely non-existent. A large proportion of the Swedish hardwood that is felled is used as pulpwood or firewood, only a very limited proportion is used as sawn timber in Sweden and a small proportion is exported as logs. The problem is often explained by a Catch-22 within the value chain - no demand leads to no production and no production leads to no demand. The large players in the market find it difficult to rationally handle the relatively small quantities of hardwoods that come out of the market. This means that the hardwood market is dominated by a few larger companies specializing mainly in floor manufacturing. In addition, the market consists of many small sawmills, all of which are included in the small and medium sized enterprises category.

The Swedish deciduous forest is dominated by Birch, a combination of *Betula pendula* and *Betula pubescens*. The total timber stock of Birch in the Swedish forest is about 386 million m^3sk (forest cubic meters), where the growth is about 14 million m^3sk per year [3]. The felling in Sweden is about 8 million m^3sk, i.e. the growth is significantly higher than the felling but of which only 77 000 m^3sk is used in the four larger sawmills in Sweden [4] for furniture and joinery without strength grading, e.g. about 1% of the total volume. The remaining material is used in pulp mills or as firewood. One of the reasons for this is that, today, there is no strength grading standard that can be used for strength grading sawn birch timber grown in Sweden. This makes it very difficult to use birch wood as structural timber in Sweden.

The objective of this paper is to present the BizWOOD findings where timber characteristics were measured for birch timber grown in Sweden. Data for strength grading, both for visually- and machine-grading will be presented for about 600 pieces. All specimens were strength tested in four-point bending, in accordance with EN 408 [5], the results for bending strength, modulus of elasticity (MOE) and density will be presented. The possible yields in different grades based on the sampled material will be presented.

The long-term aim is to establish methods that can be used to strength grade sawn timber from birch grown in Sweden and thus make it possible to use birch as a structural material in Sweden. This will broaden the raw material base in the Swedish forestry sector. The work is done as part of a larger project BizWOOD, with the aim

of finding more use of hardwood timber grown in Sweden.

2 MATERIAL AND METHODS

The sampling and measurements were done according to the principles used when setting initial values for machine strength grading in accordance with EN 14081 [6]. This meant sampling and testing more than 450 pieces of timber from the growth area. A growth area is defined, according to EN 14081-2 [7], as the source from which timber is intended to be strength graded.

2.1 Sampling of material

The sampling was carried out at 5 different sawmills in Sweden, see Figure 1, and a total number of 600 specimens of sawn timber were collected. The specimens were divided into four so-called verification samples (sub-sample): North Sweden, Mid Sweden, Southeast Sweden and Southwest Sweden. The material from the two sawmills in Mid Sweden was grouped as one sub-sample as their source areas are overlapping.

The thickness of the specimens varied between 22 mm to 66 mm, and the width from 60 mm to 200 mm. The length of the specimens was between 2,9 and 3,2 meters, which is the standard length of birch timber in Sweden. The number of specimens in each sub-sample, together with corresponding dimensions and origin, is summarized in Table 1.

Figure 1. *Locations of the five sawmills represented in the study. The material from the two sawmills in Mid Sweden was grouped into one sub-sample as the catchment area for the two sawmills were overlapping.*

The total sample of specimens were later broadened to include an additional sub-sample consisting of 120 specimens from Norway. However, these specimens are not included in the evaluation presented in this paper.

The birch grown in Swedish forest consists of a mix of *Betula pendula* and *Betula pubescens* which are not distinguishable visually when sawn to boards. Due to this reason the birch species *Betula pendula* and *Betula pubescens* are processed as one species, the number of specimens of each species in the sample is unknown. The sawmills processing birch timber are relatively small and not all of them uses kiln drying. The specimens included in sub-samples Mid Sweden and Southeast Sweden were kiln dried to approximately 12% moisture content. The specimens in the other subsamples were air-dried. All specimens were planed before testing.

Table 1. *Number of specimens from different sub-samples (geographical sources) and their dimensions and tested length (span length) in four-point bending. The dimensions marked with * could not be tested with a span length of 18h.*

Sub-sample	Nominal dimension [mm x mm]	Span length [m]	Number
North	22 x 75	1.35	40
North	48 x 75	1.35	42
North	48 x 100	1.80	41
Mid	48 x 200	3.00*	42
Mid	36 x 70	1.26	52
Mid	39 x 150	2.70	51
Mid	47 x 60	1.08	79
Mid	50 x 125	2.25	50
Southeast	45 x 95	1.71	43
Southeast	45 x 70	1.26	39
Southeast	45 x 150	2.70	24
Southwest	45 x150	2.70	27
Southwest	45 x 170	2.72*	33
Southwest	66 x 125	2.25	37
Total			600

2.2 Measurements – visual, physical, and mechanical characteristics

In the laboratory the visual characteristics were recorded, and the mechanical properties were tested for each specimen.

2.2.1 Visual characteristics

Visual characteristics of each specimen were recorded in the form of; knot sizes in the critical cross section, rot, cracks, slope of grain, and wane according to INSTA 142 [8]. If other defects were found these were noted in the protocol. The measurements were done by hand. The parameters distortion and annual ring width were not recorded.

Knots were recorded for a length of 150 mm at the critical cross section within the middle 6h of the length, i.e. the

https://doi.org/10.52202/069179-0102

part of the specimen used as the middle span in the bending tests.

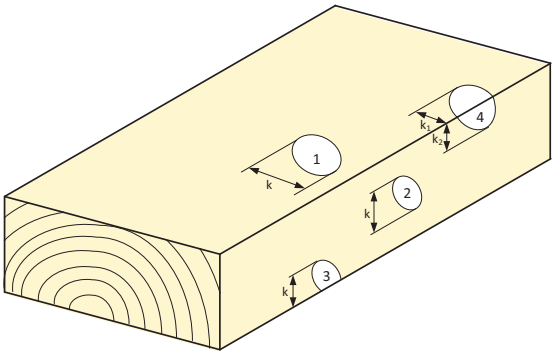

Figure 2. *Principal definition of knot measurement for five different types of knots.*

The main principle for the knot measurement was that a factor (k) was determined as length of the knot in the right angle to the length of the piece, see for example illustration of knot 1 in Figure 2. This is the principle described in INSTA 142 [8].

The knot measurement of knots fully on the edge side are measured perpendicular to the longitudinal axis (knot 2). Knots on the corner between heartwood face of the sample and the edge are measured on the edge side and counted as edge knots (knot 3). Knots on the corner between the sapwood face and the edge side (knot 4) are measured as:

$$k = k_1 + 0.5k_2 \qquad \text{(Eq. 2)}$$

and classified as an edge knot. Knots going through the specimen from one flat face to the other are measured on the sapwood face of the specimen. If the through going knot is closer to the edge than the measure (k), the knot is classified as an edge knot. If the knot is visible on the whole edge side, it is classified as an edge knot with the knot measure equal to the thickness of the specimen. Overlapping knots are not taken into account, each knot was measured as a single knot.

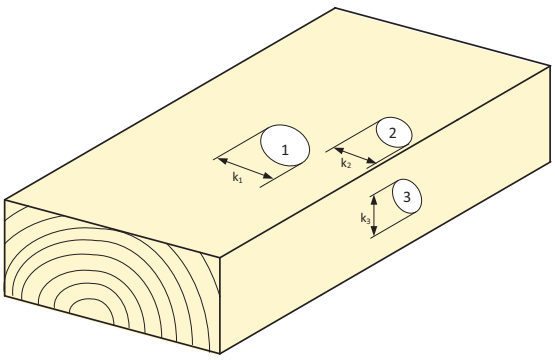

Figure 3. *Principal definition of knot group measurement.*

Knots are counted as knot group if they occur within the same 150 mm specimen length, see Figure 3. The knot measure for a knot group is defined as: the sum of the face knots (on the sapwood face) and the edge knots on both edges.

$$k_g = k_1 + k_2 + k_3 \qquad \text{(Eq. 3)}$$

Slope of grain was measured using a scribe on the sapwood face of the samples and expressed as a ratio between the "fiber deviation/ measurement length".

2.2.2 Density and moisture content

Clear wood density (ρ) was measured on a section of each sample after the bending test according to EN 408 [5]. This means measurement of the dimensions and the weight of the specimen. The test specimen was taken as close as possible to the fracture in clear wood. Clear wood density is defined as:

$$\rho = \frac{m}{V} \qquad \text{(Eq. 4)}$$

where (m) is the mass of the test sample and (V) the volume of the test sample. The volume was measured by Archimedes principle i.e., the mass of water displaced by the specimen.

Moisture content was determined using the oven drying method according to EN 13183 [9], and on the same samples as used for determining density. The moisture content (u) in percent was calculated as:

$$u = \frac{m_1 - m_0}{m_0} \cdot 100 \qquad \text{(Eq. 4)}$$

where (m_1) is the mass of the sample before drying and (m_0) the mass of the sample after oven drying.

2.2.3 Dynamic modulus of elasticity

The dynamic modulus of elasticity was evaluated for each specimen using the first resonance frequency in the axial direction. The measurement of the resonance frequency can be summarized as follows: the specimen was firstly placed on a rubber foam to simulate free-free conditions. An accelerometer was then placed at one of the ends of the specimen and a hammer was used to produce an axial shock wave through the specimen. The time signal from the accelerometer was registered and a Fast Fourier Transform (FFT) was performed. The first resonance frequency, (f_{A-1}) was picked as the first peak in the frequency spectra. The first axial resonance frequency together with the measured length and density of the specimen was then used to calculate the dynamical modulus of elasticity (E_{dyn}) according to [10] using Eq. 2.

$$E_{dyn} = 4 \cdot \rho \cdot L^2 \cdot f_{A-1}^2 \qquad \text{(Eq. 2)}$$

Where (ρ) is the density of the specimen at the measurement time based on volume and weight of the whole board, (L) is the length of the specimen and (f_{A-1}) is the first resonance frequency in the axial direction.

https://doi.org/10.52202/069179-0102

Measurement for E_{dyn} are missing for one series, why this series is omitted in figures presenting (E_{dyn}) below.

2.3 Strength testing according to EN 408

The static bending tests were performed at RISE test laboratory in Borås, accredited as testing laboratory according to EN 408 [5]. According to EN 408 [5] and EN 384 [11] each specimen was tested in edgewise four-point bending. A span length of 18 times the depth (h) of the specimen between the outer supports was used. The inner span length, i.e., the length between the loading points, was $6h$. Local and global modulus of elasticity were measured. The local modulus of elasticity was measured as curvature over a span of $5h$, see Figure 4. The global deflection was also measured giving an alternative value for modulus of elasticity.

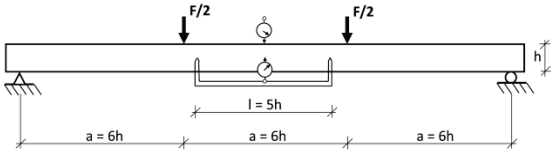

Figure 4. *Four-point bending test including span length and measurement of local and global deflection.*

The critical cross section was, if possible, centred between the loading points. The measured defects were placed randomly in either tension or compression.

The standard log length when harvesting birch in Swedish forest is about three meters. This meant that for the series with specimen depth of 170 and 200 mm it was not possible to use the length of 18 h between the supports. The span length between the outer supports were adjusted to $15h$ for the specimens with depth of 200 mm, and to $16h$ for the specimens with a depth of 170 mm.

2.4 Strength reducing characteristics and machine grading visual override

The regulations for machine strength grading includes a visual override where specimens including some strength reducing characteristics results in the specimens being assigned to a grade with a lower strength class. These characteristics include values for cracks, distortion, wane and rot. In the protocol 25 pieces were recorded as having rot to some extent. Wane was recorded in 46 pieces; where some extended over the limit of 1/3 of the face or edge. Slope of grain above 1/10 was recorded in 20% of the pieces. Other defects were noted in 10% of the protocol entries. No specimens were rejected due to the visual override. The distortion: bow, spring, twist and cup were not measured, and no specimens were rejected for testing because of distortion.

2.5 Evaluation of data

Based on the test results from the bending tests the characteristics local MOE ($E_{m,l}$), global MOE ($E_{m,g}$) and bending strength (f_m) was evaluated as:

$$E_{m,l} = \frac{a l_1^2 (F_2 - F_1)}{16 \frac{bh^3}{12} (w_2 - w_1)} \quad \text{(Eq. 6)}$$

$$E_{m,g} = \frac{3al^2 - 4a^3}{2bh^3 \left(2 \frac{w_2 - w_1}{F_2 - F_1}\right)} \quad \text{(Eq. 7)}$$

$$f_m = \frac{3Fa}{bh^2} \quad \text{(Eq. 8)}$$

where the measures (a) and (l) are defined in Figure 4, ($F_2 - F_1$) is the increment in load between 0.1 max load (F) and 0.4 of the max load (F), and ($w_2 - w_1$) the corresponding deformations either measured locally or globally. The dimensions of the specimen are depth (h) and width (b).

The evaluated data was adjusted for moisture content, depth, and length. Test values for density were adjusted to a moisture content u_{12} = 12%, according to the formula in clause 5.4.2.2 in EN 384 [11], Eq. 9. Test values for modulus of elasticity were adjusted to a moisture content u =12%, according to the formula in clause 5.4.2.3 in EN 384 [11], see Eq. 10.

$$\rho = \rho_u (1 - 0.005(u - u_{12\%})) \quad \text{(Eq. 9)}$$

$$E_0 = E_{0,u} (1 - 0.005(u - u_{12\%})) \quad \text{(Eq. 10)}$$

The measured bending strength for samples with a depth less than 150 mm was adjusted with a (k_h) factor given in EN 384 [11]. The measured bending strength for the two tested dimensions with a span shorter than the stated 18h, for these series the bending strength has been adjusted with factor (k_l) given in EN 384 [11].

$$k_h = min \left\{ \left(\frac{150}{h} \right)^{0.2} \right. \quad \text{(Eq. 9)}$$
$$\left. 1.3 \right\}$$

$$k_l = \left(\frac{48h}{l_{ef}} \right)^{0.2} \quad \text{(Eq. 10)}$$
$$l_{ef} = l + 5a$$

Where (l) is the distance between the two outer support points and (a) is the distance between the two inner loading points.

3 RESULTS

3.1 Knot size distribution

Knot size is the most important parameter for visual grading. Figure 5 shows the knot size distribution on the face side of the specimens. The majority of the knots cover less than 20% of the face side of the specimens.

https://doi.org/10.52202/069179-0102

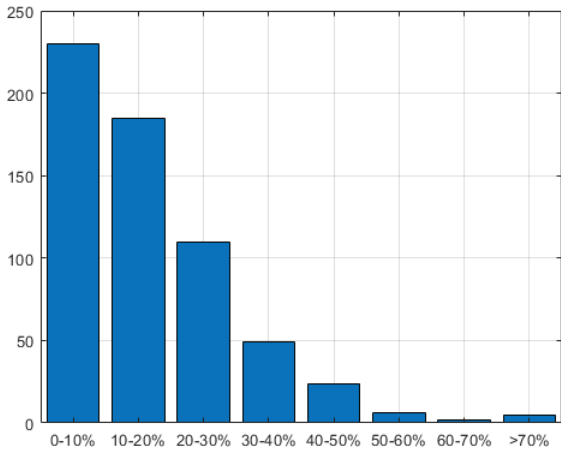

Figure 5. *Histogram of knot size (as percent of the total face) on flat face of the specimens.*

Figure 6 shows the knot size distribution on the edge sides of the specimens. The majority of the knots cover less than 10% of the edge sides of the specimens.

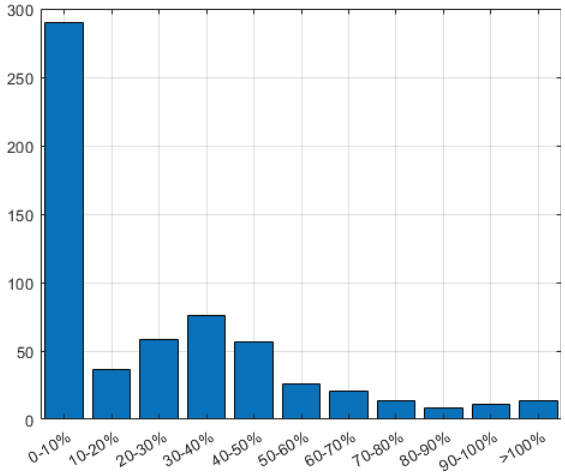

Figure 6. *Histogram of knot size on edge sides (as percent of the total sides) of the specimens.*

3.2 Variation in density, modulus of elasticity and bending strength

The parameters density, stiffness and bending strength are all defined as grade determining properties in strength grading. Figure 7 shows the distribution of density in the 600 specimens.

Figure 8 and Figure 9 show the distribution of local MOE ($E_{m,l}$) and bending strength (f_m), respectively, for all 600 specimens.

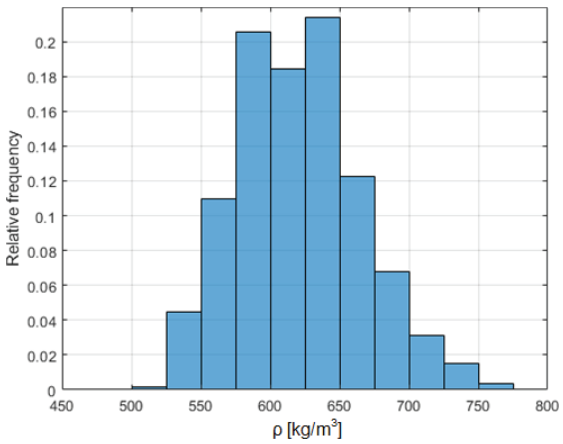

Figure 7. *Histogram for the distribution of density (**ρ**).*

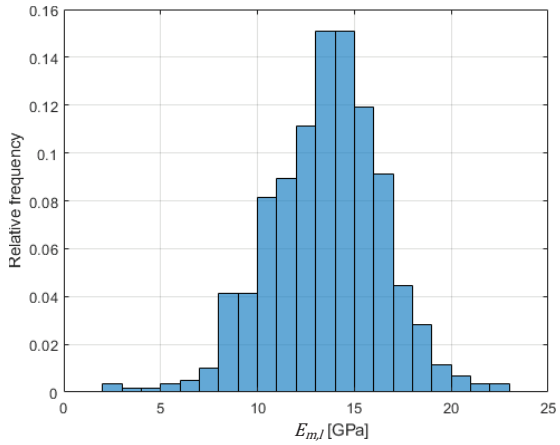

Figure 8. *Histogram for the distribution of local modulus of elasticity MOE (**$E_{m,l}$**).*

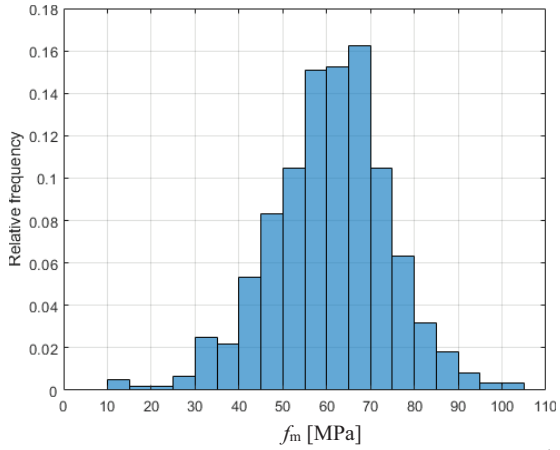

Figure 9. *Histogram for the distribution bending strength (**f_m**).*

The data was evaluated to investigate the mean values for density, modulus of elasticity and bending strength as well as the coefficient of variation (CoV) and the 5% percentile value (characteristic value) according to EN 14358 [12].

https://doi.org/10.52202/069179-0102

The mean value for bending strength shows a value of 60.9 MPa with a value for the characteristic bending strength of 38.6 MPa (5% percentile), see Table 3. The results in Table 3 also shows that the different geographical sources have similar values for both strength and Coefficient of Variation (CoV). The latter indicates that the sampling worked well and that no discrepancy can be found between the subsamples. Splitting the bending strength values between different sizes of samples shows also similar results and the same depth adjustment factor used for softwood in EN 384 [11] works also for birch.

The mean modulus of elasticity for all the samples is 13.6 GPa, when splitting between different geographical sources there is a difference in mean value varying from 12.3 to 14.6 GPa. The mean density is just over 600 kg/m^3 for all samples and varying between 603-638 kg/m^3 when split between the different geographical sources.

3.3 Visual grading

All specimens were assigned to a single grade class (T0–T4) according to INSTA 142 [8], using the requirements for knots on the edge side (k), the flat face (k), knot groups (k_g) and slope of grain as described in Table 4. The number of specimens assigned to each grade class can be found in Table 2.

Table 2. *Number of samples in each assign grade according to requirements in Table 4.*

Grade	N
Reject	21

3.4 Correlation between strength and stiffness

The correlation between stiffness and strength is an important parameter for machine strength grading. Using all the data the correlation between local modulus of elasticity and bending strength is $r^2 = 0.41$, see Figure 10.

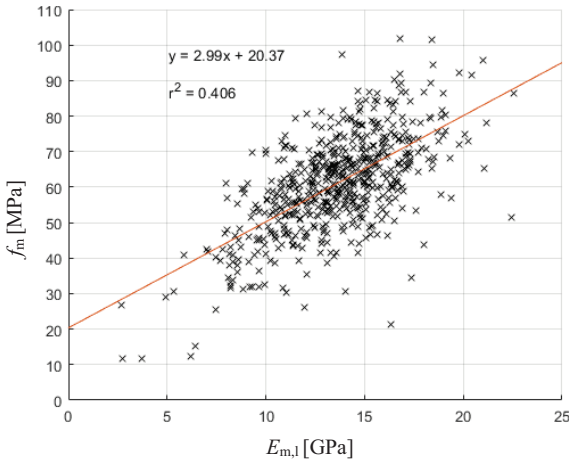

Figure 10. *Correlation between local MOE ($E_{m,l}$) and bending strength (f_m).*

4 ANALYSIS AND DISCUSSION

4.1 Mechanical properties

The mechanical properties for birch from this study can be compared to data from other studies, see Table 6. The results show that the values are similar to values obtained in Norway [13] but higher than for studies performed in Austria [14] or the UK [15] for full size timber members with defects. Note that the Norwegian and Austrian values are obtained from tensile tests.

The values are also much higher than for the normally used Norway spruce, see Table 5. The bending strength for Norway spruce from the Nordic countries are normally just over 40 MPa, with a mean MOE of about 11.5 GPa and a mean density much lower than measured for the birch in this study.

4.1 Strength and stiffness of Birch timber from the Nordic countries compared to strength classes

Sawn timber is, in Europe, normally graded into different strength classes according to EN 338 [18]. The grading is done based on the characteristic value for bending strength, mean value for modulus of elasticity and characteristic value for density, see Table 6. Values for the characteristic bending strength (f_m), mean modulus of elasticity ($E_{m,l}$) and characteristic density (ρ) for some C-classes according to EN 338 [18].

Table 1Hardwood species can be graded into D-classes and softwood species into C-classes. The D-classes are designed for denser species like oak, ash and beech. The D-classes are rarely used in the Swedish building industry; therefore, we aim for grading birch into C-classes in this paper.

The results presented in Table 3. Compiled mean value, coefficient of variation and 5% percentile (characteristic value) for bending strength (f_m), local modulus of elasticity ($E_{m,l}$) and density (ρ) for all specimens and divided for geographical source and for specimen size. show that the ungraded birch with the sampled distribution reaches the characteristic values for strength class C35. The grade determining factor that limits the strength grade is the mean modulus of elasticity of the material. The mean value of the modulus of elasticity is 13.6 GPa, which makes it possible to grade the material into C35 but not in a higher grade. The characteristic bending strength is 38.6 MPa which is also clearly in the C35 class. The mean density of 620 kg/m^3 and the characteristic density value of 551 kg/m^3 implies that the birch sample used in this study has a density much higher than required for grade C35.

Table 6. *Values for the characteristic bending strength (f_m), mean modulus of elasticity ($E_{m,l}$) and characteristic density (ρ) for some C-classes according to EN 338* [18].

Grade	f_m [MPa]	$E_{m,l}$ [GPa]	ρ[kg/m^3]
C14	14	7.0	290
C24	24	11.0	350
C30	30	12.0	380
C35	35	13.0	390
C40	40	14.0	400
C45	45	15.0	410

4.2 Strength grading of birch

Two methods for strength grading of sawn timber from birch grown in Sweden were performed in this study:

- Visual grading,
- Machine strength grading.

4.2.1 Visual grading

For visual grading the regulations in INSTA 142 [8] were used. The grading of the material was based on comparing the characteristic bending strength, mean modulus of elasticity and the characteristic density for each T group with the values for the C classes, c.f. Table 6. This gave a result as in **Fel! Hittar inte referenskälla.**, for the different T-classes. No verification has been done for the subsamples, neither has the k_n factor been used.

Table 7. *Yield percentage and C-class for each visually graded T-class.*

Grade	Class	Percent yield
Reject	R	4%
T0	C24	8%
T1	C30	12%
T2	C35	31%
T3	C40	35%

As the material has these natural properties the possibility to use simpler combinations were investigated. The first version was to combine T0 and T1 to one class and T2 and

T3 to one class. This yielded in 66% of the total sample could be assigned into strength class C40, see Table 8.

Table 8. *Yield percentage and C-class for each combination of visually graded T-class.*

Grade	Class	Percent yield
Reject	R	4%
T0 + T1	C30	30%
T2 + T3	C40	66%

The simplest combination is to grade all sawn timber in only T0 and better and reject. That yielded that all material that was not rejected could be assigned to C35, see Table 9. The limiting factor is in most cases the mean modulus of elasticity.

Table 9. *Yield percentage and C-class using only the combination T0 and better.*

Grade	Class	Percent yield
Reject	R	4%
T0 and better	C35	96%

When these thresholds are used for softwood the visually graded material in class T0 are assigned to grade C14 and material in class T2 are assigned to class C24 according to EN 1912 [19].

4.2.1 Machine strength grading

The most common method of machine grading softwood in Sweden is by using the dynamic modulus of elasticity as an indicating property. In the following figures the scatterplots for E_{dyn} versus f_m and E_{dyn} versus $E_{m,l}$ are shown.

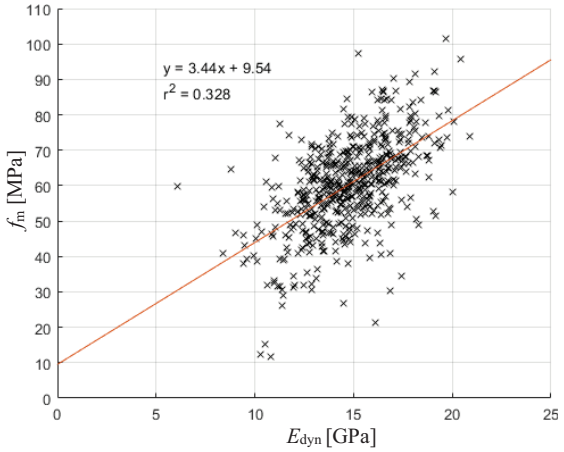

Figure 11. *Bending strength ($\boldsymbol{f_m}$) versus dynamic modulus of elasticity ($\boldsymbol{E_{dyn}}$).*

The relationship r^2 between the mechanical parameters are not as good for birch, as for softwood, see Table 10, [17], [18].

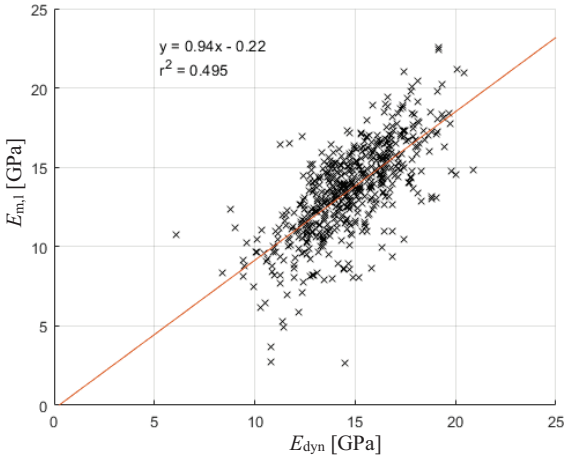

Figure 12. *Local modulus of elasticity ($\boldsymbol{E_{m,l}}$) from the static tests versus dynamic modulus of elasticity ($\boldsymbol{E_{dyn}}$).*

Table 10. *Coefficient of determination, r^2, between $\boldsymbol{E_{dyn}}$ and $\boldsymbol{f_m}$ and between $\boldsymbol{E_{dyn}}$ and $\boldsymbol{E_{m,g}}$ in this study and two studies for spruce, and $\boldsymbol{E_{dyn}}$ and $\boldsymbol{E_{m,l}}$ for birch.*

Species	E_{dyn} v. f_m	E_{dyn}v. $E_{m,g}$	E_{dyn}v. $E_{m,l}$
Birch	0.33	0.73	0.50
Spruce [17]	0.54	0.83	-
Spruce [16]	0.53	0.84	-

For simulating machine strength grading the measured dynamic modulus of elasticity was used as indicative property (IP). Using threshold values for the dynamic modulus of elasticity it was possible to assign 55% of the samples to class C45 and 35% of the samples to assign 35% to class C30. The values for characteristic bending strength and characteristic density were checked so that they fulfilled the requirements for the assigned strength class, c.f. Table 6. The threshold values presented in Table 11 were determined so that the pieces assigned to the grade fulfil the requirement of characteristic strength, characteristic density and mean MOE. No subsample control has been done, neither has the k_n factor been used.

Table 11. *Threshold values for IP ($\boldsymbol{E_{dyn}}$), strength class and percent yield for each class.*

Threshold IP	Class	Percent yield
Reject	R	10%
> 12.0 GPa	C30	35%
> 14.5 GPa	C45	55%

https://doi.org/10.52202/069179-0102

5 CONCLUSIONS

This study shows that the unsorted birch material has a higher mean bending strength, MOE and density than the softwood species used in the Swedish industry today. Studies show that mixed stands of Spruce and Birch give a higher volume growth than spruce monocultures, that is the most common silvicultural choice today.

The findings of this study show that it would be possible to strength grade birch from Sweden by using the existing set of rules from INSTA 142. This study also shows that by the means of using frequency and density measurements for indicating properties, machine strength grading would be possible. Both methods would possibly give good yields in high strength classes, for material of the same distribution as the sampled material. A combination of using both machine grading and visual grading could in some strength class combinations be favourable.

The possibility to strength grade sawn timber of birch is important for the possibility of utilizing also other hard woods grown in Sweden. This is a potential in the Swedish forest that at the moment is not possible to utilise as structural timber. This will increase both the utilisation of existing material in the Swedish forests in products with a long lifetime. This will also improve the possibility for increased biodiversity in the forest by increasing the value of the hardwoods and therefore give the forest owners incentive for also growing hardwood species.

The 600 pieces from this test will together with 120 pieces from Norway be a good foundation for publishing a new grading regulation for birch wood grown in Sweden and Norway.

FIBRE-OPTIC MEASUREMENTS FOR MONITORING ADHESIVELY BONDED TIMBER-CONCRETE COMPOSITE BEAMS

Jens Frohnmüller[1], Werner Seim[2], Ann-Charlotte Spangenberg[3]

ABSTRACT: The technology of fibre-optic sensors (FOS) enables the continuous measurement of strains along the fibre axis. This offers the possibility of studying and monitoring the behaviour of the component to which the fibre is connected at any given point. In this paper, the FOS measurement technique is applied aiming to develop a monitoring tool for checking the integrity of the adhesively bonded joint between timber and concrete. Accordingly, tests with adhesively bonded timber-concrete composite beams, which have been loaded up to ultimate failure, are conducted. The measurement results are presented and checked for plausibility with the aid of an finite element model. Subsequently, a calculation model is presented with which the shear stresses in the adhesive joint can be derived directly from the strain measurements. As a result, it can be stated that it has been possible to monitor the integrity of the bonded joint and derive shear stresses directly from the measurement, however, more research is necessary to get an even better understanding of how to analyse and post-process the measurement data.

KEYWORDS: Fibre-optical measurement, Monitoring, Adhesives, Timber-Concrete Composites, Quality control

1 INTRODUCTION

1.1 FIBRE-OPTIC SENSORS – TYPICAL AREAS OF APPLICATION

The technology of fibre-optic sensors (FOS) allows the measurement of strains continuously along the length of the sensor. This offers new and promising possibilities for the testing of structural elements in the laboratory, and especially for the on-site monitoring of load-bearing elements if possible damage can be identified.

The FOS were used, for example, by Schmidt-Thrö et al. [1] and Lemcherreq et al. [2] to investigate the basic behaviour of the fibres in the case of the bond between reinforcement steel and concrete. The optic fibre was glued onto the steel-rod in this case.

A quite extensive report on FOS for use in structural bondlines was reported by Könke et al. [3], who also investigated the use of the technology as a monitoring tool for adhesively bonded timber-concrete composite (ATCC) beams. Könke et al. hereby observed, for example, that cracks in the concrete plate could be detected. Similar observations were documented by Spangenberg [4], who identified knot-holes and air bubbles of the adhesive, which had been used to apply the fibre onto an ATCC specimen, as peak values in the measurement.

In the field of timber structures, a comparable measurement method, so-called Fibre Bragg Grating (FBG), was used by Claus et al. [5] to investigate the force distribution in self-tapping screws in timber. New effects regarding the load distribution in the interface between screw and timber could be seen and the effective embedding length of the screws was considered in more detail, comparing it to Volkersen's theory.

1.2 AIM AND APPROACH

The aim is to investigate how FOS can be used for the monitoring of structural elements, focusing on the adhesive bondline. Firstly, the materials and methods are presented. The results of the measurements for two different test series are then presented. In both cases, the strains in the adhesive joint are measured, and in one case, additionally the strains at the bottom edge of the timber (see exemplarily one of the specimens from test series ATCC-A in Figure 1).

In a next step, the experimental measurement data are validated and checked for plausibility by means of a finite element (FE) model. A calculation model is then presented, with which the shear stresses in the bondline can be determined directly from the measurement.

2 MATERIALS & METHODS

2.1 EXPERIMENTAL PROGRAMME AND TEST SET-UP

The experimental programme covers two types of specimens. The cross-section and the location of the FOS are depicted in Figure 1 (ATCC-A) and Figure 2 (ATCC-B).

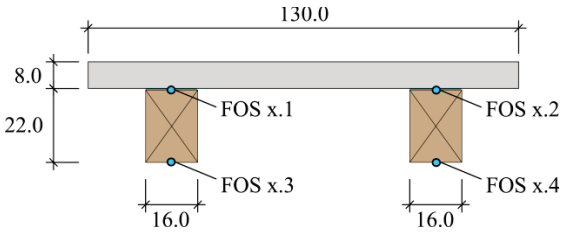

Figure 1: *Geometry and location of FOS for specimens of series ATCC-A*

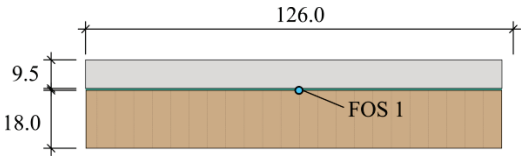

Figure 2: *Geometry and location of the FOS for specimens of series ATCC-B*

Regarding the specimens of the series ATCC-A, the FOS have been placed in the bondline (FOS x.1 and FOS x.2) and on the bottom edge of the timber beam (FOS x.3 and FOS x.4) continuously along its length. Concerning the specimen ATCC-B, one FOS has been installed directly in the bondline. The relevant parameters and decisive differences between the two types are summarised in Table 1.

Table 1: *Experimental programme*

Parameter	Type	
	ATCC-A	ATCC-B
Number of specimens	3	1
Span	6.00 m	7.68 m
Bond arrangement	Continuous (full length)	Discontinuous (strips)
Adhesive	Low viscous epoxy (2EP)	Polymer mortar (2EP)
Timber geometry	Beam	Plate
Timber quality	GL24h	GL28c
Concrete quality	C45/55	C40/50
Number of FOS per specimen	4	1

The bottom surface of the prefabricated concrete parts of ATCC-A has not been further processed after removing the formwork. The bottom surface of the concrete parts of ATCC-B has been sandblasted.

The ATCC specimens were tested in a 4-point bending configuration similar to that by Frohnmüller et al. [6]. The force was measured with a load cell, and the mid-span deflections and the relative displacement between timber and concrete with displacement transducers. The measurement was performed at a sampling rate of 2 Hz. The distance between each measurement point on the sensor length was chosen to be 1.3 mm. This led to approximately 12,000 data points (ATCC-A) and 14,500 data points (ATCC-B) along the span per second.

The strains ε_x could be converted, considering Young's Modulus E_x, into stresses σ_x using Equation 1.

$$\sigma_x = \varepsilon_x \cdot E_x \quad (1)$$

2.2 SPECIMEN MANUFACTURING

The FOS were installed by cutting a small groove at a depth of 5 mm into the timber part, laying the sensors into the groove and filling it up with a low viscosity epoxy adhesive. During hardening, the adhesive was sucked into the timber part at several points due to knot-holes or small cracks. Small air bubbles appeared in these areas, and were then pierced before more adhesive was applied.

The manufacturing process of gluing timber and concrete was different for the two test series.

2.2.1 ATCC-A

The concrete plate was turned on its back and spacers with a thickness of 2 mm were placed on the slab. The timber beams were then placed on top. They had been drilled previously at regular intervals with holes through the height of the beam. After a circumferential sealing of the joint, the adhesive was injected through the holes which were then successively closed utilising beech wood dowels. The bond width was reduced to 75 % of the original width for specimen -02 and to 50 % for specimen -03 for each beam.

2.2.2 ATCC-B

The polymer mortar for the second type was applied on the timber part with a mortar sledge, into which a toothed spatula had been installed. The prefabricated concrete plate was then placed on top of the timber plate. No turning of the concrete plate was necessary.

3 TEST RESULTS

3.1 ATCC-A

The global failure occurred in all three cases as a bending failure in the timber beam at a load level of $F_{u,exp}$ = 109 kN (ATCC-A-01), $F_{u,exp}$ = 153 kN (ATCC-A-02) and $F_{u,exp}$ = 165 kN (ATCC-A-03), whereby $F_{u,exp}$ is the load applied by the actuator. Additionally, the self-weight F_G = 11 kN of the steel structure to transfer the load must be added. The specimen ATCC-A-01 showed the peculiarity that a local bending failure occurred in the outer lamella of one beam of the timber at a load level of $F_{u,exp}$ = 93 kN. Further loading was possible up to global bending failure. The adhesive joint remained intact, with a negligible relative displacement between the timber and the concrete for all specimens.

The results of the FOS measurements along the bond length of all three specimens are shown in Figure 3. The measurement results are all presented for the same load step F_{exp} = 75 kN for reasons of comparability.

https://doi.org/10.52202/069179-0103

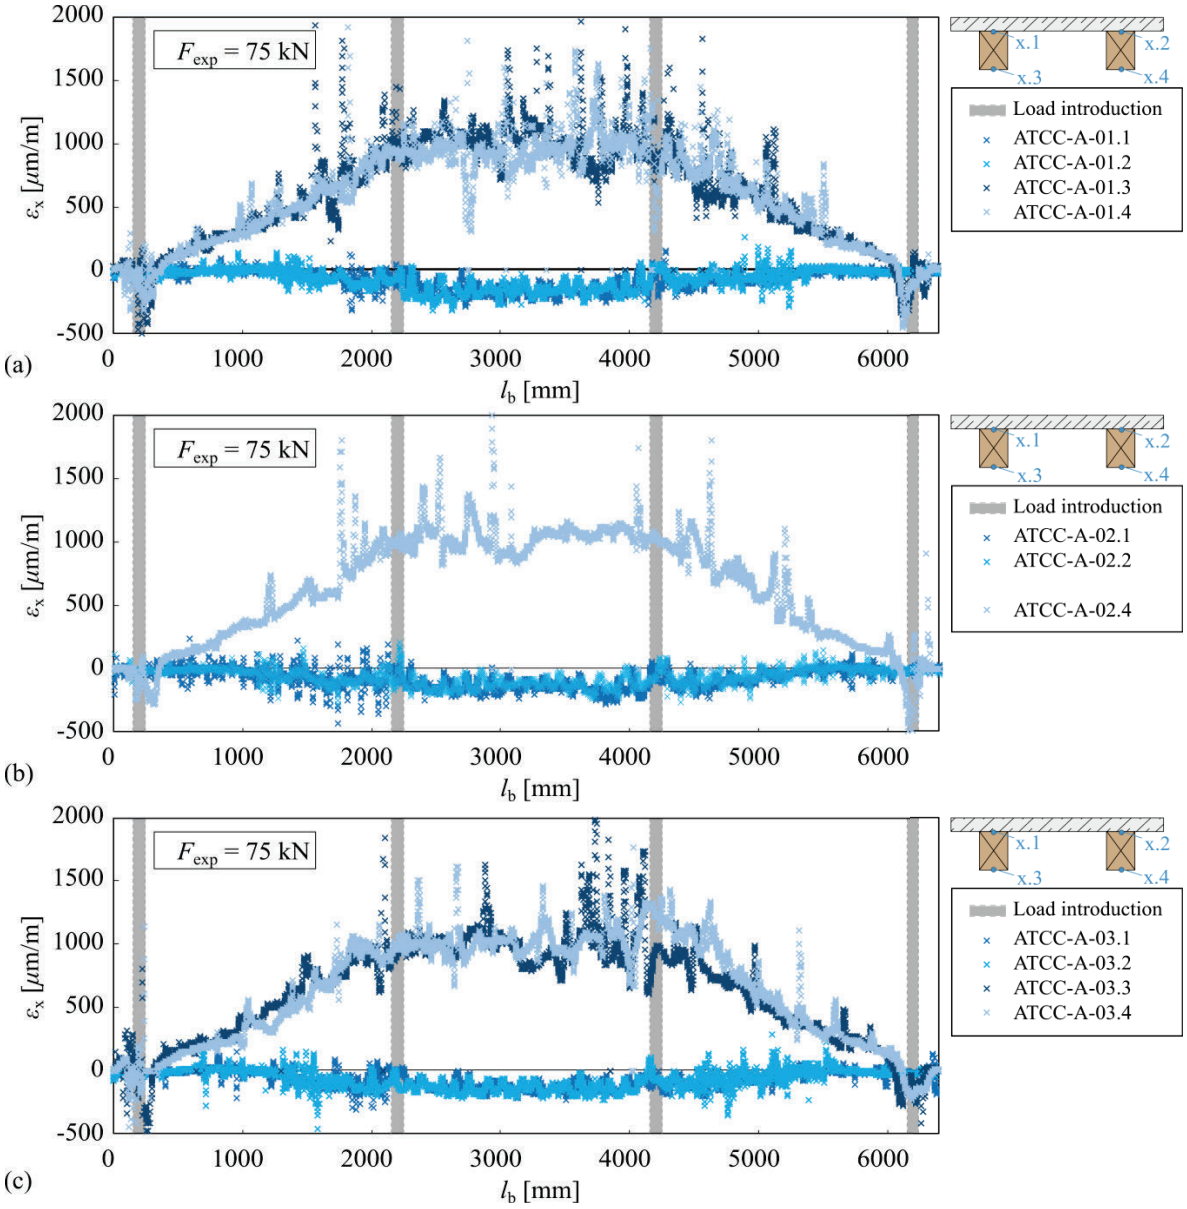

Figure 3: *Results of the fibre-optic measurements – ATCC-A-01 to ATCC-A-03. Strains ε_x along the bond length for the load step F_{exp} = 75 kN (a) ATCC-A-01, (b)B ATCC-A-02 and (c) ATCC-A-03*

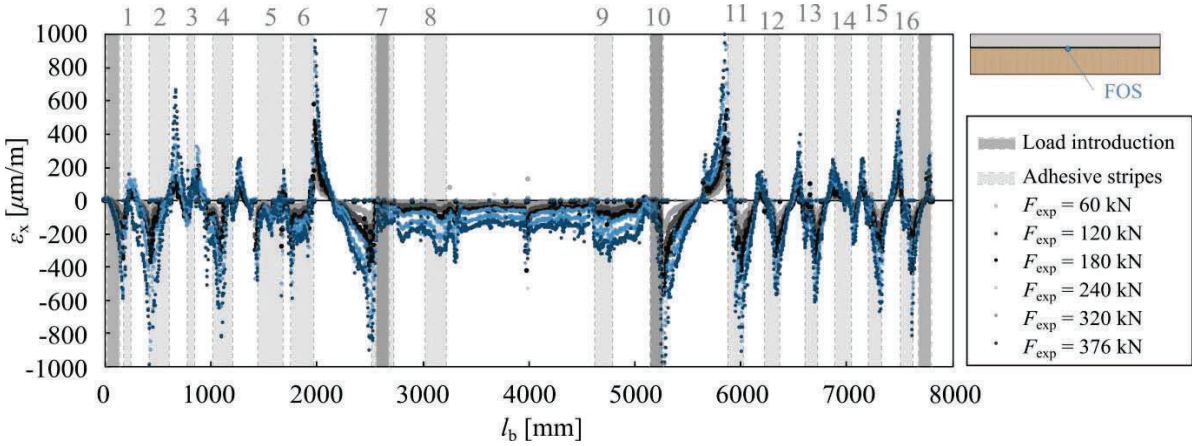

Figure 4: *Results of the fibre-optic measurements – ATCC-B. Strains ε_x along the bond length for the six load steps (The scale in the range of -1000 μm/m to +1000 μm/m is depicted; individual strain values are larger)*

https://doi.org/10.52202/069179-0103

The force from the actuator is F_{exp}, since the measurement was zeroed before the start of the FOS measurement. The steel structure for the load transfer was installed before the start and the zeroing of the measurement. No measurement data is available for the fibre 2.3 in Figure 3b due to a breakage during the installation of the fibre into the testing field.

The large peaks in the measurement (Figure 3) indicate local irregularities in the timber part, such as knot-holes or air bubbles in the adhesive used to glue the fibre into the groove. Smaller deviations are associated with cracks in the concrete, as observed by Könke et al. [3], or knot-holes in the timber, which were in close proximity to the fibre (approximately 10 to 50 mm).

A quasi linear-elastic load-displacement behaviour was observed during all three tests of the series ATCC-A. The same applies to the majority of the FOS measurement data which can be seen in Figure 5, where the normalized strains $\varepsilon_x/\varepsilon_{x,max} < 1.0$ of two different load steps are depicted. The load step $F_{u,exp} = 93$ kN complies with the load step immediately before the failure. However, an irregular behaviour of the strains becomes visible in certain areas.

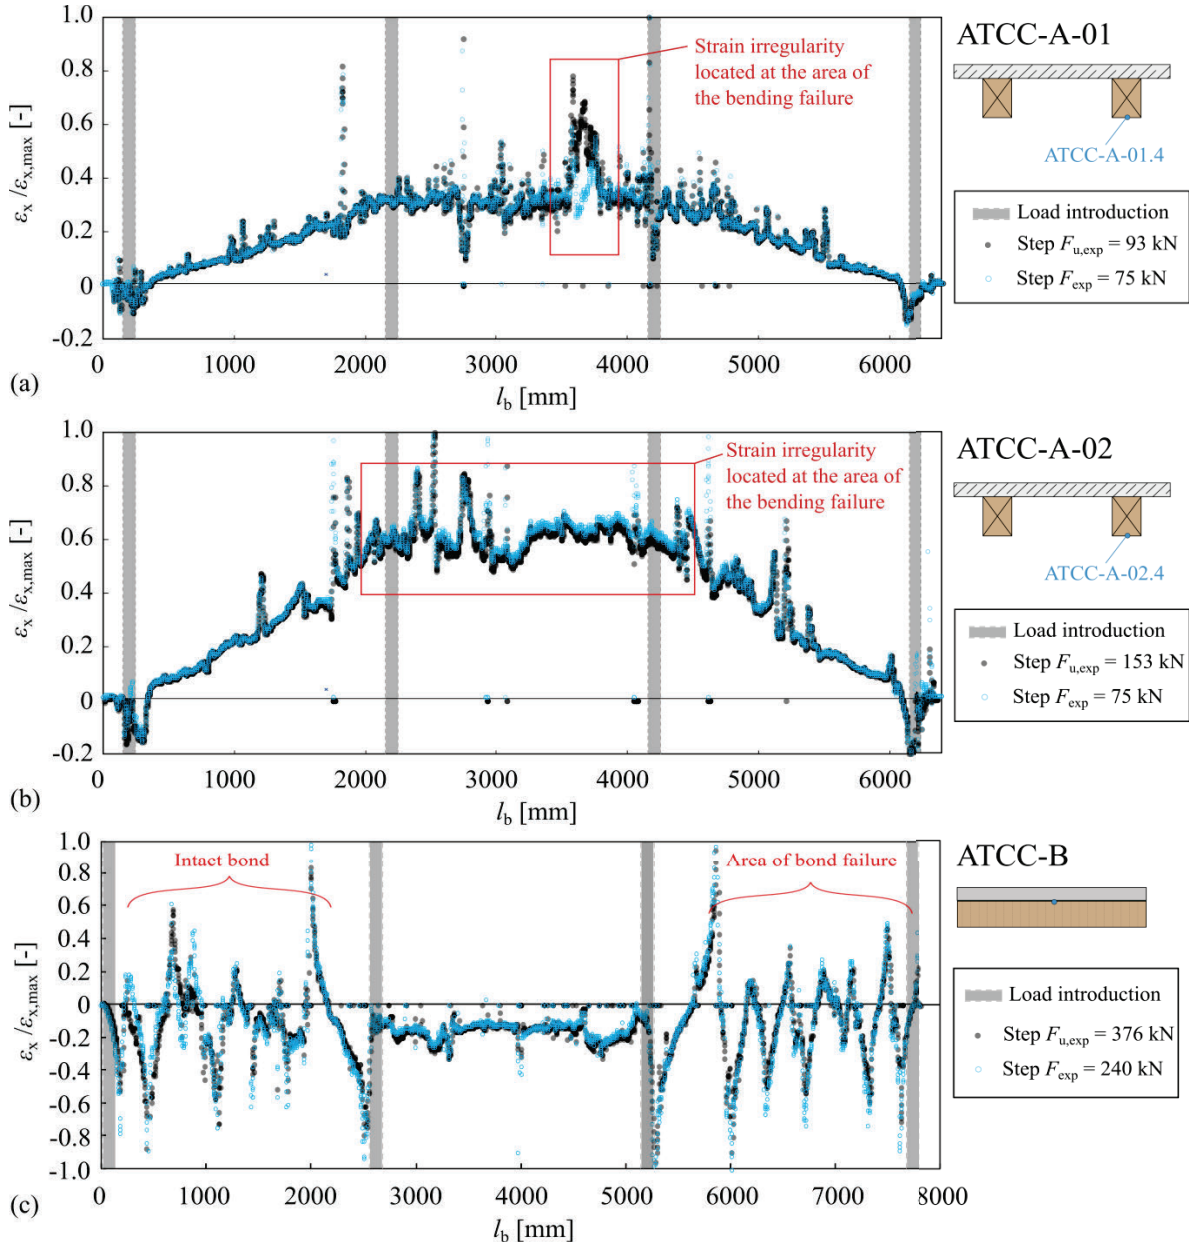

Figure 5: *Comparison of normalised strains $\varepsilon_x/\varepsilon_{x,max}$ for two load steps and (a) ATCC-A-01 (b) ATCC-A-02 and (c) ATCC-B*

https://doi.org/10.52202/069179-0103

The change of the strains of ATCC-A-01.4 happened comparatively suddenly and was concentrated locally on a certain section (Figure 5a). The sensor ATCC-A-03.3 showed a comparable behaviour.

The other sensors, ATCC-A-01.3, ATCC-A-02.4 and ATCC-A-03.4, showed a different behaviour, because the change was not concentrated but distributed mostly in the inner third of the span, where the largest bending stress occurred (Figure 5b). The irregularity in the inner third of the span happened in contrast to the irregularity which was concentrated locally, continuously over time.

3.2 ATCC-B

The failure of the composite beam occurred as expected as a combined bond failure in the timber and the concrete at a load level of $F_{u,exp}$ = 376 kN. The bond failure took place simultaneously at the strips no. 11-16 in the area of l_b = 5.0 …8.0 m and has been characterised purely by a mixed substrate failure in the timber and the concrete and no adhesion or cohesion failure could be documented. Further details of the full-scale test can be found in Frohnmüller et al. [6]. The strains measured are depicted for several load steps in Figure 4. The largest strain gradient in terms of magnitude occurred in the adhesive strip no. 11. The strains generally increased to the same extent as the load steps. Regarding the load-displacement behaviour, a linear elastic behaviour was present. This could also be confirmed for the strains based on Figure 5c, where no explicit irregularities were detected.

4 VALIDATION OF THE MEASUREMENT

4.1 FINITE ELEMENT MODEL

A validation of the strain measurement is possible by means of an FE model. The latter is implemented using the software package ABAQUS and is based on two-dimensional shell elements with a mesh size of a_E = 5.0 mm, which corresponds to about 60 FEs over the height of the component for the test series ATCC-A and 56 for the test series ATCC-B. The model consists of CPS4R elements with four nodes and one integration point in the centre of the element (reduced integration). The path where the strains are evaluated was chosen similar to the location of the FOS. The FE model is depicted exemplarily for one specimen of the type ATCC-A in Figure 6.

Both bending and bond failure occurred in a brittle manner and a linear-elastic load-displacement behaviour could be seen in the tests, therefore, linear-elastic material properties were assigned. Local axes were defined to account for the anisotropy of the timber. This orthotropic material behaviour of the timber is modelled in ABAQUS using parameters as documented in Table 2.

Table 2: *Stiffness properties of timber*

Quality	E_x [N/mm²]	E_z [N/mm²]	ν_{xz} [-]	G_{xz} [N/mm²]
GL24	11.500	510	0.45	650
GL28	12.500	510	0.45	710

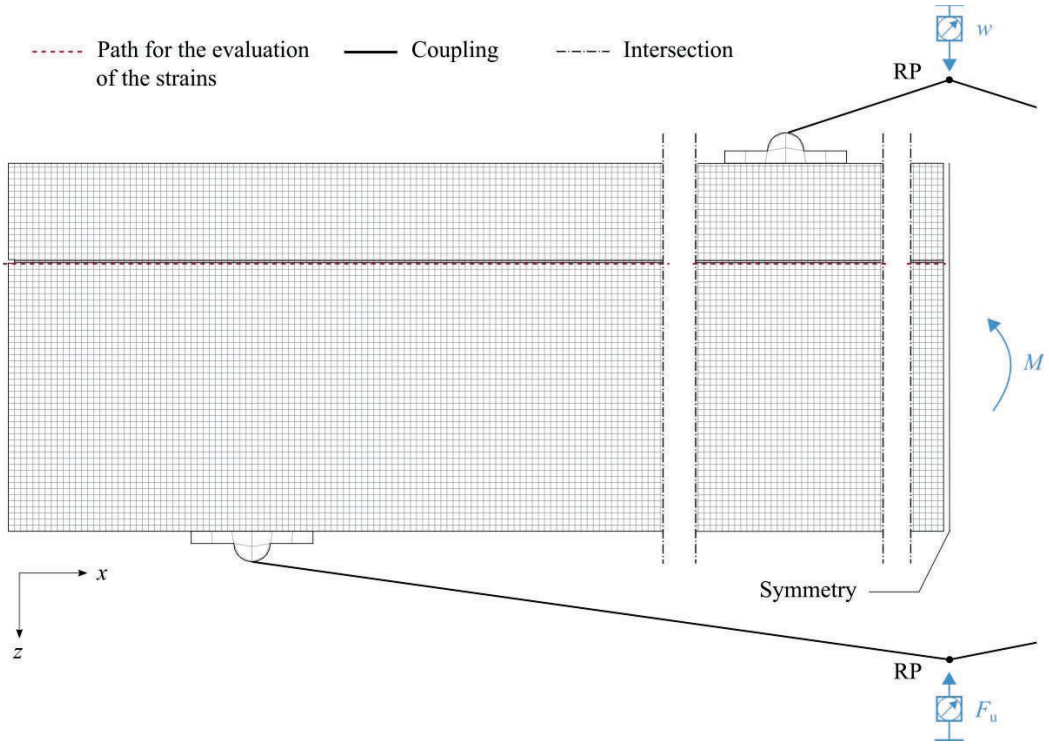

Figure 6: *Finite Element (FE) Model*

https://doi.org/10.52202/069179-0103

The isotropic material properties of concrete and adhesive are summarised in Table 3.

Table 3: *Stiffness properties of concrete and adhesive*

Material	E_x [N/mm²]	ν_{xz} [-]	G_{xz} [N/mm²]
Concrete C40/50	33.000	0.20	13.750
Concrete C45/55	34.500	0.20	14.375
2EP, low viscosity	2.500	0.40	893
Polymer mortar	25.000	0.30	10.500

4.2 COMPARISON OF MEASUREMENT AND FE MODEL

A comparison of the strains between the measurement and the FE model for type ATCC-A is depicted in Figure 7a and Figure 7b exemplarily for both beams of the specimen ATCC-A-03. The results of the FOS are depicted for the ultimate load step $F_{u,exp}$ = 165 kN.

Regarding ATCC-A, the general shape of the measurement data stands in good accordance with the results from the FE calculation. The maximum strains, however, are, in some parts, significantly higher than assumed by the calculation. Some of these peak values may be attributed to air bubbles in the adhesive with

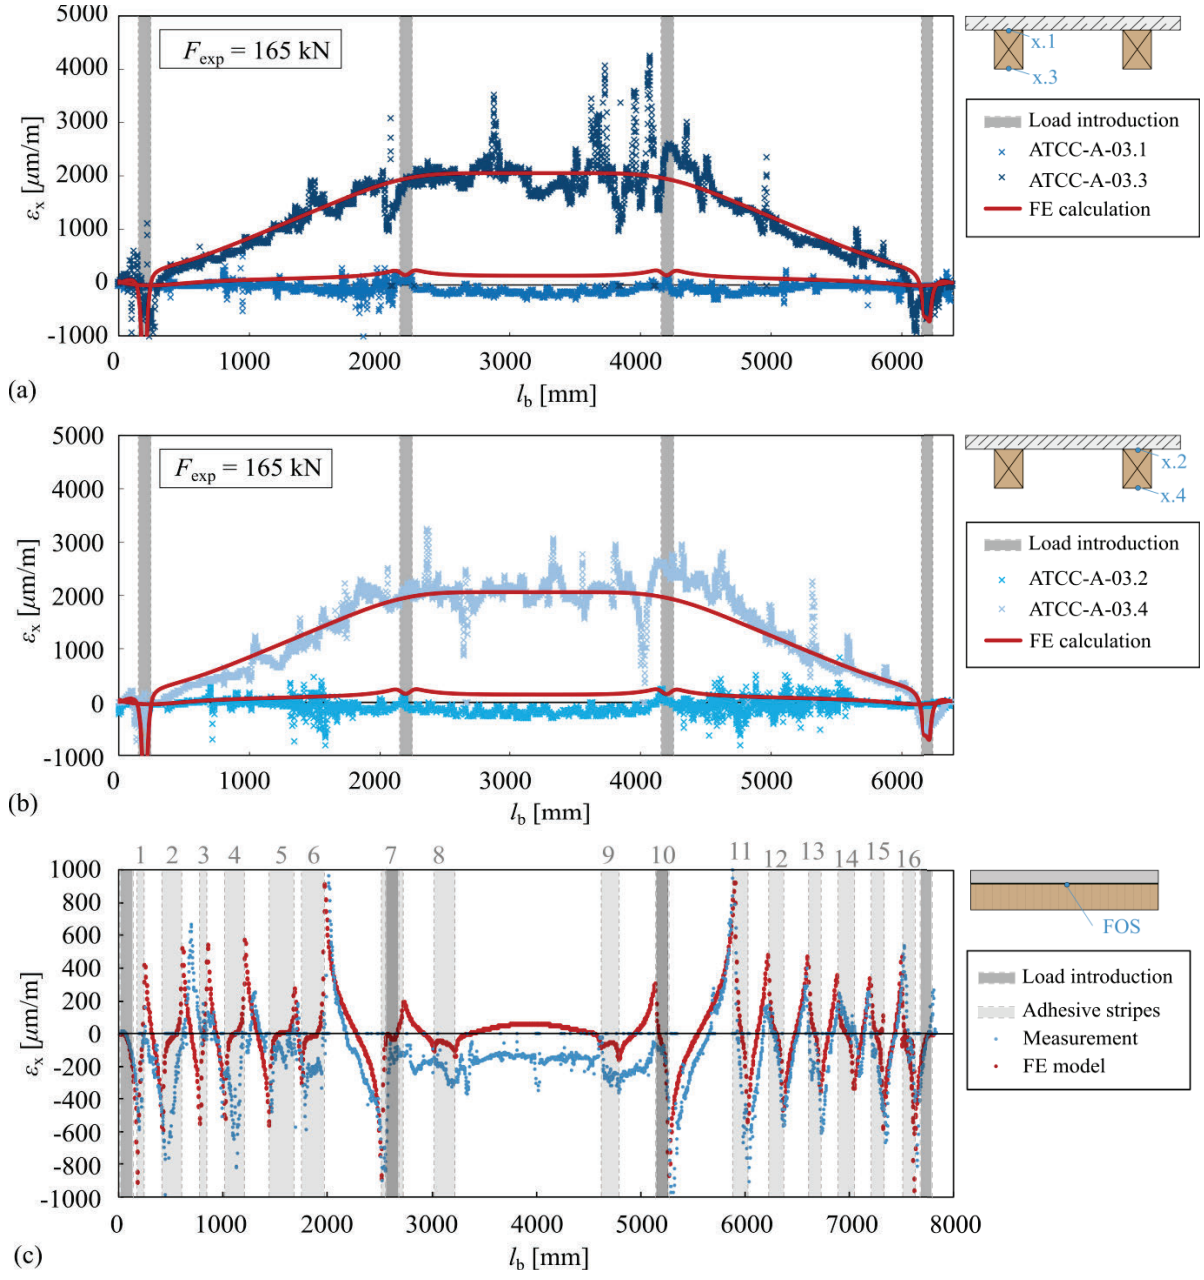

Figure 7: *Strains ε_x – comparison of measurement and FE model for ATCC-A-03*

https://doi.org/10.52202/069179-0103

which the fibre has been glued into the groove or knot-holes in the timber, as noted by Spangenberg [4]. Nevertheless, some strains clearly exceed the calculation.

A comparison of the strains between the measurement and the FE model for the composite of specimen ATCC-B is depicted in Figure 7c. A good accordance in the area of l_b = 5.5 … 8.0 m, where the bond failure occurred, can be seen both in the area of the adhesive strips and between them. It becomes evident that the bond at every strip is active, because otherwise there would no strain gradient.

Certain deviations concerning the beginning and the end of the individual adhesive strip can be seen in the area of l_b = 0 … 2.5 m and, therefore, also in the maximum and minimum values.

It should be noted that the general shape of the data curves in the area between the strips at l_b = 2.5 … 5.5 m are comparable, however, the measurement shows a timber component which is fully under compression, while the FE model indicates that the fibre is more or less located around the neutral axis of the composite beam.

5 SHEAR STRESSES

5.1 DERIVATION FROM MEASUREMENT DATA – PROCEDURE

Regarding the strains measured with FOS, the shear stresses τ_b in the bondline can be calculated directly from the measurement data if the strains have been measured both in the bondline and on the outer edge of the timber beam, resulting in two measurement points per timber beam section, as is the case for test series ATCC-A. The geometric relationships and the step-by-step procedure are shown in Figure 8.

In a first step, the strains measured are converted into stresses using Equation 1. The strains ε_o and ε_u have been averaged for 7 data points, which complies to a length of about 1 cm. The resulting forces in the timber cross-section are then determined by assuming a linear stress distribution over the height of the timber.

$$F_t = \frac{(\sigma_o + \sigma_u)}{2} \cdot A_t \tag{2}$$

The section area A_t is determined considering the height h_t and the width b_t of the timber beam.

$$A_t = h_t \cdot b_t \tag{3}$$

The determination of the force at the right edge of the cut ($F_t + \Delta F_t$) is done in the same way with the stresses at the next measuring point ($\sigma_o + \Delta\sigma_o$) and ($\sigma_u + \Delta\sigma_u$).

$$(F_t + \Delta F_t) = \frac{((\sigma_o + \Delta\sigma_o) + (\sigma_u + \Delta\sigma_u))}{2} \cdot A_t \tag{4}$$

Using the condition of equilibrium of horizontal forces $\sum H = 0$, the shear force in the joint T_b can be determined as:

$$T_b = (F_t + \Delta F_t) - F_t = \Delta F_t \tag{5}$$

The shear stress $\bar{\tau}_b$ derived from the strain can then be calculated by relating T_b to the effective bond area of the surface $A_{\Delta l}$ considered.

When the whole beam width is bonded, the width of the glued joint b_b is equal to the width of the timber beam b_t.

$$\bar{\tau}_b = \frac{T_b}{A_b} \tag{6}$$

with:

$$A_b = b_b \cdot \Delta l \tag{7}$$

The parameter Δl corresponds to the distance between two individual measuring points along the fibre.

The width, the height and the Young's modulus of each timber beam are inserted for the geometrical parameters in Equation 8: b_t = 160 mm, h_t = 220 mm and E_t = 11.500 N/mm². The bond width b_b varies depending on the specimen. For ATCC-A-01, the full width b_b = 160 mm, for ATCC-A-02 the reduced width b_b = 120 mm and for ATCC-A-03 only half of the width b_b = 80 mm is inserted. The length Δl is chosen as Δl = 0.10 m.

5.2 SPECIMENS ATCC-A

The results $\bar{\tau}_b$ of the calculation from section 5.1 are shown exemplarily for the beam 02 of specimen ATCC-A-03 in Figure 9a. The shear stresses $\bar{\tau}_b$ are compared to the shear stresses from the FE calculation. It can be seen that the values of $\bar{\tau}_b$ oscillate around the value of the FE calculation and the maximum and the minimum values differ significantly. A similar behaviour can be

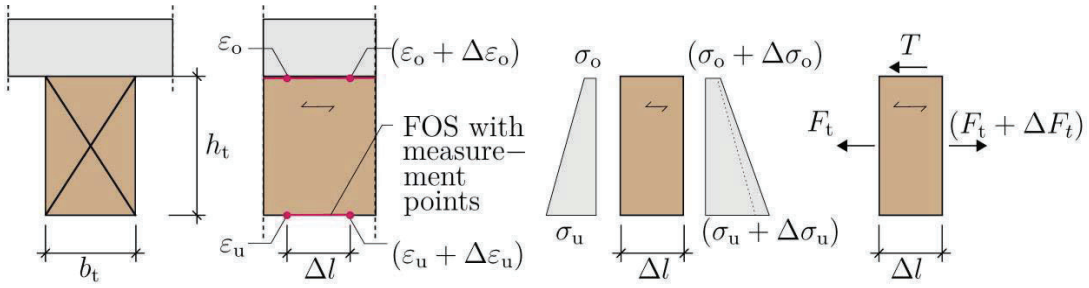

Figure 8: *Model for the derivation of shear stresses*

https://doi.org/10.52202/069179-0103

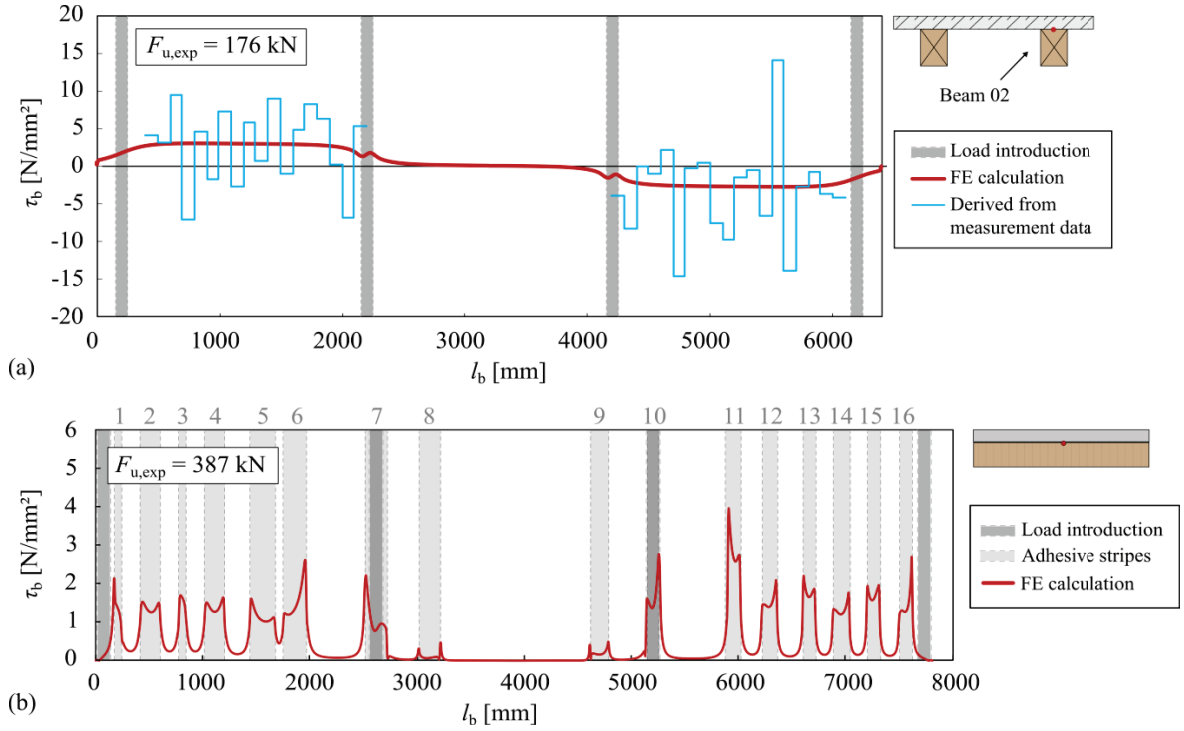

Figure 9: *(a) ATCC-A-03, beam 02: Shear stresses from FE calculation compared to shear stresses derived from measurement data for Δl = 0.10 m, beam 02*
(b) ATCC-B: Shear stresses from the FE calculation

observed for the specimens ATCC-A-01 and ATCC-A-02. At this point, it is important to point out again that these shear stresses are not ultimate shear stresses, since a bending failure in the timber has occurred in the tests and not a bond failure.

5.3 SPECIMEN ATCC-B

Only the shear stresses from the FE calculation for the specimen ATCC-B are shown in Figure 9b, with the maximum shear stress of $\tau_{b,max}$ = 4.0 N/mm² in strip 11. The procedure from section 5.1 cannot be applied there because the derivation of $\bar{\tau}_b$ requires two sensors for each timber beam.

6 CONCLUSIONS & OUTLOOK

The topic of monitoring ATCC components can be subdivided into the question of the control of the bond and the prediction of failure.

In this study, a successful adhesion could be observed by comparing the experimentally determined strains from the measurement with the values from an FE calculation. This applies both for the strains in the actual bondline, since a missing bond would be recognisable from the strain gradient, and the strains in the tension zone, which would have to be significantly greater in the case of a missing bond due to the missing composite action.
The shear transfer could further be visualised for a discontinuous bond arrangement, as is the case with the specimen ATCC-B, by means of a large strain gradient.

Regarding the three specimens from the type ATCC-A, a successful adhesion could be shown based on a calculation model, with which shear stresses have been derived directly from the measurement data. This data, however, is influenced strongly by local irregularities, such as cracks and knot-holes, which lead to a rather unsteady strain curve influenced by peaks and high strain gradients in small increments. Although the shear stresses are basically in a reasonable range, it becomes clear that this procedure is not yet fully matured and that further research is necessary. The aim should be to find either a method to determine a more constant and less unsteady strain measurement or a more robust calculation method for direct shear stress derivation. Approaches to the former can be found, for example, in Galkovski et al. [8] who place a significant emphasis on post-processing of the measurement data.

Regarding the possible prediction of a failure, the strains at the failure load were compared with those from load levels that were more distant from failure. On the basis of three specimens, it could be observed that strains behaved irregularly in some sections. Sudden changes could then indicate an imminent failure. Regarding the other two specimens, no irregular development of the strains could be observed. Whether this different behaviour is due to the fact that the corresponding sensor had not been located at the point of failure or if the irregular strain behaviour just coincided with the failure areas requires further research.
Finally, it can be stated that the FOS technology is a significant improvement compared to strain gauges, because the strips are measured continuously and not only locally, hence, a better understanding of the load transfer in the elements can be achieved.

ACKNOWLEDGEMENTS

The experimental campaigns were part of two research projects. The type ATCC-A has been conducted within the project “Adhesively bonded timber-concrete composites – pilot tests on the suitability of a commercially available epoxy resin adhesive” between the University of Kassel and fischerwerke GmbH & Co. KG, Germany. The type ATCC-B has been conducted within the project “Development of a rapid construction method for ATCC floors by means of bonding prefabricated concrete components” between the University of Kassel and BEWO-Betonfertigteile GmbH, Germany. The latter project is supported by the German Federal Ministry of Economics and Technology under the reference code ZF4147005EB9.

The authors would like to thank the research associations which funded and supervised the projects. Moreover, thanks goes to the associated companies Lübbert Warenhandel GmbH und Co. KG, Gebr. Schütt KG and RAMPF Machine Systems GmbH & Co. KG for their support and provision of materials.

ESTIMATION OF MOISTURE DISTRIBUTION IN SAWN TIMBER USING COMPUTED TOMOGRAPHY

Boris Poupet[1], José Couceiro[1], Sara Florisson[2], Lars Hansson[3], Dick Sandberg[1]

ABSTRACT: Most of the physical, mechanical, and esthetic properties of wood products are affected by the drying of sawn timber. A better understanding of moisture transport in wood during kiln drying is necessary to obtain better quality products, shorter drying schedules, lower energy consumption, and a more sustainable process. Four-dimensional X-ray computed tomography (4DCT) (three-dimensional in space and one in time) with image processing techniques can be used to study the moisture content (MC) of sawn timber during kiln drying. The development of the technique is however made difficult by computational complexity and a lack of accurate experimental validation. In this study, a method relying on 4DCT has been developed using state-of-the-art image processing techniques. The method was validated by a regression analysis of the predicted MC against gravimetric measurements for different timber cross sections and different initial MC distributions on a significantly smaller scale than has previously been investigated. It is concluded that the MC can be estimated with an average uncertainty of ±4.8 percentage points on a 10 mm scale. Sawmills could ultimately benefit from a better understanding of wood-water interactions and dry sawn timber more efficiently.

KEYWORDS: four-dimensional, drying, moisture content, elastic-image registration, Norway spruce

1 INTRODUCTION

Wood is a hygroscopic material that attracts and holds water through adsorption from the surrounding environment, but wood-water interactions are still not fully understood [1], Swedish sawmills thus use software based on numerical models dating back to the mid-eighties to determine drying schedules for timber [2]. It has been empirically shown that shorter schedules are possible, reducing energy consumption and time.

X-ray computed tomography is being used in Swedish sawmills to study logs and timber in a non-destructive manner. The investigation of the internal structure of wood by means of tomography started in the mid-eighties with a medical CT scanner with first studies focused on determining the moisture content (MC) through image processing [3]. Since then, several methods have been developed to study the MC distribution with increasing complexity: unidimensional along radial lines [4], two-dimensional by manually deforming tomograms [5] digital image correlation [6], and two-dimensional in time with image registration [7].

However, almost four decades after the first investigations to determine the MC from tomograms, no attempts have been made to expand the idea to four dimensions, i.e., processing volumetric tomographic data repetitively acquired during a certain period. Such a method would be useful to investigate e.g., moisture transport along the fibres, and moisture-induced deformations in the sawn timber. Two-dimensional methods were previously usually validated against a gravimetric reference by averaging the MC determined through CT (predicted MC) of the entire cross-section [8], although this did not allow to assess the reliability of the method on a small scale.

This study contributes to the development of an image processing method to efficiently compute the MC distribution from 4DCT data. The method is validated to quantify its accuracy and precision against a gravimetric reference on a centimetre scale.

2 MATERIALS AND METHODS

2.1 Specimen preparation

Two undried centre-yield planks of Norway spruce (*Picea abies*) were collected in a local sawmill in northern Sweden. One plank, labelled S40, had a green cross-

https://doi.org/10.52202/069179-0104

sectional area of 40×160 mm², and the other, labelled S70, 70×160 mm²; both with a length of approx. 5 m. From each plank, three specimens with a length of 200 mm containing only clear wood were cut, sealed on their exposed cross-sections with a layer of silicone Casco SuperFix+ [Sika, Baar, Switzerland], wrapped in plastic film and stored in a frozen condition to limit uncontrolled drying before the start of the experiments.

2.2 Validation

The MC computation from CT data was studied with different MC distributions achieved in three different ways: (1) with no drying (i.e., in the green condition), (2) by drying at 70°C for 1 h, and (3) by drying at 70°C for 3 h. The silicone on the end grain impeded longitudinal moisture transport to obtain MC distributions like those obtained with industrial kilns. After the treatment, two adjacent clear wood samples with a thickness of 20 mm were cut from each specimen, one labelled "CT" and the other "reference". On the exposed cross section of the reference samples, horizontal and vertical lines were drawn at centimetre intervals to form a regular grid (Figure 1).

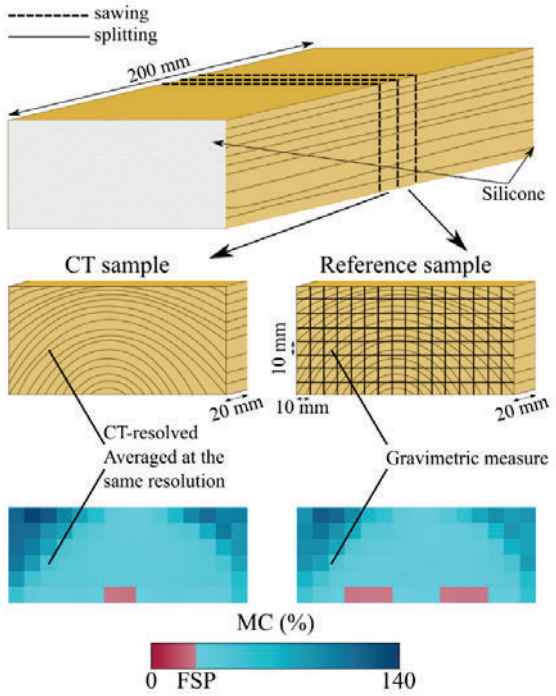

Figure 1: *CT and reference samples prepared after the specimen treatment. The MC distribution of the reference sample was determined gravimetrically by splitting it into test volumes 10 mm×10 mm×20 mm in size. The MC distribution in the CT sample was predicted with the CT method and averaged at the same spatial resolution.*

The CT sample was used to obtain the 2D density distribution ρ_{CT} after drying using a Siemens Somatom Emotion Duo [Siemens, Munich, Germany] CT-scanner at a spatial resolution of 0.98 mm×0.98 mm in the cross-sectional plane and 10 mm lengthwise. The masses after treatment of both CT and reference samples were acquired with a precision balance Ohaus AX523 [Ohaus, Parsippany, USA]. The reference samples were split with a knife along the grid lines into test volumes 10 mm×10 mm×20 mm in size and their initial masses were determined with the precision balance. The samples were oven-dried at 103±2°C (CEN 2002) and reweighed. The CT sample was rescanned with the same settings to evaluate its oven-dry density distribution $\rho_{0,CT}$.

In the reference samples, the gravimetric MC of the jth test volume (w_g^j) was computed using Equation (1):

$$w_g^j = \frac{m_i^j - m_0^j}{m_0^j} \quad (1)$$

where m_i^j is the initial mass of the jth test volume and m_0^j its oven-dry mass. Together, the measures w_g^j form the MC distribution w_g of the reference sample. The MC of the CT sample w_{CT} was predicted on the voxel scale using the method described in 1.3. For comparison with the reference MC distribution, the predicted MC was averaged in test volumes of 10 mm×10 mm×10 mm as w_{CT}^j.

Although these experiments use the 4DCT method to provide the first validation of the method, it was performed in 2D to simplify the process. It was observed in preliminary tests that the cross-sectional directions of the wood are the most troublesome to register. The gravimetric method to which the predicted MC is validated is very time-consuming, it would not be practical to repeatedly implement it for many CT/reference sample pairs contained in the same specimen.

2.3 Image processing

The image processing method was intended for use with 4DCT data, but it is applicable in fewer dimensions. Regardless of the dimensions, data reconstructed by the CT scanner are stacked as a density field in NRRD format. Processing this density data for MC computation involves three steps: image registration, density correction, and MC calculation.

2.3.1 Image registration

To compute the change in MC during drying, the density fields $\rho(\mathbf{X},t)$ at different times (t) must be compared to the oven-dry density field $\rho_0(\mathbf{x})$, where $\mathbf{X} = (X,Y,Z)$ are the material coordinates and $\mathbf{x} = (x,y,z)$ are the spatial coordinates as shown in Figure 2. This operation is made difficult by the anisotropic deformations that sawn timber undergoes while drying, which introduce misalignments between the tomograms. To solve this problem, state-of-the-art elastic image registration based on B-splines was used [9]. This technique computes a coordinate transformation from the material to the spatial coordinates $\mathbf{x} = \mathbf{T}(\mathbf{X},t)$ so that the registered densities $\rho(\mathbf{x},t)$ are spatially aligned with $\rho_0(\mathbf{x})$, as illustrated in Figure 2. The registration is performed in the image-analysis software *3Dslicer* using the *Sequence Registration* module

specially dedicated to 4D registration based on the *Elastix* toolbox [9]. With the different input data tested, the algorithm always converged to a solution as long as the deformations were continuous, i.e., provided that no cracks or material losses occurred.

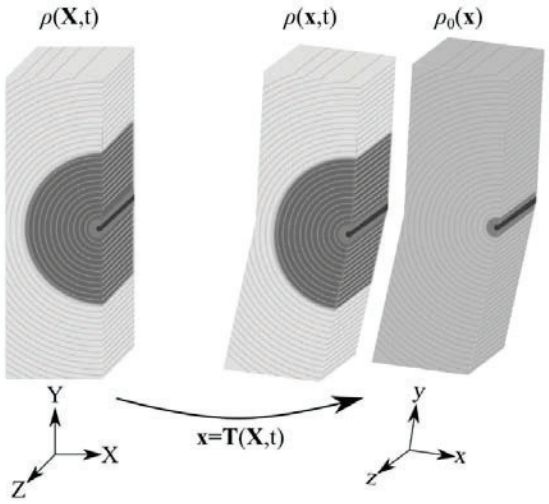

Figure 2: *Lagrangian description of the displacement experienced by a wood volume from an undeformed configuration* $\boldsymbol{\rho(X,t)}$ *to a deformed configuration (oven-dry)* $\boldsymbol{\rho_0(x)}$*. By applying the transformation* $\mathbf{T}(\mathbf{X},t)$*, the volumes become spatially aligned (shifted in the illustration by a rigid-body displacement for visualisation purposes).*

2.3.2 Density correction

The registered densities $\rho(\mathbf{x},t)$ must be interpolated and recalculated. The transformation performed by the image registration allocates the registered densities to non-voxel positions, and interpolation is necessary to assign a single density value to each voxel position. Since the image registration deforms the wood volume, the densities must be recalculated to compensate for the local volumetric strains defined by Equation (2).

$$\varepsilon_V(\mathbf{x},t) = \frac{V_0(\mathbf{x}) - V(\mathbf{X},t)}{V_0(\mathbf{x})} \tag{2}$$

Where $V(\mathbf{X},t)$ is the voxel volume in the undeformed configuration and $V_0(\mathbf{x})$ is its equivalent in the deformed configuration.

Density interpolation and rescaling were performed simultaneously with an algorithm developed by Hansson and Fjellner [10] and based on polygon clipping. The volumetric strain was decomposed as the sum of the elementary strains $\varepsilon_V = \Sigma\varepsilon_j$ computed in the regions enclosed by the undeformed grid. The rescaled densities $\rho'(\mathbf{x},t)$ were computed as shown in Figure 3 using Matlab® [MathWorks, Natick, USA].

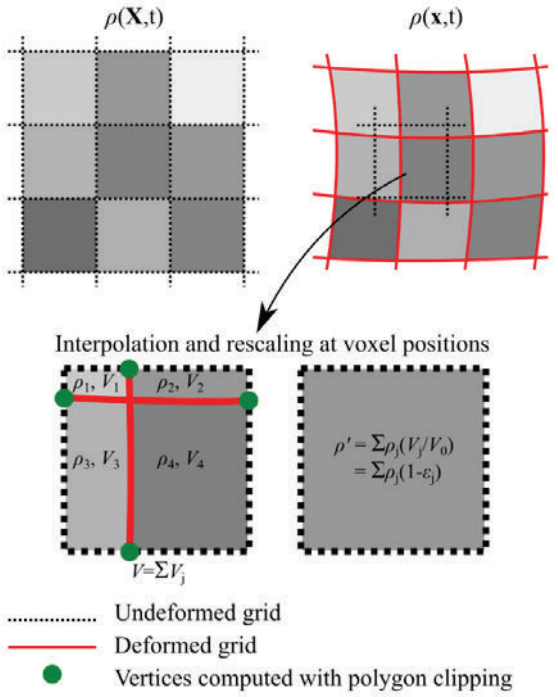

Figure 3: *Density correction. The volumes* V_j *are computed by obtaining the vertex coordinates via polygon clipping. The rescaled density is the sum of the densities weighted by their respective volumetric changes. The illustration is limited to 2D for visualization purposes.*

2.3.3 Moisture content calculation

The MC was computed using Matlab® at the voxel level from the spatial coordinates in Equation (3):

$$w(\mathbf{x},t) = \frac{\rho'(\mathbf{x},t) - \rho_0(\mathbf{x})}{\rho_0(\mathbf{x})} \tag{3}$$

2.4 Uncertainties of measurement and errors

Differences between the gravimetric (w_g) and predicted (w_{CT}) MC distributions were studied with respect to measurement limitations and errors to estimate the uncertainty of the method.

The uncertainty of the gravimetric method u_g^j was estimated in Equation (4) for each test volume as the combined uncertainty of measurement due to the scale precision u_s^j and uncertainty due to the ongoing drying of the reference samples while being splitted (u_d).

$$u_g^j = \sqrt{\left(u_s^j\right)^2 + {u_d}^2} \tag{4}$$

The precision of the balance is given by the manufacturer as $\Delta m = \pm 10^{-6}$ kg. The uncertainty u_s^j is computed in Equation (5) as the total differential of w_g^j defined in Equation (1).

https://doi.org/10.52202/069179-0104

$$u_{\mathrm{s}}^{\mathrm{j}} = \frac{\Delta m}{m_0^{\mathrm{j}}}\left(2 + w_{\mathrm{g}}^{\mathrm{j}}\right) \tag{5}$$

The uncertainty u_{d} is estimated for each reference sample in Equation (6):

$$u_{\mathrm{d}} = w_{\mu}\left(m_{\mathrm{i}}, \Sigma m_0^{\mathrm{j}}\right) - w_{\mu}\left(\Sigma m_{\mathrm{i}}^{\mathrm{j}}, \Sigma m_0^{\mathrm{j}}\right) \tag{6}$$

where $w_{\mu}\left(m_{\mathrm{i}}, \Sigma m_0^{\mathrm{j}}\right)$ is the average MC of the reference sample with initial mass m_{i}, and $w_{\mu}\left(\Sigma m_{\mathrm{i}}^{\mathrm{j}}, \Sigma m_0^{\mathrm{j}}\right)$ its average MC based on the initial mass $\Sigma m_{\mathrm{i}}^{\mathrm{j}}$, i.e., the sum of the initial masses of the test volumes. In both situations, the oven-dry mass was assumed to be Σm_0^{j}, i.e., the sum of the oven-dry masses of each test volume, as the oven-dry masses of the reference samples could not be measured before the splitting.

The uncertainty of the predicted MC ($u_{\mathrm{CT}}^{\mathrm{j}}$) is estimated for each test volume from Equation (7) as the combined uncertainty due to the density measurement of the CT-scanner u_{ρ}^{j} and the errors associated with the image processing steps $u_{\mathrm{im}}^{\mathrm{j}}$:

$$u_{\mathrm{CT}}^{\mathrm{j}} = \sqrt{\left(u_{\rho}^{\mathrm{j}}\right)^2 + \left(u_{\mathrm{im}}^{\mathrm{j}}\right)^2} \tag{7}$$

The precision of density measurement by the CT scanner was taken to be $\Delta\rho_{\mathrm{CT}} = \pm 4$ kg/m³. This value corresponds to the scatter of the density distribution measured for a 1 cm³ volume of a water phantom at thermal equilibrium with a 95% confidence interval.

This uncertainty was propagated by computing the total differential of w_{CT} and estimated for each voxel in Equation (8):

$$u_{\rho} = \frac{\Delta\rho_{\mathrm{CT}}}{\rho_{0,\mathrm{CT}}}\left(2 + w_{\mathrm{CT}}\right) \tag{8}$$

This uncertainty was sufficiently uniform in the capillary and bound water dominated regions to justify averaging the values according to Equation (9):

$$u_{\rho}^{\mathrm{j}} = \begin{cases} u_{\rho,\mathrm{c}}\,, w_{\mathrm{CT}}^{\mathrm{j}} > 0.6 \\ u_{\rho,\mathrm{b}}\,, w_{\mathrm{CT}}^{\mathrm{j}} \leq 0.6 \end{cases} \tag{9}$$

where $u_{\rho,\mathrm{c}}$ and $u_{\rho,\mathrm{b}}$ are the average uncertainties of the capillary and bound water dominated regions respectively.

The uncertainty $\Delta_{\mathrm{z}} w$ accounts for the differences in MC between the CT and reference samples, i.e., the lengthwise gradients of MC, as:

$$\Delta_{\mathrm{z}} w = w_{\mu,\mathrm{CT}} - w_{\mu,\mathrm{r}} \tag{10}$$

where $w_{\mu,\mathrm{CT}}$ and $w_{\mu,\mathrm{r}}$ are the average gravimetric MCs of the CT and reference samples respectively.

The absolute difference between the predicted MC and the gravimetric MC is interpreted as being the combined uncertainty due to the gravimetric method, the CT method, and experimental limitations:

$$\left|w_{\mathrm{g}} - w_{\mathrm{CT}}\right| = \sqrt{{u_{\mathrm{g}}}^2 + {u_{\mathrm{CT}}}^2 + \left(\Delta_{\mathrm{z}}^{\mathrm{j}} w\right)^2} \tag{11}$$

The uncertainty $u_{\mathrm{im}}^{\mathrm{j}}$ corresponding to the errors due to the image processing was not directly estimated in this study but was instead indirectly evaluated in Equation (12) by comparing the observed difference between the CT and reference MC distributions and the previously evaluated uncertainties.

$$u_{\mathrm{im}}^{\mathrm{j}} = \sqrt{\left(w_{\mathrm{g}}^{\mathrm{j}} - w_{\mathrm{CT}}^{\mathrm{j}}\right)^2 - \left(u_{\rho}^{\mathrm{j}}\right)^2 - \left(u_{\mathrm{g}}^{\mathrm{j}}\right)^2 - \left(\Delta_{\mathrm{z}} w\right)^2} \tag{12}$$

Lindgren et al. [3] determined experimentally a maximal deviation of 2 pixels when performing a non-linear transformation for a wood sample between an equilibrium MC state and a state after soaking the sample in water. These authors related this spatial mismatch to an additional density uncertainty $\Delta\rho_{\mathrm{im}} = \pm 6$ kg/m³, which is higher by a factor of 1.5 than the uncertainty due to the CT-scanner. Under this assumption, a threshold was set to evaluate whether the image registration introduced a spatial mismatch (s^{j}) greater or less than 2 pixels:

$$s^{\mathrm{j}} = \begin{cases} \leq 2 \text{ pixels} & \text{if } u_{\mathrm{im}}^{\mathrm{j}} \leq 1.5 u_{\rho}^{\mathrm{j}} \\ > 2 \text{ pixels} & \text{else} \end{cases} \tag{13}$$

3 Results

Linear regressions between the predicted and gravimetric MCs were calculated and the results are shown in Figure 4. The predicted MC tends to be overestimated, since the regression lines are located above the line of equality $w_{\mathrm{CT}} = w_{\mathrm{g}}$.

The cross-sectional area and the MC distribution of the samples were identified as the parameters which had the greatest impact on the reliability of the image processing method. An increase in the cross-sectional area was indeed expected to increase the computation complexity as more voxels must be processed. The MC distribution was expected to influence the performance of the method, since it is correlated to the degree of deformation of the wood. The MC computation should be more complex in an undeformed configuration (green sawn timber) than in an intermediately deformed configuration (between a green and an oven-dry state).

https://doi.org/10.52202/069179-0104

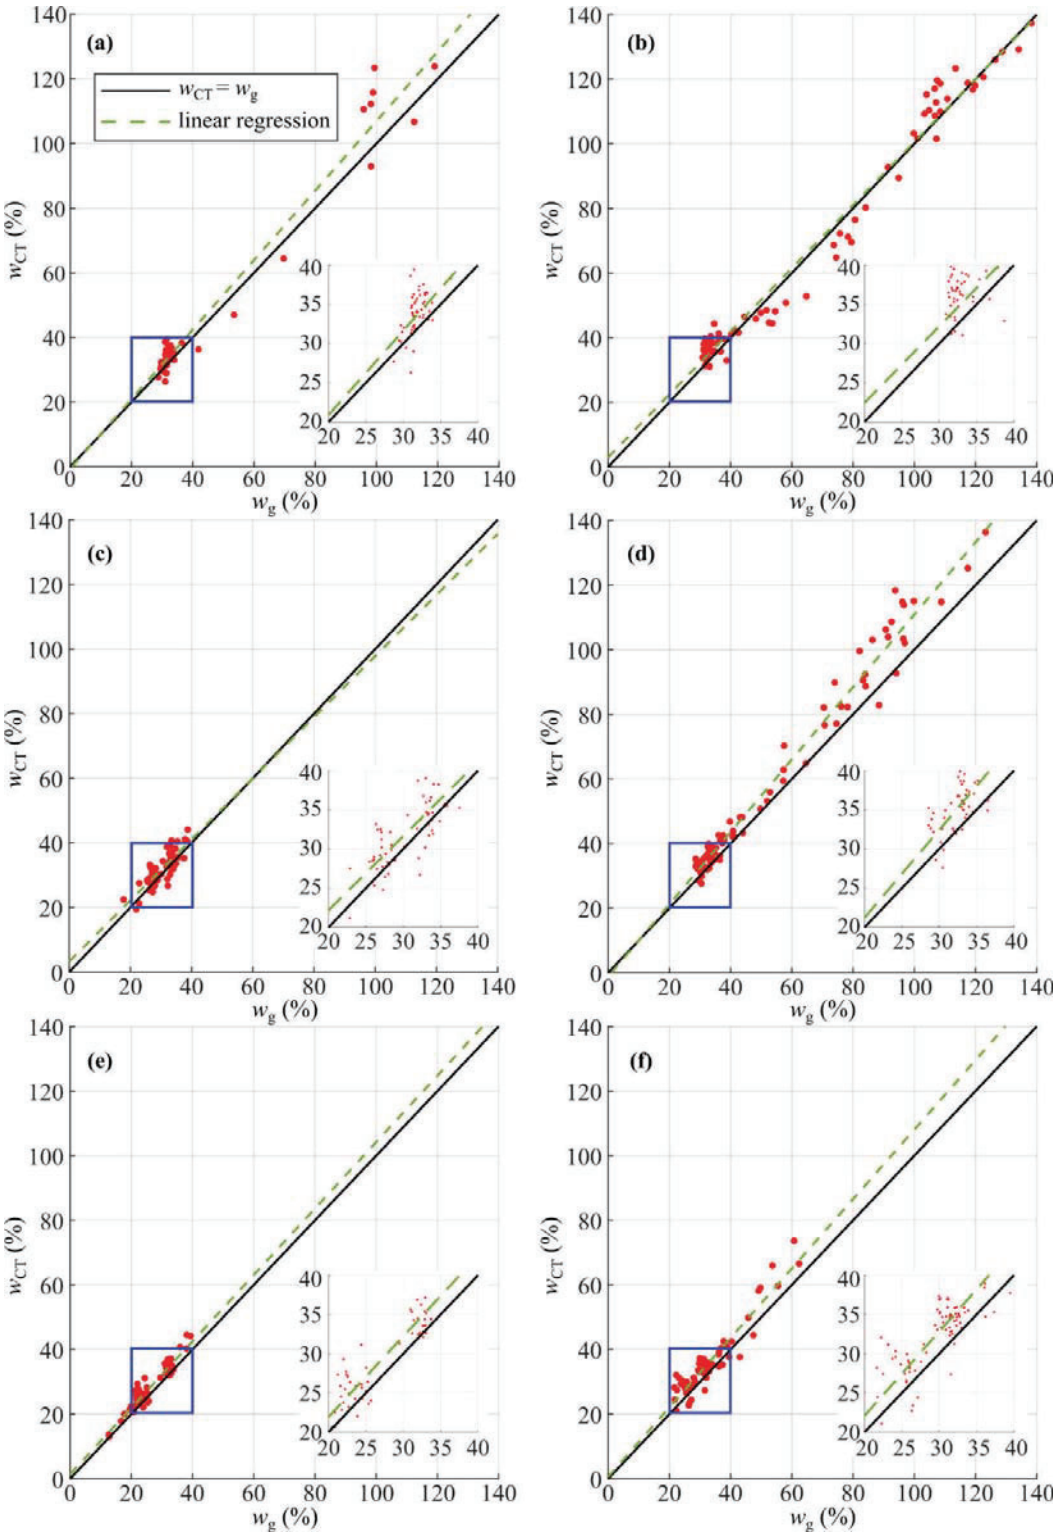

Figure 4: *The predicted MC (w_{CT}) plotted against the gravimetric MC (w_g). (a), (c), and (e) represent the S40 samples with cross-sectional area of 40×160 mm², and (b), (d), and (f) represent the S70 samples with a cross-sectional area of 70×160 mm². (a) and (b) specimens that underwent no drying; (c) and (d) specimens that underwent drying for 1h at 70°C; (e) and (f) specimens that underwent drying for 3h at 70°C. The diagonal plain line represents a perfect match between the two datasets ($w_{CT=}w_g$). The dashed line corresponds to a linear regression. The smaller graph with values from 20 % to 40 % is a region around FSP for better visualization.*

https://doi.org/10.52202/069179-0104

The validation was assessed by the root-mean square error (RMSE) which indicates the precision of the method and the coefficient of determination of the linear regression (R^2) which indicates its accuracy. The results are presented in Figure 5.

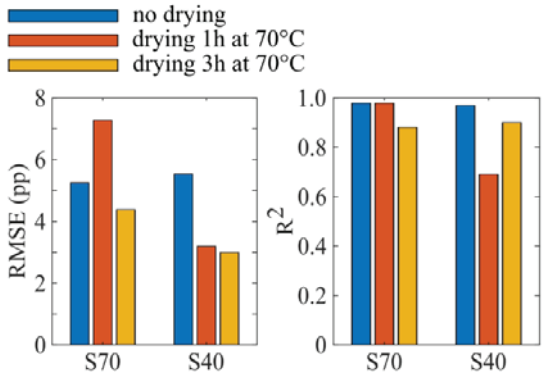

Figure 5: *Precision and accuracy of the CT-method. Root-mean-square-error (left) and R^2 (right) of the linear regressions. "pp" stands for percentage points.*

The average RMSE was higher for the larger S70 specimens than for the smaller S40 specimens, which suggests that a larger cross-sectional area is more complex to process for both image registration and density correction algorithms. The RMSE of the S40 specimens decreased from 5.5 to 3 percentage points (pp) when the drying was extended from 0 h to 3 h. The RMSE of the S70 specimens was 5.25, 7.28, and 4.38 pp for 0 h, 1 h, and 3 h drying respectively. Except for the RMSE peak at 1 h drying for the S70 specimen, these observations suggest that the image processing performs better when the sawn timber is dried, as it is easier to compute smaller deformations. A decrease in the R^2 coefficient was observed for both specimen groups with increasing drying time.

The performance of the image processing method was assessed by quantifying its uncertainty and spatially mapping it within the cross section. The uncertainty was estimated with Equations (12-13) and the results are shown in Figure 6. High uncertainties (>10 pp) considered as outliers were always found for test volumes located at the sample edge, mostly in the sapwood region. Uncertainties corresponding to spatial mismatches greater than 2 pixels (>*) were relatively more frequently found in the S70 than in the S40 samples. Drying lowered the average uncertainty value for both sample sizes.

The occurrence of test volumes with spatial mismatches greater than 2 pixels in CT samples could be related to their respective strain distributions. It was inferred that the image registration was worse for regions experiencing a high strain and shear.

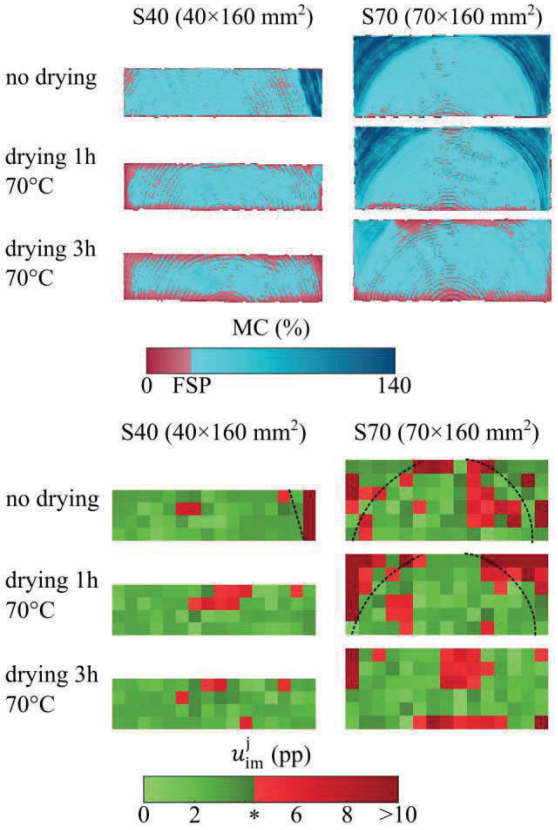

Figure 6: *Predicted MC (top) and uncertainty of the image processing method (below). The threshold marked * is set as described in Equation (13): values below or above it corresponds to spatial mismatches greater or less than 2 pixels. The value of the threshold is slightly different for each situation and ranges from 3.8 to 4.5 pp. The dashed curves indicate the sapwood/heartwood borders when they were visible in the CT data. "pp" stands for percentage points.*

4 CONCLUSIONS

It has been shown that the image processing is a suitable method for the calculation of MC with an average uncertainty ranging from 2.8 to 4.9 pp estimated on a 10 mm scale. A fine adjustment of the image processing parameters might reduce this error. Measurement limitations of the CT scanner increase this range to ±[4.4-7.8] pp, which may be improved by using another image reconstruction algorithm.

The method performed better when the cross section of the specimen was smaller, as the complexity of the image registration decreases with a decreasing amount of data to process. The method was also more precise when the transformation was computed from an intermediate deformed configuration than from an undeformed configuration (green condition). Consequently, the reliability increased with a lower MC, dry enough to initiate the deformation. The cross-sectional area of the specimen was identified as having a greater effect than the MC distribution on the precision of the method.

https://doi.org/10.52202/069179-0104

Extending this method to compute the MC in 4D can be better than existing methods for investigating wood-water relations during the drying of sawn timber, and for other processes such as wood modification or mechanical testing. The method will be expanded to characterize moisture-induced strain fields based on the displacement data obtained by image registration.

PREDICTION OF DOUGLAS-FIR SAWN TIMBER YIELD BASED ON LOG COMPUTED TOMOGRAPHY

Andreas Weidenhiller[1], Boris Sandor[2], Thomas Simlinger[3], Franka Brüchert[4], Johannes A. J. Huber[5]

ABSTRACT: Climate change affects the growth conditions for Norway spruce (*Picea abies*) which is the most important species for the European construction timber industry. As a countermeasure, the species mix in European forests is being changed to include more hardwood, but also more drought-resistant softwood species, for example Douglas-fir (*Pseudotsuga menziesii*). Previous research has shown that Douglas-fir can on the one hand be suitable to produce high-strength material. On the other hand, however, Douglas-fir wood can also have a considerably lower strength than what is expected from spruce. Therefore, there is need for improved strength prediction and strength grading methods for Douglas-fir, to enable the correct allocation of Douglas-fir roundwood to the most suitable target product. In the present study, computed tomography (CT) image reconstructions of 53 Douglas-fir logs were used to predict the strength of the sawn timber and thus to identify logs which are suitable to produce glulam lamellas. To achieve this, statistical modelling was combined with Finite Element (FE) modelling of destructive tensile tests, based on simulated fibre orientations for the boards.

KEYWORDS: Douglas-fir (*Pseudotsuga menziesii*), strength prediction, glulam lamellas, statistical modelling, simulated fibre orientations, Finite Element Analysis

1 INTRODUCTION

Europe aims to proceed towards a sustainable bio-based economy, which should be less dependent on fossil resources [1]. Forest based products, including construction timber products, are an important element in this strategy. At the same time, the growth conditions are declining for spruce (*Picea abies*) which is Europe's most important wood species for construction timber products – due to climate change, temperatures are rising, and the risk of drought is increasing. Douglas-fir (*Pseudotsuga menziesii*) is seen as one of the tree species which could complement spruce in the future, due to its drought resistance, fast growth and interesting material properties [2]. Sauter [3], e.g., observed an average tensile strength of more than 40 N/mm², but with unusually high coefficients of variation (CoV) of 50%-60%. Rais et al. [4] reported, for material from a plant density trial, average tensile strengths between 17 N/mm² and 25 N/mm² with CoV in the range of 30%-40%. Such high variations in sawn timber properties can be a challenge for the construction timber industry. Therefore, our study presents methods to predict the sawn timber strength already at the roundwood stage and thus to allow identification of suitable raw material for glulam production.

2 MATERIAL AND METHODS

2.1 MATERIAL

For this study, 53 Douglas-fir logs from two stands (age of 60 years) close to Vienna (Austria) were selected, focusing on qualities which are typically used for construction timber production. The share of quality class A according to Austrian wood trade practices was 9%, that of quality class B 76%. 15% of the wood corresponded to the quality class C. The roundwood diameters were between 25 cm and 46 cm.

2.2 ROUNDWOOD SCANNING AND SAWING

The logs were scanned with the roundwood CT scanner at the Forest Research Institute Baden-Württemberg in Freiburg, Germany. Based on the CT image reconstruction, several wood properties were extracted, among them heartwood, knots and pith. For the knots, parametric descriptions similar to Johansson et al [5] were computed.

Further, the longitudinal eigenfrequency f of each log was measured using a Microtec ViScan device, and the dynamic modulus of elasticity $E_{dyn,log}$ was calculated for each log using Equation (1):

$$E_{dyn,log} = 4 \cdot \rho_{log} (l \cdot f)^2 \quad (1)$$

Where ρ_{log} was the average log density from CT scanning and l was the log length.

The logs were sawn according to the cutting patterns given in Figure 1. 14 logs were sawn according to pattern a, 23 logs according to pattern b, and 16 logs according to pattern c. One log in pattern c was accidentally sawn so that it had four more side boards. In total, sawing yielded 267 main boards and 156 side boards. The boards were dried to a target moisture content (MC) of 12%. The main boards were planed to a thickness of 45 mm; the side boards were all planed to a thickness of 25 mm.

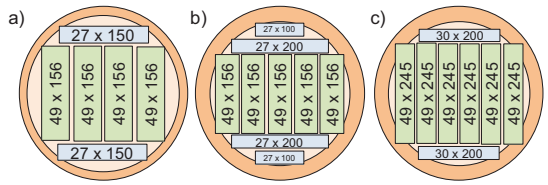

Figure 1: *Cutting patterns used for sawing the Douglas fir logs (board dimensions in mm). One of the logs in pattern c had 4 additional side boards of the dimensions 30 x 100 mm².*

2.3 SAWN TIMBER SCANNING AND TESTING

After planing, the boards were strength graded with a Microtec GoldenEye 706 machine including X-ray and eigenfrequency measurement. At the laboratory of Holzforschung Austria, the boards underwent destructive tensile testing according to EN 408 [6], including measurement of dry wood density and MC on a small clear sample of each tested board, and corrections of the values according to EN 384 [7]. However, it was decided to exclude the 28 side boards of dimension 27x150 mm² from destructive testing, as their number was so small.

Further, 14 main boards and 14 side boards had to be excluded due to various reasons, like breakage during machine strength grading or excessive wane.

The final yield was: 253 main boards with the cross sections 45x145 mm² and 45x230 mm², and 104 side boards with 25x90 mm² and 25x185 mm².

2.4 TRACKING OF TIMBER POSITIONS

The position of each board in the respective log was tracked using log end templates [8]. Those templates were sheets of paper containing the log ID as well as angular information and distance to the pith (see Figure 2a). The sheets were glued to one log end and remained there during sawing, drying, planing, industrial strength grading and destructive testing (Figure 2b). At the end of the process, the templates on the boards were scanned and manually arranged to reconstruct the original positions of the then dry boards in the green log CT reconstruction. To easily arrange the images, a dedicated tool was programmed by the authors (Figure 2c) using R [9] and the shiny package [10].

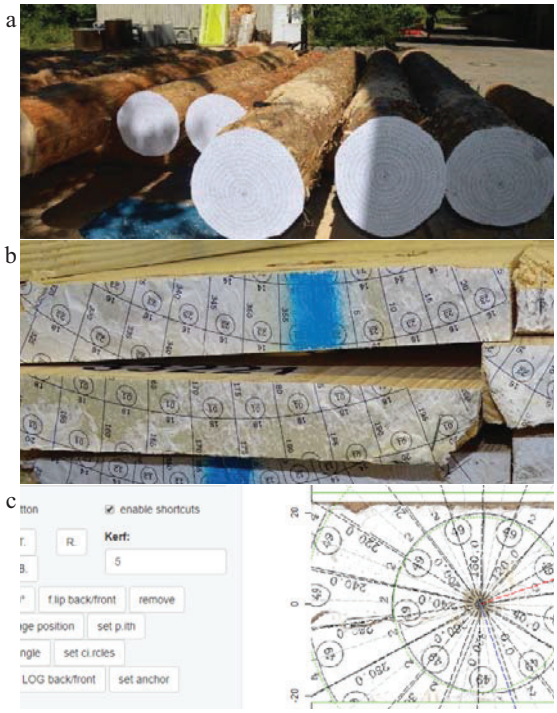

Figure 2: *Log end templates. a) glued to the log end, b) remaining on the board throughout the board processing, c) detail screenshot of the tool to arrange the scans.*

2.5 VIRTUAL SAWING

Using the reconstructed board positions, virtual boards were created from the CT images of the log. For each virtual board, descriptive variables were calculated, including heartwood density, distance from pith and percentage of knot volume. Further, a board X-ray scan was simulated by calculating average densities along the direction of the board thickness, which resulted in density data arrays of the dimensions "board width" by "board length". These green densities were assumed to have been measured at an MC of $u = 29\%$ (fibre saturation point) and were corrected to an MC of $u_{\text{ref}} = 12\%$ using Equation (2) (EN 384 [7]).

$$\rho = \rho(u)\big(1 - 0.005(u - u_{\text{ref}})\big) \quad (2)$$

2.6 SIMULATION OF FIBRE ORIENTATIONS

Based on the parametric knot descriptions calculated on the CT images and using the reconstructed board position, fibre orientations were simulated along the length and width of the central plane for each board at a resolution of one grid point per mm, using the approach described by Huber et al. [11]. A detail of such reconstructed fibre

https://doi.org/10.52202/069179-0105

orientations is shown in Figure 3. For the figure, the resolution was reduced to one grid point per 5mm.

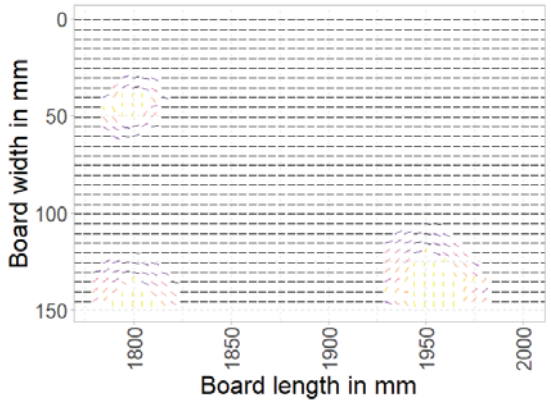

Figure 3: *Detail of simulated fibre orientations: flow of fibres around three knots in board 23047. Each line segment corresponds to one grid point, colours indicate the magnitude of the grain deviation.*

2.7 FINITE ELEMENT MODEL

Using COMSOL Multiphysics® [12], tensile tests were simulated on a two-dimensional plane stress model of each board. The calculated fibre orientations (section 2.6) were used to generate a locally varying coordinate system. This system transforms the three-dimensional cylindrical (LRT) material properties defined by the reference stiffness tensor C [13] to the two-dimensional model of the board – see Equation (3).

$$C(\rho) = \frac{\rho(x,y)}{\rho_{ref}} \begin{bmatrix} 11162 & 504 & 435 & 0 & 0 & 0 \\ & 866 & 281 & 0 & 0 & 0 \\ & & 528 & 0 & 0 & 0 \\ & & & 620 & 0 & 0 \\ & sym & & & 500 & 0 \\ & & & & & 23 \end{bmatrix} \quad (3)$$

Due to the density dependence of this stiffness tensor the local values were linearly scaled from the reference density of $\rho_{ref} = 390$ kg/m³ according to the local density $\rho(x,y)$ obtained from the virtual board (section 2.5). The discretization was performed with a uniform quadrilateral mesh with a resolution of 1 mm. In order to determine the Young's Modulus one side of the board was constrained in both spatial directions while the other side was prescribed a displacement of 5 mm along the x-axis. From the reaction forces, the Young's Modulus was calculated for each board.

2.8 MODELLING THE SAWN TIMBER STRENGTH GRADING

We wanted to predict the grade yield achieved by the GoldenEye 706 sawn timber strength grading machine. For this purpose, we modelled the GoldenEye Indicating Property (IP) for strength with linear regression, based on descriptive variables extracted from the virtual boards, the Young's Modulus from the FE model, as well as the $E_{dyn,log}$ in various combinations. The regression coefficients were calculated on the training data set, which encompassed 60% of the logs in the study (33 logs, 208 boards). The following predictors for the GoldenEye 706 strength IP were calculated:

- VB ("virtual board") using the virtual board's knottiness, heartwood density and distance to pith information (section 2.2);
- VB+FE, using in addition the Young's Modulus from the FE model (section 2.7);
- VB+Edyn,log, which combined the virtual board's knottiness and heartwood density with the $E_{dyn,log}$ (section 2.2).

2.9 YIELD PREDICTION

For the GoldenEye strength IP, a setting S for strength grading into strength class T14 was calculated on the training set, using a simplified approach based on EN 14081-2 [14]. The T14 strength class is defined in EN 338 [15] with the following properties: 5th percentile of tensile strength ($f_{t,k}$) at least 14 N/mm²; average tensile modulus of elasticity ($E_{t,0,mean}$) at least 11 kN/mm², and fifth percentile of the density (ρ_k) at least 350 kg/m³. T14 is one of the most important strength classes for producing glue laminated timber (glulam) of strength class GL24h [16].

Boards with an IP below the setting value S were rejected, and all other boards were assigned to T14. The same setting S was applied to the three IP predictors calculated on the log scanning data (section 2.8). This was used to predict the yield of T14 boards from the sawn timber strength grading.

2.10 LOG PRESORTING

Log pre-sorting was done by assigning only such logs to the production of T14 boards where the predicted yield was above a certain threshold T, which we varied from 0% to 100%.

The efficiency of the pre-sorting was defined as obtaining as many T14 boards as possible from the given logs while producing as few rejected boards during the sawn timber strength grading as possible.

This trade-off was visualised using the following two quantities in Equations (4) and (5).

$$total\ yield\ T14 = \frac{n_{T14,grading}}{n_{boards,sawn}} \quad (4)$$

$$relative\ yield\ T14 = \frac{n_{T14,grading}}{n_{boards,grading}} \quad (5)$$

where $n_{T14,grading}$ means the number of boards assigned to T14 during strength grading, $n_{boards,sawn}$ means the number of all boards sawn from all logs, and $n_{boards,grading}$ means the number of boards sent to the strength grading process. Thus, the $total\ yield\ T14$ is the percentage of T14 boards relative to the number of all

boards sawn from all logs, and the $relative\ yield\ T14$ is the percentage of T14 boards relative to the number of boards sent to strength grading.

To get a more complete picture, the whole range of pre-sorting thresholds was calculated, which resulted in a curve of values in the diagram $total\ yield\ T14$ vs. $relative\ yield\ T14$. These curves were compared between the three predictors VB, VB+FE and VB+Edyn,log.
Finally, the curves for each predictor were compared to those obtained on the test dataset, which encompassed 40% of the logs in the study (20 logs, 149 boards). Similar curves between training and test are an indication that the pre-sorting approach could also work on future unknown data.

2.11 CALCULATIONS AND VISUALISATION

All calculations were done with R 4.2.1 [9]. The diagrams were created in R using the ggplot2 package version 3.4.0 [17].

3 RESULTS AND DISCUSSION

3.1 FINITE ELEMENT SIMULATIONS

In Figure 4, the Young's modulus calculated by the FE models was compared to the modulus of elasticity determined during the destructive tensile tests. We observed a moderate correlation with a coefficient of determination of $r^2 = 0.46$.

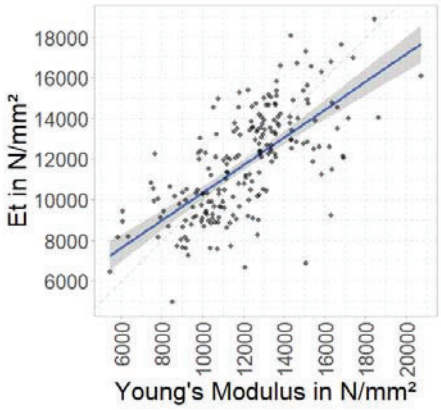

Figure 4: *The Young's modulus obtained from the FE models against the modulus of elasticity* $\boldsymbol{E_t}$ *from the destructive tensile tests for the 208 boards from the training dataset; coefficient of determination* $\boldsymbol{r^2 = 0.46}$.

For comparison: Olsson et al [18] achieved up to $r^2 = 0.70$ of their models with local modulus of elasticity in bending, $r^2 = 0.80$ if they included density, and $r^2 = 0.84$ if they included the longitudinal dynamic modulus of elasticity of the board ($E_{dyn,board}$).
When we used a two-dimensional density array measured on the dry boards during industrial strength grading (section 2.3), the coefficient of determination increased from 0.46 to 0.52, but this information is never available at the log stage. In other words, the knowledge of the boards' dry density improved the FE model – therefore, it would be desirable to develop an improved prediction of the dry density based on the green density.
Also, $E_{dyn,board}$ is never available at the log stage. However, a linear regression model for E_t, based on the Young's modulus from the FE model and on $E_{dyn,log}$ led to an $r^2 = 0.67$. Therefore, we also looked at yield prediction models including $E_{dyn,log}$, even though this quantity is not used in practice in Europe – for logs in intermediate states between frozen and thawed, $E_{dyn,log}$ cannot be determined reliably [19].
A further possibility for improving the prediction of the Young's modulus would be to base the FE model on a three-dimensional grid of fibre orientations instead of on a two-dimensional grid. This is planned as a next step in our research.

3.2 YIELD PREDICTION

Each of the three predictors predicted the correct grade for about 85% of the boards in the training data, with a clear tendency to overestimate the number of T14 boards – between 60% and 70% of the wrongly predicted boards were rejected boards which were assigned to T14 by the predictors.

3.3 LOG PRESORTING

In Figure 5, the *relative yield* was plotted against the *total yield* of T14 boards from the training data. This resulted in three curves for the three yield predictors VB, VB+FE and VB+Edyn,log. In the background of Figure 5, also the curve resulting from perfect yield prediction is displayed as a thin grey line.

An increase in the relative yield could only be achieved at the cost of a decrease in the total yield.

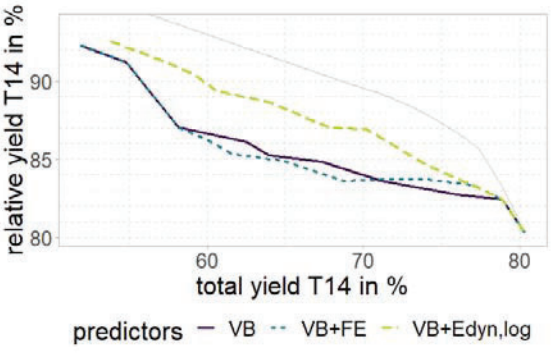

Figure 5: *Relative yield vs. total yield for the three yield predictors VB, VB+FE and VB+Edyn,log, based on the 208 boards from the training data. The thin grey curve to the right is the best possible pre-sorting, resulting from perfect foreknowledge of the final grading result.*

https://doi.org/10.52202/069179-0105

In Figure 5, this is apparent because the curves all decrease from left to right, even the thin grey line based on perfect yield prediction.

This trend is directly related to the pre-sorting strategy (section 2.10). We excluded logs with a predicted yield of T14 which was below a certain threshold *T*. A low predicted yield of T14 means a high predicted number of reject boards. Excluding these logs meant that the logs chosen to produce T14 boards had a lower share of reject and a higher share of T14, i.e. a higher relative yield. However, even from logs with a low yield of T14, we would be able to produce some T14 boards. When those logs were excluded based on the yield threshold *T*, those T14 boards could not be produced, and the total number of produced T14 boards decreased. This implied a lower total yield of T14.

When comparing the curves for the three yield predictors, curves further to the right (i.e., with a higher total yield for any given relative yield) indicate a higher pre-sorting efficiency, because this means that a given relative yield can be achieved while maintaining a higher total yield. Therefore, the thin grey line based on a perfect yield prediction is always furthest to the right. In Figure 5, the curve of the predictor VB+Edyn,log was closest to the perfect prediction curve and thus had the highest pre-sorting efficiency. We had expected that the predictor VB+FE would have a higher pre-sorting efficiency than VB, but, in fact, those two predictors were at the same level. It seems that a more accurate FE simulation of the Young's Modulus is needed to improve the pre-sorting efficiency, for example by basing the FE model on a three-dimensional grid.

In Figure 6, the yield curves were compared between the training data and the test data separately for each predictor. For all three predictors, the training data and the test data led to similar curves, given the rather small number of logs involved. Therefore, the pre-sorting strategies defined in this study should also work on new unknown data, although a repetition of the present study on a larger data set is recommended.

In Table 1, some selected value combinations of total yield and relative yield were extracted from Figure 6. Further, the values for the perfect prediction (as if one knew the result from board strength grading already when pre-sorting the logs) were added. To get a total yield value for a certain given relative yield value for all predictors, the total yield values were linearly interpolated between data points.

A relative yield of 80% was the baseline, where no logs were excluded. Therefore, all predictors had a total yield of 80% for this row. In the test data, this corresponded to 119 T14 boards and 30 reject boards.

A relative yield of 85% (test data), was achieved by the predictors VB and VB+FE at a total yield level of 66%. This corresponded to 99 T14 boards and 22 boards rejected during grading, but by excluding some logs, the opportunity to produce 20 more T14 boards was traded against having 13 less reject boards.

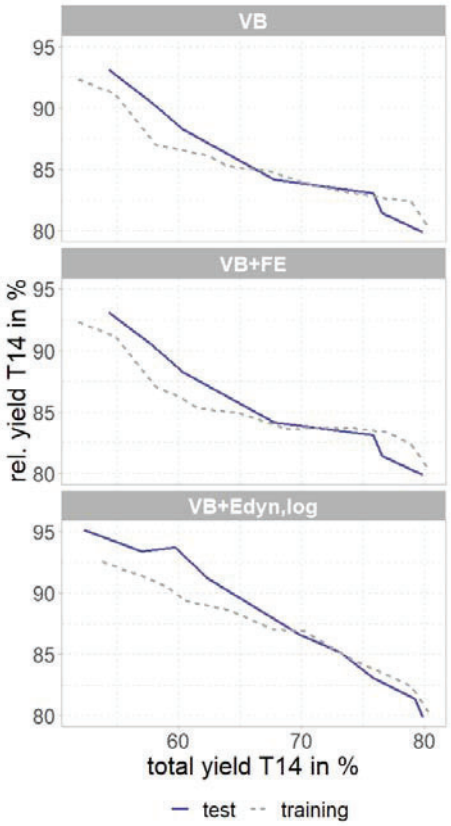

Figure 6: *The yield curves from Figure 5 (training data, 208 boards), compared to the curves resulting from the test data (149 boards).*

Table 1: *Interpolated values for the total yield at a certain level of relative yield for the different predictors and for the perfect prediction, for the training data and the test data.*

	relative yield in %	total yield in %			
		VB	VB+ FE	VB+ Edyn,log	perfect prediction
training (n = 208)	80	80	80	80	80
	85	66	64	73	78
	90	56	56	60	69
	92	52	52	55	62
test (n = 149)	80	80	80	80	80
	85	66	66	73	75
	90	58	58	64	68
	92	55	55	60	64

Again for a relative yield of 85%, the predictor VB+Edyn,log was able to produce 109 T14 boards; here, the trade-off was 10 fewer T14 boards and 11 fewer reject boards, which is considerably more efficient.
At the same level of relative yield, the perfect prediction traded 7 fewer T14 boards against 10 fewer reject boards.
At the highest relative yield level in Table 1 (92%), VB and VB+FE only led to a production of 83 T14 boards, VB+Edyn,log to a production of 89 T14 boards, and the perfect prediction to a production of 96 T14 boards.

4 CONCLUSIONS

In this study, data from log scanning were successfully used to predict the yield of the final strength grading of dried sawn timber. The input data were based on images from log computed tomography (CT) and dynamic modulus of elasticity of the log. As an additional input to the yield prediction models, a Finite Element analysis based on the CT images and using simulated fibre orientations was performed.
Based on these yield predictions, a pre-sorting strategy was tested where only logs with high predicted yield in the strength grade T14 were directed towards producing machine strength graded timber.
Using this approach, the T14 grade yield at the sawn timber strength grading process step could be increased from 80% to up to 92%, at the cost of losing up to 30% of the T14 boards which could have been produced if all of the logs in the study had been sent to the strength grading process.
Although the results on Young's modulus from Finite Element analysis had a coefficient of determination of 0.46 with the tensile modulus of elasticity, using this result for predicting the strength grading yield did not improve the pre-sorting efficiency.
Further research should be directed towards increasing the accuracy of the Finite Element analysis, e.g. by basing it on a three-dimensional board grid instead of a two-dimensional board grid. It is also expected that a better prediction of the density of the dry board from the CT images could improve the accuracy of the Finite Element analysis.

ACKNOWLEDGEMENT

The research for this study was part of the project READiStrength, which was funded by the ERA-NET Cofund Call "ForestValue – Innovating the forest-based bioeconomy" as well as by the national funding agencies Vinnova, Fachagentur Nachwachsende Rohstoffe e.V. and the Austrian Federal Ministry for Agriculture, Regions and Tourism.

CONSIDERATIONS FOR GRADING SPECIES COMBINATIONS. THE EXAMPLE OF DOUGLAS FIR WITH LARCH IN IRELAND AND UK

David Gil-Moreno [1], Dan Ridley-Ellis [2], Annette M. Harte [3]

ABSTRACT: This paper examines the grading of Douglas fir (*Pseudotsuga menziesii*) and larch (*Larix* spp.) as a strength grading species combination for the growth area formed by Ireland and the UK. The two genera produce higher timber quality than Sitka spruce (*Picea sitchensis*), the main commercial timber species in the two countries. Developing this species combination may increase the volume of timber available for the market, making these species more commercially attractive to sawmills, particularly if there are common settings that can be used for either species whether mixed in production or not. Simultaneously, the paper examines the challenges of mixed species grading within the framework of the European standard EN14081 for machine control grading, as the requirements for combining species are not clearly defined. More than 1600 pieces are used for this study. The results found that the ranges of modulus of elasticity, strength and density of both species are similar, but special considerations are required to ensure the safe grading of the timber.

KEYWORDS: Wood properties, Strength grading, Douglas fir, Larch, Species combination, Standards

1 INTRODUCTION

The main timber species grown in Ireland and UK is Sitka spruce (*Picea sitchensis* (Bong.) Carrière). Commercially, it is common to refer to it as "British spruce", WPCS [1], a long-standing commercial combination where Sitka spruce is often mixed in the forest and the sawmills with Norway spruce (*Picea abies* (L.) H.Karst). The amount of each species in the mixture depends on the relative volumes available in the forests, which varies geographically. The overall percentage of Norway spruce is low but nevertheless a batch with 100% Norway spruce could be processed and sold as British spruce. The mixture is possible because the grade determining properties (GDPs) are similar. This paper will focus on GDPs as those primary properties determined for grading on the usual bending strength basis, namely modulus of elasticity (MOE), strength and density. The wood of the two species also has practically identical visual appearance and is not separated in production. Such industry practise species combinations are not uncommon, but this is also potentially a way to combine lesser used conifers with an established species, or grade lesser conifers together, as a convenient route to market.

There are many other species combinations in use. For example, Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco) and western larch (*Larix occidentalis* Nutt.) are graded together as a species combination, WPSM [1], as well as a part of other species combinations in North America. The properties of both species are somehow similar, and can be mixed for selling [2, 3] following grading rules of different agencies, like WCLIB, WWPA or NLGA. The combination is commonly used for glulam in the US [2].

Although western larch is not grown commercially in Europe, in Ireland, larches and Douglas fir are currently the second and third largest timber species in terms of forest area after spruces [4]. In Great Britain, larch is the third largest timber species, and Douglas fir is the fifth [5]. In 2018 and 2020, as part of the WoodProps programme at the University of Galway, machine grading settings were developed for Douglas fir [6], PSMN, and larch (WLAD: European larch (*Larix decidua*), hybrid larch (*Larix x eurolepis*) and Japanese larch (*Larix kaempferi*)), separately [7], for the grading area formed by Ireland and the United Kingdom (UK). Douglas fir and larch produce higher timber quality than British spruce and it would be desirable to have more material available on the market. However, the relatively small and dispersed volume of these species in Ireland may not always make grading these species on their own attractive to sawmills.

New construction projects in Ireland are now using locally grown Douglas fir (Figure 1). An option to concentrate the timber volume and increase the use of the local timber resources currently available is a combined approach for production and marketing. For this, it is desirable to have common machine grading settings that could be used for either WLAD or PSMN whether mixed in production or not.

There is very little literature on how to develop machine control grading settings for a mixture of two or more species. Regarding the sampling for testing, the standard EN14081-2 [8] says that when species are graded together without being differentiated, the sampling should be representative of the species proportion. The standard thus leaves open the question as to whether the approach should be different if the species are more commonly differentiated, but desired to be graded by a common process. The standard also states that the species within a species combination need to be "sufficiently similar", but it does not explain how to satisfy this requirement.

In order for timber to be graded under the European machine control system, the thresholds (settings) for the machine indicating properties (IPs) are calculated based on their predictive relationship to the GDP values, as determined by a large testing programme. The characteristic values for strength and density are the lower 5th percentiles and for MOE the mean. It would be expected that when populations of different species have similar GDP mean and variances, characteristic values, and correlations with the grading parameters, the species can be graded together as species combination. However, the fact that the relationships between the GDPs can be similar in two species (falling within the confidence intervals), does not guarantee that the relationship between a grading machine's IP and all the GDPs is also similar. Likewise, it is worth knowing what would happen if, in the effort to study "sufficiently similar" samples, timber of higher or lower characteristics is overlooked.

This paper examines the grading of the species combination PSMN with WLAD for the first time in Europe, in particular for the grading area formed by Ireland and the UK, while suggesting an appropriately cautious approach to develop machine settings of species combinations within the scope of EN14081.

2 MATERIALS AND METHODS

2.1 MATERIALS

The study uses timber from normal production runs in sawmills sampled from across the Republic of Ireland and the United Kingdom. As usual for grading work, specification was given to each sawmill that the timber provided should be unsorted for quality, except for the removal of any pieces that fail visual override criteria as described by EN 14081-1 [1, 9]. The sampling also included timber from research studies in the two countries, considered representative of the timber in production. A total of 704 pieces of PSMN and 899 of WLAD were available and split into four verification samples per genus (Table 1) for the analysis, where A to D correspond to PSMN and E to H correspond to WLAD.

Table 1: *Pieces sampled by cross-section size and source.*

Size (mm^2)	Sample	WLAD	PSMN
35x75	H	96	-
37x75	B	-	70
45x100	A, D	-	277, 109
47x100	E, F,	166, 126,	
"	G, H	126, 60	
50x100	C, D	113, 75	-
47x150	E	17	-
75x150	F, G, H	80, 80, 94	
76x225	B	-	60
100x275	F, G	27, 27	

2.2 METHODS

The pieces were tested at the University of Galway using a Zwick/Roell 500 kN Servo Hydraulic testing machine, and at Edinburgh Napier University using a Zwick Z050 universal testing machine. The tests followed the requirements of the European standards EN408 [10] and EN384 [11]. For WLAD, local MOE was used to calculate the settings, whereas for PSMN, global MOE and the correction to shear free MOE (Clause 5.3.2 of EN 384:2016+A2:2022, E_0=1.3 x $E_{global,u=12\%}$ - 2690 N/mm^2) was applied. The choice of one or the other moduli of elasticity influences the grading yields, particularly when MOE limits the allocation to a strength class [12, 13]. MOE and density were adjusted to 12% moisture content and strength to 150 mm depth in accordance with EN384 [11]. The moisture content of every specimen was determined using the oven drying method, or estimated by moisture meter [14]. The symbols and units used in this paper are listed in Table 2.

Table 2: *Symbols and units.*

Symbol		Units
Bending strength, adjusted to 150 mm width		
f_{mean}	Mean	N/mm^2
f_k	5th percentile	N/mm^2
Bending modulus of elasticity, parallel to grain, MOE		
$E_{0,mean}$	Mean, at 12% mc	kN/mm^2
Density		
ρ_{mean}	Mean, at 12% mc	
ρ_k	5th percentile, at 12% mc	

In order for timber to be graded, the dynamic modulus of elasticity (MOE_{dyn}) was chosen as the IP. This IP was developed through modelling using non-destructive acoustic properties as predictor variables of the GDPs. The methodology for the calculation of IP thresholds, or "settings", followed the requirements in EN14081-2:2018+A1:2022, from the calculation of the

optimum grading to the determination of the cost matrix using Annex C. However, this paper focuses on the specific issue of verification for new settings of the whole sample and verification samples, with the aims of investigating how settings can distinguish the upper-grade timber from the lower-grade timber taking species into account, and providing a good practice example for future work on grading of species combinations.

As per the existing approach, in the first step, the calculation sought to determine the lowest IP value that defined a population whose characteristic values met those of the target grade. Secondly, a check was carried out to ensure that that each of the eight verification samples studied (EN14081-2:2018+A1:2022 states that the whole sample must be divided into at least four) achieved at least 90% of the characteristic values of strength and density of the target grade and 95% of the required mean modulus of elasticity. Strictly speaking, these two steps would suffice to verify the grading settings according to the current procedure in EN14081-2. However, developing grading settings must ensure that the assignments are safe beyond the calculations required by the standards. There are questions unanswered when developing grading for a species combination: What happens if one sample is noticeably better or worse than the others? How many samples there must be for each species? What happens if the grading of the species is limited by a different GDP? Can the two species be safely graded separately but using the same settings? In order to address those questions, in particular to ensure that the grading is safe, an additional (not specified by EN14081-2) requirement was added. This was implemented so that the settings fully satisfied (100%) the required strength class values of the GDPs for Douglas fir and larch separately to explicitly confirm correct grading of each species alone. In fact, EN14081-2 does suggest the verification procedure to be applied on non-geographical subsets of the whole, when there is reason to be cautious. This approach is also similar to the expansion check carried out for expansion of existing settings to a larger setting area.

3 RESULTS

3.1 GPDs of UNGRADED TIMBER

The properties of the timber (ungraded) are summarised in Table 3. The moisture content at the time of grading varied between 9.8% and 25.9%, with a mean of 15.3%. The moisture content at the time of testing varied between 8.8% and 22.8%, with a mean of 13.5%. Overall, WLAD had slightly higher strength and density values than PSMN, but lower modulus of elasticity. However, sample A had the highest GDP values of all, and certainly much higher than the rest of PSMN values. This large variation is likely the result of microsite factors and differences in forest management, and it must be understood that this variation can occur in a sawmill and is therefore important to include it in the sampling. In fact, the results are comparable to data reported for PSMN from the UK [15], and data collected within the GradeWood project by BRE (unpublished). The two genera produce higher timber quality than Sitka spruce [7, 16] and the GDPs are comparable enough between themselves producing yields above 80% for the strength class C18 investigated in this paper as shown in Table 3.

Table 3: *Summary of properties by sample.*

	Sample	f_{mean}	f_k	$E_{0,mean}$	ρ_{mean}	ρ_k
PSMN	A	50.4	29.2	13400	561	481
	B	27.8	14.1	8980	454	394
	C	34.3	17.1	8960	453	360
	D	28.7	11.5	8410	452	376
	PSMN	38.0	15.4	10550	495	397
WLAD	E	41.9	21.7	9400	483	405
	F	37.7	22.0	9560	497	404
	G	38.9	20.3	10100	499	415
	H	43.6	25.7	10500	532	426
	WLAD	40.5	22.5	9920	504	410
	All	39.4	19.0	10200	500	405

Figure 2 shows the relationships between the three GDPs and the distribution of values as density plots. The results show that both species have comparable values of GDPs, with a slightly wider distribution of values of the GDPs in PSMN as previously mentioned. The figure also shows that the correlations between density and strength and density and stiffness are stronger in PSMN (orange) than in WLAD (green).

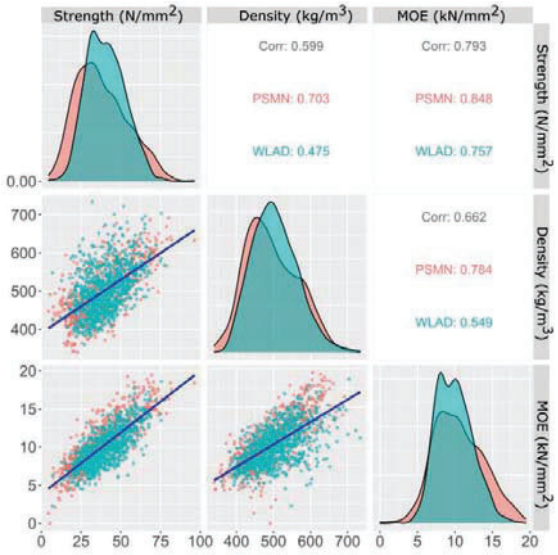

Figure 2: *Distribution of the GDPs and Pearson correlations.*

The optimum grading for the entire population was C20, that is, the one that results from using the values of the destructive tests instead of those based on the IP. For this purpose, the 0.95 factor was applied to the required characteristic value $E_{0,mean}$, and 1.12 to f_k (for non-portable grading machines). However, it can be observed that PSMN on its own would only achieve C18, largely penalised by the low characteristic strength value of sample D. WLAD on the other hand, would achieve C22. Previous studies analysing these datasets in part or in full, reported that the grading of PSMN was in general limited by strength [6], whereas WLAD was typically limited by

https://doi.org/10.52202/069179-0106

MOE [17]. This can be observed in Figure 3 and Figure 4, which illustrate the grading for strength and MOE respectively using MOE_{dyn} as IP. The y-axis represents the characteristic values (f_k and $E_{0,mean}$, respectively), where the lowest value corresponds to the characteristic value of the whole population. Each successive point corresponds to the characteristic value as the ranked board values increase. Thus, f_k and $E_{0,mean}$ typically increase while the yields decrease until the board/s with the highest strength and stiffness, respectively, are reached. Figure 3 shows that the characteristic value of strength for PSMN is lower than that of WLAD for most of the sample. Roughly 60% and 75% of PSMN and WLAD, respectively, are below the 10.5 kN/mm^2 threshold. However, the characteristic value of MOE for PSMN is higher for almost the entirely range of MOE_{dyn} values (Figure 4).

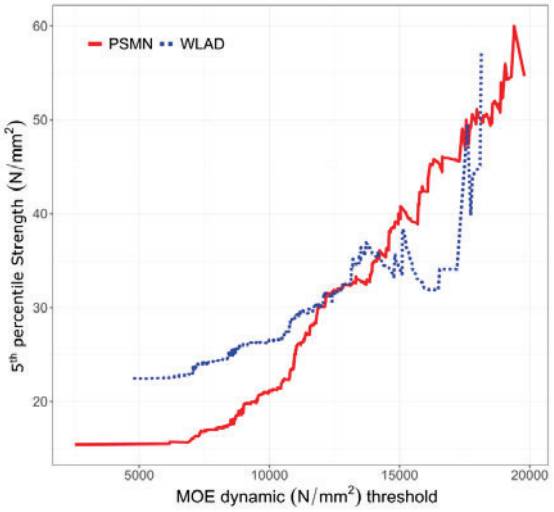

Figure 3. *Timber grading for strength using MOE_{dyn}*

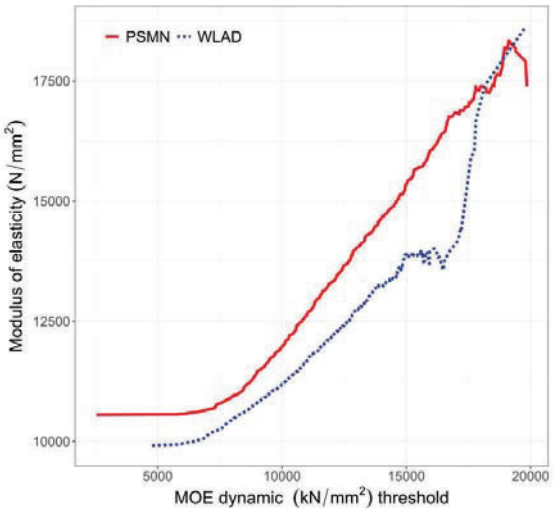

Figure 4. *Timber grading for MOE using MOE_{dyn}*

For the development of grading settings it is typically the limiting GDP that is modelled as priority. In the current dataset, the limiting GDP is different for each species. There is therefore the risk of grading an entire population of PSMN, as part of the species combination with WLAD, based on an IP that predicts MOE (for which the correlation with MOE_{dyn} is typically higher than for strength or density) and that may result in graded timber that does not meet the requirements for strength. For comparison with the derivation of machine settings for a single species, this scenario would be an analogous situation where the required characteristic values of the three GDPs must be met for the whole sample.

Although superficially similar, there are meaningful differences in the species combination that presents, a priori, a great challenge when it comes to develop the grading settings. For this reason, an additional requirement, not required by the letter of the standard but required by the spirit, was added, where it was required to also verify that the settings satisfied 100% the required strength class values of the GDPs for each species separately to confirm correct grading of each species alone.

3.2 CALCULATION OF SETTINGS

The timber of both species was non-destructively assessed with the Viscan Plus (Microtec s.r.l. – GmbH). This device measures the natural frequency of vibration in the longitudinal direction of a board, and together with density enables calculation of dynamic modulus of elasticity MOE_{dyn} using Equation (2):

$$MOE_{dyn} = \rho\,(2Lf)^2 \text{ N/m}^2 \qquad (2)$$

where ρ is the wood density (kg/m^3), L the length of the specimen (meters) and f the first mode resonance frequency (Hz) at which the stress wave propagates.

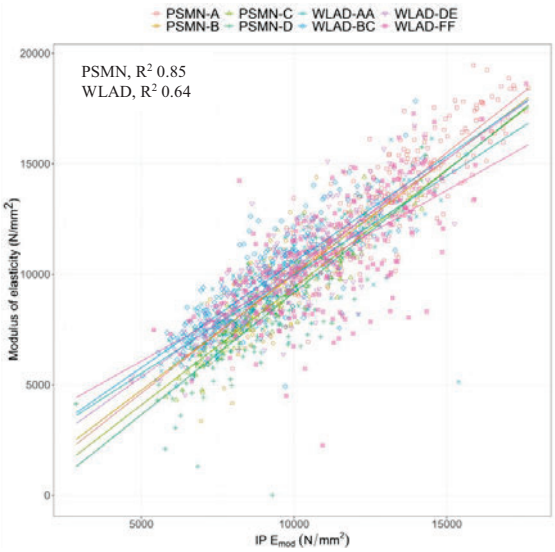

Figure 5: *Relationship between modulus of elasticity and IP by sample (R^2 0.42 to 0.88, overall 0.75)*

The strongest correlation of the IP was with modulus of elasticity (Figure 5), followed by density (Figure 6) and strength (Figure 7). The IP generated by MOE_{dyn} is closely related to the static MOE, therefore the stronger

https://doi.org/10.52202/069179-0106

correlation is expected. By species, MOE_{dyn} explained 85% of the variation in MOE of PSMN and 64% of WLAD. In all the cases, MOE_{dyn} was more strongly related to the GDPs of PSMN than of WLAD.

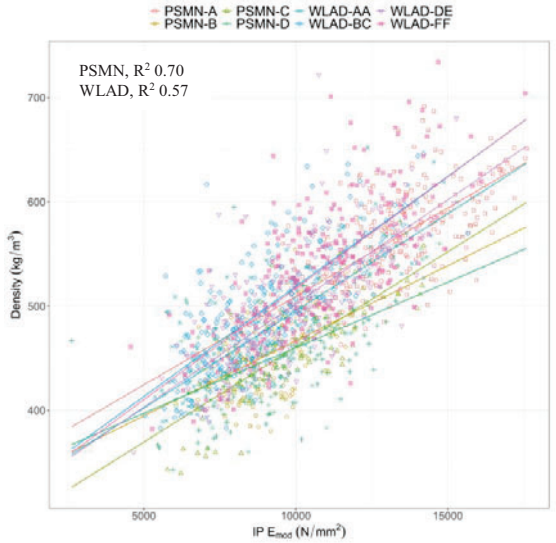

Figure 6: *Relationship between density and IP by sample (R^2 0.19 to 0.65, overall 0.58).*

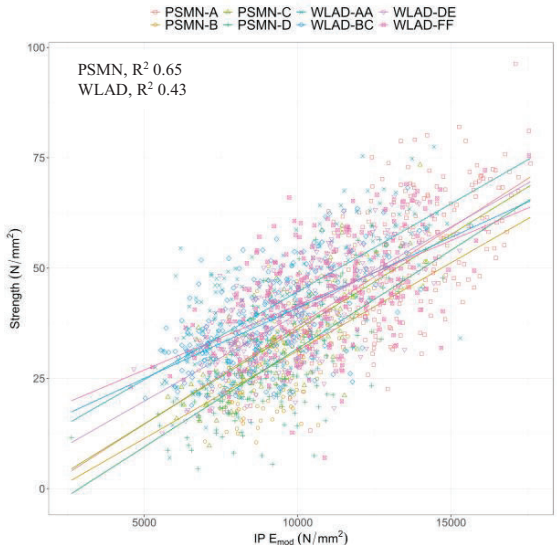

Figure 7: *Relationship between bending strength and IP by sample (R^2 0.22 to 0.56, overall 0.49).*

For grading, the analysis addressed initially the strength class combination C18/C14/reject. The setting must ensure that the whole population assigned to a grade must achieve 100% of the required strength class values of the GDPs. As well as that, at least 90% of the required target value for strength and density and 95% of stiffness must be met for each subsample.

In the first step, the settings for the upper grade was calculated. The first challenge was to find the threshold that would satisfy the requirements of the upper grade for subsamples B and D of PSMN. These samples had the lowest values for strength, and due to the large differences in GDP values between subsamples, it was possible that satisfying the requirements as a whole population was far from satisfying those of each subsample. This issue however, is not specific to the grading of a species combination.

Table 4 shows that the ratios between the derived characteristic values of the whole population and the required strength class values were 100% satisfied. The ratios for the eight subsamples (results not shown) also satisfied the requirements (90% of the target value for strength and density and 95% of stiffness). Under the current specifications of EN14081-2, the derived settings would be within the requirements of the standard. However, the strength of the PSMN population graded as C14 did not achieve 100% of the required value, 12.5 N/mm^2, of the strength class. Since the number of boards graded as C14 in samples A, B and C was less than 40, the parametric method was used to calculate f_k, which as Figure 3 shows is subjected to large fluctuations for a small number of pieces. To satisfy the species requirement it was not possible to simply increase the C14 setting, and that of the higher grade C18 had to be increased in beforehand so that more pieces were assigned to C14. As a result, the number of rejected pieces increased by 0.8 % points. Table 4 also shows settings for the combination C18/batten14. Batten14 is a user-defined strength class with characteristic values of: f_k = 14 N/mm^2; $E_{0,mean}$ = 7.5 kN/mm^2 and ρ_k = 330 kg/m^3 [7]. The peculiarity of this grade is that f_k is the same as in C14, but $E_{0,mean}$ and ρ_k are higher. This combination aimed to investigate how the higher requirement for $E_{0,mean}$ may influence the grading of WLAD. However, without the additional requirement, it was PSMN that did not achieve 100% of $E_{0,mean}$. On the contrary, WLAD, even though limited by MOE, achieved 100% of the GDPs without the additional requirement.

Table 4: *Ratios between the derived characteristic values, of the whole population and of species, and the required strength class values (re for MOE, rf for strength, rd for density).*

Strength Class	*Sample*	re	rf	rd

https://doi.org/10.52202/069179-0106

In order to investigate further the effect of the additional species requirement, the analysis for this paper also calculated the settings for C18/reject for the total sample less:

1) the best and worst quality samples;
2) the best quality sample, PSMN-A;
3) the worst quality sample, PSMN-D

Table 5 summarises the resulting yields under the three cases, and the following grading of the remaining pieces. Using the eight samples (case 0), the lowest C18 setting that satisfied the requirements of the whole and verification samples also met the requirement for each species alone. Excluding the best and worst samples (case 1), it was necessary to increase the C18 setting so that PSMN as a whole achieved 100% of the required strength class values. Consequently, the overall yield dropped considerably. Excluding the best subsample (case 2), again PSMN did not achieve 100% unless the additional requirement was applied. As expected, if the setting was calculated excluding the worst subsample (case 3), the setting value was considerably lower, and the overall yield increased. However, this practice would not make grading safe as the strength ratio reached for the otherwise not included PSMN-D was only 81%. EN14081-2 contains a verification procedure for checking that existing settings are grading correctly in a particular location. This requires that the graded timber being checked achieves at least 90% of f_k and ρ_k of the target grade and 95% of the required $E_{0,mean}$. That check would fail for PSMN-D.

As well as that, EN14081-2 requires knowledge and experience to be applied when designing the sampling strategy, and states that *if weak areas* (i.e., low quality) *are known, they should be taken into account accordingly*. While it may be tempting to remove or avoid sampling low performing data from the calculation on the grounds that it is different, it would certainly be incorrect to do so. In the previous version of EN14081-2:2012 [18], the verification checks were applied differently, so that the required characteristic values for each grade were achieved for the total sample less one geographical sample in turn. In that procedure the mean setting could not be more than 15% different from the most conservative setting or otherwise the setting had to be adjusted by 15% towards the mean value. It was realised that this procedure becomes ineffective as more samples are included in the settings calculation even though, as illustrated above, there can be significant issues with individual samples. In revising the standard, the verification checks were made more robust and explicit in their function. The standard also states that the same procedure can be used to check non-geographical samples that are suspected to be different. The standard mentions cross-section size as the example, but it is valid also for species. It is therefore recommended to apply the species check to ensure that the grading is safe.

One might also wonder whether to group the dataset by species and country, resulting in four samples, which is the minimum verification samples required in the standard. This approach gave the lowest rejects for C18/reject, 45 boards over the whole population. However, in view of the results shown in Table 5, it may be advisable from a safety point of view to consider at least four samples per species. Since EN14081-2 requires at least one hundred specimens per sample, four samples per species leads to at least 800 specimens for a combination of two species. This will provide a larger dataset to analyse, and more variability of the timber source than the 450 specimens given in the standard as the minimum number required for deriving settings. In developing grading settings, the first objective must always be safety of grading and it is sometimes necessary to do more than the minimum required by the standard, and accept some loss in yield, in order to achieve that.

Table 5: *Pieces allocated to C18/reject under different cases and the subsequent grading of the remaining pieces without (No Sp. Req.) and with the additional species requirement.*

Case		Samples	PSMN	WLAD	Reject
0	No Sp. Req. Sp. Req.	ALL	605	688	310
1	No Sp. Req.	a)	231	810	101
		PSMN-A & D	442	-	19
	Sp. Req.	a)	193	679	270
		PSMN-A & D	406	-	55
2	No Sp. Req.	b)	329	688	309
		PSMN-A	276	-	1
	Sp. Req.	b)	316	673	337
		PSMN-A	273	-	4
3	No Sp. Req. & Sp. Req.	c)	507	810	102
		PSMN-D	166	-	18

The study here presented used a machine that uses MOE_{dyn} for grading, a relatively simple case due to the direct link between the IP and GDPs. The additional check by species may become more important when grading timber using characteristics such as knottiness. Knots are related to GDPs in a much more complicated way with differences in species and growth conditions. The IPs determined by grading machines using knottiness are typically obtained through linear regression between the knots (and density) and the GDPs on all available test data. If one of the species has small knots compared to the other(s), and is widely represented in the sampling used to develop the settings (which EN14081-2:2018 specifies should broadly similar to that in practice), the influence of the knot characteristics on the model will be less, which may benefit other species with larger knots in the combination.

4 CONCLUSIONS

This paper has shown that it is possible to grade PSMN -Douglas fir- with WLAD -larch- together as a species combination for the grading area formed by Ireland and the UK. In doing so, this paper also outlines an approach to develop machine grading settings for species combinations. In particular, it includes an additional check (in line with EN14081-2, but not

required by it) so that the required characteristic values of the target grade are fully satisfied for the two (or more) species within the combination. The additional requirement aims to ensure that the grading is safe, particularly if the species are graded separately. It is shown that while larch and Douglas-fir look superficially very similar in their properties and grading, there are some meaningful differences. Further, it is shown that as long as differences are accounted for, the strength grading of the species combination can still be safely achieved. The disadvantage is that it requires an even larger testing programme than normal, and the ability to separate the species in testing.

Having common settings that can be used for Douglas fir and larch, whether mixed in production or not, is an advantage both economically and from a logistical point of view to sawmills and may increase the volume of timber available for the market, making these species more commercially attractive for processing.

ACKNOWLEDGEMENTS

This work was developed within the WoodProps programme funded by the Forest Sector Development Division of the Department of Agriculture, Food and the Marine, Ireland. The authors gratefully acknowledge the support of Coillte, Murray Timber Group, and MiCROTEC s.r.l. – GmbH. The contribution of University of Galway staff who one way or another helped to complete this programme is appreciated. The work also draws on data from other projects at University of Galway and the SIRT project at Edinburgh Napier University, and the authors are also grateful to its funders and research partners.

CONSIDERATIONS FOR GRADING SPECIES COMBINATIONS. GENERAL REMARKS ON SCENARIOS AND REQUIREMENTS.

Dan Ridley-Ellis[1], David Gil-Moreno[2], Annette M. Harte[3]

ABSTRACT: This paper discusses the situations in which timber species might be combined in commercial combinations, and the considerations relating to strength grading work. It is expected that more species combinations will be developed in the years to come, as the timber value chain diversifies. However, it is not clear how the grading standards and associated procedures should best adapt to cover situations where there is no long-standing industry experience. This paper presents some considerations and examples, with the aim of assisting people doing grading work in taking informed, safe steps based on their knowledge of the resource. This paper gives examples from the European standards, and mostly temperate species, but the principles are general.

KEYWORDS: Wood properties, strength grading, species combinations, standards, taxonomy, growth conditions

1 INTRODUCTION

The species of tree from which timber comes is an important consideration for strength grading, since it is part of what influences the wood properties, and the grading process required. For practical convenience (or necessity), species are commonly grouped into species combinations. There are many such species combinations in common and long-standing use. However, the matter of what "species" means exactly, as far as the grading standards are concerned, is not entirely clear. This means that the requirements and considerations for forming new species combinations are also unclear.

There is an increasing need for new species combinations, as hitherto lesser-used timber species come to market. Lesser-used species might be included as a new minor component of an already established species combination, or form a new combination with other relatively lesser-used species. Common species might also be combined in new ways, and familiar species combinations might be created from new growth areas, or be graded by methods that work on new principles.

Continued advances in tree breeding, hybridisation and clones add further complexity since they represent differences below the species level. Taxonomy is also not completely stable for some species, which may be regarded as varieties, subspecies or separate species by different authorities, and consequently be recognised differently in different countries. This raises the question of what a species combination even means.

In future, it is expected that some of what is currently monoculture plantation forestry will move to more diverse and intimate species mixtures for changing forest management objectives, such as climate resilience. It is also expected that species that were previously coming from logging of natural forests will instead come from plantations. Such things change the resource, even though the species is the same.

There is also growing need to be able to assess the strength of timber *in-situ* and grade timber from building deconstruction, where identification might only be possible to a list of likely species.

These give cause to reflect on the purpose of species combinations, the way they should be handled by the standards, and the way that industry can adapt to a changing resource.

It is first important to recognise that, for timber strength grading, the concept of "species" serves a different purpose than it does for botany.

2 NEED FOR SPECIES DISTINCTION

The species is one of the key determinants of timber properties. For structural timber, the important aspects are the species influence on strength, stiffness and density, averages, standard deviations, and correlations. Importantly, this includes the correlations of grade determining properties like strength, with the criteria used for grading (whether that is by visual grading or machine). Density and stiffness could be directly assessed for each piece non-destructively, but strength will always depend on predictive models.

The growth conditions are also key determinants of timber properties, and this interacts with the species and the within-species variation. The phenotype (the resulting timber) is a combination of the genotype and the environment:

- Phenotype, *e.g.*
  - Tree size and log shape
  - Knots (size, distribution, etc.) and ring width

[1] Dan Ridley-Ellis, Edinburgh Napier University, UK, d.ridleyellis@napier.ac.uk
[2] David Gil-Moreno, University of Galway, Ireland, david.gil-moreno@universityofgalway.ie
[3] Annette M. Harte, University of Galway, Ireland, annette.harte@universityofgalway.ie

https://doi.org/10.52202/069179-0107

  - Wood properties
- Genotype, *e.g.*
  - Species
  - Seed provenance
  - Tree selection or genetic improvement
- Environment, *e.g.*
  - Site: soil, climate, wind, temperature, seasons, *etc.*
  - Management: forest type, spacing, pruning, thinning, age at felling, *etc.*
  - Pests, diseases, storms, fires, *etc.*

These complex interactions are the reason why timber strength grading is necessarily linked to species and growth area, and may also change over time.

For example, knots indicate timber strength because of their influence on grain deviation within the sawn timber, but the knots are also determined by growth conditions, which additionally influence wood strength in other ways. The tree's branching results from a combination of genetics and environment, which are things that also change other aspects of the wood microstructure on account of the different biomechanical needs of the tree.

For timber strength grading, it is therefore not possible to completely separate the concept of species from the concept of growth area. It can also connect with timber sizes, since certain cross-sections and lengths come from differently sized trees, which have different growth conditions.

The genotype–environment interaction is part of the reason why it is common in the trade to distinguish between, for example, French oak and English oak as if they were different species, but not necessary to make a distinction between the oak species within these resources: *Quercus robur* and *Q. petrea*. This is also part of the reason why, even after significant research effort toward the aim, there has been little harmonisation of visual strength grading standards in Europe [1,2]. Strength grading across very broad sets of species has been shown to be possible within certain limits, but not completely independently of species due, especially, to the effect of knots when present [3].

3 THE CONCEPT OF SPECIES

For structural timber, unless appearance, durability or some other species aspect is an additional criterion, the species *per se* is less important than the declared structural properties. Indeed, a key concept of general strength class systems such as in the European Standard EN338 [4] is that timber can be specified with almost no regard to its species.

In that sense, the limitation of species in strength grading performs a similar role to the limitation of growth area. These two things are part of what determines how the timber should be graded, and what design properties can be obtained. Indeed, a fine distinction of species may well be a way of indirectly being more specific about growth area within countries that have varied growth conditions.

The taxonomy of trees is done by botanists, rather than timber engineers. Family, genus and species are assigned based on the morphology of the tree's features and, more lately, from genetic sequencing. For wood properties, a fine distinction between species may be of no consequence, but it can also be the case that differences below species level do affect the grading enough that they need to be accounted for. This could be because the subspecies or variety is different because of the growth conditions it has naturally adapted to, or because cultivars, seed provenance or clones have been chosen because of their desirable timber characteristics.

Even the matter of strict botanical species is not necessarily clear cut, and since there is no single central authority on taxonomy, even being specific about species can be tricky; especially when historical trade names and documents do not correspond exactly to the latest botanical state-of-the-art.

Therefore the concept of species in timber grading is not the same as the botanical one. In timber grading we might refer to *Handroanthus* (a genus in taxonomy) and *Pinus nigra* subsp. *nigra* (a subspecies level distinction) both as a "species", and *Larix decidua*, *Larix kaempferi* and *Larix×marschlinsii* as a "species group" (even through the hybridisation of larch is something of a spectrum).

We might even include some other aspect into our concept of species that is to do with the growth conditions. In Europe, machine control grading gives us one example in having a distinction between *Pinus pinaster* and *Pinus pinaster* trees at least 40 years old (Xyloclass F machine settings Table 21-2 [5]).

Less obviously, growth conditions maybe the reason we need to make some subspecies level distinctions, such as for the various types of *Pinus nigra* that appear in European grading rules and standards (see below). This also gives us another example: The description of *Pinus nigra* and *Pinus nigra* subsp. *laricio* each as a "species", and a mixture of *Pinus nigra* subsp. *laricio* and *Pinus nigra* subsp. *nigra* as a "species group".

It is not always clear how best to control species in structural timber grading, and in many respects it might be helpful; to regard all timber as a kind of mixture, even if nominally the same species.

4 THE DESCRIPTION OF A SPECIES COMBINATION

A species combination can be specified at different levels:

1) Listing at genus level.
2) A specific list at species level, but regarded as if a single species
3) A specific list at species level, regarded as a combination of species
4) A list with items below species level, such as subspecies, variety or clone.

A specification at genus level might be more restricted than it first appears, since the way the trade operates might limit in other ways. It is also the case that a list of species might be a long one and it is common to combine species that are only distantly related genetically. As an example, Figure 1 shows a phylogenetic diagram ending in species

https://doi.org/10.52202/069179-0107

and species combinations that appear in European strength grading documents, and Table 1 lists the species combinations. These are not exhaustive since there are additional items in national standards.

In practice, these four ways of describing a species combination are not completely distinct since taxonomy can differ. It is also the case that a specification of a single species, might be regarded as mixture of below species level distinctions. For example, in the European grading system *Pinus sylvestris* is not sub-divided (except by growth area) but it could be considered as a mixture of *P. sylvestris* var. *sylvestris, P. sylvestris* var. *lapponica, P. sylvestris* var. *hamata, and P. sylvestris* var. *elicinii.* Europe also has (non-native) *Pseudotsuga menziesii* var. *glauca* and *P. menziesii* var. *menziesii*, but the two are covered under a single listing of *Pseudotsuga menziesii*, and for timber strength grading the benefit of distinguishing varieties taken out of their native growth conditions is, anyway, questionable.

For timber grading, the matter of whether a resource should be treated as a species combination or not should be about the considerations that can affect grading, and not strict botanical taxonomy, which has no concern to wood properties. This can mean treating a single species as if it was a combination of elements, or ignoring botanical distinctions that are of no consequence to the timber.

5 SOME EXAMPLES

In the most recent draft of the European Standard EN1912 [6], the standard which lists assignments to strength classes (design values) from visual grading, pine from France is specified as a group with the exception of *Pinus pinaster*. This is because the available test data showed that this species (from France) graded less well (had lower design properties) than the other pines (when done to the French visual grading standard). Since it would be possible for a batch of timber to be of a single pine species it was necessary to either exclude *P. pinaster*, or lower strength class assignment (design values) to the level of *P. pinaster*. The first option was chosen as the better compromise for the industry.

The standard EN1912 [6] also lists a very specific entry for poplar from France, *Populus×canadensis* cv 'Robusta', 'Dorskamp', 'I 214', 'I 4551' due to the high level of variability across the poplar cultivars in the country. However, thanks to extensive additional testing, settings for machine control grading with several machines [5] were approved in 2019/20 for the very general species description: *Populus spp.*

Larches readily hybridise where they meet naturally, and where they are planted. This makes strict distinction by species unachievable in some situations. There are machine grading settings for *Larix sibirica* under the European system [5] but also confusion with *Larix gmelinii* (in [7]) with which it hybridises in Siberia and with no distinct line between the two. Some botanists also recognise a species *Larix sukaczewii* separately from *L. sibirica* on the basis of morphological differences that others regard as environmental rather than phylogenetic. In cases like this, the species distinction and growth area distinction are hard to separate.

The latest draft of EN1912 [6] also includes an entry for fir from Türkiye, which combines *Abies cilicica* with *Abies nordmanniana*. However, since some botanists regard the sub-divisions *A. nordmanniana* subsp. *equi-trojani* and *A. nordmanniana* var. *bornmuelleriana* as species in their own right (*Abies bornmuelleriana and Abies equi-trojani*) it is not clear cut whether the combination of Caucasian and taurus fir from Türkiye is two species or four.

6 KINDS OF MIXTURE

It is also necessary to take into account the possible different kinds of species combination, which include:

1) Intimate mixtures in the forest, which are not practical to separate in the wood value chain. The wood is processed, graded and sold as a mix. Batches of processed timber might be expected to contain reasonably consistent ratios of the different species components (although it may not be possible to know this).
2) The species are separate in the forest, but harvested at the same time. They could be separated, but there are commercial reasons not to. The species are processed, graded, and sold as a mixture. Batches might contain quite varied ratios of components, because logs of different species are not so well mixed as in case (1).
3) The species are separate in forest, and are not harvested at same time. Species are processed as individual species but graded on common basis and sold as species combinations for market convenience. Batches contain very varied ratios of components because the species are only combined later in the process.
4) The species are separate in the forest, and not harvested at same time. They are processed and graded as individual species but sold under a species combination for market convenience. Batches of timber are generally always not a mixture when graded, but they could be mixed by merchants and end users.
5) Species are processed and sold separately, but under a common grading process which covers a number of different species.

7 CONSIDERATIONS FOR MIXTURES

7.1 Before strength grading

In the case when sawmills have some choice as to whether or not to process logs of different species together, there are several practical factors to consider including whether the species are similar for debarking, sawing and drying. The way the sawmills process the timber will have an effect on the species mix in the packs of graded timber, but even if the species are well mixed in production, the packs are likely to be less mixed, due to the number of boards that come from individual logs ending up together.

Genus level as if a single species	
Temperate	
Poplar spp.	Poplars
Tropical	
Qualea spp., Ruizterania spp. *	Mandio (gronfolo)
Chrysophyllum spp. (syn. *Gambeya spp*)	Longhi
Dipterocarpus spp.	Keruing
Dryobalanops spp.	Kapur
Beilschmiedia spp.	Kanda
Handroanthus spp.	Ipé (Ebene verte)
Peltogyne spp.	Amarante (Purpleheart)

A species list as if a single species	
Temperate	
Quercus petraea, Quercus robur	European oak
	Tropical
Erythrophleum ivorense, Erythrophleum suaveolens	Missanda (Tali)
Intsia bijuga, Intsia palembanica	Merbau
Milicia excelsa, Milicia regia	Iroko
Shorea glauca, Shorea maxwelliana	Balau (bangkirai)

A species list as a species combination	
Temperate	
Abies alba, Picea abies	Spruce & fir whitewood
Abies alba, Picea abies, Pinus sylvestris	Redwood & whitewood
Abies amabilis, Abies concolor, Abies grandis, Abies magnifica, Abies procera, Tsuga heterophylla	Hem-fir
Abies balsamea, Abies lasiocarpa, Picea engelmannii, Picea glauca, Picea mariana, Picea rubens, Pinus banksiana, Pinus contorta, Pinus ponderosa	S-P-F (spruce-pine-fir)
Abies balsamea, Abies lasiocarpa, Picea engelmannii, Pinus contorta, Pinus lambertiana, Pinus monticola, Pinus ponderosa, Tsuga mertensiana	Western white woods
Abies nordmanniana, Abies cilicica, Abies bornmuelleriana, Abies equi-trojani	Caucasian and taurus fir
Larix decidua, Larix × marschlinsii, Larix kaempferi	Larch (European, Japanese and hybrid)
Larix decidua, Larix × marschlinsii, Larix kaempferi, Pseudotsuga menziesii	Larch and Douglas fir
Larix occidentalis, Pseudotsuga menziesii	Douglas fir-larch
Manilkara bidentata, Manilkara huberi	Balata Franc (Massaranduba)
Picea abies, Picea sitchensis	British spruce
Picea abies, Pinus sylvestris	Norway spruce and Scots pine
Pinus caribaea, Pinus oocarpa	Caribbean pitch pine
Pinus echinata, Pinus elliottii, Pinus palustris, Pinus taeda	Southern pine
Pinus elliottii, Pinus taeda	Loblolly pine and slash pine
Pinus nigra, Pinus pinaster, Pinus sylvestris	Pines
Pinus nigra subsp. *laricio, Pinus nigra* subsp. *nigra*	Austrian & Corsican pine
Pinus nigra subsp. *laricio, Pinus nigra* subsp. *nigra, Pinus sylvestris*	French pine (not including maritime)
Pinus nigra subsp. *laricio, Pinus sylvestris*	British pine

* EN13556 [8] does not include *Ruizterania*

7.2 During strength grading

The considerations during strength grading depend on the kind of grading, in particular:

- For machine grading, the nature of the things the machine assesses, and how those are combined in the particular indicating property model used for those settings.
- For visual grading, the features possible to assess, how they are quantified (especially knots and ring width) and the grade limits.
- The grade determining properties of the different species (particularly the means, standard deviations and correlations).
- The strength class (design value) requirements, the combination of strength classes being graded, and the particular grade determining property (if any) that is limiting the grading.

Some species influences might not be immediately obvious. For example, the standard EN14081-1 [8] requires visual grading standards to have a rule about ring width or density, with ring width intending to function as a predictor of density when it is not directly measured. However, the kind of species affects this (the transition of earlywood to latewood in softwoods and the ring porous / diffuse porous spectrum for hardwoods), as well as influencing how easy it is to assess ring width. It also interacts with growth condition effects as ring width is also connected to geographical origin and to radial position in the log. Depending on how important ring width is in a particular visual grading scenario, it may or may not limit the possible species combinations.

In the case of grading to a single strength class with near 100% yield the considerations to do with species and grading method may not be so important, especially if the grade limiting property is not the strength. But generally speaking, for effective grading, the species would ideally have similar grade limiting properties, which correlate in a similar way with the grading criteria. Properties that are not grade limiting need not correlate in a similar way with the grading criteria. The degree to which this affects the grading of species combinations depends on both the grading method and the target strength classes (design values).

It is commonly expected that the difference between the species in a combination are ideally of similar variation seen within a single species (within the growth area), but this is not an easy requirement to quantify.

In the case of machine grading, it is also important that the species can be graded with the same indicating property adjustments for moisture content, temperature, cross-section size and machine operating speed.

When grading is controlled via testing in production (known as output control in Europe) the effect of species is only accounted for if the feedback to machine settings is fast enough to adapt to any large deviation in species mix ratio. Measures to separately check individual species in the production testing can mitigate this.

The European strength grading system does not prohibit a species combination that combines both hardwoods and softwoods, although such a thing would need to be based on the "softwood" strength classes due to the secondary properties. It is already the case that lower density hardwoods like *Populus*, *Castanea sativa* and *Eucalyptus nitens* can be given "softwood" strength class assignments.

7.3 After strength grading

Strength grading ensures the key mechanical and physical properties for structural use, but there are still practical considerations such as similar treatability with preservatives and similar workability from the user perspective (finishing, gluing, moisture movement, dead knots, resin pockets, need for pre-drilling etc), especially for use in laminated timber products. Product and usage standards might also have specific restrictions based on species.

To a certain extent there needs to be similar appearance for market acceptability, and similar average density (for predictable self-weight, handling, drilling etc). However, in the European system, the grading is only concerned with a minimum characteristic (5^{th} percentile) density and the mean density is not explicitly controlled.

If the different species are distinguishable as sawn timber, the grading should still be safe even if the end user or merchant separates them for some reason.

8 VERIFICATION OF GRADING

Whether or not species should be included as a specific aspect of the grading verification calculation (and sampling for the testing) depends on the situation. If the species cannot be distinguished before, during and after grading in real production, it is usually appropriate not to treat species separately in the verification. However, it is still necessary to consider how similar those species are to allow for the expected variation in the mixture from sawmill to sawmill and timber pack to timber pack. For that reason, if species can be distinguished in sampling it is advisable to do so.

If species can be distinguished, it is prudent to check each species individually. In the framework of machine control grading in Europe [9] this could be done by creating additional verification samples in a similar manner to the geographical ones. An example of this is provided in an accompanying paper [10].

A full separate check on species is expensive in test data, and if species differences are thought comparable to growth area differences, it may be appropriate to treat the addition of a species to an existing grading route in a similar way to the route for an already included species to an extended growth area.

When it is not economic to do a large enough testing programme to fully resolve the uncertainty, the grading assignment should be correspondingly conservative. It is not enough that a resource as whole grades correctly since it is packs of timber that are used in structures, and grading must work correctly at that level whatever

https://doi.org/10.52202/069179-0107

realistic separation of the species has occurred before, during or after grading.

There are two additional ways in which fully separate grading verification calculations could be combined, although since they require a large amount of testing they are less useful for bringing minor species to market:

1) Separate calculations but with the same indicating property model and thresholds (or visual grading rule and assignment) so that the grading process can be common.
2) Separate calculation and also different grading settings (or visual grading rules), but the graded timber marked and sold as a combination for market convenience.

9 RECOMMENDATIONS

It is recommended that national grading experts work to develop a framework for establishing grading assignments for new species combinations, rather than develop requirements for sampling and verification on an *ad hoc* basis as new grading reports are prepared. This would make it clearer for those developing the grading assignments, and also help to ensure that relevant considerations are accounted for from the planning stage. Nevertheless, it will still be necessary to be able to adapt this framework as more information is revealed through experience. Whatever the approach, it would be important that it is not subservient to strict botanical taxonomy, but rather use taxonomy as part of the way that the resource is defined.

Developing the grading assignments by treating each species (or other relevant resource division) separately is the most robust approach, but requires a very large dataset and it is not always practically possible to distinguish the individual species during the grading development work, while still maintaining the overarching requirement for the sampling to be representative of the resource. The best course of action depends on the context both before and after grading.

For new grade combinations, and lesser-used species, it may be advantageous to also include a mean or upper percentile density to allow for fact that actual density may be considerably higher than the declared value, in order to avoid over-weight problems for handling and transport.

PREDICTION OF TIMBER TWISTING BASED ON MEASURED SPIRAL GRAIN OF SPRUCE TRUNKS AND LOGS

Kloiber Michal[1], Kunecký Jiří[2], Kotmel Miroslav[3]

ABSTRACT: This work focuses on the prediction of timber (beam) twisting based on the measurement of spiral grain under the bark of spruce trees (using Fakopp) and the subsequent measurement of spiral grain of logs during manipulation using a slope of grain detector. When selecting wood, it is necessary to take account of the effect of spiral grain on sawing; based on international practice, a spiral grain up to 5% deviation per 1 m of log length is not considered a defect. However, it is important whether the spiral is left-handed or right-handed, as measured on the log perimeter. Left-handed spiral increases after log processing while right-handed spiral decreases. The perimeter of an element from a left-handed log that was within the acceptable 5% angle deviation per 1 m of length manifests a considerably higher deviation when machined, which markedly affects the timber twist during drying. By contrast, beams from right-handed logs with up to 5% deviation per 1 m of length have perimeter without spiral grain, and they are not defected by twist during drying. This phenomenon has been confirmed by the study conducted. Further, a good prediction of spiral grain in trees has been achieved using non-invasive equipment, Fakopp ArborSonic Microsecond Timer.

KEYWORDS: Timber, spiral grain, twist, structural repair.

1 INTRODUCTION

All trees (and also Norway spruce) can contain spiral grain under the bark. Spiral grain trees have better resistance to strong wind and it helps them prevent breaking. When straight grain trunks are loaded, the side closer to the loading force is under tensile stress while the other side is compressed, which causes tension. In spiral grain trunks, the compression and tensile forces are transferred along the spiral to the other side of the trunk, which balances the tension. Many trees begin to grow twisted under the strong pressure of wind and snow. Under such conditions, the grain can deviate up to 30° from the vertical direction of growth. This twisted growth provides the tree with a better protection against mechanical damage; it can be considered a type of protective response [1].

If a tree grew perfectly straight, only the needles above the roots would receive water from them, and the roots directly below the needles would receive nutrients. Damaged roots on one side would then lead to dying of branches on that side. Twisted trees supply water from one root to all the needles, and conversely, nutrients from one branch flow to all the roots [2].

Twisted growth means spiral grain along the pith. In the saw machining practice, the spiral grain within 5% of angle deviation per 1 m of length is not considered a defect, which is very tolerant and often unacceptable for the final user of the timber as the product is damaged by twist. The reasons for spiral grain vary, slanting of cambial cells is most often mentioned. Cambial cells - spindle-shaped initials - are elongated and capable of coordinated reorientation in response to internal and external stimuli. Their intensity decreases rapidly as the tree ages [3]. The bark is very different in this respect because it is produced outside the vascular cambium, without the oriented spindle cells [4]. Therefore, it is not possible to predict the twist on logs without debarking.

The direction of the spiral grain can be left-handed, right-handed, or there is straight grain. The spiral can change along the trunk and there is no regularity. Across the trunk, it can change from a left-handed to a right-handed spiral from the pith towards the perimeter [5][6]. In Norway spruce, the left-handed spiral is usually the greatest in the 4th to 10th tree ring, counted from the pith. Subsequently, the spiral usually decreases and the spruce becomes straight-grained somewhere between the 40th and the 70th tree ring [7]. With the increasing number of tree rings within the rotation period, the spiral gradually turns to the right. This pattern applies to all species within the *Picea*, *Abies* and *Larix* families, plus almost every member of the *Pinus* family [8].

Spiral grain is usually found in trees growing in sparse stands and in avenues of solitary standing trees, which testifies relation to the tree growth speed [9]. This suggests that the decrease in spiral is not only related to

the effect of tree age or diameter, but may be influenced by the availability of nutrients and water to stimulate growth. The effect of wet snow and high winds on the spiral degree has been presented in the past [10], [11].
The spiral grain direction is the same whether you look from the crown to the roots or vice versa. Therefore, the spiral grain direction can be established also for short logs where the bottom and the top cannot be determined.
For Norway spruce, the undesirable left-handed spiral mainly appears in young trees, that is why timber from thin trunks twists more often than that from trunks from a mature stand [12]. Therefore, the central (juvenile) part of spruce logs is not suitable for use as structural timber. The general impact of spiral grain on timber utilization depends on the rate and duration of the development from the pith towards the cambium [8].
The spiral grain may have a considerable impact on the timber behaviour during drying, particularly twisting [13]. In consequence, the angle of spiral grain is an important parameter for each model that aims to describe the sawn timber deformation after drying and the subsequent moisture content changes during storage and use. The higher the spiral grain angle, the greater the timber twist when drying [15], [16], [17].
Various techniques have recently been proposed to determine the degree of the spiral, e.g. [18] developed an automated method for measuring twist on logs; the method uses the light-conducting properties of softwood tracheids to measure the grain orientation on the external side of debarked logs. This method has enabled high resolution measurements over large areas and segregation of material with visible spiral. The applicability of visible light and laser is limited by the presence of bark on the log [19].
Other non-destructive methods for measuring spiral of logs, e.g. using X-rays are presented by authors [20], [21]; use of microwaves is presented in [22], [23]. These techniques require expensive equipment and powerful mathematical modelling; yet, they are increasingly commercially applied. The variation there is up to 10 degrees. The most accurate method to determine the spiral is splitting [24].
A very precise yet simple method is pressing a sharp tip into the wood surface and marking the longitudinal direction of the grain with a slope of grain detector [25]. The slope of grain detector consists of a steel rod, which is loosely placed in a rotating wooden handle at one end, with a needle (tip), which is pressed into the wood, protruding at the other end. This simple tool allows for satisfactory results and can be used with great accuracy if its limitations are understood and measures are taken to eliminate them.
The tendency for spiral grain of tree trunks can be detected directly under the bark or can be seen in the roots [26] and also branches [27]. The spiral grain estimation from branches was used in the past by shingle manufacturers, who thus eliminated unsuitable left-handed logs. However, research has shown that the spiral of branches and trunks is not identical. For example, [27] took detailed measurements of 11 *Larix kaempferi*, *L. gmellinii* trees and found that the mean values for spiral and their standard deviations were twice as large in the trunk as in the branches.
The processes used to detect the spiral grain direction of wood need not be applied to sawn timber or debarked logs only. Some methods can be used for standing trees without permanent damage, e.g. bark stripping. [28] used ultrasonic testing equipment Pol-Tek to determine the direction - sound pulses propagate at maximum speed in the direction along the grain. Our measurements, made by indenting probes through the bark of standing trees, showed the method applicability to determine the spiral grain direction on the tree trunk perimeter under the bark with an accuracy approaching 90 %.
The study reported here was designed to provide information on the spatial variation in Norway spruce trunk spiral grain, using:
• the prediction of spiral grain based on trunk measurement by stress-wave;
• the prediction of timber twisting during drying based on trunk measurement by stress-wave;
• the prediction of timber twisting during drying based on sawlog measurement by a slope of grain detector;
• the prediction of timber twisting during drying based on the actual timber measurement by a slope of grain detector.
Thirty spruce logs from 22 trees were examined to improve our understanding of the spatial variation of spiral grain within a trunk and the ability to predict it given the potential distortion of beams during drying.

2 SPIRAL GRAIN MEASUREMENT

For the purpose of the experiment, the spiral grain was measured in 22 selected trees of Norway spruce (*Picea abies* (L.) H. Karst.) from the forest stand near Oblajovice municipality, which is a part of Natural Park Polánka, in the western part of the Českomoravská vrchovina Highlands (central area of the Czech Republic). The trees grew at an altitude of 650 m a.s.l., i.e. at the bottom line of Norway spruce natural occurrence. The selection of the trees was carried out with exclusion of damaged trees and other defects arising during tree growth (swollen rootstock, crooked trunk, cracks, branched lower part of the trunk, etc.). The breast height diameter of the trees ranged between 40 cm and 60 cm. After harvest, 6m logs were cut out.
The spiral grain was measured at the breast height by means of Fakopp ArborSonic Microsecond Timer. This device is supplied to the market by the Hungarian manufacturer Fakopp Enterprise. The principle consists in measuring the passage time of a stress wave through the trunk [29]. The equipment uses push-in sensors that provide the signal transfer and the contact with the wood. The wave passes through material in a constant speed, the frequency depends on the hammer force on the sensor head. The push-in sensors are fitted using a specialised template (Fig. 1) 50 cm apart from each other in the trunk longitudinal axis and 5 cm far from the trunk axis at the same time, so that the top sensor (excitation) is displaced to the left and the other sensor (receiver) to the right. This sensor placement allowed measuring the speed in the left-handed direction. When the sensors were changed to

measure the right-handed direction, the top sensor was placed 5 cm to the right from the longitudinal axis and the lower sensor 5 cm to the left (Fig. 2).

Figure 1: *Measuring the tree spiral grain in the bark by means of Fakopp ArborSonic Microsecond Timer and a template*

After the time of stress wave passage through the left- and right-handed placement of sensors was measured, the propagation speed ($m.s^{-1}$) was calculated. The difference between right- and left-handed speed measurements were correlated with the real slope of grain on logs after harvest using the slope of grain detector (Fig. 3), consisting of a wooden handle in which a metal rod is inserted so that it can turn freely. The rod is bent in the right angle and its tip is fitted with a metal spike.

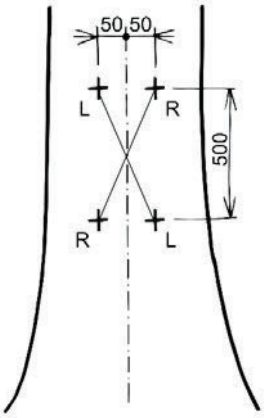

Figure 2: *Positions and placement (mm) of sensors for measuring the stress wave propagation speed in the longitudinal direction of the tree (L-left-handed and R-right-handed measurements)*

Before the slope of grain detector was used, the bark had been removed with a drawshave and the log axis had been marked with a carpenter pencil and a ruler. Then the spike was pushed in the axis marked on the trunk and the real grain deviation was carved. The grain deviation from the log longitudinal axis (mm/m) was measured along a distance of 20 cm and then calculated per 1 m of length, as standards apply, e.g. EN 1310:1997 [31]. The spiral grain established by means of the slope of grain detector was measured on both ends of 6m logs and then averaged for each log. In the case of trees with a large diameter, two 6m logs were used for the measurement: 0-6 m of the tree height (22 pcs) and 6-12 m of the tree height (17 pcs), 39 logs of spruce in total. The diameter of the upper logs had to be large enough to yield a beam of 20×25 cm profile. I.e., the log diameters corresponded to the common processing procedure, in which sometimes two 6m logs are taken out from one tree and sometimes only one is possible. The condition was applied that the final sawmill product (20×25 cm structural beam) needs to have sharp edges without rounding.

Figure 3: *Measuring the spiral grain under the bark by means of slope of grain detector*

When the measurement of logs was finished, they were sawn into 20x25cm beams, 6 m long, which were stored in a pile and dried in a natural way to 16% moisture content. Out of a total of 39 spruce logs, 30 were used for sawing. The naturally dried beams were subjected to twist measuring: one end of the beam was stabilised in the vertical position using a spirit level and the twist deflection was measured on the vertical surface of the other beam end (Fig. 4). The measured deflection was used to calculate the twist angle of the naturally dried beams.

3 RESULTS AND DISCUSSION

Recently, emphasis has been placed on the quality of timber, which is dependent on our understanding of spiral grain and its effect on sawmill products [32]. The selection of suitable logs based on the determination of the spiral grain and a prediction of timber behaviour during processing are essential for processing. In this study, a non-invasive approach of detecting spiral grain directly on the tree using the Fakopp 2D instrument has been proven to be effective; the probes of the instrument are arranged in an X-shaped pattern at the breast height of the trunk, i.e. both left- and right-handed directions of stress wave propagation are covered (Fig. 2). The differences in the propagation speed of the stress wave in both directions can predict the direction and especially the degree of the spiral grain with an accuracy of R^2=0.93, which is confirmed by the results presented in Fig. 5. The high accuracy is related to the bottom log, i.e. 0-6 m from the tree base. In the case of the spiral grain prediction for two 6m logs (0-12 m tree height), the coefficient of determination decreases slightly R^2=0.87 (Fig. 6.) In the case of predicting spiral grain only for the upper log (6-12 m tree height), the coefficient of determination is R^2=0.78 (Fig. 7).

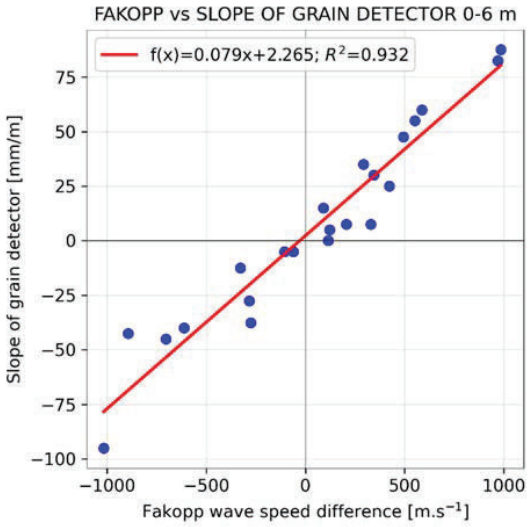

***Figure 5**: Dependence of the difference in longitudinal stress waves speed from Fakopp measured at tree breast height compared to spiral grain as measured by the slope of grain detector, measured on logs 0-6 m from the tree base*

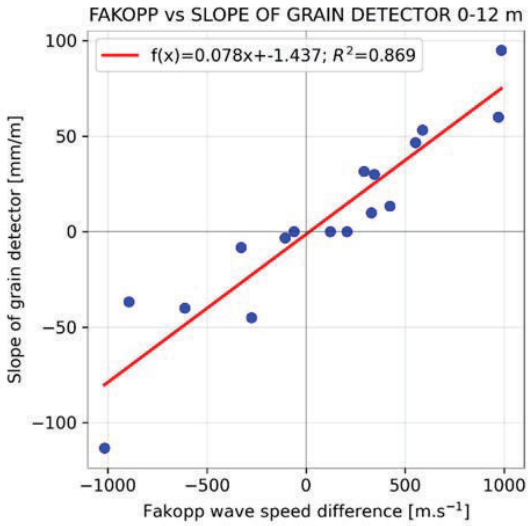

***Figure 6**: Dependence of the difference in longitudinal stress waves speed from Fakopp measured at tree breast height compared to spiral grain as measured by the slope of grain detector, measured on logs 0-12 m from the tree base*

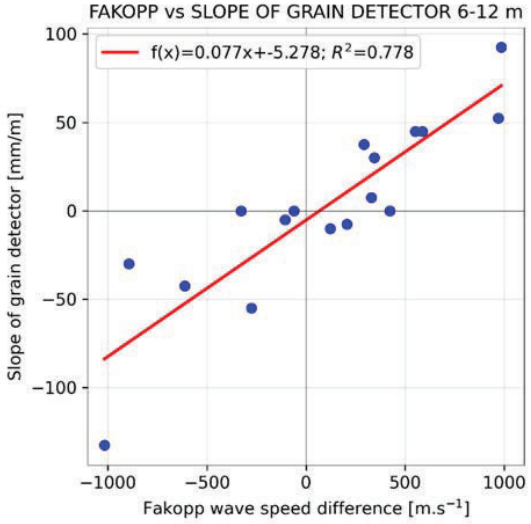

***Figure 7**: Dependence of the difference in longitudinal stress waves speed from Fakopp measured at tree breast height compared to spiral grain as measured by the slope of grain detector, measured on logs 6-12 m from the tree base*

When trying to predict the timber twisting (0-6 m from the tree base) after natural drying from the differences in the stress wave propagation velocity for the two directions of spiral grain measured using the Fakopp 2D instrument, the coefficient of determination is R^2=0.81 (Fig. 8). The upper logs (6-12 m from the tree base) yield an even better coefficient of determination: R^2=0.92 (Fig. 9), and the combined logs (0-12 m from the tree base) reach a coefficient of R^2=0.95 (Fig. 10).

The graphs show that for left-handed spiral, we can accept speeds of up to 250 $m.s^{-1}$ when predicting the spiral grain from differences in the stress wave speed, in order to avoid the undesirable twist (greater than 5° in a 6 m long

log) when drying the timber. Speed differences for left-handed spiral greater than 250 m.s^{-1} mean that such timber should be avoided as it will represent significant loss caused by material acquisition and cutting costs. On the contrary, the differences in the stress wave speed in the case of right-handed spiral indicate that the twist of the sawmill product will be minimal even if the differences in measured speeds reach 1000 m.s^{-1}(Fig. 8-10).

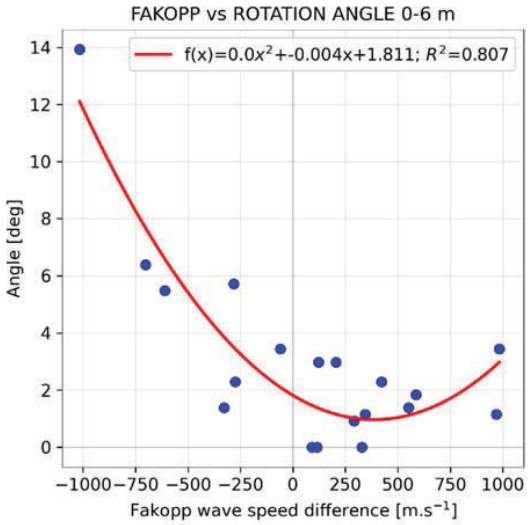

***Figure 8**: Dependence of the difference in longitudinal stress wave speeds from Fakopp measured at the breast height compared to the twist of a 20×25×600 cm beam from a log cut at 0-6 m from the tree base*

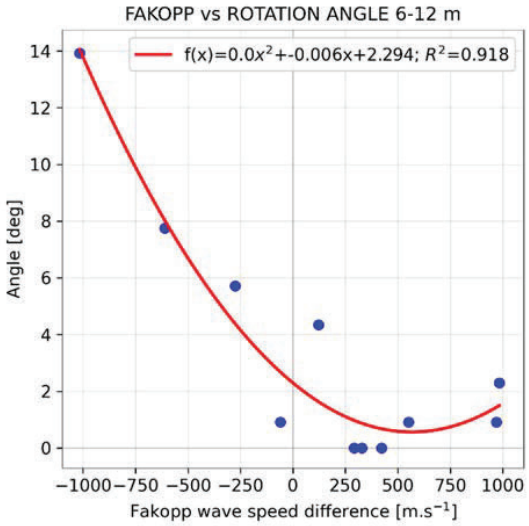

***Figure 9**: Dependence of the difference in longitudinal stress wave speeds from Fakopp measured at the breast height compared to the twist of a 20×25×600 cm beam from a log cut at 6-12 m from the tree base*

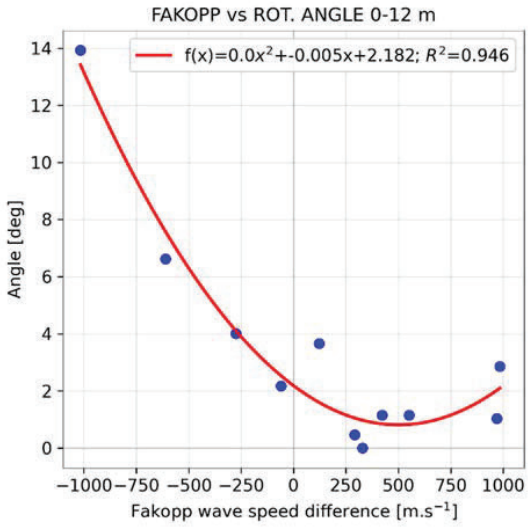

***Figure 10**: Dependence of the difference in longitudinal stress wave speeds from Fakopp measured at the breast height compared to the twist of a 20×25×600 cm beam from a log cut at 0-12 m from the tree base*

The above dependences between the differences in the stress wave speeds measured on a tree with the Fakopp 2D instrument and the beam twisting show that this is a very accurate prediction, which can be obtained directly in the forest using totally non-invasive measurements on the tree. The prediction accuracy is also confirmed by the following graph in which timber twisting is in direct dependence on the spiral grain as measured by the slope of grain detector on logs - the coefficient of determination reaching R^2=0.82 (Fig. 11). It is therefore a prediction that can be carried out in the storage facility or directly in the forest during harvest.

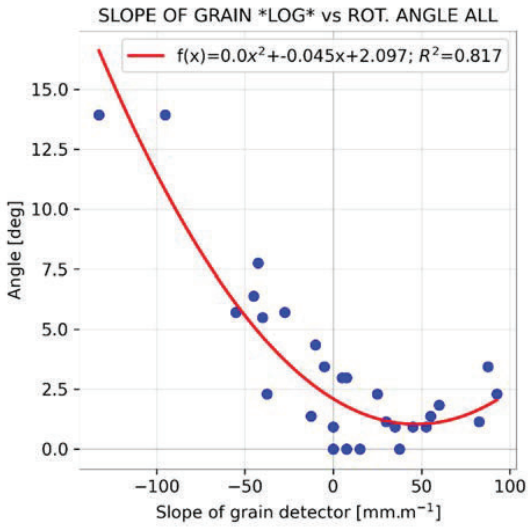

***Figure 11**: Dependence between the spiral grain measured by the slope of grain detector in a 6m log and the timber twisting*

https://doi.org/10.52202/069179-0108

The coefficients of determination reach a similar level to the prediction of speed differences using stress waves measured directly on the tree. In order to gain a twist of maximum 5° per length in a 6m beam, the grain deviation of the left-handed spiral can be 25 mm/m at maximum (Fig. 11). On the other hand, in the case of right-handed spiral, grain deviation detected by the slope of grain detector can be as high as 75 mm/m, and the beam twist will meet the maximum tolerance of 5°.

Therefore, it can be argued that spiral grain and the resulting problems with timber processing for construction purposes can be eliminated directly in the forest when selecting trees, or later in a storage place. Naturally, this concerns small volumes, for example, when selecting timber suitable for repairing structural elements of roof trusses, ceilings or other parts of historic buildings. The results of this study show that the spiral grain is an important variable affecting the twist of timber. Data analysis shows that the direction of spiral and its deviation have a significant effect on the twisting. The data on spirals show that the spiral pattern across the trunk starts from an initial left-handed direction, gradually decreases towards the log perimeter, and in about half of the cases it turns into a right-handed pattern, as already suggested by [13], [14], [17]. The above statement can be supported by the dependence between the grain deviation determined by the slope of grain detector directly on the beam and its twisting during natural drying (Fig. 12). The spiral grain variance at the same angle of beam twist is the same for the left-handed and right-handed sides (ideally 0 mm/m). This is different from the spiral grain found on the perimeter of logs, where the ideal degree was around 40 mm/m to the right.

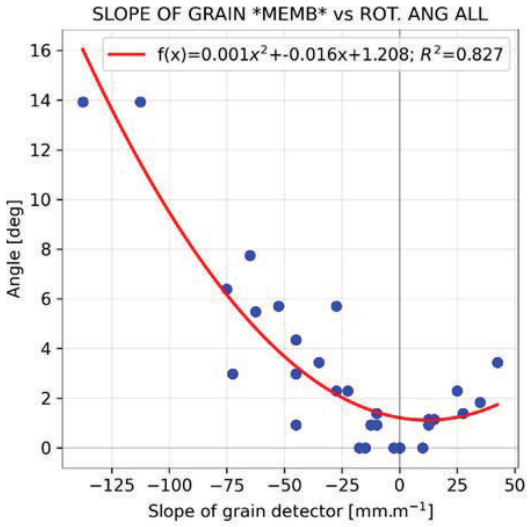

***Figure 12**: Dependence between the spiral grain measured by the slope of grain detector in a 6m beam and the beam twisting*

Previous observations suggested a shortage of straight-grained spruce timber [7]. This finding was confirmed in this study by measurements of 6m logs. Right-handed logs have greater torsion stability than left-handed logs. A likely reason for the greater stability in timber made from logs with a right-handed twist on the perimeter is the balancing of the shrinkage stress during drying [8]. The shrinkage stresses should work against each other, right-handed wood on the log perimeter against the left-handed wood in the central part of the log.

On the other hand, the logs that showed a left-handed spiral grain on the perimeter twist to the left with nothing to prevent them, after the required 20×25cm beams are made. The degree of spiral grain has also been proven to have a significant effect on the timber twist. In addition, previous research shows that left-handed wood has lower strength [21], [33].

4 CONCLUSIONS

The aim was to test the hypothesis that timber selection based on spiral grain measurement on the trunk surface can considerable help reduce the number of sawn timber prone to twist. The quality of timber is markedly affected by the wood spiral grain, which can be non-destructively investigated as early as during the selection of trees in a stand. Fakopp ArborSonic Micosecond Timer proved to be a suitable tool for the spiral grain determination through stress wave propagation speed measurement. The differences in stress wave propagation speed for the left- and right-handed directions, as measured at the breast height, allowed determining the spiral degree with up to 93% accuracy for 6m logs. The impact of left-handed spiral grain on the twist of timber during drying has been confirmed. The optimum log spiral grain proved to be in the range of 0 to 75 mm/m towards the right, then the twist during drying of the structural beams reached a maximum of 5° per 6 m of length. In the case of 0 to 50 mm/m slope of grain to the left, the logs are prone to twist, reaching 7,5° per 6 m of length. A grain deviation greater than 50 mm/m to the left represents a serious damage to timber and this cannot be used for structural purposes.

The problems of timber twisting during the drying process was pointed out by [7], [8], [13], [14]. A possible option to counter the damage is to reduce the tolerance in timber grading. Our recommendation for the production of structural members is to limit the use of logs with a left-handed spiral grain from the 50 mm/m stipulated in standards to 25 mm/m. In the case of right-handed logs, the spiral grain of 50 mm/m is usable as the twist of the final structural member reduces to required deviations close to 0°.

ULTRASONIC-BASED DEFECT IDENTIFICATION IN TIMBER USING UNIFORM MANIFOLD APPROXIMATION AND PROJECTION (UMAP)

Prashanth Gunasekaran[1], Mehrisadat Makki Alamdari[2], Hamid Valipour Goudarzi[3]

ABSTRACT: Naturally occurring strength-impacting defects in timber, such as grain deviation and knots, are common in commercial timber. Additionally, defects caused by the environment such as fungal decay and termite damage are also attributed to strength reduction which can lead to the failure of structural timber. This work provides a demonstration, of applying Uniform Manifold Approximation and Projection (UMAP), a novel feature extraction tool, for the purpose of identifying such defects in structural timber, with the use of an ultrasonic-based examination of the test specimens. Two case studies are presented, the first demonstrating UMAP's capability in identifying grain deviation and knots in timber, and the second, showing its ability to distinguish healthy sections from that with known internal damage. In both case studies, 54kHz pressure waves were transmitted transversely through pre-defined sections of known damage state and were analysed with UMAP – producing highly favourable clustering and data separation between defect states, compared to wavelet packet decomposition, a state-of-the-art signal analysis framework. The key contributions of the study are – UMAP is successfully applied for the first time for damage identification in commercial bare timber, and it is demonstrated to be able to identify signals sent through sections of different defect types. This demonstration in this area opens the door to future works, which may then scrutinise in-depth material-specific factors for the aim of defect characterisation in timber and timber composites using UMAP.

KEYWORDS: Ultrasonic testing, Pressure wave, Wavelet decomposition, Feature extraction, Damage identification

1 INTRODUCTION

Strength-reducing defects are highly common in commercial timber and are either naturally occurring at growth, or induced due to the service environment or loading. Some examples of these defects include grain deviations and knots, associated with the former, and that related to termite damage, fungal decay and splitting damage associated with the latter. Additionally, local splitting failure caused by the rupturing of in-service structural timber due to higher loads also leads to the creation of weak zones. These weak zones incited by these defects have been shown to often be the initiation point of further damage [1], and hence their detection while in-service can be used to inform rehabilitation decisions.

Non-destructive testing (NDT) methods used for the purposes of assessing defects in timber have evolved over the last few decades. Current ultrasonic-based NDT techniques adopted on timber [2] to investigate these defects, face challenges in the signal processing stage. Wavelet packet decomposition (WPD) is one of the leading current signal processing approaches adopted for these purposes in the literature [3]. In [4], the structural integrity of timber utility poles was assessed using WPD, and their embedment depth has also been investigated using similar techniques [5]. In these studies, it was found that its chief challenge was parameter calibration. In WPD, different hyperparameters (levels of decomposition, choice of mother wavelet and filter functions) need to be trialled in order to attain separation of data between healthy sections and defective sections – a time-consuming and multi-variate process.

In this paper, a novel dimensionality reduction and feature extraction tool, Uniform Manifold Approximation and Projection (UMAP) [6], is applied for the first time, for the purposes of timber defect identification. The study is presented in two case studies. In the first case study, a timber specimen exhibiting multiple states including healthy sections, a section with visible grain deviation, and one with a visible knot are tested ultrasonically. The choice to adopt a test specimen with visible defects is justified in the study via the following consideration – the received signal is a function of the medium it was propagated through, regardless of the external visibility of the defect. Hence, the same outputs can be drawn from a test specimen with identical defects that were not externally visible. Accordingly, through visual inspection, the ground truth of the defect state of the specimen can be ascertained and thereafter compared with the output of the adopted signal analysis techniques, serving as an evidence-based mechanism in this study to demonstrate the efficacy of the algorithm.

54 kHz ultrasonic pressure waves (P-waves) are transmitted between the sections transversely, and the signals are analysed first using WPD. Thereafter, the signals are comparatively analysed using UMAP, with the differences between the two methods examined and the superiority of the latter being demonstrated. In the second case study, a test specimen exhibiting healthy sections is adopted, with a void fabricated internally in the middle, creating loss of material – serving as a proxy for a piece of timber that has experienced interior termite damage, fungal decay or internal splitting damage. 54 kHz P-waves were transmitted transversely through pre-defined discretised locations in the timber. Similar to the first case study, the signals were analysed with WPD first, and thereafter compared with a UMAP analysis, their results further discussed.

2 THEORETICAL BACKGROUND

The theoretical background behind the two signal analysis approaches compared in this study is briefly recalled in the succeeding sections.

2.1 WPD METHODOLOGY

WPD is a technique used to fundamentally capture the frequency characteristics of the assessed signal while time-domain information is still retained [3]. A two-stage process is used in the decomposition: (1) The signal is processed with a wavelet transform, wherein features of the signal similar to the adopted mother wavelet are extracted at a particular scale and time. The mother wavelet is scaled and translated over the input signal with the aid of discrete scaling and translation parameters in the transform function. This wavelet transform is recalled in Equation 1. Thereafter; (2) A pair of low-pass filters (LPF) and high-pass filters (HPF) are used to conduct sub-band coding on the signal to delineate time-frequency features, in which the approximate and detail wavelet coefficients are obtained, respectively. The LPF and HPF formulas are recalled in Equation 2 and 3.

$$G_{k,j} = \int_{-\infty}^{\infty} f(t)\psi_{k,j}(t)\,dt \tag{1}$$

where G = wavelet coefficients, ψ = mother wavelet function, k = scaling parameter and j = translation parameter.

$$y_{low}[v] = \sum_{t} f(t) \cdot c(2v - t) \tag{2}$$

$$y_{high}[v] = \sum_{t} f(t) \cdot u(2v - t) \tag{3}$$

where f = input signal, c = low-pass filter impulse response factor, u = high-pass filter impulse response factor, t = translation parameter and v = subsampling parameter.

The level of decomposition is an inherent hyperparameter to be chosen when conducting the analysis. Representations of both the two-level and three-level sub-band coding schema are presented in Figure 1.

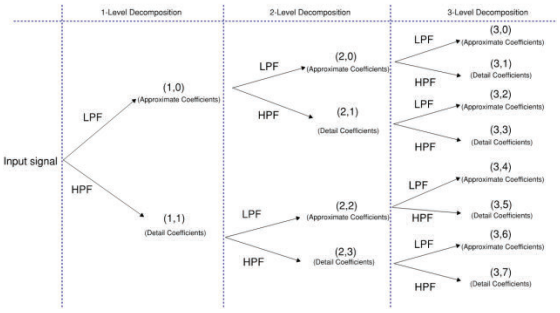

Figure 1: *Illustration of the sub-band coding schema for a 2 and 3-level wavelet packet decomposition.*

Apart from the level of decomposition, another key hyperparameter to select would be the mother wavelet, with a large variety of popular wavelet types adopted in the literature [7-10]. In this study both the Daubechies' 'db2' and 'db4' wavelets were investigated, and both 2 and 3-level decompositions were conducted, their results assessed in the succeeding sections.

2.2 UMAP METHODOLOGY

UMAP as an algorithm exists in the dimensionality reduction space, wherein the signal is represented as a point in a multi-dimensional space whose coordinates correspond to its amplitudes. UMAP then reduces the dimensions of the space to an easily comprehensible output graph.

The aim of the algorithm is to cluster signals with similar characteristics together and accurately and distinctively separate those with differing characteristics. It does so in two main stages. The first stage involves constructing the data's high dimensional topology as simplicial complexes. The Nerve theorem is applied, such that each signal is established as a 0-simplex and connections are made between each closely related signal – thereby approximating the topology of the high dimensional distribution of signals. These connections are made through the following process: (1) Spheres of varying radii are created around each signal based on density, through a fuzzy cover, wherein connections are formed with signals of intersecting radii. Mathematically, this is accomplished by first constructing the high dimensional signals on a Riemannian Manifold and establishing the spheres around each signal with a unit size. The required variable radii property is achieved through the homeomorphisms of these unit sized spheres on the manifold and their counterparts in Euclidian space, the latter allowing for such a property via varying notions of

https://doi.org/10.52202/069179-0109

distance. To maintain the same number of neighbouring signals allowed around each signal, fed into the algorithm as a hyperparameter, smaller notions of distance are used in Euclidian space for regions in the topology with higher density, and vice versa. (2) For efficient processing of the connections for each signal, concepts of Random Projection Trees [11] and Nearest Neighbour Descent [6] are utilised. (3) Connections between signals are mathematically represented through connection probabilities, considered via a 'neighbouring' matrix which holds each individual connection probability between signals in the original high dimension. In some regions of the topology, signals could have multiple connection probabilities associated with neighbouring signals in different metric spaces, due to the overlap of multiple spheres, and hence, distances of notion. Probability theory is utilised to condense these multiple connections to a single ideal connection between pairs of signals, by considering the combined probability of all connections between the signal pair.

In the second stage of the algorithm, the higher dimensional simplicial complex is projected to an easily comprehendible lower dimensional space. This done through a cross-entropy process, applied on the complexes, to cluster signals of similar characteristics together, and separate those with dissimilar features, projecting the topology into a two-dimensional graph [6]. The former, considered an attractive component between signals in the operation, is a commonly found trait of modern dimensionality reduction tools. UMAP's strength lies in the latter component of the cross-entropy process, considered a 'repulsive' operation, wherein the requisite distances between dissimilar signals are established. This results in the final output graph attained at the end of the algorithm.

The key hyperparameters to be calibrated for the algorithm are: (1) 'k' nearest neighbours – the number of nearby signals allowed for a given signal in the local metric space; (2) Minimum distance – referring to that between nearby signals in the final output. This hyperparameter is known to assist with the visualisation and cluster depiction; (3) Distance model – chosen for the mathematical calculation of distance between each signal.

3 ULTRASONIC TESTS ON TIMBER SPECIMENS

3.1 CASE STUDY 1

To investigate the versatility of the algorithm in structural defect detection and localisation in plain timber, the following test was conducted. The test specimen features an externally visible knot and grain deviation.

3.1.1 Specimen description

A 300mm long piece of machine-graded Australian *radiata pine* (MGP10), 90mm in width and 45mm in thickness was utilised, shown in Figure 2. Figure 2 also shows a schematic of the visible features in the test specimen. The knot in the specimen can be considered 'dead' due to a visible loss of fibre continuity between itself and the surrounding pieces of wood. The specimen was discretised into 4 sections. The centre of the knot is aligned with Section 4, and the grain direction change due to the presence of the knot is also within Section 3. Sections 1 and 2 did not show any visible signs of defects in the timber and featured longitudinally aligned grains - hence being classified as healthy sections.

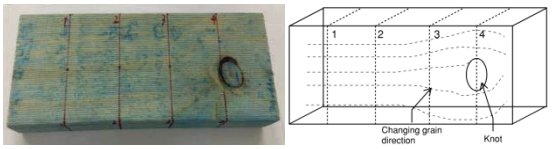

Figure 2: *Machine Graded Pine (MGP10) specimen (left) and schematic expressing defects (right).*

3.1.2 Time signals

P-waves of 54 kHz were transmitted transversely through the specimen, parallel to its 45mm thickness, in the perpendicular to grain direction. At each section of the specimen, 10 signals were transmitted with the transmitter on one end and the receiver on the other, thereafter having their positions swapped and measuring another 10 signals - amounting to a total of 20 signals at each measured section, summarised in Table 1.

Table 1: *Case Study 1 - Section information summary*

Section	Defect Status	Number of signals
1	Healthy	20
2	Healthy	20
3	Grain Deviation	20
4	Knot	20
Total number of signals		80

Figure 3 illustrates a sample of the ultrasonic signals sent through the timber specimen. The vertical axis represents signal energy, and for clearer visualisation, they are translated vertically with respect to each other. From visual inspection of the signals, the presence of the knot in Section 4 causes the most disruption to the received signal relative to the grain deviation in Section 3, when benchmarked against the signals from the healthy sections (1 and 2). The signal from Section 4 exhibits significantly lower wave energy than that of healthy sections, while the signal from Section 3 has similar wave amplitudes.

Prior studies have been conducted using stress waves in timber, wherein recorded phase velocities of signals transmitted transversely (perpendicular to grain) are smaller to that transmitted longitudinally (parallel to grain) - showcasing the significant effect that grain direction has on phase velocities [12,13].

https://doi.org/10.52202/069179-0109

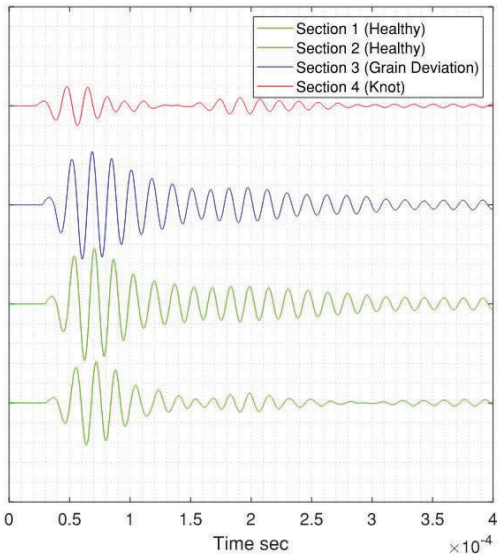

Figure 3: *Sample of time signals measured for each section in Case Study 1. The vertical axis represents signal energy, although each signal has been translated vertically for clarity. The signals are presented in order, with Section 1 featured as the lowermost and Section 4 as the uppermost signal.*

Where phase velocities are concerned in this test, Sections 1 and 2 exhibited similar P-wave speeds, with an average of 1660 m/s. However, in Section 3 with the presence of grain deviation, the average recorded phase velocity was 1838 m/s. In Section 4, wherein the largest disruption of grain direction was visible with the presence of the knot, the recorded average phase velocity of 2340 m/s was the fastest of all sections. This feature is in-line with findings from the aforementioned literature [12,13] demonstrating that in Sections 3 and 4, the grains were deviating in such a way that they were becoming more aligned with the transmitted signals, amounting to a parallel to grain transmission compared to the perpendicular to grain transmission conducted in Sections 1 and 2. This is also complementary with visual inspection of the test specimen shown in Figure 2.

The signal window used for the analysis with UMAP needs to be calibrated prior to use. P-waves exhibit higher phase velocities than surface waves, the latter being a component of ultrasonic signals that are often found to succeed the former [14]. As evidenced in Figure 3, it can be seen that the P-wave component of the signal cannot be easily identified due to significant overlap with the surface wave components. As such, beginning from the largest recorded arrival time from the 80 signals, the upper bound of the signal window used for the analysis needs to be calibrated in order to fine tune the results obtained, while the lower bound of the signal window is set at the start of the signal – although it should be noted that the sensitivity of the output of UMAP to this calibration is low.

3.1.3 Wavelet analysis results and discussion

Firstly, all 80 signals measured in Case Study 1 were analysed using WPD. The two key hyperparameters of WPD to be trialled are levels of decomposition, and mother wavelet type. For this study, both 2 and 3 levels of decomposition are conducted, and both the Daubechies' 'db2' and 'db4' mother wavelets have been trialled in this study.

2-level decomposition

Once both the detail and approximate wavelet coefficients are extracted, following Equation 1 to 3, their wave energies are then calculated. To encapsulate the outputs of the analysis in a single graph, a matrix scatter plot can be used – allowing the relationships of the wave energies of the decomposed signals between frequency band pairs to be expressed. This is represented in the off-diagonal plots presented in Figure 4, making any dependencies between the frequency band pairs easily discernible. The distribution of the wave energies of the decomposed signals within the associated frequency band is plotted on the diagonal plots in Figure 4, allowing single variable dependence to be ascertained.

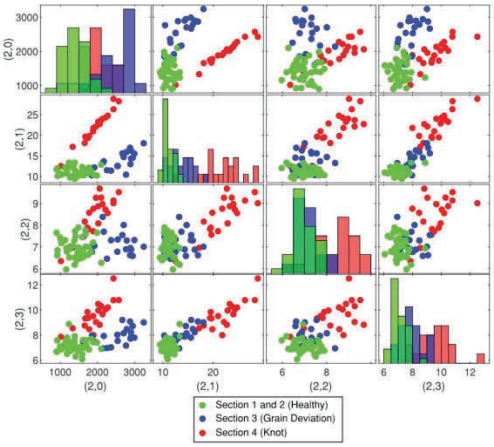

Figure 4: *Case Study 1 - Scatter plot of the signal energies in 4 frequency bands - decomposition level 2 and 'db2' mother wavelet.*

Some of the scatter plots shown in Figure 4 demonstrate some separation between data from Section 4 (knot) and the other sections. In particular, plots comparing frequency bands (2,1 – 2,0) show a promising separation of the majority of the wave energies of Section 4 from the rest, although notably there is still some overlap of the wave energies of some decomposed signals of Section 4 and healthy sections (1 and 2). The same can be said about the overlap of data from Section 3 and that of healthy sections (1 and 2). Investigating the other off-diagonal scatter plots, it can be seen that no distinct separation between data from the sections of each defect type and that of healthy sections can be discerned. The distribution for the wave energies of the individual studied frequency bands computed in each diagonal plot also illustrates

https://doi.org/10.52202/069179-0109

some separation between the section categories, with frequency band (2,1) showcasing the most promise - albeit significant overlap between the studied section categories is still present, with no high-confidence separation between the data.

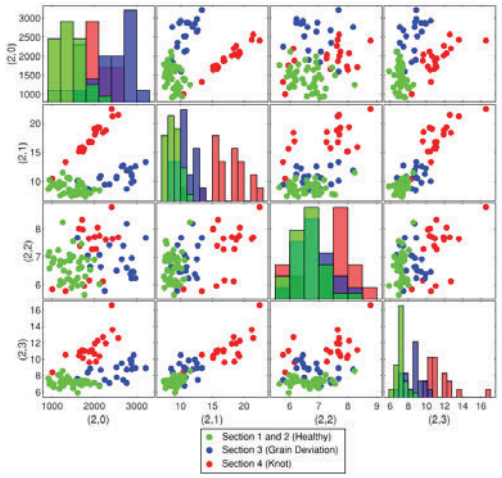

Figure 5: *Case Study 1 - Scatter plot of the signal energies in 4 frequency bands - decomposition level 2 and 'db4' mother wavelet.*

A similar scatter plot to the 'db2' decomposition can be plotted using the 'db4' mother wavelet, as in Figure 5 – the outcome of this analysis also being similar - showing a low sensitivity of the final output to changes in the Daubechies' mother wavelet type. Although some separation in signal energies corresponding to frequency band pairs (2,1 – 2,0) can be seen, none of the off-diagonal scatter plots depict a high-confidence separation of wave energies related to the desired section categories. The distributions of each frequency band plotted on the diagonal also feature large portions of overlap between signal energies of different section categories, also amounting to an undesirable outcome. Ultimately, the analysis using wavelet packet decomposition at 2 levels of decomposition with both the 'db2' and 'db4' mother wavelet does not achieve the desired data separation and clustering required to be able to tell the studied sections apart based on defect status.

3-level decomposition

Similar to the 2-level decomposition, a 3-level decomposition can be conducted on the transmitted signals. As expressed in Figure 1, at the third level of the sub-band coding schema, 8 frequency bands can be analysed, identified from (3,0) to (3,7).

When comparing the wave energies of the 'db2' wavelet decompositions of all 80 measured signals amongst the 8 frequency band pairs in the scatter plot matrix shown in Figure 6, it is clear that the majority of the frequency band pair plots do not show adequate separation between the section categories - a similar result being obtained when a decomposition with the 'db4' wavelet is done, shown in Figure 7. Notably, in Figure 6, some separation of the wave energies of Section 4 is seen, away from that of Sections 1, 2 and 3 in frequency band pairs (3,1 - 3,0) and (3,2 - 3,0).

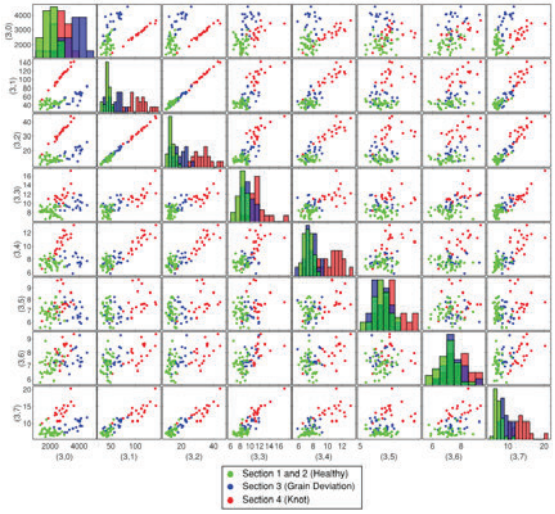

Figure 6: *Case Study 1 - A sample set of decomposed signals over 8 frequency bands with mother wavelet 'db2'.*

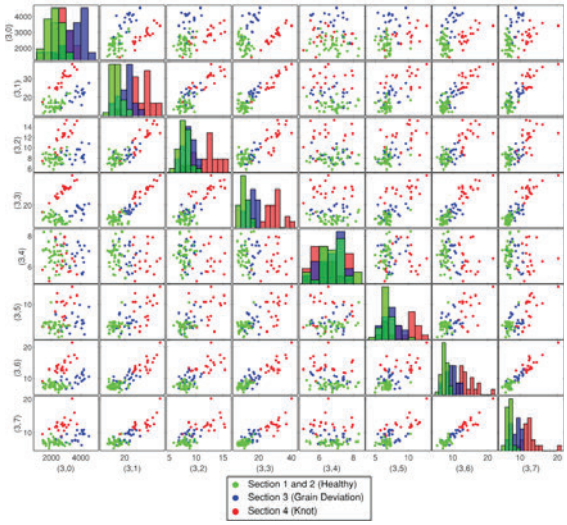

Figure 7: *Case Study 1 - A sample set of decomposed signals over 8 frequency bands with mother wavelet 'db4'.*

However, the distinction of wave energies in Section 3 from Sections 1 and 2 is not sufficient in these frequency band pairs. This feature is missing when studying the scatter plot output of the 'db4' decomposition (Figure 7), revealing the increased sensitivity of the output to the Daubechies' mother wavelet choice at this level of decomposition.

In summary, the preceding investigation could not yield a high-confidence separation between the signals transmitted through healthy sections and defective

sections. Moreover, no separation between signals sent through sections of varying defect types was discernible.

3.1.4 UMAP analysis results and discussion

The UMAP algorithm was also used to analyse the signals. It should be noted that for the UMAP analysis, the same signal window as that used in WPD was adopted. The key hyperparameters needed to be set were: (1) target embedment dimension, (2) k-nearest neighbours, (3) minimum distance, and (4) distance model. (1) refers to the dimension of the final output graph – a value of 2 dimensions being selected for simplicity of comprehension of the final results, additionally allowing for an easy comparison of the UMAP output with that of WPD demonstrated in the preceding sections. (2) and (3) work to control the level of clustering of the signals, changing how condensed or sparsely spaced the data points are, wherein the former sets the number of neighbouring signals which can be associated with a given signal, and the latter controls the minimum separation between neighbouring signals in the output graph. For this investigation, (2) was set at a value of 0.07 and (3) was set to 15 as they provided the most distinct clustering – although it should be noted that the sensitivity of the final output on these parameters is very low. (4) refers to the model used to express the distance between each signal, with many options available in the literature [15-18]. In this study, the Chebyshev distance model [18] was adopted, due to the highly favourable results obtained with this choice.

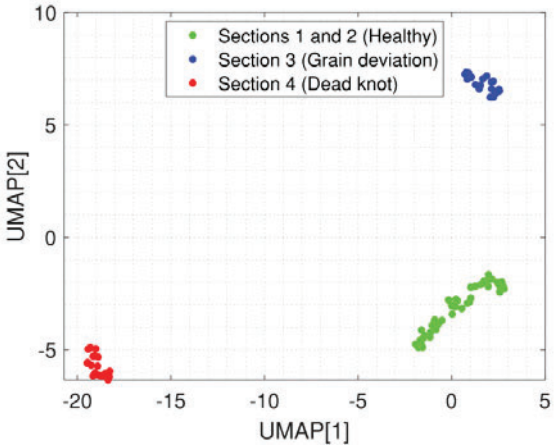

Figure 8: *Case Study 1 - UMAP two-dimensional (2D) reduction output.*

The UMAP results are shown in Figures 8 and 9. There is strong clustering of points with respect to each section. Clusters from both Sections 3 and 4 are separated from that of 1 and 2. Notably, wave behaviour in Section 3 is not clustered together with Section 4, showing the separation between a defect location characterised by grain deviation within a part of the specimen which is still intact with fibre continuity, and a defect location characterised by the centre of a dead knot.

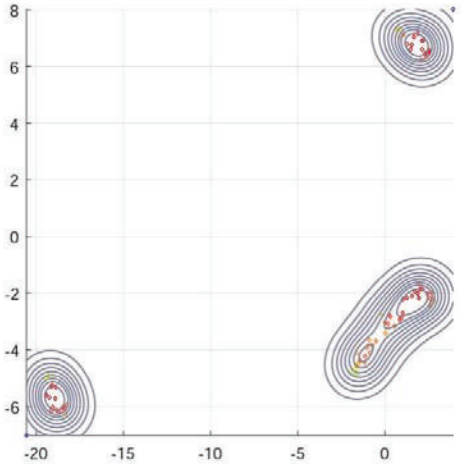

Figure 9: *Case Study 1 - UMAP two-dimensional (2D) cluster topology.*

A schematic of the relevant visual features of the specimen is shown in Figure 2. The outcome is highly desirable, especially since the results are not as sensitive to hyperparameter calibration, compared to the wavelet approach. The results are congruent with visible findings of the timber specimen, clearly distinguishing regions with material defects from those without any. The results demonstrate UMAP's capability of ultimately distinguishing between sections of sound wood and those with strength-reducing characteristics. Additionally, its ability to separate sections experiencing different types of strength-reducing characteristics is highly useful in structural health monitoring applications.

3.2 CASE STUDY 2

To examine the behaviour of both WPD and UMAP for defects caused by fungal decay, termite damage or splitting damage – ultimately eventuating in fibre discontinuity or voids in the centre of the cross-section, Case Study 2 was developed.

3.2.1 Specimen description

A piece of machine-graded Australian *radiata pine* (MGP10), similar to that used in Case Study 1 was employed. The specimen features a 190mm width and 45mm thickness. The specimen was carefully selected, such that no grain deviation or knots were present, with only longitudinally aligned grains visible – signifying a standard healthy section of timber.

3 sections were devised for the case study, a picture of the test specimen and its schematic shown in Figures 10a and 10b, respectively. Sections 1 and 2 are located within the healthy zone of the timber. To simulate the loss of material and fibre discontinuity due to the aforementioned defects, a hole was drilled at the centre of the cross-section, with a 6mm drill bit, as shown in Figures 10a and 10b. This method of simulating either splitting damage or that due to decay or termite attack is justified with two considerations: (1) Termite attack and fungal decay have

https://doi.org/10.52202/069179-0109

been shown to manifest as a material loss with the creation of voids within structural timber [19]; (2) Splitting damage manifests as longitudinally aligned cracks along the length of the timber element, with similar creation of voids used to artificially recreate such damage, as utilised in previous studies [20].

Figure 10a: *Case Study 2 – Test specimen*

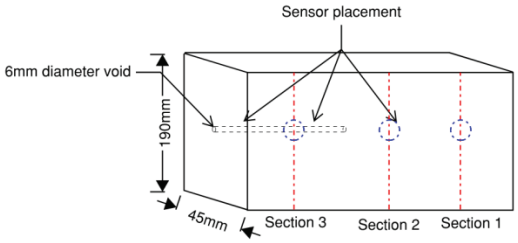

Figure 10b: *Case Study 2 – Specimen schematic*

A point directly aligned over the position of the created void was marked as Section 3, representing the fabricated defective section.

3.2.2 Time signals

54 kHz P-waves were transmitted over each of the sections, similar to the process adopted in Case Study 1. 10 ultrasonic signals were transmitted with a given transmitter and receiver position, and another 10 were recorded with their positions swapped, amounting to 20 signals measured at each location, and 60 signals measured in total for the analysis. A summary of the recorded signals is reflected in Table 2.

Table 2: *Case Study 2 - Section information summary*

Section	Defect Status	Number of signals
1	Healthy	20
2	Healthy	20
3	Drilled	20
Total number of signals		60

The measured time signals reflected a similar phase velocity across all sections, with the recorded averages being 2152 m/s, 2157 m/s and 2159 m/s for Sections 1, 2 and 3 respectively. It can be seen that they have negligible differences between each other, as evidenced by a largely similar wave pattern comparing Section 3 with that of Section 1 and 2, observed in Figure 11, which illustrates a sample of the signals, recorded at each section. This could possibly be due to the small size of the void.

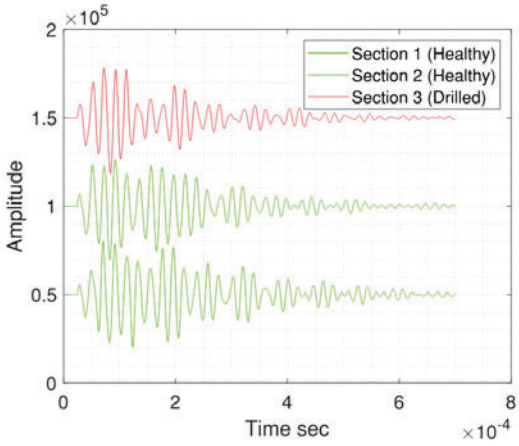

Figure 11: *Sample of time signals measured for each section in Case Study 2. The vertical axis represents signal energy, although each signal has been translated vertically for clarity. The signals are presented in order, with Section 1 featured as the lowermost and Section 3 as the uppermost signal.*

Similar to the observation made in Case Study 1, the distinction between the P-wave component of the signals and the surface waves is not evident from visual inspection and hence, calibration of the signal window for the output of UMAP is required, just as was done in Case Study 1.

3.2.3 Wavelet analysis results and discussion

All 60 recorded signals were analysed using WPD, with both 2 and 3 levels of decomposition trialled, and the 'db2' and 'db4' mother wavelet applied – the identical analysis approach adopted in Case Study 1.

2-level decomposition

Figure 12 provides a depiction of a concise plot comparing the wave energies of all 60 decomposed signals of all 3 sections within pairs of frequency bands to visualise their dependencies, similar to that depicted in Case Study 1. The outcome of the analysis shows significant overlap between the signal energies of the defective section, shown in red, and the healthy sections shown in green, in the off-diagonal scatter plots. The plots comparing wave energies in frequency band pair (2,2 – 2,1) show the strongest positive correlation, with no discernible separation between signals of healthy sections and that of the defective section. The plots comparing frequency band pairs (2,1 – 2,0), and (2,2 – 2,0) show some promising separation, but notably, it can be observed that there is still some overlap between the signals – an unfavourable outcome. This outcome is akin to that demonstrated in Case Study 1.

The same analysis was conducted with the 'db4' mother wavelet, the final scatter plot is shown in Figure 13. Of note, the strong positive correlation of frequency band pairs (2,2 – 2,1) which was evident with the 'db2' mother

wavelet analysis is missing with the 'db4' mother wavelet.

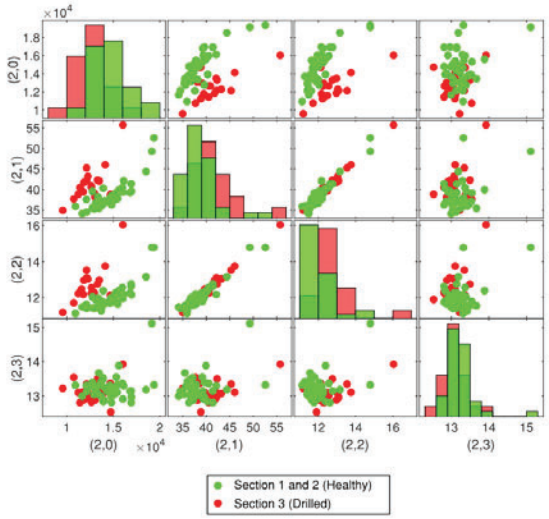

Figure 12: *Case Study 2 - Scatter plot of the signal energies in 4 frequency bands - decomposition level 2 and 'db2' mother wavelet.*

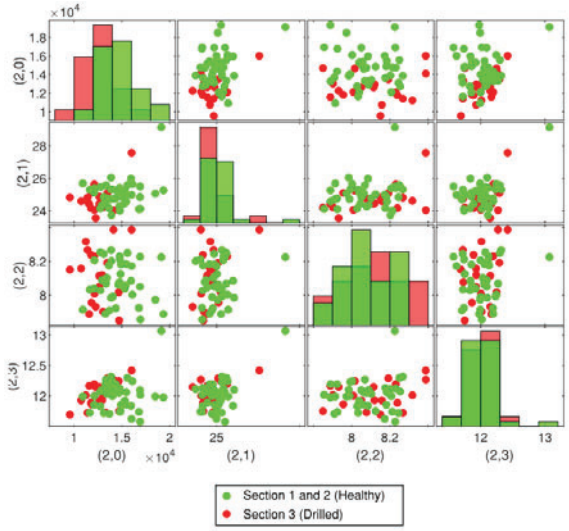

Figure 13: *Case Study 2 - Scatter plot of the signal energies in 4 frequency bands - decomposition level 2 and 'db4' mother wavelet.*

The wave energies are more scattered in the plots compared to that shown in Figure 12, signifying a reduced correlation between the frequency band pairs when 'db4' is adopted, relative to 'db2'. The outcome of the analysis, however, is still not favourable, with no high-confidence separation in the data seen in the bivariate relationship comparisons in the off-diagonal plots, or the univariate analyses depicted on the diagonal plots.

3-level decomposition

Just as was conducted in Case Study 1, 3-level decompositions can also be carried out with the 60 measured signals. As depicted in Figure 1, the 3-level decomposition yields 8 frequency bands ranging from (3,0) to (3,7) – amounting to 56 possible frequency band pair comparisons – shown on the off-diagonal plots, and 8 plots visualising the distribution of wave energies within a given frequency band – shown on the diagonal plots. Figure 14 depicts this analysis with the use of the 'db2' mother wavelet and Figure 15 features that conducted with the 'db4' mother wavelet. In the former, several of the frequency band pairs – (3,2 – 3,1), (3,4 – 3,1), (3,4 – 3,2) – show a strong positive correlation, with high levels of overlap between signals of healthy sections and that of the defective section. This feature is missing from the 'db4' analysis, an artefact also found in the 2-level decomposition described in the preceding section.

Similar to that shown in Case Study 1, both the 'db2' and 'db4' analyses yield an ultimately unfavourable result, with no high-confidence separation of the wave energies between healthy and defective sections, as intended.

In summary, all of the trialled hyperparameter variations in the study – levels of decomposition and mother wavelet type – were unable to yield a desirable outcome. Although some separation of signals was observed in certain cases, as established in the preceding discussion, the lack of complete, high-confidence separation of signal clusters points to an inability of the adopted WPD methodology and trialled hyperparameters to accurately serve the purpose of the detection of a defect of this nature in timber.

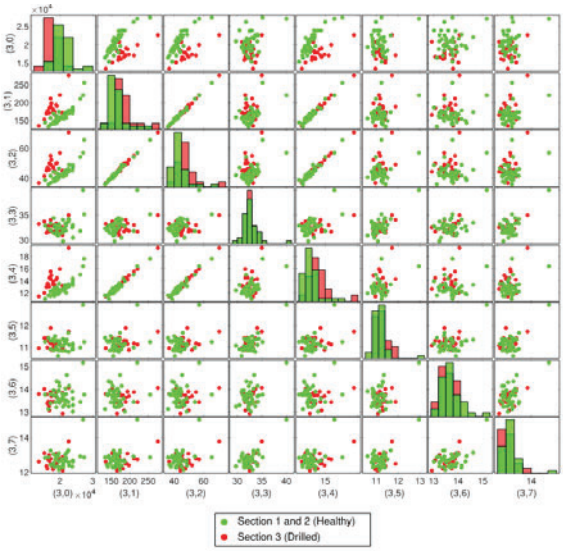

Figure 14: *Case Study 2 - Scatter plot of the signal energies in 4 frequency bands - decomposition level 3 and 'db2' mother wavelet.*

https://doi.org/10.52202/069179-0109

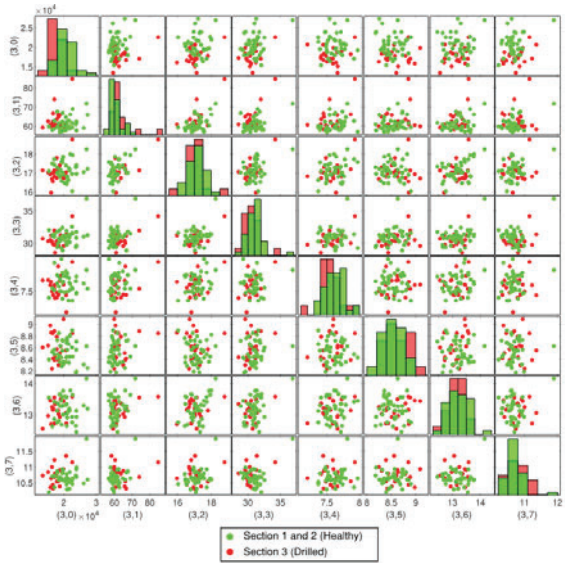

Figure 15: *Case Study 2 - Scatter plot of the signal energies in 4 frequency bands - decomposition level 3 and 'db4' mother wavelet.*

3.2.4 UMAP analysis and results

All 60 signals were thereafter analysed with UMAP, similar to Case Study 1. The hyperparameters used in the analysis were similar to that used in Case Study 1, with minimum distance being set to a value of 0.07 and k-nearest neighbours being set to 15. It should be noted that just as in Case Study 1, the values of both minimum distance and k-nearest neighbours had minimal impact on the output graph, primarily altering the density of the clustering of the signals and influencing the cluster separation. The Chebyshev distance model was adopted for the analysis. The 2-dimensional output graph is shown in Figure 16, with the associated data topology shown in Figure 17.

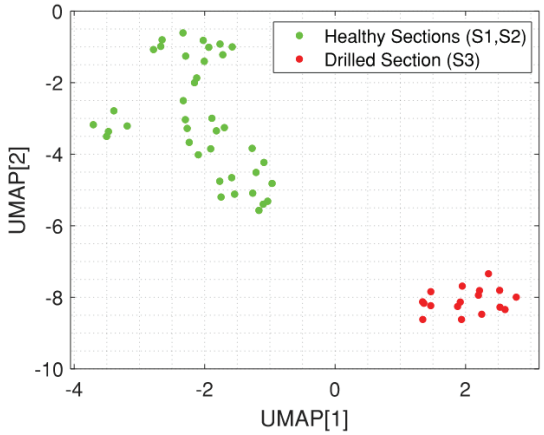

Figure 16: *Case Study 2 - UMAP two-dimensional (2D) reduction output.*

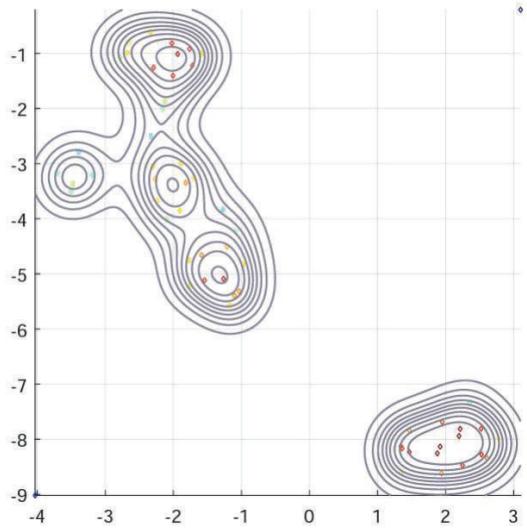

Figure 17: *Case Study 2 - UMAP two-dimensional (2D) cluster topology.*

As depicted, the output of the UMAP analysis is highly favourable, with complete and distinct separation between signals sent through the defective Section 3, and that sent through healthy Sections 1 and 2. Signals from Sections 1 and 2 are treated as being part of the same cluster, as shown in the cluster topology in Figure 17. This positive outcome is congruent to that found in Case Study 1.

4 CONCLUSIONS

This study attempts for the first time to investigate the effectiveness of a novel feature extraction algorithm for the purpose of identifying defects within the timber. UMAP proved to be very effective in separating signals from damaged and healthy sections in timber, requiring little calibration, and providing an easily visualisable output graph. UMAP was versatile in performing successfully under differing defect types in timber. In the first case study, UMAP was able to successfully distinguish between healthy sections and those with naturally occurring defects such as grain deviation and knots. A key positive attribute of the algorithm is its ability to separate the signals of sections featuring differing defect types as opposed to merely clustering them together – providing further insight into the different material characteristics inherent in sections of starkly different grain orientation and fibre make-up. In the second case study, the algorithm proved to be able to successfully distinguish signals transmitted through healthy sections and a defective section fabricated with a void in the centre of the cross-section, meant to simulate material loss and fibre discontinuity caused by defects such as fungal decay, termite damage or splitting damage. The study also juxtaposes the highly favourable outputs of UMAP against competing wavelet-based frameworks, proving the former's robustness and applicability for the intended purpose proposed in the study, compared to the latter. The low sensitivity of the final output of UMAP

due to changes in its hyperparameters, and the versatility of the algorithm in being able to identify various defect types in timber demonstrates the capability of the algorithm for the application of defect identification in timber.

This study acts as an initial proof-of-concept for the viability of UMAP as a signal analysis tool for defect identification in timber. The positive demonstration of the algorithm can hence open the door to future works investigating in-depth the efficacy of the algorithm in more complex, built-up sections of engineered timber, wherein the occurrences of defects are not visible from the exterior of the element. These investigations are currently in progress by the authors.

ACKNOWLEDGEMENT

GLUED-IN HARDWOOD RODS USING BIO-SOURCED ADHESIVES — PART I: INVESTIGATIONS UNDER LABORATORY CONDITIONS

Jana Kolbe[1]*, Stephanie Koesling[2], Till Vallée[3], Nils Monard[4], Jona Haupt[5]

ABSTRACT: Glued-in Rods (GiR) have proven to be a particularly good method for connecting timber structures, in which steel or FRP steel rods are yet commonly bonded with two-component epoxy resin or polyurethane adhesive systems. However, from a sustainability point of view, this poses a problem. This paper summarises preliminary results of a research project investigating to which extent the currently used glued-in steel rods in softwood can be substituted by rods made of hardwood for load-bearing functions. The project also reports on the performance of bio-sources adhesives to substitute the chemical adhesives currently used. The results presented herein focus on the performance of corresponding small scale GiR under laboratory conditions; the companion paper, also presented at the WCTE2023, will extend these findings towards more critical environmental conditions.

KEYWORDS: glued-in-rods, structural, joints, adhesion, bio-sourced

1 INTRODUCTION

1.1 SETTING THE FRAMEWORK

Glued-in-rods (abbreviated as GiR in the following) form a subset of bonded connections, in which load is transferred from one timber block to another via one (or several) bonded rods [1–3]. Design parameters involved for GiR are the choice of materials (timber, adhesive, and rods) and their sizing (cross-section of the timber members, adhesive layer thickness, and embedment length). Because of the complexity of this joint type, failure can take multiple forms. Figure 1 summarises them graphically, for more details refer to [1–3]. Each of these is associated with specific material and geometry parameters of the GiR, which cannot be discussed at length in this paper [4–6].

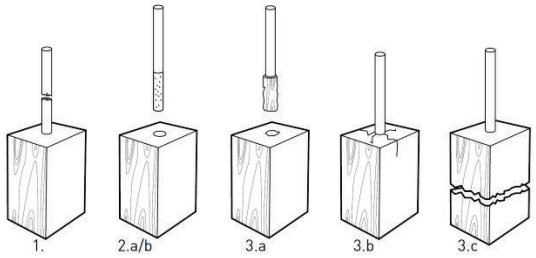

Figure 1: *Failure modes of glued-in-rod connections*

For most current applications, the rods are either threaded rods [7] or rebars [8], seldom fibre reinforced polymers [9]. Regarding the adhesive, almost all experimental investigations consider two-component epoxies (2K-EPX) or 2K-polyurethanes (2K-PUR) [2], both being of petrochemical origin. While timber engineering is widely acclaimed for its sustainability [10], the use of metallic and polymeric material for the joints may be questioned.

The research summarised in this paper addresses the question to which extent the concept of glued-in rods can be pushed towards sustainability by substituting the metallic rods by hardwood ones, and the "chemical" adhesives by bio-sources alternatives.

https://doi.org/10.52202/069179-0110

Surprisingly little research has been documented on gluing-in hardwood rods to connect structures in timber engineering. Among those, Koizumi and Jensen [11–13] presented experimental results on dowels (in fact rods) made of Maple (*Acer saccharum*) glued into Cedar (*Cupressus japonica*). The results showed that average shear strengths of beyond 8 MPa were achieved with a 2K-PUR, and beyond 10 MPa using a 2K-EPX.
Adhesives based on renewable resources have been used since the dawn of humanity in conjunction with timber. Both their availability, and performance, proved sufficient to fulfil all demands up to World War II, where they were still used to manufacture aeroplanes [14]. Nowadays, adhesives based on natural raw materials are classified into glutine (in the following referred to as animal glue), casein, lignin, tannin, and dextrin [15,16]. They achieve, on spruce shear strengths up to 9.6 MPa, and for beech strength up to 11 MPa
.

1.2 OBJECTIVES

The research summarised in this publication aimed to three different objectives: (1) Investigate the potential hardwood dowels (or bars) offer as an ecologically sustainable alternative to steel, and FRP, rods; and (2) extend the sustainability of GiR through the substitution of "chemical adhesives" by "natural" ones.

2 MATERIALS AND METHODS

2.1 Adhesives

The adhesives used in this study were all derivatives of "Technical Gelatine 400/115" from the Company Fritz Häcker GmbH in Germany. The basic adhesive, is a gelatine currently commercially available. A feature relevant for this study is the relatively high water-content during processing of the adhesives.

The technical gelatine is delivered in a dried state in form of granulate. As a first step it is swollen in water. Therefore 25 parts of technical gelatine is mixed with 75 parts of water. The gelatine must be soaked in water for at least two hours before it can be further processed. To improve laboratory workflow, the mixtures are usually soaked overnight. In the next step the adhesive was molten in a water bath at 50 °C. In this state, the adhesive is now ready for processing.

Modifications of the basic formulation involve aspects such as reduction of the water-content, the addition of solid particles (as chalk, saw dust), and further reactants (as tannin etc.) A summary of the modifications, all labelled M*XX*, is shown in Table 1and Table 2

Table 1: Summary of adhesive modifications to improve the formation of larger adhesive layer thickness (% are related to the mass)

REF	Technical Gelatine 400/115: water-content 25:75
M29	REF with water-content reduced to 25:60
M30	REF with water-content reduced to 25:45
M31	REF + 30% chalk
M32	REF + 50% chalk
M33	REF + 30% sawdust

The modifications of the adhesive were performed following two objectives:
Firstly, the one discussed in this part, aimed at enabling the adhesive to form the relatively large layers (0.2 to 0.5mm) required for the glued-in rods, as opposed to the almost nil thickness needed in lap shear samples. The issue herein is related to the large water content of the gelatine-based adhesives.
Secondly, gluing with technical gelatine means that the processed adhesive contains 75 % of water. For the usual applications for this adhesive, like gluing books, folding boxes or cardboard this is not an issue. Animal glues are adhesives which have been used for centuries to bond wood. However, because of their high water-content, they have problems to fill large adhesive layer gaps above 200 µm. To overcome this limitation the idea was to increase the solid content. One way was to work with less water. The other way was to incorporate fillers. Therefor we chose two different fillers: Chalk and sawdust. Chalk is used very often in adhesives. We worked with the product Omyacarb HSB from Omya.GMBH / Germany. And another interesting filler for us was sawdust, due to the application of gluing wood. Working with a filler, is changing a lot of the adhesive characteristics like viscosity, stiffness or the thermal expansion coefficient. By choosing sawdust, we saw a high chance to improve several characteristics of the adhesive and additionally get a bio-based filler so to fulfil the requirement of sustainability. We used the product HAHO 120/F from JELU-WERK J. Ehrler GmbH & Co. KG / Germany for the sawdust. Secondly, improving—if necessary—the mechanical performance of the adhesives under elevated moisture contents, an aspect further developed in the second part of this publication.

Table 2: Summary of adhesive modifications to improve the performance under elevated moisture environment

M7	1 % tannic acid
M10	3 % kalinite
M14	0,3 % gallic acid
M26	1 % tannic acid + 9 % linseed oil
M10C	M10 + 30% chalk
M14C	M14 + 30% chalk

2.2 Investigations on lap shear samples

The preliminary investigations focused on a comparison of the mechanical performance of the adhesive used in lap shear samples (acc. to DIN EN 1465).
The substrates consisted in beech wood (*Fagus sylvatica*) in the dimensions 19.5 × 5.2 × 80.5 mm³, which were conditioned to 23 °C and 50% relative humidity (rH) for at least 7 days prior to bonding.
During the bonding, a pressure of 0.7±0.1 MPa was exerted on the overlap, the resulting adhesive layer thickness was almost nil.

https://doi.org/10.52202/069179-0110

For the results presented in this part, bonded lap shear samples were conditioned for 7d @ 23 °C and 50% rH prior to testing.
Testing occurred in an UTM under displacement control, with 5mm/min, until failure occurred. Ten samples were tested in each series.

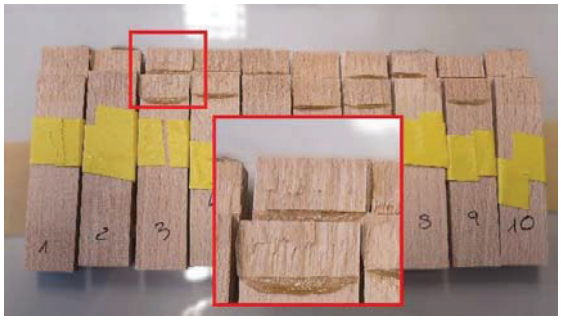

Figure 2: A set of ten lap shear samples after testing (the enlargement shows a typical substrate failure)

The results subsequently presented herein are given as average lap shear strength, which corresponds to the failure load divided by the bonded area surface, which was measure using a calibrated calliper for each individual sample.
Additionally, the fracture surface has been characterised so to distinguish between substrate failure (SF) and adhesive failure (AF).

2.3 Investigations on glued-in rods

The mechanical performance of bio-sourced adhesives was compared to that of widely used "chemical" ones. Tests were performed on the following wood species. Spruce, which constitutes the base material of all GiR, and beech for the rods. Two increasing levels of complexity were considered. Firstly, lap shear samples acc. to DIN EN 302; secondly, small scale GiR consisting of 45x45x120 mm³ spruce blocks in which ø6mm hardwood rods were bonded
The spruce blocks are drilled to precisely 6.4 mm with an automatic drilling machine, to achieve an accurate adhesive layer thickness between the two substrates. This results in a radial distance of 0.2 mm.
To ensure axiality, the glued in rods are centred during the gluing process with thin spacers around the hole top. The wooden rods are deburred and thoroughly cleaned with isopropyl alcohol.

Preparing the lap shear samples with the ecological adhesive is identical to the process of the lap shear samples, however the application process is different. After mixing of the adhesive, the viscous fluid is transferred to a syringe and subsequently used to fill the lateral hole in the spruce block with adhesive. The outside of the hardwood dowel is coated in a film of the same adhesive. The rod is then pressed into the hole with a spring-loaded guide mechanism until it bottoms out, for further details regarding the bonding process cf. [17].
These bonded samples are then cured and conditioned under the same environmental conditions as the lap shear samples (7d @ 23 °C and 50% rH).

Figure 3: Process of injecting the adhesive into the hole, coating the rod and combining them

2.3.1 Test setup

Testing the adhesive performance is conducted by rigidly clamping each side of the sample in the UTM, under displacement control and 2mm/min, until failure.
Clamping the hardwood rod directly did not produce adequate findings, due to deformation of the wood fibres and therefore induced stress fractures and reduced tensile strength of the dowel. This resulted in the premature failure and breakage of the rod during testing.
To limit the compression of the wood across the grain, multiple options were followed.
Bonding an aluminium sleeve with a chemical adhesive to protect the wood from crushing, did not achieve satisfactory results due to poor adhesion between the metal and wooden substrate.
Gluing a block of beech wood to the exposed part of the dowel still resulted in both brittle fractures as well as the wood splitting along the grain.

Figure 4: (Top) Aluminium sleeve bonding failure, (bottom) rod failure with beech block

https://doi.org/10.52202/069179-0110

The hardwood rods therefore not only break due to excessive compression and reduced surface area, but also due to pulling forces not being parallel to its grain structure.
To finally solve the issue, a secondary spruce block with identical dimensions was affixed to the opposite end of the rod using double the adhesive layer length. Either block is also drilled through on the side. A specific testing setup was devised to ensure perfect coaxiality.

During testing the samples are fixed in the UTM by inserting metal rods into these holes. This allows in conjunction with a bearing fixture for up to five degrees of freedom during the test. This setup achieved adhesive or substrate failure every time, and no hardwood rod failed.

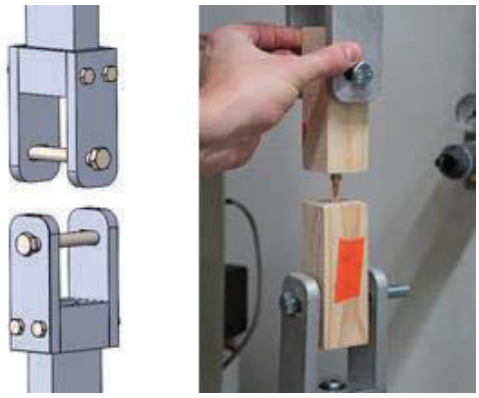

Figure 5: Test setup for the GiR

3 RESULTS AND DISCUSSION

3.1 Investigations on lap shear samples

The results of the lap shear tests with the different adhesive modifications described in

Table 1 are summarised below in Figure 6.
The original formulation of the adhesive, labelled herein REF, resulted in a lap shear strength of 12.7 MPa, with a variance (defined as standard deviation divided by the average) of 10%. Reducing the water-content, i.e., considering the modification M30, resulted in a reduction of the average lap shear strength by roughly one third, while increasing the variance to a relatively value of 25%. Regarding chalk, it is to be noted that the addition of 30% (M31) did neither affect strength nor variance; for 50% (M32), however, the average lap shear strength increased marginally by 8%, with an almost unchanged variance of 12%. Lastly, adding 30% sawdust to the basic adhesive formulation (M33) reduced the average lap shear strength by 20%, without affecting the variance.

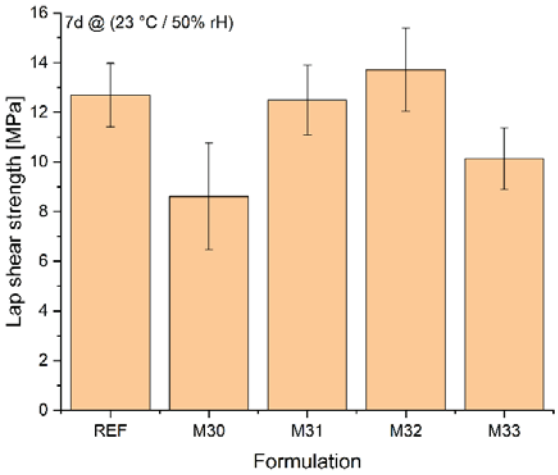

Figure 6: Experimentally determined lap shear strengths with the formulations allowing for larger adhesive layer thickness

Animal glue is made from collagen. While the polymer molecules in collagen are present as a triple helix, in animal glues they are converted into random coils. During swelling, melting (processing of the adhesive) and drying (within the adhesive layer), the polymer molecules partially convert back to triple helix. These triple-helix structures act like nodes in a physical network. Reducing the water content during processing of the gelatine-based adhesive affects this conversion from random coils to triple helix. The decreased adhesive bonding strength of the samples with reduced water content may be an indication of a weaker physical network due to the lower content of these triple-helix structures.

The aforesaid short summary of the results may lead to the conclusion that the different adhesive formulations may be easily ranked in terms of mechanical performance. However, because of the statistical nature of all experimental work, a closer statistical look through an analysis of variance (ANOVA) is required. Accordingly, the data was viewed through Tukey's test at a significance level of 0.05, and allowed for conclusions with regard to the statistical significance of differences. The ANOVA showed that reducing the water content resulted in a significant decrease of strength compared to the reference, both chalk series, but not if compared to the addition of sawdust. On the other hand, adding the chalk (in both proportions, 30 and 50%) did neither significantly increase nor decrease strength. Lastly, the addition of sawdust, although resulting in lower average strength, did not significantly impact the mechanical performance.

https://doi.org/10.52202/069179-0110

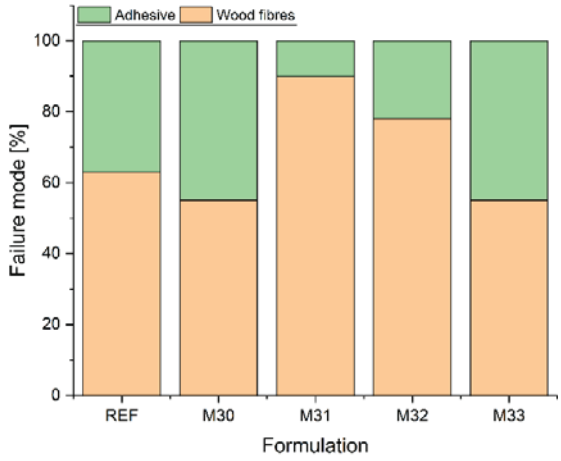

Figure 7: Failure modes observed in the lap shear tests

Focusing on the failure patterns, summarised in Figure 7, it appears that there are significant differences between the different adhesive formulations. While for the reference adhesive, slightly over 60% of all failure surface was withing the wood, this proportion slightly decreases when the water content is reduced. Chalk on the other hand seems to result in much more wood being torn off, although this results also depends on the chalk content, as higher values tend to increase the proportion of adhesive failure. Lastly, the addition of sawdust leads to the lowest observed proportion of wood being ripped-off—barely more than 50%.

Regarding the second aspect, which was to prepare adhesive formulations prone to better perform under moist conditions, and which resulted in the modifications described in Table 2 only preliminary results obtained under "normal" conditions, i.e. +23 °C and 50% rH, are presented herein in Figure 8.

The reference gelatine adhesive mixtures were modified using different techniques. For M7, Technical gelatine was first swollen overnight in demineralized water, and then tannic acid was added. The mixture was heated to 50°C, and a 10% solution of tannic acid (by weight) was introduced, resulting in gelation of the adhesive. For M10, Technical gelatine was first swollen overnight in a solution of gallic acid, and the mixture was then melted and stirred at 50°C. During this process, compressed air was introduced for 1.5 hours to modify the adhesive. In the case of M14, Technical gelatine was first swollen overnight in a solution of kalinite. The mixture was then heated to 50°C and stirred, resulting in adhesive modification. Finally, for M26, Technical gelatine was first swollen overnight in demineralized water and mixed with linseed oil before the addition of tannic acid. The mixture was heated to 50°C and stirred, resulting in the modification of the adhesive. This method is similar to M7, with the addition of linseed oil as a modifying agent.

To improve moisture resistance, we tried two different ideas: using Potassium alum, and crosslinking. Previous studies [18] suggest that Potassium improves the moisture resistance of glutine adhesives. Kalinite is also used as tannin agent and surely as in impact on collagene.

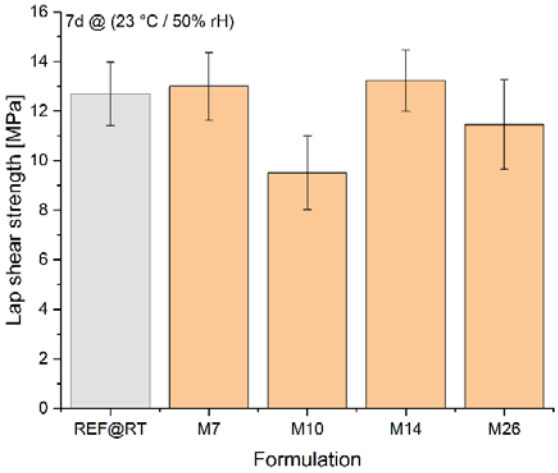

Figure 8: Experimentally determined lap shear strengths with the formulations allowing for higher moisture contents (tested under RT conditions)

It appears that, if related to the original formulation (REF), all but one (M10) modification result in very similar lap shear strengths under normal conditions that cannot be distinguished statistically (using an ANOVA, Tukey's test, p=0.05) from the original one. Similar is the situation regarding the scatter, expressed as variance. The mechanical behaviour under moist conditions will be the subject of the second part of this study.

3.2 Investigations on glued-in rods

An initial round of testing to determine an optimal adhesive layer thickness between the rod and the drilled hole resulted in the results presented in Figure 9. The minimum hole diameter is limited in part due to the natural deviations in roundness of the rod and the pressure required for inserting it into pre-filled holes. With an initial layer thickness of 0.2 mm and a gradual increase in thickness up to 0.5 mm an obvious trend of reduced adhesion strength between the substrates is identifiable.

Figure 10 presents a summary of the results from the GiR tests conducted using the various adhesive modifications. The different formulations include but are not limited to those shown in

Table 1. An epoxy adhesive series was also added as a comparison.

Some increases in average shear strength were observed when comparing the original REF formulation to the subsequent M29 and M30 modifications, which have the same components but differ only in water content. The M29 showed little to no effect on strength, though the variance increased from 14% to 18%. Further reduction of the water content to 60% of the REF formulation with the M30 however, increased shear strength from 4.9 MPa to 5.4 MPa, while also slightly increasing the variance. The addition of chalk to the original formulations as a filler,

https://doi.org/10.52202/069179-0110

resulted in increased adhesive strength in both cases. With M31 outperforming the reference by 27% on average shear strength and decreasing the relative variance by a third.

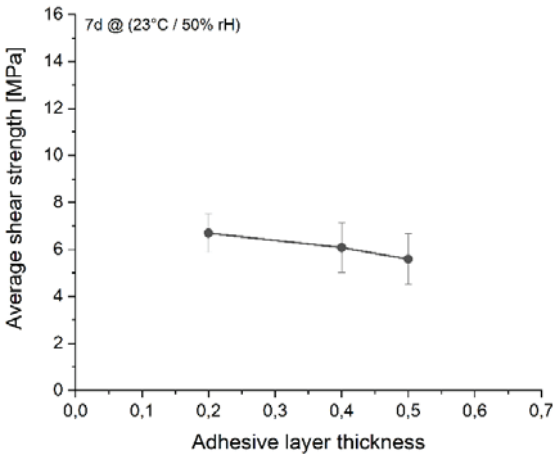

Figure 9: Test results of the GiR with selected ecological adhesives *(t_a indicates the adhesive layer thickness)*

Although still surpassing the previously observed strength values at 5.8 MPa, the M32 modification exhibits a slightly lower mean value compared to M31, with a corresponding increase in variance to 16%. Finally, adding fine sawdust to the adhesive resulted in an improved strength performance compared to the original formulation with 5.2 MPa, though with a comparatively high variance of 32%.

The 2K-epoxy which was chosen as a comparison for an adhesive able to bridge very high layer gaps, was very comparable to the M31, with an average shear strength of 6.7 MPa, which is only around 7% higher than the best ecological adhesive from this series.

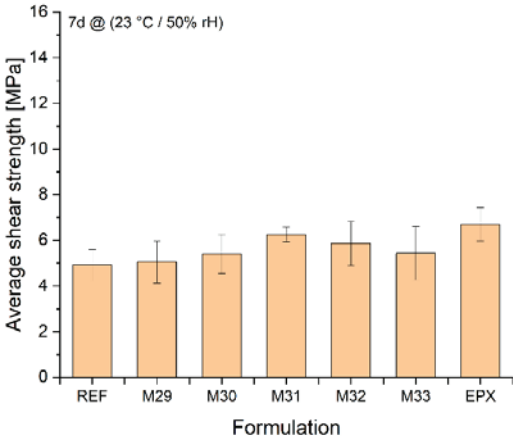

Figure 10: Test results of the GiR with selected adhesive formulations *(0.2 mm adhesive layer thickness, all embedment lengths are 30 mm)*

The testing revealed that the most common failure modes encountered were related to wood tear-out of the spruce block, which is a typical behaviour of this relatively soft material. This kind of failure occurs when the strength of the adhesive exceeds that of the wood, which can cause the wood fibres to tear apart.

Figure 11: *Typical failure of GiR with hardwood rods and eco-sourced adhesives*

Figure 11 depicts a common scenario of wood failure over adhesive failure. However, accurately quantifying the amount of wood tear-out versus adhesive failure is challenging due to the similarities in colour between the adhesive and the substrate. As the embedment length increases, the failure mode shifts from wood tear-out to splitting or fracturing of the hardwood rod either along or across the grain.

Shear strength tests on small, and large, scale glued-in rods (GiR) composed of hardwood rods glued into softwood (spruce) blocks confirmed the results obtained on the lap shear tests; mechanical performance of the "natural" adhesives ranged just slightly below that of the "chemical" ones.

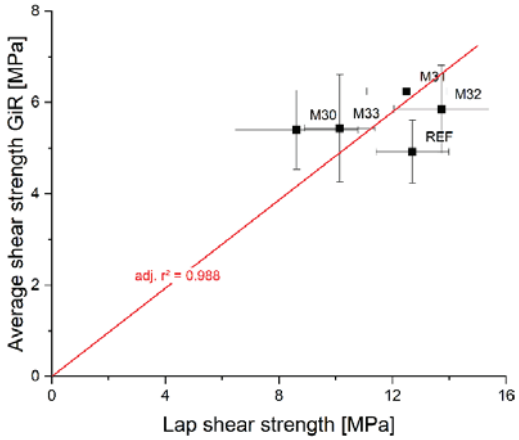

Figure 12: Comparison between lap shear strength (obtained in 1/lap shear samples) and average shear strength (obtained on GiR) for selected adhesives

When comparing the lap shear strengths to the average shear strength of the GiR, it may be difficult to compare the adhesive formulations individually from each testing method. Figure 12 aims to compare each mixture directly between lap shear and average shear strength.

While the absolute strength values differ, a direct correlation between the result can more easily identified. It is shown that some formulations form a close correlation between the two testing methods, like the M31, M32 and M33, showing that the adhesive mixtures are cross-comparable between the glued-in rods and the lap shear samples. However, outliers such as the M30

https://doi.org/10.52202/069179-0110

which performed better in GiR samples, or the reference mixture which performed very well in lap shear samples, show trials of both testing variants has to be done, especially for elevated moisture conditions like those done in the second part of this study [19], to ensure accurate findings.

In order to ensure comparability between the lap shear test samples and the GiR samples for the adhesive formulations designed to perform under moist conditions, their average shear strength was also tested under RT conditions.
To also adapt these formulations to increased adhesive layer thicknesses, a preselection was made for the M10 and M14 and the mixtures were expanded to include a further series with chalk as a filler. For both formulations 30% filler was added, additionally to their original formulation. The results of this series of tests can be seen in Figure 12. For simplified comparability of the results, both the reference formulation and M31, which have the same chalk content as the M10C and the M14C, were included. The M10 adhesive was 25% weaker than the reference mixture at only 3.93 MPa and a variance of around 11%. However, the basic M14 formulation outperformed not only the reference mixture by over 10% at RT, but also some of the formulations directly aimed at improving layer adhesive gaps. The M10C, modified with 30% chalk improved on its adhesive strength, though still underperforming compared to the reference adhesive. The M14C even outperformed the M31 mixture and had very similar strengths to that of the 2K epoxy adhesive at 6.60 MPa and a variance of 8%.

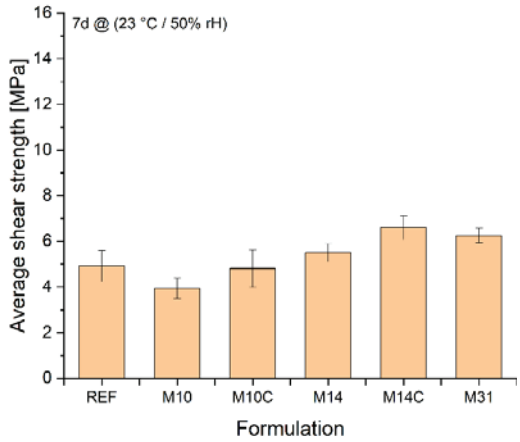

Figure 13: Test results of the GiR with moisture resistant adhesive formulations *(0.2 mm adhesive layer thickness, all embedment lengths are 30 mm)*

4 CONCLUSION

As a first conclusion, it appears that the considered ecological, or naturally sourced, adhesive, has the potential to achieve relatively high levels of lap shear strength. The measures taken to mitigate the effect of the high water-content, most prominently the addition of chalk and sawdust, improved the mechanical performance, especially for increased adhesive layer thicknesses.
Similarly, a series of modifications to ensure that strength is not degraded under moist conditions have been developed. Most of them resulted in lap shear strength in essence statistically not distinguishable from that of the reference formulation. The glued-in rods had very similar results and showed promising improvements for increased strength when additional filler was added to the mixture.
However, due to the different mechanical properties of the hardwood rods, if compared to steel, it proved necessary to adapt geometrical parameters (as embedment length, slenderness ratio l/d). Numerical modelling proved adequate to predict the load bearing capacity of all experimental series with sufficient accuracy.
The follow-up study, also submitted to the WCTE [19], will investigate if these promising results are also obtained under adverse environmental conditions (in particular high moisture content).

GLUED-IN HARDWOOD RODS USING BIO-SOURCED ADHESIVES — PART II: IFNFLUENCE OF ENVIRONMENTAL CONDITIONS

Jona Haupt[1], Nils Monard[2], Till Vallée[3], Stephanie Koesling[4], Jana Kolbe[5]*

ABSTRACT: The first of this two-part series presented an ecological alternative to the commonly considered metallic rods glued into wood using conventional, petrochemical based, adhesives. A series of tests spanning from lap shear samples, small-scale glued-in rods (GiR), to large scale GiR featuring hardwood rods in spruce blocks and eco-sourced adhesives, proved the feasibility of a substitution concept under laboratory conditions. This second part investigates the influence of environmental conditions on the load-capacity of aforedescribed GiR.

KEYWORDS: glued-in-rods, structural, joints, adhesion, bio-sourced

1 INTRODUCTION

1.1 SETTING THE FRAMEWORK

Glued-in-rods (abbreviated as GiR in the following) form a subset of bonded connections, in which load is transferred from one timber block to another via one (or several) bonded rods [1–3]. While most investigations focus on so-called laboratory conditions (e.g. 23 °C and 50-65% rel. humidity), it is well known that conditions deviating therefrom are more critical. On one hand, temperature directly affects the performance of the adhesive [4], on the other hand moisture strongly influences the behaviour of wood [5]; additional effects results from the temperature and moisture induced deformations [6]. All these effects potentially lead to a reduction of the load-bearing capacity of bonded joints involving wood. Aforesaid is also true for glued-in rods (GiR) [7–9].

Gelatine adhesive is a type of adhesive that has been used for a long time, but its durability and resistance to environmental conditions have been questioned. Recent studies have shown that gelatine adhesive has good potential for use in various applications, such as wood and paper conservation. However, its performance may depend on factors such as the preparation method and the environmental conditions it is exposed to. Gelatine adhesive may be vulnerable to degradation by factors such as humidity, temperature, and microorganisms, which can affect its long-term stability. Some researchers have suggested that gelatine adhesive can be improved by modifying its properties or using it in combination with other materials. Overall, more research is needed to fully understand the durability of gelatine adhesive and how it can be optimized for different applications. To improve the durability of gelatine-based adhesive to environmental conditions, several additives can be used. One effective approach is to modify the gelatine itself to enhance its properties. For instance, adding crosslinking agents or modifying the gelatine with other polymers or resins can improve its mechanical and water resistance properties. Other additives that may improve the durability of gelatine-based adhesive include plasticizers, which can improve flexibility and reduce brittleness, and preservatives, which can protect against microbial degradation. Additionally, fillers and reinforcement materials, such as cellulose or silica, can be added to improve mechanical properties and reduce shrinkage. The specific choice and amount of additives will depend on the specific application and the desired properties of the adhesive.

1.2 OBJECTIVES

The research summarised in this publication continue those presented in the companion paper [10], in which the potential substitution of metal by hardwood for rods and petrochemical adhesives by eco-sourced ones has been demonstrated under laboratory conditions. The focus of this second part is set on environmental conditions considered critical for most eco-sourced adhesives, and timber engineering in general.

2 MATERIALS AND METHODS

2.1 Adhesives

The fundamental information related to the adhesive used, Technische Gelantine 400/115, a gelatine marketed by the German company Fritz Häcker GmbH, was reformulated in several modifications so to result in two types of improvements. Firstly, enabling the adhesive to form the relatively large layers (0.2 to 0.5mm) required for the glued-in rods, as opposed to the almost nil thickness needed in lap shear samples. The issue herein is related to the large water content of the gelatine-based adhesives. Secondly, improving—if necessary—the mechanical performance of the adhesives under elevated moisture contents. Both aims were achieved to a series of modifications summarised in Table 1.

Table 1: Summary of the adhesive formulations

REF	Technical Gelatine 400 / 115
M30	REF with water-content reduced to 25:45
M31	REF + 30% chalk
M32	REF + 50% chalk
M33	REF + 30% sawdust
M7	1 % tannic acid
M10	3 % kalinite
M14	0,3 % gallic acid
M26	1 % tannic acid + 9 % linseed oil
M10C	M10 + 30% chalk
M14C	M14 + 30% chalk

Modification with tannic acid: One part of Technical Gelatine was mixed with three parts of demineralised waters and left to swell overnight. This prepared adhesive was melted in combination with stirring in a water bath at 50 °C. A solution of tannic acid (10 mass %) was adjusted to pH 8 with the aid of NaOH and added to the adhesive. The reaction started immediately and gelation of the adhesive begun.
Modification with gallic acid: A solution of gallic acid (0.1 mass %) was adjusted to pH 8 with the aid of NaOH. One part of Technical gelatine was mixed with three parts of gallic acid solution and left to swell overnight. The adhesive was melted with stirring in a water bath at 50 °C and clean compressed air was introduced into the reaction mixture for 1.5 hours.
Modification with kalinite: One part of Technical gelatine was mixed with three parts of kalinite solution (1 masse %) and left to swell overnight. The adhesive was melted with stirring in a water bath at 50 °C
Modification with tannic acid and linseed oil: same procedure like modification with tannic acid alone. Linseed oil is added to the molten adhesive (before tannic acid is added).

This second part of the study focuses on the mechanical performance of the original adhesive's modification described above. For more details refer to the first part of this study [10]. For that, several series of ten lap shear samples (DIN EN 1465) were manufactured from beech (*Fagus sylvatica*) substrates (19.5 × 5.2 × 80.5 mm³) conditioned at 23 °C and 50% relative humidity (rH), bonded, and subjected to different environmental conditions. The first thereof was a co-called climatic Box briefly described as follows: samples were placed in a lockable plastic box over a saturated salt solution. A sensor recorded temperature and moisture. We worked with saturated solution of sodium chloride. The box was placed in a circulating air-drying cabinet at 40 °C for 7 days. Inside the box 75 % relative humidity was measured; that was exactly what was to be expected. Lap shear samples were removed immediately bevor testing without drying time at room temperature.

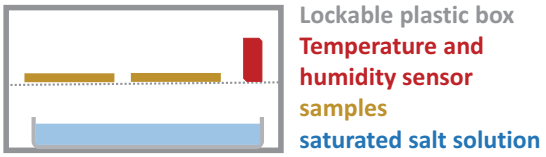

Figure 1: Principle of the climatic box

The second being a classical climate chamber set up for 45 °C and 85% rH. Samples were removed from the chamber and stored at room temperature until tested.

All tests were performed in a UTM under displacement control, with 5mm/min, until failure occurred. The results subsequently presented herein are given as average lap shear strength, which corresponds to the failure load divided by the bonded area surface, which was measure using a calibrated calliper for each individual sample.

2.2 Glued-in rods (GiR)

As part of the second round of testing with changed environmental conditions, the GiR are also subjected to different moisture and temperature levels.

Hence, the adhesives listed in Table 1 were evaluated against commonly used "chemical" adhesives by subjecting them to elevated levels of humidity and thermal conditions to determine their mechanical performance. The tests were conducted on various wood species including spruce, which served as the base material for all GiR, as well as beech, ash, and oak, which were used for the rods. The GiR samples comprised spruce blocks measuring 45 x 45 x 120 mm³, to which ø6 mm hardwood rods were affixed using the adhesives under evaluation.

Overcoming the challenges of manufacturing and testing of the GiR samples was thoroughly discussed in the first part of this study [10]. Therefore, the manufacturing process is herein summarized. The adhesive layer thickness was carefully controlled to achieve a radial adhesive layer thickness of 0.2 mm, and spacers were used during the gluing process to ensure concentricity of the wooden rods. The rods were also cleaned with isopropyl alcohol to remove any debris and left to fully evaporate.

https://doi.org/10.52202/069179-0111

In the initial study described in reference [10], the adhesive application process involved using a syringe to inject the adhesive into the lateral hole in the spruce block, while simultaneously coating the hardwood rod with the adhesive. The rods were then cantered and pressed into the hole using spacers to ensure precise concentricity.
However, during the process of liquefying the M10 adhesives at 50° C, the resulting mixture remained very viscous and would gelatinize immediately. This meant that the adhesive had to be applied immediately, within seconds, after melting so to avoid it solidifying in the syringe.
To speed up the process of pressing the gelatinous adhesive mixture into the gap, a different bonding method was used. Specifically, in large-scale GiR test trials involving chemical adhesives, the adhesive is injected laterally into a hole that is perpendicular to the hole for the hardwood rod. The rods are inserted into the hole beforehand, and the adhesive is then pressed in until it visibly emerges from the sides of the rod at the top opening of the hole. Adopting this process however was not as straight forward.
Because the adhesive layer thickness for the ecological glues is smaller by a factor of 5 than that of chemical adhesives, increased hydraulic pressure was generated when the adhesive was pressed in, which caused the wooden rods to be forced out like a piston. To prevent this from happening, a specially designed bonding device, which is shown in Figure 2, was used to pretension and centre the hardwood rods using tension springs and guide rods.

Figure 2: Bonding device designed for the rapid application of adhesives

After applying the adhesive, all samples were cured and conditioned for 7 days at 23°C and 50% rH. In the same fashion as the second variant of environmental conditions of the lap shear samples, all GiR were placed in a climate chamber at 45°C and 85% rH for 14 days after curing.

Testing the adhesive performance involved rigidly clamping each side of the sample in the UTM under displacement control and 2 mm/min until failure. However, clamping the hardwood rod directly resulted in inadequate findings due to deformation of the wood fibres, inducing stress fractures and reducing tensile strength of the dowel. To limit compression of the wood across the grain, to stop the rod from failing before the adhesive, several options were tried.
Increasing the hardwood rod diameter for instance still did not achieve satisfactory results, due to the dowel still breaking during testing. Other different attempts are thoroughly discussed in part one of the study [10].
The hardwood rods broke due to excessive compression, as well as pulling forces not being parallel to its grain structure. To reduce the pulling forces and combat the other issues a combination of different elements solved this problem.

One of these elements involved reducing the bonding depth of the glued-in rod to decrease the tensile load on the rod during testing. However, the most significant improvement was achieved by affixing a secondary spruce block with identical dimensions to the opposite end of the rod using double the adhesive layer length. Either block was also drilled through on the side, and a specific testing setup was devised to ensure perfect coaxiality. During testing, the samples were held in the UTM by inserting metal rods into the side holes, allowing for up to five degrees of freedom during the test. This setup achieved adhesive or substrate failure every time, and no hardwood rod failed.

3 RESULTS AND DISCUSSION

3.1 Lap shear samples

In a first round of experiments, samples were first conditioned for 7days at 23 °C and 50% rH, and then placed in the aforedescribed climatic box (40 °C and 75% rH) for another 7 days.

The resulting lap shear strengths, shown in Figure 3, ranged from extremely low 0.95 MPa (for the basic formulation, labelled REF) to 12.87 MPa (for M26, with 1 % tannic acid + 9 % linseed oil). The scatter, if expressed as standard deviation divided by the average, ranged from 9 to 15%, which remains acceptable for wood-based samples. The poor performance of the REF-samples was attributed to the favourable conditions for fungi growth in the climatic box, which contrasted with the results observed in the classical climatic chamber. After conducting an analysis of variance using Tukey's test with a significance level of 0.05, it was concluded that there was no statistically significant difference in measured strength among all series except for the REF adhesive, which was excluded from the analysis.

Comparing the performance of the aforesaid adhesive modifications after conditioning in the climatic box with that under RT (i.e., 23 °C and 50% rH) resulted in the

following: save for the REF-series, which exhibited the already presented fungi issue, lap shear strength was on average the same, with M7 presenting a 9% lower and M10 a 20% higher value. The differences series-wise being not statistically significant—again taking out the REF-series.

Turning the focus to the failure modes (again discarding the REF-series for the reasons already stated), almost all series exhibited a clear substrate failure that manifested in ripping of a thin layer of wood, as shown in Figure 4.

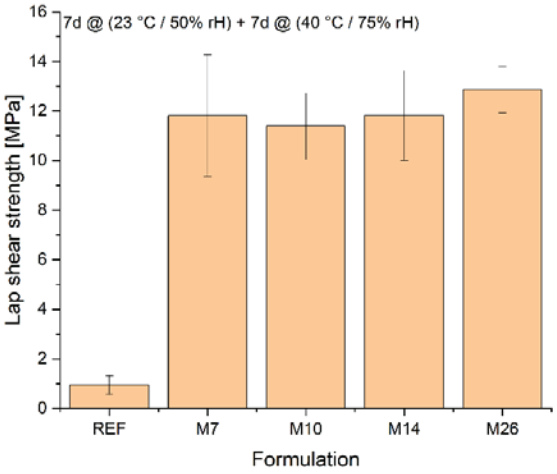

Figure 3: Experimental results obtained in the climatic box (without reconditioning to RT)

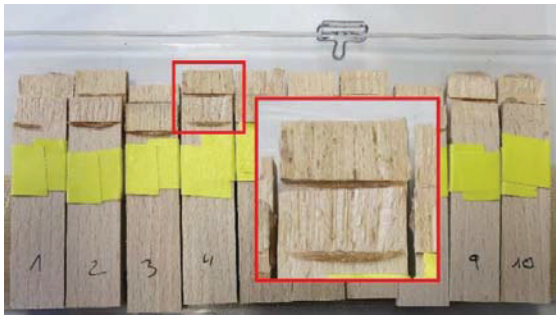

Figure 4: Typical failure mode observed

In the second round of tests, which involved a classical climatic chamber, samples were first conditioned for 7 days at 23 °C and 50% rH, then 14 days at 45 °C and 85% rH before being tested. The experimental results are presented in

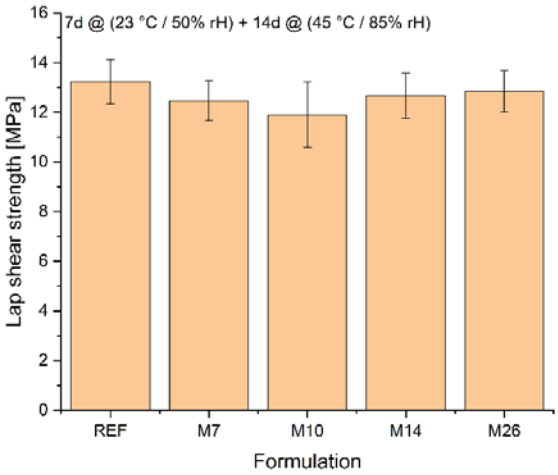

Figure 5: Experimental results obtained in the climatic chamber (with reconditioning to RT)

According to the results, the average lap shear strength for each series ranged from 11.9 MPa (for modification M10) to 13.2 MPa (which was surprisingly observed for the unmodified REF-series that no longer had fungi-related problems). On average, the variation, indicated by the standard deviation relative to the average, was 8% (with M7 having 6% and M10 having 11%).

In comparison to the lap shear strength tests carried out under room temperature (RT) conditions, the lap shear strength was observed to be higher by an average of 7%. However, statistical analysis through ANOVA using Tukey's test with a significance level of 0.05 revealed that these differences are not statistically significant. Similarly, when compared to the lap shear strength tests conducted in the climatic box, the average lap shear strength was higher by 4%, but not statistically significant, except for the REF-series, which exhibited fungal issues.

The issue with the moisture resistance of technical gelatine is due to the fact that technical gelatine can absorb a lot of water and swells. This reduces the mechanical properties, including the cohesive strength.
The first step was storing samples in a climate chamber. After removing the specimens after 7 in the climate chamber, these samples lay for an indefinite time at RT and had the opportunity to dry back. This means that at the time of testing, the technical gelatine was no longer in a swollen state. The test result shows two things:

- The technical gelatine is able to re-dry very well.
- Secondly, no ageing in the form of a loss of strength due to hydrolytic degradation could be detected.

In order to measure the strength of the bonds in the swollen state of the technical gelatine, we carried out the humidification in the box over a saturated NaCl solution. The box was taken to the testing machine after being exposed to the increased temperatures and moisture in the closed state. The samples were removed from the box just

https://doi.org/10.52202/069179-0111

before they were clamped in the testing machine and then tested immediately. The adhesive had no time to dry back. These tests show:
The unmodified technical gelatine has a low bond strength of less than 1 MPa in the swollen state (as was to be expected). The modifications, however, significantly improved the moisture resistance with an average lap shear strength of 12 MPa.

3.2 Glued-in Rods

The measurement of moisture content in the wood is a critical aspect of evaluating and comparing the adhesive strength to those not exposed to higher levels of humidity. To analyse the moisture content of the test samples after conditioning in the climate chamber (14d @ 45°C/85% rH), the glued in rods were measured in regular intervals during their period in the climate-controlled environment.
For this study, we employed two methods to measure the moisture content of wooden blocks. The first method was a pin-type moisture meter, which is a widely used tool for determining the moisture content of wood. This type of moisture meter can only measure the moisture content up to a depth of a few millimetres. This limited depth measurement can be a challenge when trying to assess the overall moisture level of a wooden block, as the surface of the wood can become saturated with ambient humidity very quickly, while the interior may remain dry.

To address this issue, we also measured the weight of each wooden block at regular intervals. This method provides a more accurate and comprehensive assessment of the moisture content of the wood, as it captures the changes in weight over time, reflecting the moisture uptake or loss. Figure 6 shows the results of both the moisture meter and weight measurements.

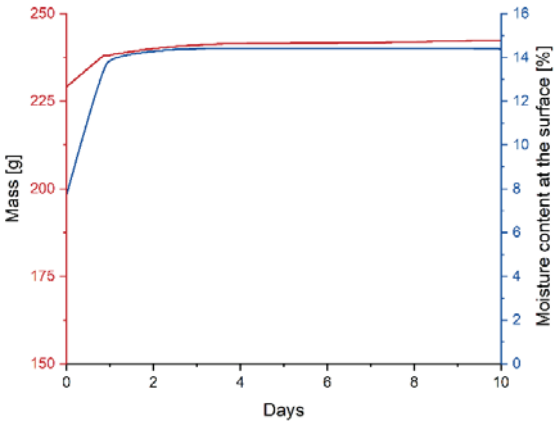

Figure 6: Measured wood moisture in comparison to weight increase over time

Our findings revealed that although the humidity values measured with the moisture meter reached a stable plateau within the first 48 hours, the moisture level in the wooden blocks continued to increase significantly until day four of their exposure in the climate chamber. After that, the moisture content plateaued and did not increase any further.

The first part of this study [10] conducted a series of GiR tests comparing the different variations and mixtures of the adhesive formulations, also listed in Table 1 (Ref, M29-M33). Following the findings of that study, a preselection of those mixtures, based on the adhesive strength for higher layer thickness was made, as seen in Table 2. The highest performing as well as formulations without additional fillers were chosen.

Table 2: GiR adhesive selection

		Shear strength dry [MPa]
M10	3 % kalinite	3.93 ± 11%
M10C	M10 + 30% chalk	4.81 ± 17%
M14	75% gallic acid + 25% gelatine	5.49 ± 7%
M14C	M10 + 30% chalk	6.59 ± 8%
M30	REF with water-content reduced to 60%	5.40 ± 16%
M31	REF + 30% chalk	6.25 ± 5%
M33	REF + 30% sawdust	5.44 ± 22%
EPX	Chemical Epoxy	6.70 ± 11%

The effect of warm temperatures and high moisture levels (45 °C and 85% rH) for 14 days on the adhesive properties was investigated with the aforementioned adhesives. The results as presented in Figure 7 showed that all ecological, gelatine-based adhesives performed poorly.

The ecological formulations exhibited a reduction in tensile strength on average by approximately 80% after exposure in the climate chamber. Differentiating between the different mixtures, the M33 showed the highest average tensile strength of 2.50 MPa with a variance of 5%. On the other hand, the M30 exhibited an average tensile strength of 2.00 MPa similar to the M31, with a variance of 6%.

To compare the GiR samples against an adhesive that is moisture resistant, the same 2 component chemical epoxy from the first study [10] was used. It performed only 20% worse compared to its dry tensile strength counterpart at 5.92 MPa. It is noteworthy that the failure mode exhibited mostly wood tear-out and not adhesive failure. The decreased tensile strength performance can be explained by the fact that when wood is exposed to warm temperatures and high moisture levels, the lignin, which is the natural glue holding the wood fibres together, can degrade and lose its adhesive properties. This can lead to a weakening of the intermolecular bonds between wood fibres and result in decreased strength of the wood. In addition, moisture can cause wood to swell and deform, further reducing its strength and durability.

https://doi.org/10.52202/069179-0111

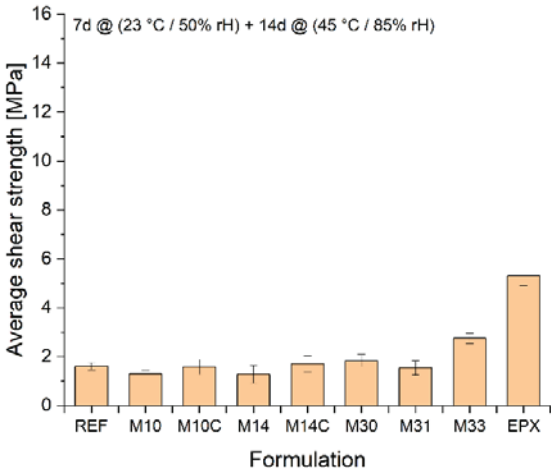

Figure 7: Average shear strength of the GiR (without reconditioning to RT)

In conclusion, the results of the tests of the mixtures tested at RT part one of this study [10] indicate that the ecological adhesive formulations can perform well under room temperature and humidity conditions. However, they are not be suitable for applications where the wood will be exposed to elevated temperatures and high moisture levels for extended periods.

To improve the performance of the ecological, gelatine-based adhesives, the specially formulated mixtures for humid environments (M10, M14 and M10C, M14C) were also tested as GiR samples. A comparison of the M10 and M14 and their chalk modified counterpart, against the other eco-adhesive variations from Table 2: GiR adhesive selectionTable 2 and the chemical epoxy, is depicted in the same Figure 7.

The reference adhesive, consisting of 3-parts water and 1-part technical gelatine, was used as the basis for the new formulations. The M10 mixture, which substituted the water for a kalinite solution, exhibited an average strength of only 1.30 MPa during the climate chamber experiment. Further regression was observed with the M14 formulation, which substituted the water with gallic acid, resulting in a further 2% decrease in adhesive performance. Both eco-adhesives displayed a high variance with the M14 mixture reaching 30%.

When compared to the gelatine-based adhesives not specially formulated to withstand higher levels of moisture, it was evident that the M10 and M14 eco-adhesives were not able to effectively adhere to wood. The series of tests with additional 30% chalk content, while marginally better at 1.57 MPa and 1.69 MPa for the M10C and M14C respectively, could not realistically improve on the adhesive performance.

Figure 8: Wood tear out (left) and adhesion failure (right)

Quantifying the failure modes of the adhesives, all ecological adhesives showed considerable adhesion failure, with little to no wood failure. Figure 8 depicts a comparison of the typical wood tear out experienced during the tests performed at RT versus the same formulation under the increased moisture and temperature levels. The hardwood rod is clear of any adhesive and shows virtually no sign of any adhesion.

4 CONCLUSION

In this second part of a study devoted to ecological, or sustainable adhesives, and their use in a structural context, the investigations presented in [10], which were carried out at RT, were extended towards more severe environmental conditions (+45 °C and 85% rH).

Firstly, an existing gelatine-based adhesive was modified so to improve its performance under the previously mentioned severe environmental conditions. This resulted in four additional mixtures.

Secondly, the lap shear strength of the aforesaid formulations, additionally to that of the reference gelatine, were determined under two different environmental scenarios: in a climatic box, with tests performed without reconditioning at RT, then in a climatic chamber with reconditioning to RT. The results indicated that it is possible to achieve similar lap shear strength under these climatic conditions, if compared to RT. It is to be noted that in the lap shear samples, the adhesive layer thickness was almost zero.

Lastly, tests on glued-in rods (GiR) were performed. A first round of tests was performed with the original formulation, to which different fillers were added (for more details refer to [10])—which were not optimised for humid environments and tested without reconditioning. These were, in a second run, compared to some of the formulations that were optimised, also without reconditioning to RT. Unlike the lap shear samples, the adhesive layer thickness in the GiR tests was set to 0.2 mm due to technological reasons. If compared to the similar tests described in [10], which were performed

https://doi.org/10.52202/069179-0111

under RT, joint capacities significantly decreased by around 80% (averaged over all series). If comparing the performance of a 2K-epoxid taken as reference, exposure to elevated temperature and moisture only resulted in a decrease of roughly 20% in strength.

Regarding the resistance to temperature and moisture of ecological gelatine-based adhesives, the study showed that the influence of the adhesive layer is paramount. It is therefore not sufficient to assess the performance of such adhesives only at the level of lap shear samples (with very thin layer thicknesses).

MATERIAL FLOW ANALYSIS AND CARBON FOOTPRINT OF FOREST RESOURCES IN JAPAN: A CASE STUDY ON BUILDING MATERIALS

Hongjun Wang[1], Atsushi Takano[2]

ABSTRACT: The importance of wood products' environmental properties, such as renewability and carbon storage capacity, is well recognized in sustainable development. For the sustainable use of wood, the deeply linked supply and demand relationships are important. However, few studies have been conducted to develop a comprehensive understanding of the forest resource flow. The objectives of this study are to conduct holistic analyses on the material flow and carbon footprint of forest resources in Japan, focusing on building materials; draw holistic flowcharts on the basis of the inventory; and based on that, discuss problems and possibilities from resource and environmental points of view. In the material flow, a large amount of forest wood waste is unmanaged, and the replanting ratio is continuously low. Since major GHG emissions originate in manufacturing and waste management, attentions should be paid to the utilization of biomass energy and the choice of waste management.

KEYWORDS: Material Flow Analysis (MFA), Forest resources, Wood products, Carbon storage

1 INTRODUCTION

Due to a decrease in domestic wood supply and an increase in imports, the wood self-sufficiency rate in Japan dropped from 86.7% in 1960 to 18.8% in 2002. To improve this situation, the government has implemented measures to promote the use of domestic wood. As a result of such effort, the wood self-sufficiency rate recovered to 36.2% in 2017 and a goal of 50% or more has been set for 2025 [1]. Meanwhile, the importance of wood and forest product with environmental properties, such as renewability and carbon storage capacity, is widely recognized in the context of sustainable development nowadays. Carbon storage in forests and wood products is especially regarded as a key to tackling climate change. Since forest products such as timber and pulp are produced from the same resource, the linkage between the related industries: forestry, manufacturing, construction, and waste management is important.

Against such background, researchers in various countries have performed Material Flow Analysis (MFA) of forest resources. For instance, Lenglet et al. [2] have made an MFA of the French forest-wood supply chain to compensate for the absence of consistent accounts for wood product production and consumption. They have attempted to fill this gap and evaluate the potential consequences of raw wood export reduction policies in France. Gonçalves et al. [3] have developed an MFA of forest biomass in Portugal to clarify circularity and resource efficiency. They have created material circularity indicators and cascade factors for different product sectors and pointed out heterogeneity in the circulation of wood products in Portugal. For studies on a larger scale, Mantau [4] has assessed wood flow throughout Europe to produce a tool for setting policy targets. He has quantified resource potentials, cascades and carbon effects. In addition to MFA, the carbon footprint of forest resources has been assessed worldwide. For instance, Zhang et al. [5] have created the life-cycle carbon budget for Harvested Wood Products (HWP) in China to clarify the role HWP play in climate change mitigation. They have assessed carbon stock and emissions from HWP in China, considering production, end-use, post-service disposal stages, and pointed out that in-use HWP account for 73.7% of the life-cycle carbon stock. Head et al. [6] have developed a database of greenhouse gas (GHG) life cycle inventory, focusing on the wood used in Canadian buildings, to facilitate comparisons of climate change impact with non-wood materials. They suggested that most wood building products provide net negative climate change impact scores, but there is still a lack of data for the development of this modular database.

In Japan, there are not yet many studies related to MFA or the carbon footprint of forest resources. Kobayashi et al. [7,8] have developed material flow of forest resources and calculated the environmental loads during manufacturing. They have calculated the carbon footprint of timber,

[1] Hongjun Wang, Kagoshima University, Japan, Hongjun_Wang@protonmail.ch

[2] Atsushi Takano, Kagoshima University, Japan, takano@aae.kagoshima-u.ac.jp

https://doi.org/10.52202/069179-0112

plywood and wood waste, and the CO_2 emissions from building materials. They have pointed out the importance of reforestation and suggested that the utilization of wood waste may compensate for the emissions. To compensate for the insufficiency of emission factors, Nambu et al. [9] have developed an LCA database of wood materials, mainly focusing on imports. They have pointed out the lack of evaluation of imported wood materials and the insufficiency of unit values. In many cases, the assessment of forest resources ended with the accomplishment of the material flow or the database of emission factors, and few have gone on to discuss the issue from environmental perspectives. Emissions from the manufacturing sector have been assessed, while emissions from other processes such as forest management, construction, waste management, and so forth were not considered. Additionally, emissions from imported forest products have not been evaluated so far, though emission factors have already been calculated.

Against this background, this study aims to a create comprehensive overall image of the current state of forest resources in Japan through an examination of forestry, manufacturing, construction, and waste management. To fulfill this objective, this study:
1) presents a holistic flowchart of forest resources in Japan, mainly focusing on building materials.
2) performs MFA on the basis of the inventory.
3) analyses carbon footprint: processing GHG emissions and carbon content flow, on the basis of the inventory.
4) discusses the situation and points of improvement in terms of forest resources in Japan from material flow and environmental perspectives.

2 MATERIALS AND METHODS

2.1 SYSTEM BOUNDARIES

The system boundaries of this study are summarized in Figure 1. The life cycle stages studied are named according to the modularity principle of a building life cycle (EN 15978: 2011) [10], which consists of four main stages (module A1-3: product stage, A4-5: construction stage, B: use stage, and C: end-of-life stage) and an additional information module (module D: benefits and loads beyond the system boundary) has been added.

2.2 MFA

The inventory was carried out on the basis of statistical data published by relevant authorities, such as the Ministry of Agriculture, Forestry and Fisheries [11] and the Food and Agricultural Organization (FAO) [12]. The reference year is 2017. The definition of four sectors in the flowcharts are shown in Table 1, and the rules of flowcharts are explained in section 3.1. Most of the data are known in cubic meters, while data that are known in other units are converted by the following rules: data in "ton" are divided by the weight conversion factor from the Japanese Industrial Waste Information center [13], data in "square meter" are multiplied by the wood utilization conversion factors from the Japanese Ministry of Land, Infrastructure, Transport and Tourism [14]. Estimates were made using conversion factors and formulas referenced in the relevant publication by the Japanese Forestry Agency, the FAO and the Japanese Ministry of Environment [1, 12, 15].

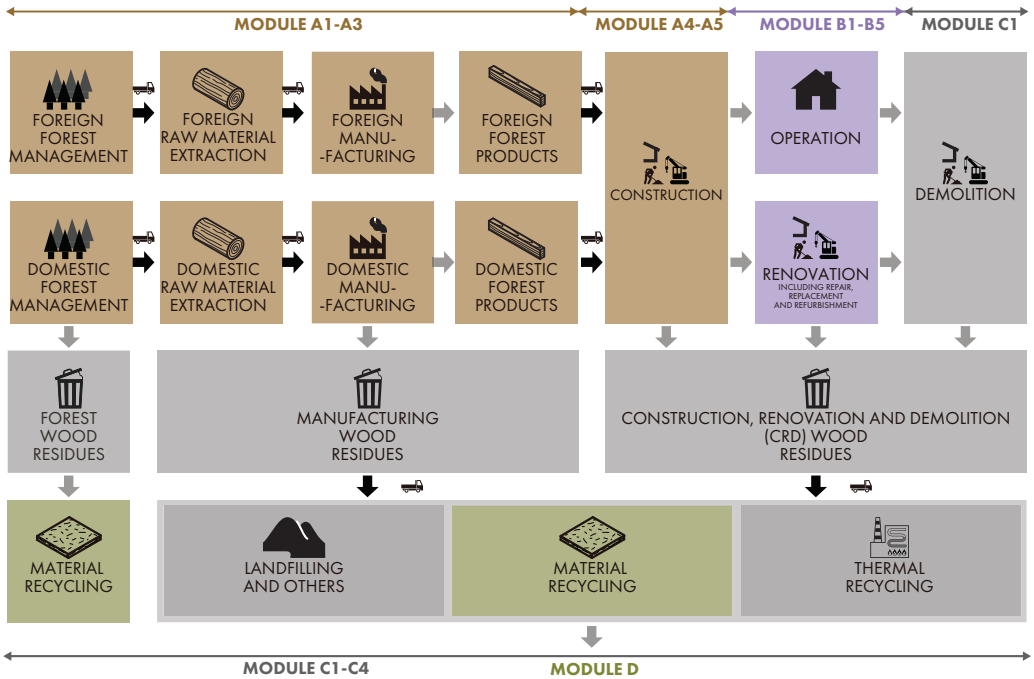

Figure 1: *System boundaries of this study.*

Table 1: Definition of sectors in this study.

Sectors	Contents of each sector
Forestry	Forest management, growing stock (by forest type and age class) and the annual increment of it, forest wood waste
Manufacturing	Production, imports, exports and consumption of forest products, manufacturing wood waste
Building	Wood stock in existing buildings (by construction method) and the annual increment/decrement of it
Disposal	Construction, renovation and demolition (CRD) wood waste, wood waste management

2.3 CARBON FOOTPRINT

2.3.1 Processing GHG emissions

On the basis of the inventory, GHG emissions generated during forest management, forest product processing, construction, demolition, selection, and waste management are assessed. Carbon release from incineration of post-use wood was not counted as processing GHG emissions. Emissions associated with domestic forest product processing, construction, demolition and wood waste management were calculated in accordance with the unit values from the Inventory Database for Environmental Analysis [16]. GHG emissions of imported forest products were calculated using the LCA database created by Nambu et al. [9]. The calculations were carried out by multiplying the unit values by the amount of each product.

2.3.2 Carbon content flow

The carbon content flow of the entire process was also assessed based on the inventory. Carbon content in forest resources was quantified based on the National Greenhouse Gas Inventory Report [15] and Intergovernmental Panel on Climate Change's guidelines for national GHG inventories [17]. In the carbon content flow, "stock" refers to the trees in forests and wood used in buildings; "carbon storage" refers to the carbon in the stock; "carbon uptake" refers to the annual increment of carbon in forests, forest products and wood used in buildings; "carbon release" refers to carbon released after disposal and carbon in exported products. The carbon content related to forests and forest products was calculated using relevant equations and carbon factors [16]. The carbon storage in the existing building stock and carbon uptake in new construction were calculated using relevant carbon fractions [17]. The carbon release was assessed for exported forest products and wood waste by multiplying either the volume or mass according to their carbon fractions [16, 17].

3 RESULTS AND DISCUSSION

3.1 MFA

The result of MFA in Japan is summarized in Figure 2 as a flowchart. Volume of four sectors: forestry, manufacturing, building, and disposal are shown from left to right. In the forestry sector, each tree icon represents $1x10^8$ m^3 of wood volume in growing stock and the dotted circle shows the annual increase of the wood volume. Gradational colors of tree icons represent trees of different age classes, in which trees from young to old are classified by colors from light to dark respectively. In the manufacturing sector, the area of ring is in proportion to the volume of each type of forest product. Each ring with two different colors shows the direct material input (DMI, equals production plus imports): production is shown in the darker color and imports are shown in a lighter color. The lighter ring above the two-color ring shows the exports of forest products. In the building sector, each house icon represents $1x10^8$ m^3 of wood stock in buildings and the dotted circle shows the annual increase of the wood stock. In the disposal sector, the area of the ring is in proportion to the volumetric data. Gradational gray colors from light to dark represent wood waste disposed of by material recycling, thermal-recycling, incineration without electricity production, landfill or other disposal methods.

3.1.1 Forestry

Japan has $25.05x10^6$ ha of forest, of which 51.02% is covered by coniferous trees and the remaining 48.98% is covered by non-coniferous trees. In $5,242x10^6$ of growing stock, 71.08% is coniferous and 28.92% is non-coniferous. Of all the coniferous forest, 52.96% of trees is aged 41~60 years, followed by 21.76% aged 61~80 years and 12.81% aged more than 80 years. There is an average annual increase of $68.26x10^6$ m^3 or 1.40% in growing stock, including 78.26% in planted forests and 21.74% in natural forests. 84,226 ha of forest are harvested, but only 22,069 ha or 26.20% of the harvested area is replanted. The composition of Japanese forest by area is different from the composition by volume, since the density of conifer trees in planted forests is much higher than that of trees in natural forests. As for the age class, of all the coniferous forests, more than 30% is aged 61+ years and ready for harvesting. The non-coniferous forests are generally older than coniferous forests since non-coniferous forests depend on natural regeneration and very few areas are replanted.

3.1.2 Manufacturing

Japan produces $28.68x10^6$ m^3 of roundwood, $9x10^6$ m^3 of timber, $2x10^6$ m^3 of Glulam (Glued Laminated Timber) and CLT (Cross-Laminated Timber), $3.57x10^6$ m^3 of veneer sheets, $3.06x10^6$ m^3 of plywood, $0.18x10^6$ m^3 of LVL (Laminated Veneer Lumber), $5.19x10^6$ m^3 of wood chips, and $1.89x10^6$ m^3 of wood-based panels. Among all roundwood production, 42% is Japanese cedar, 10% is Hinoki cypress, 23% is Japanese larch, Yezo spruce and

https://doi.org/10.52202/069179-0112

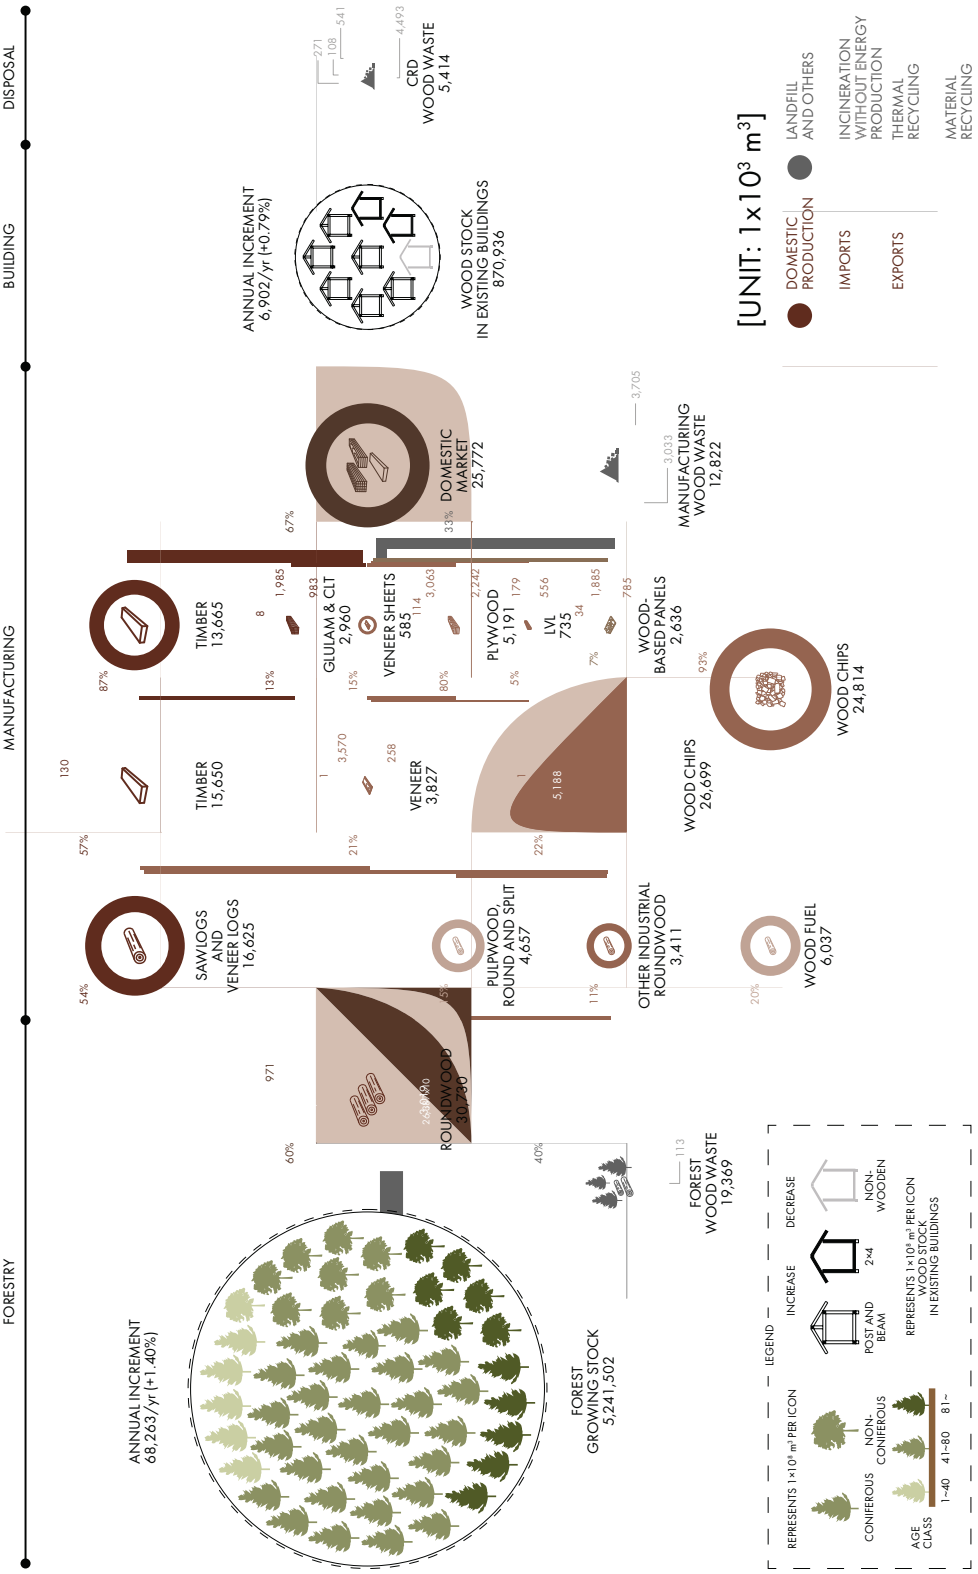

Figure 2: *Material flow of forest resources in Japan (Reference year 2017)*

https://doi.org/10.52202/069179-0112

others, the remaining 25% is unclassified. To meet domestic consumption, approximately 10% of roundwood DMI, 40% of timber DMI, 33% of Glulam & CLT DMI, 7% of veneer sheet DMI, 42% of plywood DMI, 76% of LVL DMI, 81% of wood chip DMI, and 29% of wood-based panel DMI is imported. As for the main source of imports, 85.66% of roundwood imports is from North America, 78.88% of timber imports is from Europe and North America, 81.18% of Glulam imports is from Europe, 83.53% of veneer sheet imports is from Russia, and 92.95% of plywood imports is from Southeast Asia. Of all roundwood consumption, 54% is consumed as sawlogs and veneer logs, 15% is consumed as pulpwood, round and split, 11% is consumed as other industrial roundwood, and 20% is consumed as wood fuel. Of all timber consumption, 13% flowed to glulam and CLT manufacturing, and 87% is used directly in construction and other industries. 25.77×10^6 m^3 of forest products flowed to the domestic market and an average of 1.19% of domestic production is exported. For the composition of the domestic market, 53.02% is timber, 11.48% is glulam and CLT, 2.27% is veneer sheets as the final product, 20.14% is plywood, 2.85% is LVL and 10.23% is wood-based panels. For the sustainability of harvesting, although the increase of most forest types is greater than removals, since the harvesting-replanting ratios are different by forest type, the sustainability of roundwood from different forest types should be evaluated separately and the harvesting should be controlled. For the inflow of forest products, Japan has tried to lower the volume of material imports but still has a great dependency on foreign products. For most types of forest product, the majority of imports are from particular regions, which throws more doubt on the reliability of forest product DMI. For the consumption of forest products, the majority of timber production is still being used directly in construction and other industries. Since the demand for Glulam is increasing because of the recovery of new housing construction and the utilization of CLT is being promoted by the Japanese government, the demand for EWP (Engineered Wood Products) will probably increase in the near future.

3.1.3 Building

Of 81.71×10^6 m^2 of new housing construction, 63.59% is wooden construction (W), 19.66% is reinforced concrete construction (RC), and 16.14% is steel construction (S). Among 52.97×10^6 m^2 of new non-housing construction, 71.85% is S, 15.60% is RC, and 8.64% is W. The volume of the wood stock in total new construction is 12.32×10^6 m^3. Wood stock in new construction is composed of 87.68% in W, 6.72% in RC, and 5.41% in S. Japan has $8{,}381 \times 10^6$ m^2 of existing building stock, which 48.93% is W, 30.52% is S, and 18.51% is RC. The volume of wood stock in existing buildings is 870.94×10^6 m^3, containing 89.94% in W, 6.06% in RC, 3.82% in S, and tiny in SRC and CB. Most of the wood is stocked in wooden housing, while 12% is stocked in non-dwelling buildings using other construction methods because of their large area. Thus, wood stock used in non-wooden constructions should also be accounted for. The composition of the wood stock in new construction are similar to that in existing buildings, but the share of wood stock in wooden constructions in new construction in 2017 is 2.26% smaller than that in existing buildings. Despite the promotion of wooden construction and wood for furnishing these years, the share of it is still lower than in the past.

3.1.4 Disposal

Japan generates 19×10^6 m^3 of forest wood waste, which is 40.31% of the volume of harvested roundwood. Of 5×10^6 m^3 of CRD wood waste, 40% is generated during construction and 60% is generated during demolition. Wood waste generated during renovation is minor. 99% of forest wood waste is unmanaged and less than 1% is material-recycled as wood chips. 47% of manufacturing wood waste is landfilled or disposed of by other waste management, 29% is material-recycled and 24% is thermal-recycled. 83% of CRD wood waste is thermal-recycled, 10% is material-recycled, 5% is incinerated without electricity production, and 2% is landfilled or disposed of by other management method. Although GHG emissions and energy payback ratio in utilization of forest wood waste may be higher than that of fossil fuel [18], the majority of forest wood waste is still unmanaged due to reasons such as the difficulty of collection and the greater cost. Moreover, due to the high water-content ratio very little waste is estimated to be recycled and less than 1% is actually accounted for. Together with the promotion of forest wood waste recycling, methods raising the mechanization rate of collection and lowering the expense should be considered. Since most of the manufacturing wood waste is small particle and ideal as a source of composting material for agricultural purposes, half of the amount is disposed or used by agriculture without recycling. CRD wood waste is usually combined with metals and other matters, which makes the selection time-consuming, so most of it is incinerated for energy use.

3.2 PROCESSING GHG EMISSIONS

The assessments result of processing GHG emissions are summarized in Figure 3 in the same manner as Figure 2. The darker grey line represents processing emissions from domestic production and the lighter grey line represents emissions associated with imported products. The width of each line is relative to the amount of GHG emissions.

3.2.1 Emissions from forest management and roundwood manufacturing

Of 486,306 t-CO_2eq of GHG emissions during roundwood processing, domestic production accounts for 36.80% and importation accounts for 63.20%. Half of the GHG emissions during domestic roundwood manufacturing come from Japanese cedar, followed by 25.51% from unclassified trees and 12.29% from Hinoki cypress.

https://doi.org/10.52202/069179-0112

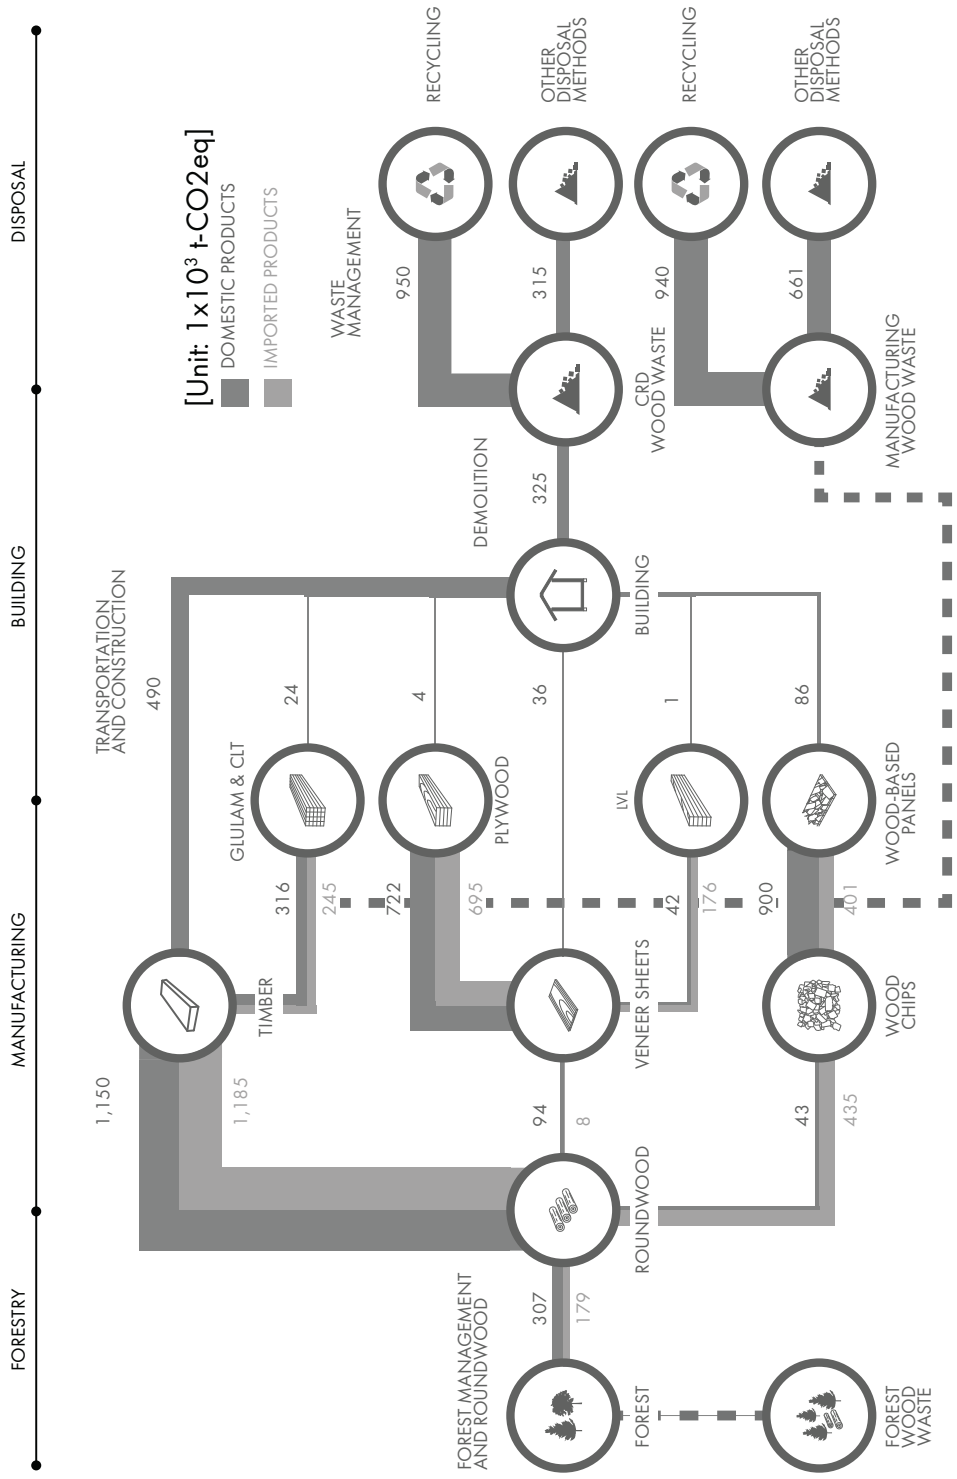

Figure 3: *Processing GHG emission flow of forest resources in Japan (Reference year 2017)*

https://doi.org/10.52202/069179-0112

3.2.2 Emissions from forest product processing

Of $6.41x10^6$ t-CO_2eq of GHG emissions during forest product processing, 51% is from domestic production, 21.40% from Southeast Asia, followed by 10.05% from Europe, 5.90% from North America, 5.79% from Russia and 5.90% from other regions. Of $3.27x10^6$ t-CO_2eq of GHG emissions from production, 35.21% come from timber processing, followed by 27.56% from wood-based panel processing, 22.09% from plywood processing, 9.66% from glulam & CLT processing, and the remaining 5.47% from other processes. Of $3.15x10^6$ t-CO_2eq of GHG emissions from imports, 37.67% come from timber processing, followed by 22.08% from plywood processing, 13.83% from wood chip processing, 12.75% from wood-based panel processing, and the rest 13.77% from other processes.

3.2.3 Emissions from construction and demolition

$0.97x10^6$ t-CO_2eq of GHG emissions come from building material transportation, construction and demolition, of which 66.29% is from building material transportation and construction, 30.20% is from demolition and 3.51% is from the selection of CRD waste. 76.63% of GHG emissions resulting from these processes is from timber, followed by 13.43% from wood-based panels and 9.93% from other forest products. 76.72% of the GHG emissions related to the utilization of forest products come from wooden construction, followed by 12.79% from steel construction, 9.59% from reinforced concrete construction, and less than 1% from others.

3.2.4 Emissions from wood waste management

$1.60x10^6$ t-CO_2eq of GHG emissions come from manufacturing wood waste management, of which 58.71% is from recycling and 41.29% is from other disposal methods. 71.29% is from collection and transportation, followed by 21.14% from thermal-recycling, 7.37% from landfilling and others. $1.26x10^6$ t-CO_2eq of GHG emissions come from CRD wood waste management, of which 75.13% is from recycling and 24.87% is from other disposal methods. 39.62% is from thermal recycling, followed by 38.18% from collection and transportation, 2.39% from pure incineration, and 19.81% from landfilling and others.

3.2.5 Total GHG emissions

The amount of GHG emissions associated with all forest products is $10.67x10^6$ t-CO_2eq, of which 68.84% is from domestic processing and 31.16% is from foreign processing. Of the total GHG emissions resulting from forest resource processing, 59.71% is from forest product processing, followed by 26.85% from wood waste management, 9.05% from CRD activities, and 4.39% from forestry. The most (21.80%) is generated during timber processing, specifically 11.60% from timber imports and 10.70% from domestic timber construction. This amount is tremendous mainly because of the great volume, and the use of fossil fuel during the wood-drying process. To reduce the GHG emissions during timber processing, methods such as biomass substitution during the subprocess of drying should be brought into the discussion. The second largest (15.00%) is generated during manufacturing wood waste management, and as much as 11.86% is from CRD wood waste management. Wood waste in Japan is difficult to collect or select, which transforms into high unit values. The transportation distance and the choice of wood waste management methods may have a great influence on total GHG emissions.

3.3 CARBON CONTENT FLOW

The assessment results of carbon storage, uptake and release (defined in section 2.3.2) are summarized in Figure 4 in the same manner as Figure 2. Most of the rules are the same as for the material flow, while values of carbon storage in forests and buildings are represented by rings with two layers, which are proportionally 25 times larger than single-layer rings.

3.3.1 Carbon storage and uptake

Of $7{,}268x10^6$ t-CO_2eq of carbon storage, 90.11% is stored in the growing stock and 9.89% is stored through wood utilization in existing building stock. More specifically, 55.17% is stocked in coniferous forests, 34.94% in non-coniferous forests, 8.89% in wooden construction buildings, and 1% in other construction. Of $104x10^6$ t-CO_2eq of carbon uptake, 78.56% is from growing stock and 21.44% is from forest products. 45.44% of carbon uptake in forest products is stored in buildings, while the remaining 54.56% is discarded during construction or flows to other industries. Similar to the volumetric composition, $22.36x10^6$ t-CO_2eq of carbon uptake in forest products flowed to the domestic market, with 51.33% being from timber, followed by 22.75% from plywood, 12.71% from wood-based panels, and a combined 26.44% from others. 39.48% is stored in imports and 60.52% is stored in production.

3.3.2 Carbon release

$1.08x10^6$ t-CO_2eq is exported in forest products and $17.69x10^6$ t-CO_2eq is released through wood waste management. Carbon loss consists of 60.36% in forest wood waste, 25.84% in manufacturing wood waste and 13.81% in CRD wood waste. Since the majority of forest wood waste is unmanaged and industrial wood waste is mostly treated through thermal recycling, almost all the carbon in wood waste is released.

4 SCENARIO ANALYSIS

4.1 GOAL OF WOOD SELF-SUFFICIENCY RATE

Although the demand for wood was predicted to decline from $82x10^6$ m^3 in 2017 to $79x10^6$ m^3 in 2025, the goal of wood self-sufficiency has been increased from 36.2% in 2017 to 50% in 2025 [1]. Thus, the amount of self-sufficient wood is assumed to increase from $29x10^6$ m^3 in 2017 to $40x10^6$ m^3 in 2025. This variation may trigger impacts on the sustainability of forest resources.

https://doi.org/10.52202/069179-0112

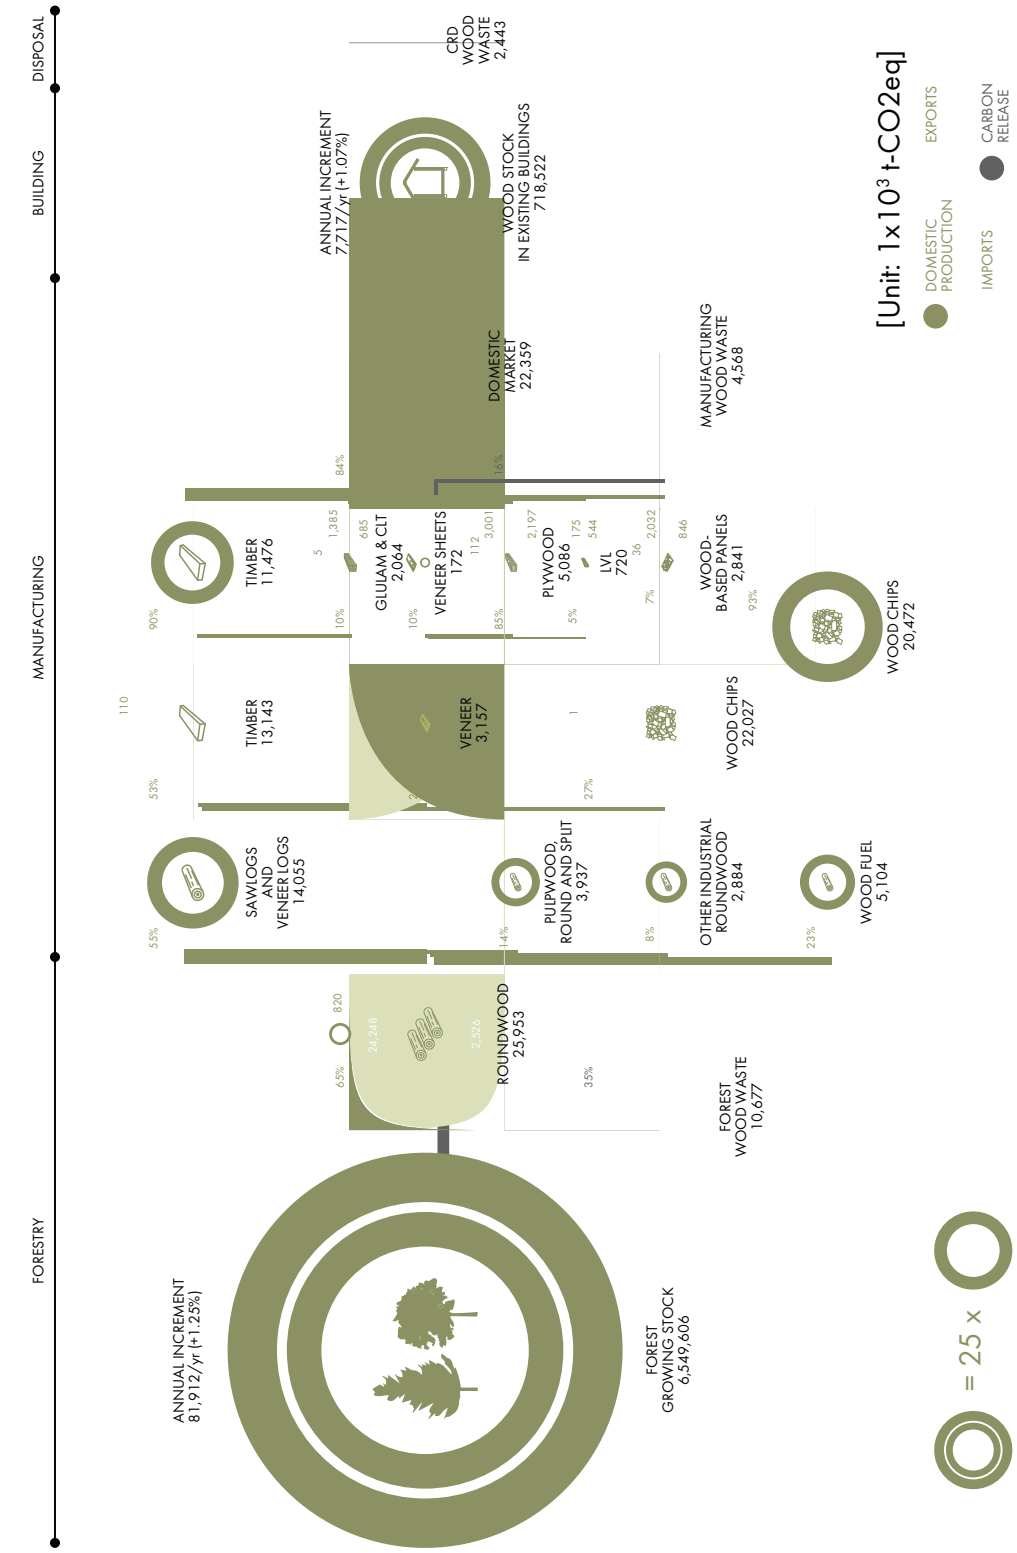

Figure 4: *Carbon content flow of forest resources in Japan (Reference year 2017)*

https://doi.org/10.52202/069179-0112

In 2025, the roundwood removals and imports are predicted to change by +36.29% and -25.27%, respectively. A reduction of forest area by 92,721 ha is predicted to be caused due to the low planting ratio and the difficulties of natural regeneration [18]. In terms of processing GHG emissions, 5.83% more of total GHG emissions is predicted to be generated, which is 14.27% more from forestry, 6.15% more from manufacturing, 6.77% more from disposal, but 3.12% less from building due to the decline in demand. In the carbon content flow, the carbon uptake in forests and forest products is predicted to decline by 25.54% and 3.12%, respectively. This is predicted to lead to a 20.73% decline in total carbon uptake. As a result, there is predicted to be a lower dependency on imports, worse sustainability of forests, a greater amount of GHG emissions, and a lower amount of annual carbon uptake. To solve these potential threats, both the improvement of forest resources sustainability and the reduction of GHG emissions resulting from domestic manufacturing should be taken into consideration. With a higher replanting ratio of harvested forest lands, there are predicted to be more sufficient domestic forest resource and more carbon uptake in forests. This may compensate for the material volume loss by domestic harvesting and the GHG emissions released by domestic manufacturing. The promotion of biomass energy utilization should be also encouraged since the substitution of biomass for fossil fuel is predicted to be efficient in terms of emission reduction (discussed in section 4.3).

4.2 BIOMASS SUBSTITUTION DURING TIMBE R MANUFACTURING

As mentioned before, a large amount of GHG emissions is generated from timber processing. For the details of this process, Komata et al. [19] suggested that most of GHG emissions due to domestic timber processing are from the drying process. They pointed out that the substitution ratio of biomass for fossil fuel in Japan is relatively low (41%), compared to countries in Europe (90%), Oceania (85%) and North America (80%). Thus, this scenario analysis was conducted to discuss the reduction of GHG emissions using different levels of biomass substitution. On the basis of the case study on biomass substitution in different countries [9], and the emission factors for the kiln-drying process [20], three scenarios with different levels of biomass substitution were estimated. S1 was assumed as timber processing without biomass energy use (fossil fuel: 100%, biomass energy: 0%). S2 was assumed as the lowest level of biomass substitution (fossil fuel: 60%, biomass energy: 40%). And S3 was assumed as the highest level of biomass substitution (fossil fuel: 10%, biomass energy: 90%). In S2, the GHG emissions from domestic timber processing is predicted to decrease by 19.26% and the total GHG emissions from forest resource processing is predicted to decrease by 1.89%. In S3, GHG emissions from domestic timber processing is predicted to decrease by 42.28% and the total GHG emissions from forest resource processing is predicted to decrease by 4.15%. Theoretically, the substitution of biomass energy during the wood-drying process of domestic timber manufacturing alone will reduce the GHG emissions by a relatively large amount. Considering the GHG emissions from long-distance overseas transportation of imported timber, the promotion of biomass energy utilization during manufacturing may allow domestic timber to be more competitive in the future.

4.3 OUFLOWS OF WOOD WASTE

When discarded forest products are material-recycled, carbon is not released and it can be stored for a longer period of time [21], material-recycling should be encouraged. However, very little wood waste is material-recycled and flows back to the carbon pool at the moment. Thus, this scenario analysis was conducted to discuss the reduction of GHG emissions and carbon release by two scenarios to the achievable improvement of wood waste management. S1 was assumed as the improvement reducing 10% more volume of total wood waste. S2 was assumed as the improvement with 10% more shares of material-recycling in all disposal methods of wood waste. In S1, there is predicted to be a decline in total GHG emissions by 2.69%. There is predicted to be a decline in carbon outflows by 9.42%. In S2, the GHG emissions are predicted to decrease by 13.36%, specifically manufacturing wood waste management by 5.25% and CRD wood waste management by 23.62%. This leads to a decline in total GHG emissions of 3.59%. The carbon release is predicted to decrease by 11.24%, specifically forest wood waste by 10.06%, manufacturing wood waste by 14.06% and CRD wood waste management by 11.11%. By reducing the volume of wood waste, there would be lower GHG emissions and less carbon release. By disposing more wood waste through material-recycling, the GHG emissions and carbon release would decrease even more. A better choice of recycling methods guarantees less GHG emissions and less carbon release, than the pure reduction of wood waste. To improve wood waste management, efforts should be put into both the reduction of volume and the choice of recycling methods.

5 CONCLUSIONS

The sustainable use of forest resources is one of the main challenges in the society, while the state of forest resources in Japan can be enhanced in terms of material flow and environmental perspectives. To understand the overall image of forest resources in Japan, this research has attempted to perform analyses of material flow and carbon footprint. The results show that the large amount of unmanaged forest wood waste, the low replanting ratio, and the lack of monitoring on supply-demand relationships are some of the main problems of forest resources in Japan at present. By 2025, we have predicted a decrease in the sustainability of forests due to greater domestic production. To solve these problems, policies encouraging waste management and replanting, as well as standards of evaluation on the sustainability level of harvesting are needed. For the carbon footprint of forest resources, major GHG emissions originate in imported

https://doi.org/10.52202/069179-0112

products, waste management, and timber processing. To improve the disposal of wood waste, efforts should be put into both the reduction of volume and the choice of recycling methods simultaneously. Since there is a relatively low biomass substitution ratio in Japan, the promotion of biomass energy may contribute to the decline of emissions from timber processing. This research resulted in inventory and holistic flowcharts of forest resource flow focusing on the quantities, processing GHG emissions, and carbon content flow. The inventory and flowcharts could be used to perform other analysis of forest resources, or as a platform for discussion on the current problems and points of improvement. The results may be useful for environmental policy development.

GROUND IMPROVEMENT EFFECT OF TIMBER PILES BURIED IN SOFT CLAY GROUND

Tadashi Hara[1], Yoshitaka Kubojima[2], Hidao Kato[3], Satomi Sonoda[4]

ABSTRACT: Promoting use of timber piles for ground reinforcement requires determining the effectiveness and sustainability of ground consolidation and compaction after burial, according to soil type. In this study, from simple soundings we determine penetration resistance near timber piles buried in a soft clay layer and its change over time to analyze the degree of solidification and extent of improvement. The results of a series of field tests showed that penetration resistance in a cohesive soil layer significantly increases in the vicinity of timber piles immediately after their installation, with the consolidation area concentrically expanding over time; that buried timber piles act as drainage columns and caused consolidation phenomena deep in the ground; and that the longer the piles have been buried, the greater the effects. Because the results of this study demonstrate the effectiveness and continuity of timber piles as ground reinforcement materials, we can expect their active use in the future to promote ground disaster prevention and contribute to global warming countermeasures by storing carbon in the ground.

KEYWORDS: Ground improvement, Timber pile, Soft clay layer, Penetration resistance

1 INTRODUCTION

Wood as a civil engineering material is easy to process and environmentally friendly. In a land environment where the population is concentrated on plains, ground-related damage such as loose or sunken road surfaces and sinking or tilting of structures is likely to occur, and damage will be frequent. There is great social interest in the use of wood as a ground improvement material and its application to disaster prevention, for example as a countermeasure against ground deformation and shaking in earthquakes. In Japan, abundant forest resources were actively utilized as civil engineering and construction materials until the period of rapid economic development in the 1950s, and large amounts of timber pile were buried in applications such as pile foundations to support structures and compact reclaimed ground. Even today, many structures have exceeded a service life of 50 years, withstanding earthquakes and other natural disasters as well as providing safety and security [1]. In Venice, which is known for its timber pile foundations, many structures supported by timber piles driven into soft ground (muddy soil) are still in service some four hundred years after their construction [2].

In cooperation with a private company, the authors developed the Log Piling Method for Liquefaction Mitigation and Carbon Stock (LP-LiC) as a measure to mitigate ground liquefaction damage in the event of a Nankai Trough earthquake, which has a high probability of occurrence [3]. Artificial materials for civil engineering are easy to handle and process and are in wide use, so actively utilizing historically popular wood in civil engineering works for disaster prevention will require grasping the presence or absence of cross-sectional loss due to biodeterioration of timber piles in the ground as well as the degree and sustainability of solidification of the ground after construction, according to the soil material in question.

In a study of sandy soil with high liquefaction potential, Yoshida et al. [4] performed model tests to verify the effectiveness of log casting for soil prone to liquefaction, finding that the circumferential friction force of logs greatly affects the bearing capacity of the soil. Hara et al. [5] conducted multiple sounding tests on reclaimed sandy soil improved by the LP-LiC method to investigate the effects of soil improvement depth and casting intervals. In a study focusing on the bearing capacity of timber piles, Yamauchi et al. [6] evaluated the effect of compacting sandy soil from laboratory soil tests by collecting soil samples around pine piles that had been used as bridge foundations for about 70 years. In field loading tests, Mizutani et al. [7] investigated the bearing capacity of cedar timber piles jacked into cohesive soil layers, finding that

the values for the same shape were larger for steel, concrete, and timber piles, in that order. There have thus been several studies on the effects of compaction by timber piles, mainly in sandy soils at some point in time after burial. In contrast, there have been few field studies and experiments involving clayey soil layers, and there are few examples of studies through field investigations that systematically analyze the degree of soil solidification, the extent of improvement, and sustainability of the effects of buried timber piles.

In this study, we performed simple sounding tests to determine softness or hardness near timber piles buried in a soft clay layer and then analyzed changes in properties after piles were buried. Specifically, we evaluated the superiority of timber piles as a ground improvement material by summarizing changes in ground solidification due to timber pile burial, the extent of any improvement, changes in ground solidification immediately after installation, and the durability of effects from the viewpoint of penetration resistance and the elapsed time after installation.

2 GENERAL INSTRUCTIONS OUTLINE OF THE INVESTIGATION SITE AND BURIED TIMBER PILES

The study site was located on the premises of the Forestry Research and Management Organization in Tsukuba City, Ibaraki Prefecture (Figure 1). Figure 2 shows a geologic columnar section from the study site. The target site is a developed alluvial plain, in which soft layers with N values of less than 10 as obtained by standard penetration tests are distributed. Strata where the timber pile was buried consisted of andosol as the buried soil from ground level (GL) −0.50 to −4.5 m and former topsoil surface up to GL−–2.00 m, tuffaceous clay with similar properties from GL −2.00 to −4.70 m, and fine clay mixed with a small amount of medium to coarse sand from GL −4.70 to −5.80 m. Among the tuffaceous cohesive soils, there was extremely soft, clayey blue-gray cohesive soil with $N = 2$ around GL −3.00 to −4.70 m. There was no clear groundwater table throughout the entire formation, but the old topsoil and clay layers were saturated, and borehole logs showed perched groundwater at around GL −2.65 m.

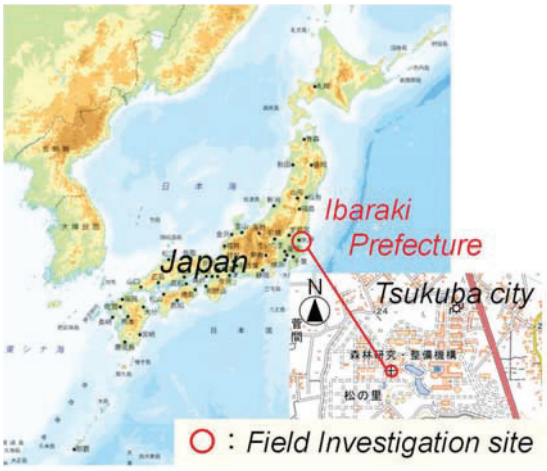

Figure.1: *Field investigation site (Tukuba city, Ibaraki Prefecture, Japan)*

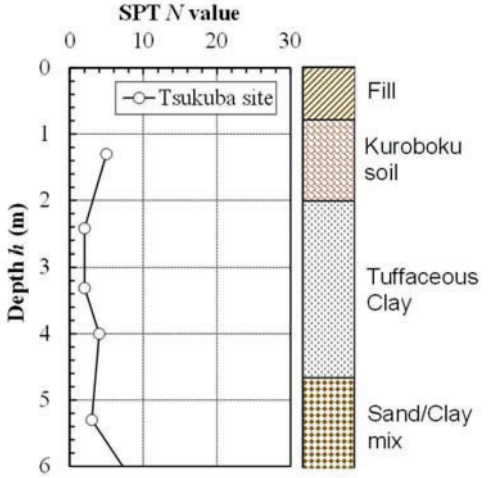

Figure.2: *Layer composition of the ground at the investigation site*

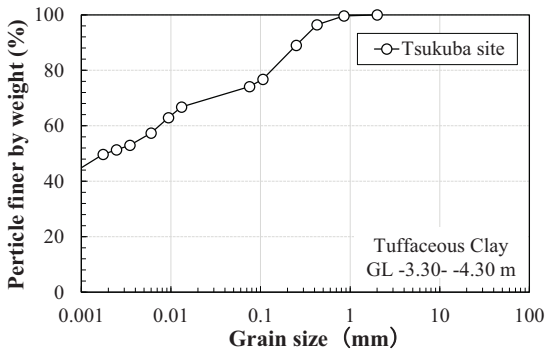

Figure.3: *Particle size distribution curve for tuffaceous clay*

Figure 3 shows a particle size distribution curve for tuffaceous clay collected from the site. The fine-grained content F_c is a large 74.1%, indicating that the soil is predominantly fine-grained. The plasticity index I_p obtained from liquid limit and plasticity limit tests was 60, indicating that the clay content was high.

Figure 4 shows a timber pile buried at the study site. Cedar logs (140 mm in diameter, 4.00 m long) from Fukushima Prefecture were used as timber piles. Young's modulus E_{ft} values for the timber piles as obtained by the longitudinal vibration method were 6.74, 6.76, 6.78, 8.21, and 9.50 GPa [8], showing some variation. The moisture content of timber piles pulled about one year after burial ranged from 74% to 149%, above the fiber saturation point at all sites and increasingly higher with greater depth than the average estimate (94%) prior to burial [9].

We buried the timber piles on 3 Dec 2020. After removing relatively hard pebbles from the ground surface at a depth of −1.00 m, we used a small pile borer (Komatsu BA-100) to continuously and statically jack-in the pile as shown in Figure 5, without prior excavation using an auger, until the pile mouth reached a depth of −0.30 m from the ground surface. The depth of the timber piles, including

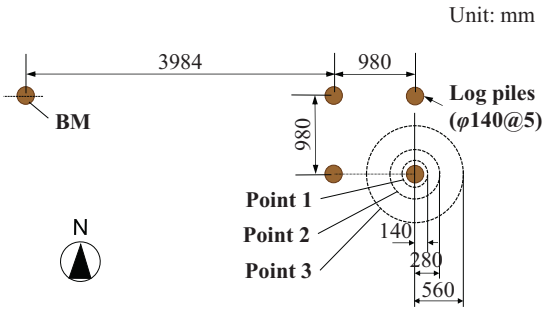

Figure.7: *Location of the build of the timber piles and place to perform PDCP test*

the pile length, was −0.43 m. Spacing between buried timber piles was about seven times the distance between centers of adjacent piles.

3 CHANGES IN PENETRATION RESISTANCE AND SOLIDIFICATION RANGE DUE TO BURIAL OF TIMBER PILES

We performed soundings using the portable dynamic cone penetration (PDCP) test [10] to determine changes in timber pile strength before and after burial. As Figure 6 shows, the PDCP test determines the degree of soil softness or hardness by determining the number of times N_d required to drive a cone attached to the tip of a rod 100 mm into the ground by dropping a 5-kg drive hammer from a height of 500 mm, allowing determination of a relative value for soil softness or hardness. Using continuous sounding blows, we obtained soundings every 100 mm from GL −1.00 to −5.50 m, which was a depth of −1.20 m below the tip of the timber pile (GL −4.30 m). As Figure 7 shows, we selected four basis measurements (BM) not subject to changes in ground properties due to the construction, located close to the sides of the timber piles, about 140 mm from the pile core (Point 1), about 280 mm away (Point 2), about 560 mm away (Point 3), and about 4 m west of where the timber pile was driven.

Figure 8 summarizes the relation between depth from ground surface h and penetration resistance N_d from the results of PDCP tests performed at Points 1, 2, and 3 one day after burial (4 Dec 2020). The same figure also shows BM results from 15 Dec 2020. The BM N_d values show that the ground at the investigation site is continuously below $N_d = 10$ up to about GL −3.50 m, indicating the characteristic properties of extremely soft clay soil, as shown in the results obtained from the standard penetration test in Fig. 2. Comparing the surveyed points, the data of Point 1 near the timber pile shows an increase at almost all layers immediately after the installation, while the data of Points 2 and 3 far from the timber pile shows an increase in a limited area, below GL −3.00 m, and a large change near GL −4.00 m, which is close to the tip of the pile. From this, we can infer that in areas where the timber pile and the ground are in close contact, clay around the

https://doi.org/10.52202/069179-0113

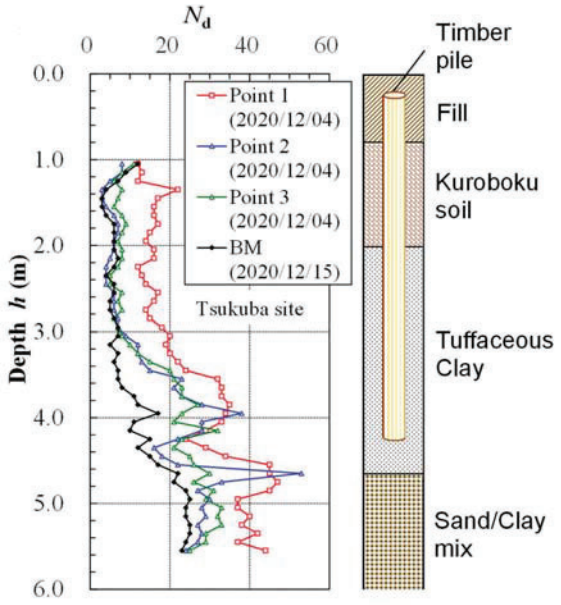

Figure 8: *Relationship between N_d value and Ground depth (1 day after build of a timber piles)*

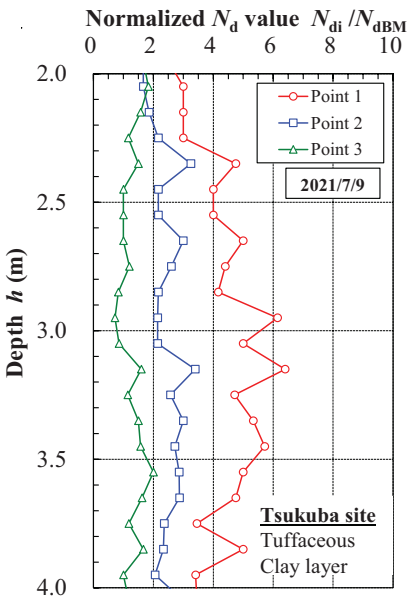

Figure 9: *Relationship between Normalized N_d value and ground depth (218 days after build of timber piles)*

circumference of the timber pile is temporarily disturbed and its strength is reduced during the timber pile burial, but near the pile and at the pile tip, interstitial water moves horizontally to the pile surface and, as seen in sandy soil, is absorbed by the timber pile shortly after installation [10], and consolidation of the clay layer occurs immediately. Values for N_d at GL −3.50 m and below show an increasing trend at all depths, whereas values from GL −5.00 to −5.50 m below the pile tip increase with depth, unlike in the standard penetration test results shown in Fig. 2. This is due to the compressive effect of the ground around the timber pile during jack-in and the increase in apparent penetration resistance due to friction between the penetration rod and the ground [11].

Figure 9 summarizes the results of penetration tests at Points 1 and 3 in tuffaceous clay (GL −2.00 to −4.00 m) about six months after burial (on 9 July 2021) with regards to the depth from the ground surface h and the normalized penetration resistance N_{di}/N_{dBM}. The normalized penetration resistance is the normalized value obtained by dividing the penetration resistance N_{di} obtained at each survey point (i = 1, 2, 3) by the BM penetration resistance N_{dBM}, and is a multiplier of the penetration resistance obtained at the reference point. The largest increase in penetration resistance of about four times is at Point 1, near the timber pile, but even at Points 2 and 3, which are far from the timber pile, the increase over time is about two times, indicating that the area solidified by pile burial extends in concentric circles.

4 CHANGES IN ELAPSED DAYS AND PENETRATION RESISTANCE

Figure 10 shows the results of PDCP tests at each study site one day (4 Dec 2020), one week (14–15 Dec 2020), three months (16 Mar 2021), six months (9 Jul 2021), about one year (30 Nov 2021), and about two year (6 - 7 Dec 2022) after the timber pile was buried, compared with results obtained on 23 Jun 2022, more than 10 years passed the burial on 15 Dec 2011. Although the results show different trends due to local ground variations, the penetration resistance after timber pile burial is globally greater than that of the BM, regardless of the burial period. The penetration resistance N_d at Point 1 shown in Fig. 10(a) increases significantly from relatively shallow depths immediately after construction, whereas those at Points 2 and 3 shown in Figs. 10(b) and 10(c) significantly increase near the timber pile tip at GL −3.00 to −4.50 m. Focusing on the passage of time after installation, at Point 1 in Fig. 10(a), N_d significantly increases immediately after burial in the clay layer near the ground surface below GL −1.50 m, and gradually increases with time after installation near the pile tip at around GL −4.00 m. The results at Point 2 in Fig. 10(b), which show a local increase of only N_d at depths below GL −3.00 m one day after burial, show a significant increase across all layers where the timber pile was buried about three months after burial, with that effect continuing for a long time as with Point 1. At Point 3 in Fig. 10(c), the increase in N_d is slower immediately after the construction than at Points 1 and 2, but gradually increases over time, and soil solidification extends across spread from the center to the tip.

Figure 11 shows PDCP test results obtained at the pile tip at GL −1.05 to −1.35 m, in the middle of the timber pile at GL −2.05 to −2.55 m, and at the pile tip GL −3.85 to −4.35 m as a function of days elapsed from installation and normalized penetration resistance, N_{di}/N_{dBM}. The plots in that figure show normalized penetration resistance values obtained every 100 mm and averaged for the depth of each section of interest. Compared with the

https://doi.org/10.52202/069179-0113

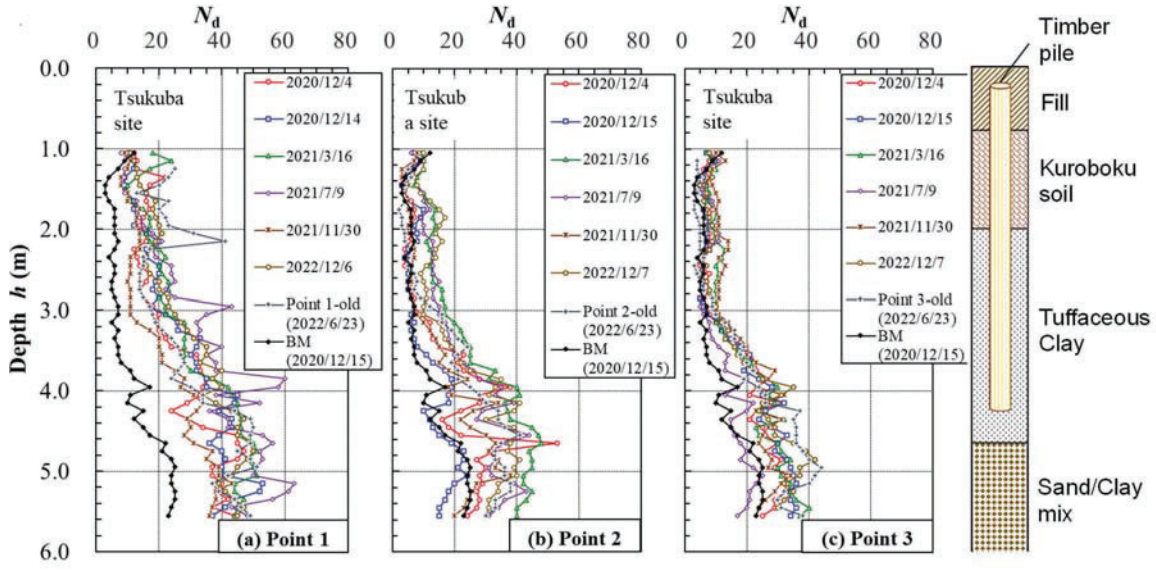

Figure 10: *Relationship between N_d value and ground depth (All investigations)*

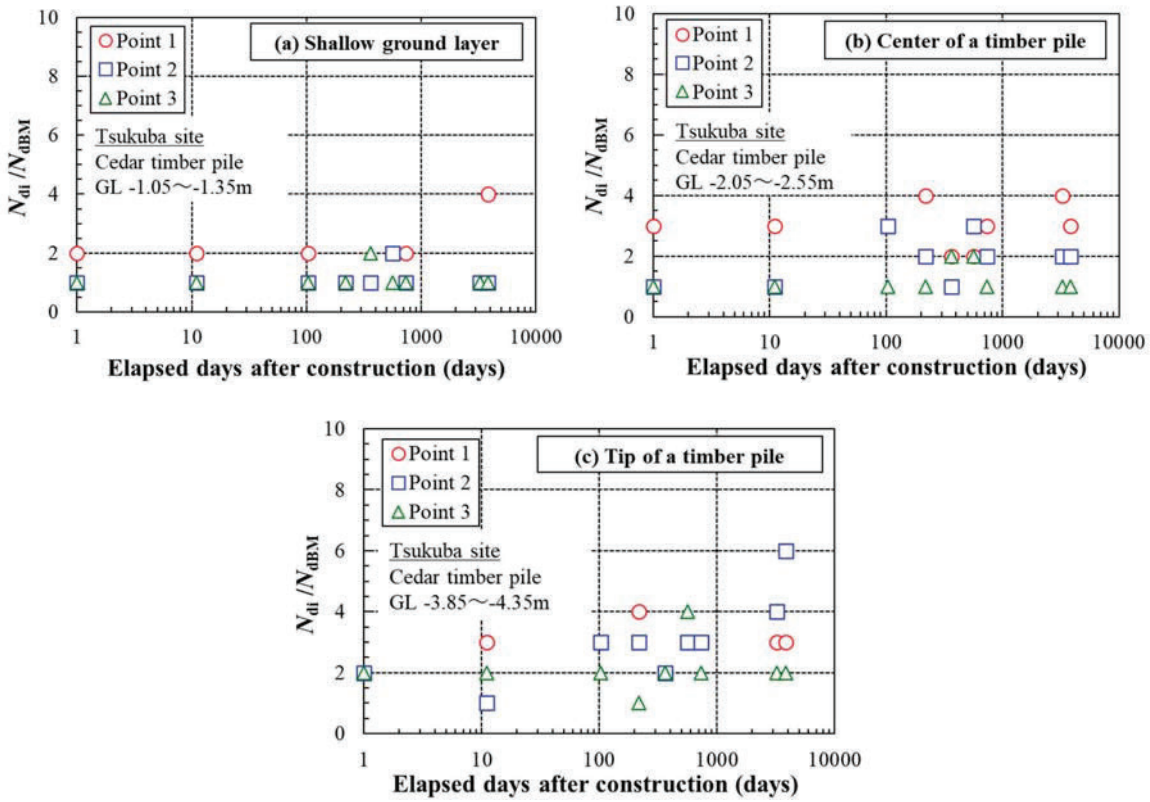

Figure 11: *Relationship between Elapsed days after construction and Normalized N_d value*

BM results, the penetration resistance increased at each depth after timber pile burial, and the effect continued throughout the burial period, but the increase in resistance was more pronounced near the pile at Point 1. Figure 11(c) shows that the increase in N_d at the pile tip was slower than in Figs. 11(a) and 11(b), but that penetration resistance rapidly increases after 200 days at Point 2, and after about ten years the resistance even at Point 3, which is farthest from the timber pile, is two times higher than the BM.

Figure 12 shows results obtained from a series of soundings as the relation between mean depth h and normalized

https://doi.org/10.52202/069179-0113

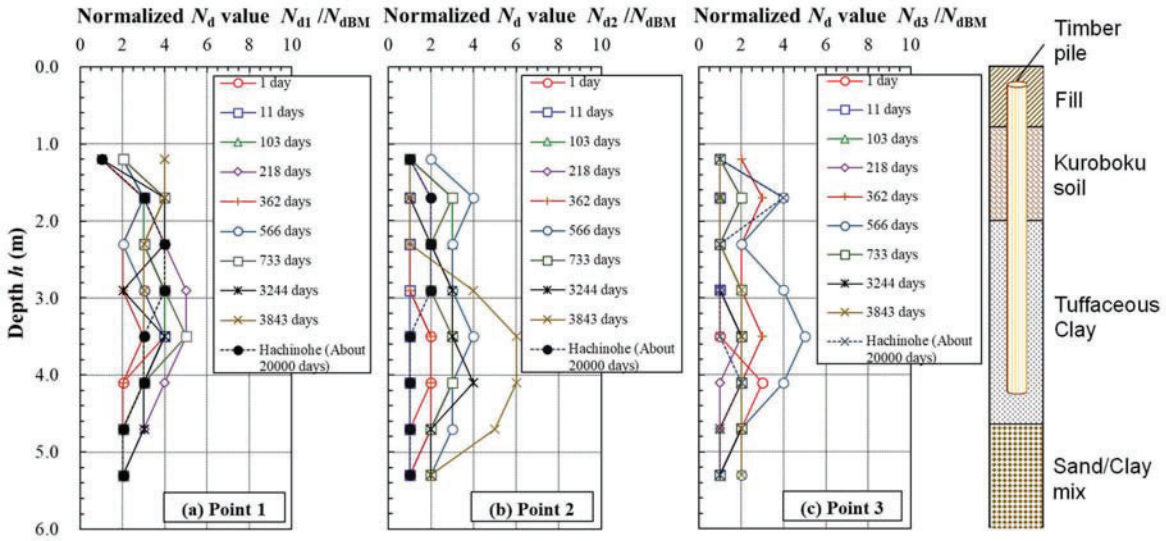

Figure 12: *Relationship between penetration resistance N_{di}/N_{dBM} and average depth (All investigations)*

penetration resistance N_{di}/N_{dBM}. The results in that figure show the normalized penetration resistance from GL −1.05 to −5.55 m as the relation between average depth and average value for normalized penetration resistance at 0.50 m intervals from GL −1.05 m near the ground surface. Although the degree of increase in the values varied depending on the surveyed location, consolidation of the soil based on the normalized penetration resistance values by timber piles embedded in clay were greatest in the center of the timber pile installation at GL −2.00 to −3.00 m for a period of about one year after construction. The trend for normalized penetration resistance about nine years after installation is different from the results from about one year after the installation. From GL −3.00 m at points 2 and 3, slightly deeper than at the center of the timber pile, the normalized penetration resistance of the piles increases in a bulbous manner, becoming greatest from the center of the pile to the tip at GL −3.00 to −4.00 m, and decreasing below about GL −4.00 m. This is presumably because in addition to horizontal interstitial water movement [11], the buried timber pile acts as a drain column that promotes drainage into the ground, where interstitial water in the deep clay layer, which has a higher confining pressure compared with the shallow layer, is absorbed by the wood, and over time consolidation develops from the pile tip. Compared with shallow layers in contact with planks, soil moisture is more easily absorbed by the timber pile in the deeper soil surrounding the wood surface at the pile tip. This accelerates consolidation, which is expected to progress over a wider area, spreading its effect to deeper soil where the timber pile is not buried. Figure 12 also shows results for a timber pile that was buried for approximately 55 years, installed using an impact method in reclaimed sandy soil with pile spacing similar to that in this study [13]. Although the characteristics of this soil are very different from that of the cohesive soil in this study, burial of the timber pile similarly tightens the soil, and the effect concentrically spreads out against the timber pile.

Increased resistance to ground penetration is considered to be influenced by the permeability of the soil type in question and the nature of soil particles. In sandy soils with high hydraulic conductivity, where liquefaction occurs more frequently than in clay soils, excess interstitial water pressure dissipates in a relatively short period at laying and consolidation effects by compaction are present immediately after burial, but this study showed that consolidation and compaction by timber pile burial continues on a yearly basis with higher effects near the timber pile.

5 CONCLUSIONS

From simple soundings, we continuously determined penetration resistance and its change in the vicinity of timber piles buried in a soft clay layer from immediately after burial, and we analyzed the degree and extent of solidification. The results of a series of field tests showed that penetration resistance in cohesive soil layers significantly increases near the timber piles immediately after their burial, that soil consolidation concentrically spreads over time, that buried timber piles act as drainage drain columns and promote the consolidation of cohesive soil, and that these effects are greater in soil in which piles have been buried for longer times. The results of model tests have shown higher water content and heightened consolidation phenomena with vicinity to timber piles, and that the vertical bearing capacity of piles increases with time since installation [14], both of which are consistent with the results of this study. This effect is not seen when using artificial materials such as steel or concrete. Consolidation of clayey soils presumably increases over time due to the combined effects of changes in soil microstructure caused by age effects and leaching of cementation materials from wood, in addition to the above-described accelerated consolidation associated with interstitial water movement into the timber pile immediately after burial. Through field surveys and laboratory tests, we will continue to quantitatively analyze factors promoting soil solidification to elucidate other advantages over artificial materials.

STUDY ON ENVIRONMENT DECOMPOSITION AND STRENGTH OF CLT WHEN TEMPORARILY USED ON CIVIL ENGINEERING

Naoya Iizawa[1], Kei-ichi Imamoto[2], Chizuru Kiyohara[3], Hideyuki Nasu[4], Satoshi Onishi[5],

ABSTRACT: This study examines the civil engineering use of CLTs; if the civil engineering use of CLTs is promoted, the supply of domestically produced CLTs will increase and stabilize, and the price of CLTs will decrease. The purpose of this study is to verify the conditions of use and decomposition in a civil engineering environment. As initial tests, visual observation, 3-point bending tests, and compression tests were conducted to verify the rate of strength degradation and degradation conditions for each elapsed month. As a result, since there was a large strength fluctuation at the same moisture content in terms of the embedded yield strength, an additional verification using small specimens was conducted. The results suggest that the strength reduction in the buried specimens was due to the absorption of water during the burial period, as well as minor but significant biodeterioration.

KEYWORDS: Timber material, CLT, Civil engineering use, Degradation, Strength reduction rate, Moisture content

1 INTRODUCTION

In recent years, against the backdrop of global environmental issues, Cross Laminated Timber (hereafter, CLT) is expected to become a wood-based building material that can curb CO2 emissions and effectively utilize forest resources. In Japan, however, the post-war period saw a sharp increase in demand for lumber, but a significant shortage in the supply of domestic lumber caused the price of domestic lumber to skyrocket, leading to a massive supply of imported lumber. As a result, the demand for imported lumber increased dramatically, and the demand for high-priced domestic lumber decreased dramatically. In addition, many trees were planted before the supply of imported timber, but the dramatic increase in demand for imported timber has resulted in many the planted trees being left unattended. Furthermore, Japan has many steep mountains that prevent large heavy machinery from entering the mountains, making it difficult to secure a stable distribution volume of lumber, and the complicated transportation system has led to high intermediate costs, which have caused lumber prices to skyrocket. Therefore, CLT is currently used only for low to mid-rise buildings and subsidized projects.

Therefore, we aim to expand the use of CLTs by making them more versatile. One idea is to apply CLTs to civil engineering materials, where the amount of used is small compared to the economic scale and there is room to expand its use. To increase the demand for timber and to utilize forest resources, civil engineering use of timber is already in progress, such as the use of wooden dams and ground improvement using wooden piles. When CLTs are used for this purpose, they can be substituted for the steel plates used to prevent the ground from being dented by the weight of large heavy machinery at construction sites. Usually, steel plates are collected after temporary construction and used again, but this is very disadvantageous in terms of transportation because they are extremely heavy and dangerous to work with. In addition, some people bury it without collecting them after construction is completed, but this is a major burden on the environment. Replacing these materials with CLTs will greatly reduce the weight, thus improving safety during transportation. In addition, since timber can be returned to the soil, even if it is not recovered and buried, it will lead to a reduction in the environmental burden. If the civil engineering use of CLTs is promoted, the supply of domestic lumber will increase and stabilize, which will contribute to a reduction in the price of domestic lumber. However, it is necessary to clarify the conditions under which CLTs can be used and the conditions and length of time required for their return to the natural world, and whether they can be buried and decompose naturally.

Therefore, this study verifies the conditions of use, conditions of return to nature, and the number of years of use of CLTs, and proposes a deterioration prediction equation that serves as an index for the number of years of use. As an initial verification, the strength degradation rate and degradation condition of CLT were verified for each elapsed number of months.

2 SUMMARY OF EXPERIMENT

2.1 STRENGTH TEST

A summary of the specimens is shown in Table 1. The effects on strength and degradation were tested with and without adhesive bonding at the width-bonding area. The effects of different gaps in the width joints on degradation were also examined (Figure 1). In addition, the effects of different fiber orientations on strength and degradation were also verified. For some of the specimens, the difference in deterioration was compared between when the specimens were buried in the soil and when they were left outdoors.

2.2 VISUAL OBSERVATION

The deterioration of the specimens was visually observed, and image analysis was conducted to determine the area ratio of the deteriorated portions on the specimen surface.

Table 1: *List of experimental specimens*

Specimen name	Overview
Japan Standard	Bonding the width-bonded sections
European Standard	No bonding the width-bonded sections
Gap 2.5 mm	2.5 mm gap and bonding at each width joint (Figure 1)
Gap 5.0 mm	5.0 mm gap and bonding at each width joint
Laminated timber	The lamina fibers are aligned, laminated and glued together.

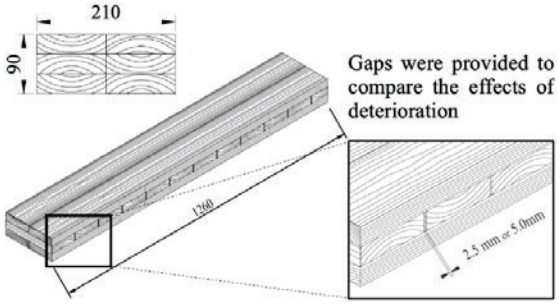

Figure 2: *Gap Specification Diagram*

2.3 EXPERIMENTAL PROCEDURE

2.3.1 BENDING TEST

Three-point bending tests were performed on a 2000 kN universal testing machine (Figure 2). The specimen was a 3-ply, 3-layer, 3-ply CLT of 1260×210×90 mm. After measuring the yield load and initial stiffness, the rate of strength loss was calculated for each elapsed month, and the strength loss and its factors were compared and discussed.

2.3.2 EMBEDDED COMPRESSION TEST

Tests were conducted using a 2000 kN universal testing machine (Figure 3). The specimen was cut out from the part with the least damage after the three-point bending test. The specimen was 210 x 210 x 90 mm in size, and a 100 x 100 mm loading plate was placed in the center of the end face. The test was conducted by loading the specimens until the flexural displacement exceeded 20 mm, measuring the load and flexural stiffness, and then calculating the strength degradation rate for each elapsed month to compare and discuss the strength degradation and its factors.

2.4 MOISTURE CONTENT MEASUREMENT

Moisture content was measured to verify the relationship between strength and moisture content. A high-frequency capacitance moisture content meter (HM-520) was used to measure the moisture content of the specimens.

3 TEST RESULTS AND DISCUSSION

3.1 VISUAL OBSEVATION

The results of image analysis are shown in Table 2, which shows that the surface of the first layer of the specimen showed slight discoloration and insect bite marks starting from the fourth month. 2.1% of the specimen was discolored at the fourth month and 4.8% at the sixth month, which is a very small percentage of degradation, but it was confirmed that the longer the specimen was buried, the more the discolored areas increased. Regarding the deterioration factors, the sapwood, which is lighter in color, showed more damage, while the core timber, which is darker in color, showed less damage. The sapwood has low decay resistance, whereas the core timber has high decay resistance, and the fact that the damage looks like insect bites suggests that the cause of deterioration may be biodeterioration.

3.2 BENDING TEST RESULTS

Test results are shown in Table 3. Compared to CLT, the yield bending strength and bending stiffness of the glued laminated timber were greater. The laminated lumber is laminated in the parallel fiber direction, so all three layers exhibit performance when bending occurs, whereas the CLT is laminated in the transverse fiber direction, so the first and third layers in the fiber direction exhibit performance in bending, but the second layer in the transverse fiber direction has less resistance to bending. In fact, the section modulus for each fiber direction was calculated, and the section modulus of the second layer, which is transverse to the fiber direction, was about one-ninth that of the first and third layers, which are in the fiber direction. This characteristic is also manifested in the fracture properties: the CLT has low resistance to bending in the second layer, since the timber in the second layer often cracks (Figure 4). But no significant difference in bending stiffness of CLT was observed between the different specimen types.

Figure 5 shows the rate of decrease in yield bending strength. All the specimens showed a large decrease in the second month, but the rate of decrease fluctuated afterwards repeatedly since then. Although there was some variation, the rate of decrease in strength of the glued laminated timber was smaller than that of the CLT. Within the scope of this test, there was no clear difference in the effect of securing gaps as a route of entry for rotting fungi and termites, or of the presence or absence of gluing of the width-bonding. It was also confirmed that the strength loss of the specimens exposed outdoors was smaller than that of the specimens buried in the soil.

The specimens were removed from the soil and dried indoors for 5 days before bending strength tests were conducted. Therefore, the moisture content of the specimens at the time of the flexural strength test was different. Figure 6 shows the relationship between the moisture content at the time of measurement and yield bending strength. It was confirmed that the moisture content increased to 30% after 2 months of burial. The strength decreased significantly with moisture content up

Figure 4: *Fracture Properties*

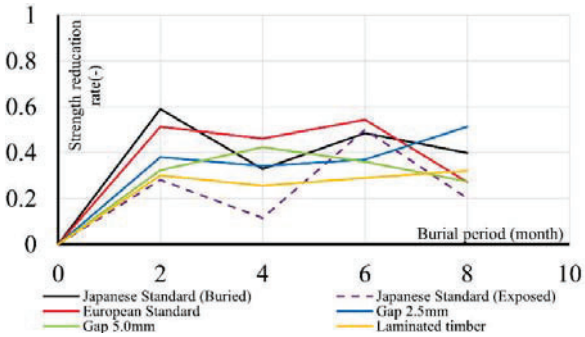

Figure 5: *Yield Bending Strength Reduction Rate*

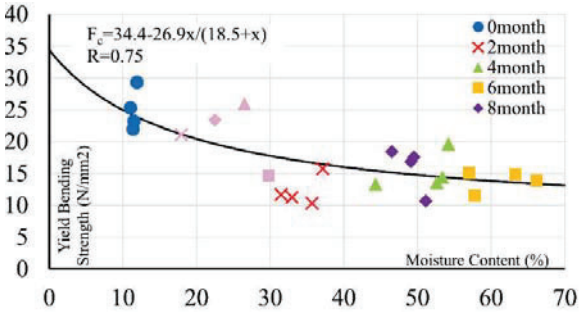

Figure 6: *Yield Bending Strength - Moisture Content*

https://doi.org/10.52202/069179-0114

to the fiber saturation point of 30%, but the decrease in strength with increasing moisture content tended to be small for moisture contents above 40%. The coefficient of variation of yield strength is 17% according to Sasaki et al. [4], and the image analysis results in Table 2 suggest that the factor of yield strength reduction shown in Figure 6 is due to the absorption of moisture during the burial period, and the influence of biological deterioration such as decay fungi and insect damage could not be confirmed within the scope of this test.

3.3 RESULTS OF THE COMPRESSIVE TEST

The test results are shown in Tables 4. Unlike the bending strength properties, there was no significant difference between the glued laminated timber and CLT specimens in terms of the embedded stiffness. The percentage of decrease in yield strength under shear (Figure 7) shows that the percentage of decrease in yield strength under shear was larger than that of yield bending strength for all the specimens. Therefore, in outdoor use of CLTs, it is necessary to consider the decrease in the embedded strength during the service period.

In terms of the embedded yield strength, the rate of strength reduction tends to be greater for glued laminated timber than for CLT. The parallel fiber lamination of the glued-laminated timber may have weakened its resistance to compression. A comparison of fracture properties (Figure 8) shows that timber cracking was concentrated in the first layer of CLT, whereas cracking also occurred in the second and third layers of glued-laminated timber. In addition, in the glued-laminated timber, the timber in the upper layer was embedded into the timber in the lower layer, which is thought to be one of the reasons for the reduction in bearing capacity that is assumed to occur when the timbers are stacked in the parallel direction to the fibers.

Next, Figure 9 shows the relationship between moisture content at the time of the strength test and the yield strength of the specimens with a 2.5 mm gap. As with the yield bending strength, the embedded yield strength decreased significantly with decreasing moisture content up to 30%, the fiber saturation point, and the rate of change in strength with increasing moisture content was small when the moisture content was 45% or higher.

The coefficient of variation of the embedded yield strength is 12% according to Ido et al. [5], and the variation of

the embedded yield strength in this test is large for the same moisture content. Therefore, in the next section, the effect of moisture content on the embedded yield strength of undamaged solid timber and CLT specimens will be examined.

4 RELATIONSHIP BETWEEN EMBEDDED YIELD STRENGTH AND MOISTURE CONTENT

4.1 VERIFICATION USING SMALL SPECIMENS

The change in compressive strength under penetration

8	16.90	0.03	8.67	0.38

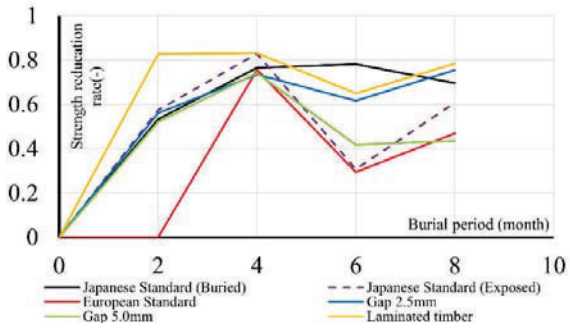

Figure 7: *Embedded Yield Strength Reduction rate*

Figure 8: *Fracture Properties*

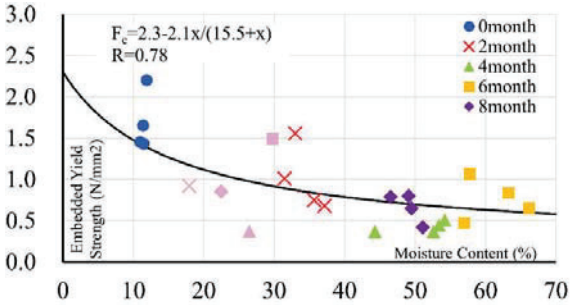

Figure 9: *Embedded Yield Strength - Moisture Content*

https://doi.org/10.52202/069179-0114

was verified using solid Japanese cedar specimens with different moisture contents. All specimens were dried in a constant-temperature room at 40°C and allowed to absorb water naturally to keep the moisture content in the range of 0% to 70%. Since it takes time for the specimens with high moisture content to absorb water, the specimens were vacuumed for 1 hour, allowed to stand for 1 hour after water injection, and then recompressed for 1 day, as shown in Figure 10. The test was conducted using a 50 kN table-top precision universal testing machine with a 10×10mm loading plate. The test was displacement-controlled, and force was applied at a rate of 2 mm/min. The test was terminated when the force reached 5% of the edge length. The embedded yield strength was calculated, and the coefficient of variation was calculated from the mean value and standard deviation to evaluate the variation. The results are shown in Table 5 and Figure 11. While the embedded yield strength decreases significantly as the mass water content changes up to the fiber saturation point of 30%, the strength decrease tends to be smaller when the mass water content is 40% or higher. According to Sawada [6], the coefficient of variation of the embedded yield strength of solid SUGI lumber is estimated to be around 20% to 30%, and in this test, the coefficient of variation of the embedded yield strength was 5 to 20%, which is within the range of variation. Although there was some variation in vacuum water absorption, many of the specimens were within the variation range, suggesting that they could be evaluated in the same manner as the other specimens.

Using these test results as a baseline, similar tests were conducted on smaller CLT specimens in the next section to verify the variation of the yield strength due to the change in moisture content.

4.2 VERIFICATION USING CLT SMALL SPECIMENS

The effect of moisture content on the yield strength of CLT is verified by using a small CLT specimen. The test specimens were 100 mm square pieces of 3-ply CLT after the flexural strength test used in Section 3.2. The test specimens were prepared in the same way as the small specimens, with moisture content ranging from 0 to 70%, and vacuum water absorption was performed for moisture contents of 50% to 70% based on the results of the small specimens. The test method was the same as for the small specimens, and the size of the loading plate was 40 × 40 mm. As with the small specimens, the yielding strength was calculated, and the coefficient of variation was calculated from the mean and standard deviation of the yielding strength to evaluate the variation.

Table 6 and Figure 12 shows the test results. Like the results of the small specimen described above, the yield strength of the specimen decreased significantly as the moisture content increased up to 30%, the fiber saturation point, but the decrease in strength tended to be small when the moisture content increased above 40%. Only one specimen had high embedded yield strength in the moisture content range of 15-30% and 30-50%, but this is due to the presence of knots on the compression surface.

Table 5: *Small Specimens Results*

Parameter		Embedded Yield Strength (N/mm^2)	Moisture Content (%)
0%	Average	1.68	0.50
	Standard Deviations	0.32	0.71
	Variation Coefficient (-)	0.19	1.44
15~30%	Average	0.91	22.71
	Standard Deviations	0.16	3.77
	Variation Coefficient (-)	0.18	0.17
30~50%	Average	0.75	37.92
	Standard Deviations	0.16	4.43
	Variation Coefficient (-)	0.21	0.12
50~70% (Vacuum Suction)	Average	0.76	68.36
	Standard Deviations	0.30	0.95
	Variation Coefficient (-)	0.40	0.01
50~70% (Natural Suction)	Average	0..74	66.39
	Standard Deviations	0.06	0.81
	Variation Coefficient (-)	0.09	0.01

Figure 10: *Vacuum Suction*

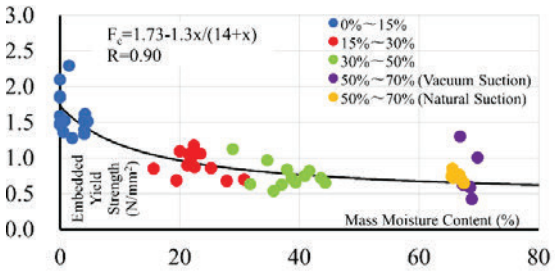

Figure 11: *Embedded Yield Strength - Moisture Content*

The specimens with vacuum-absorbed water also showed some variation. One of the reasons for this may be that CLTs are subjected to a greater load than solid timber because the expansion of CLTs is inhibited by the adhesive, which is a factor in the expansion of timber as a result of water absorption. The adhesive used was a water-based polymer isocyanate adhesive, but the effect of the adhesive needs to be further investigated.

https://doi.org/10.52202/069179-0114

Next, a comparison was made with the small specimens and the strength tests in Section 3, considering the dimensions of the specimens and the pressurized plate, and the yield strength of the specimens was calculated using the following equation (1).

$$Fc = Fy / (b \cdot l) \quad (1)$$

where Fc=Caving-in yield strength (N/mm^2), Fy=Yield load (N), b=Specimen width (mm), l=Length of pressurized plate (mm).

Compared to the small specimen, the yielding strength of this test was slightly higher than that of the small specimen. This is due to the orthogonally stacked CLT fibers. The relationship between the embedded strength and the moisture content in the soil test (Figure 13) is compared. Since the slopes of the approximate formulas are similar before the fiber saturation point, the strength reduction of the buried specimens is due to the absorption of water during the burial period. On the other hand, after the fiber saturation point, the strength difference is larger, suggesting that biodeterioration, although small, has affected the strength of the buried specimens. However, due to the small number of specimens, the approximate formula needs to be further studied.

5 CONCLUSIONS

The findings of this study are as follows.

1) Although differences in strength and stiffness were observed between laminated timber and CLT, no differences in specifications between CLTs were identified at this time.

2) Visual observation suggested the possibility of biodeterioration, but no effect of biodeterioration on the strength of the specimens was observed within the scope of the strength tests in Section 3.

3) The results of the compressive test on small specimens of solid timber and CLT indicated that the strength loss of the buried specimens was due to the absorption of moisture during the burial period as well as to a small amount of biodeterioration

DEVELOPMENT OF FUTURE-ORIENTED CONCEPTS FOR AGRICULTURAL CONSTRUCTION WITH WOOD

Carina Hartmann[1], Özlem Özdemir[1], Annette Hafner[1]

ABSTRACT: This paper presents the interdisciplinary project "Development of future-oriented concepts for agricultural construction with wood - from planning to deconstruction" (ZukunftLaWiBau). The aim of this project is to increase the share of agricultural buildings in wood construction by means of future-oriented concepts, taking into account technical and socio-economic issues. The result of the project will be a planning guide "Agricultural Building with Wood in the 21st Century". The guide includes current issues of climate protection, animal welfare, regional value creation, durability of wood as a building material, resource efficiency and economic viability as cross-sectional fields. An interdisciplinary research team is working on the issues in a holistic manner. In the following, this interdisciplinary cooperation and the goal will be explained in more detail.

KEYWORDS: Agricultural buildings, timber buildings, wood, circularity, sustainability

1 INTRODUCTION

The goal of becoming nearly emission-free in the building sector by 2045 is important and ambitious, not only because the sector, which includes the construction, maintenance and operation of buildings, is responsible for around 40 % of all greenhouse gas emissions in Germany. Particularly in agricultural construction, large potential is seen in the use of wood, a regionally available and already historically used raw and as construction material. In Germany, the diverse, sustainably managed forests and domestic wood are currently not reflected enough in agricultural construction. The timber construction quota in agricultural construction in Germany was only 35% in 2021 [1]. The use of wood in agricultural construction has been obvious for a long time, as farms often also own forests and could thus utilize their own wood.
To ensure sustainable land management, regional cycles should be included and made usable. An economic evaluation in this respect has been lacking up to now.

2 PROJECT

The use of wood in agricultural construction has a very long tradition. However, in recent decades, the importance of wood decreased compared to other building materials [1]. Regionally, there are differences in the size and typology of the category grouped as agricultural buildings. From the data of the Federal Statistical Office on new non-residential buildings, it is to recognize that there is a tendency for agricultural buildings to be larger in the north and smaller in the south, but that the number of buildings in the south is significantly higher. Farmers traditionally often own (small) private forests, which could provide wood supplies at least for their own needs. Various studies show that the use of domestic wood raw materials can consolidate regional value chains in rural areas [2]. In the current structures, however, there are too few incentives and implementation possibilities to use this potential for own buildings.

The difficulty for the application of wood in agricultural construction, especially regarding the use of spruce in agricultural buildings without preventive chemical wood preservation measures (according to DIN 68800), could already be reduced within the research project of the TUM and the LfL "Agricultural buildings in timber construction without preventive chemical wood preservation (use class 0" [3]. Within the scope of the project, it could be shown that, with a few exceptions (potato storage halls), a classification of all forms of use in livestock and storage through constructive measures, in conjunction with the recommendation to use kiln-dried wood, seems possible in service class 0 (according to DIN 68800). However, the proof of these positive, but still selective results for the breadth of the typologies of wood structures used in agricultural construction in Germany is still pending. Technically, wood can be used in most agricultural buildings, but there are additional requirements for individual components.

However, a central open question with regard to the sustainable use of wood or wood products in livestock farming is the predominantly negative assessment of the hygiene status on the part of the official veterinarians As representatives of public interests in the context of the building permit procedure, but also in their control function for current facilities, they repeatedly complain about barn facilities made of wood or point out that they must be removed and burned in the event of an epidemic. In some cases, requirements are placed on the surface finish that do not comply with the relevant hygiene regulations.

[1] Carina Hartmann, Özlem Özdemir, Annette Hafner, Department of Civil and Environmental Engineering, Resource efficient building, Ruhr-University Bochum, Germany, carina.hartmann@ruhr-uni-bochum.de

https://doi.org/10.52202/069179-0115

There is also uncertainty about the storage of harvested products due to requirements from the relevant regulations. As a result, farmers who build new buildings or remodel existing ones often opt for plastic or steel. Scientific studies on the hygiene status of tools and wooden surfaces (e.g. cutting boards in large slaughterhouses), on the other hand, confirm that certain types of wood have the best germ-inhibiting or killing effect. However, in view of the relevant guidelines, this is obviously not sufficient for the transfer of these results into practice. The situation is aggravated by the fact that no research projects have been carried out on this issue in the last 20 years.

A continuing obstacle is the lack of a broad database for the environmental assessment of agricultural buildings and their use of resources. This is necessary in order to make the data usable for calculating the product store of carbon in wood products and thus to be able to meet the requirements of agricultural construction in the 21st century with regard to climate protection. The project "Development of forward-looking concepts for agricultural construction with wood - from planning to deconstruction (ZukunftLaWiBau)" therefore aims to increase the proportion of agricultural buildings in timber construction again, taking into account technical issues. To this end, planning principles for agricultural buildings are being brought into the 21st century on the basis of model buildings. For this purpose, planning principles for agricultural buildings are used on the basis of a small and a large hall. Regional value chains in rural areas will be taken into account, current issues of hygiene and wood products will be considered and possibilities to use the potential of existing wood will be proposed. In addition, the database on climate and resource protection of agricultural buildings made of wood will be updated and deepened and made usable for the Charter for Wood 2.0 process in Germany.

The result of the project is a planning guide "Agricultural construction with wood in the 21st century". The guide incorporates current issues - climate protection, animal welfare, regional value creation, durability, resource efficiency and economic viability - as cross-cutting fields. Since the subject area is so broad and the expertise of very different stakeholders is needed, a structure with interlocking work packages was developed to be able to answer all questions holistically (see figure 1).

3 PROJECT PARTNERS AND WORK PACKAGES

An interdisciplinary team of project partners is working together to develop a holistic guideline for future agricultural construction. This team consists of the Chair of Resource Efficient Construction at the Ruhr University Bochum (RUB), the Technical University of Munich with the chair wood Science (TUM-WS) and the chair Timber Structures and Building Construction (TUM-TS). Furthermore the Bavarian State Research Center for Agriculture with the Institute for Agricultural Engineering and Animal Husbandry, the working group Agricultural Construction, the Department of Veterinary Medicine, Institute for Animal Hygiene and Environmental Health at the Free University of Berlin and the Friedrich-Loeffler-Institute with the Federal Research Institute for Animal Health are involved.

In order to deal with the interdisciplinary topics in a holistic manner, work packages (WP) were developed (see figure 1). The results from these work packages are linked in the planning guide. The starting point (WP1) is an integrated inventory analysis and data collection of the main building types currently used in agricultural construction in Germany (what is currently being built, including a map of regional differences in construction methods). These data form the basis for a comprehensive analysis in the following areas: Status-quo Analysis (WP 1), Life cycle assessment (LCA) buildings (WP 2), resource potential (WP 3), wooden products (WP 4), hygiene (WP 5), durable constructions (WP 6), design for reuse (WP 7) and economic structures (WP 8). The results of these analyses, as well as the suggestions for improvement derived from them, will be discussed and synthesized. The results from analysis, optimization, discussion and consolidation will be incorporated into the guide .

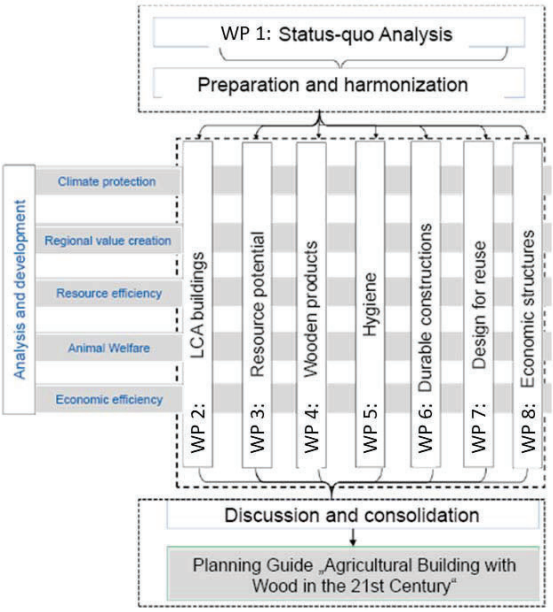

Figure 1: *Work steps within the framework of the development of the design catalog and associated work packages3.1 Status-quo Analysis (WP 1, LfL)*

https://doi.org/10.52202/069179-0115

3.1 Status-quo Analysis (WP 1, LfL)

In WP 1, typical procedures in agricultural animal husbandry and storage in Germany are recorded and systematized for status quo recording and compared with the associated building typologies and building geometries. In the process, not only utility buildings in timber construction are recorded, but also buildings and barn facilities in all otherwise common materials (e.g. concrete, brick, steel, plastic). The resulting catalog serves as the basis for all further work packages of the project partners. Starting with the compilation and allocation/categorization of inventory data (including planning and construction documents, publications, consulting documents) on agricultural buildings for livestock and storage (from the 1970s onwards), the second step is an initial assessment of the substitution potential for non-wood materials with wood products or a comparison of the same processes/building typologies in non-wood construction or wood construction. In the following, the entire data material will be processed (in electronic form) for further use in the following work packages and the selection of sample buildings and processing for further use, especially in WP 2.

3.2 LCA buildings (WP 2, RUB)

In WP 2, the functional unit "building" with its system boundaries is defined in accordance with DIN EN 15978 and the systematics for agricultural building types is adapted and defined by all project partners. For this purpose, the necessary building material data will be updated if necessary and transferred to the LEGEP software and the results on building level will be generated in a calculation program and validated by a critical review according to DIN EN ISO 14040 and ISO TS 14071. The life cycle assessments necessary for calculating the environmental impact of timber buildings and their alternatives in the defined market segment as well as estimating possible efficiency improvements will be calculated. Scientific publications will be developed over the duration of the project, continuously updated data from ÖKOBAUDAT will be entered into the calculation software. The system boundaries and the functional unit for LaWiBau will be defined and standardized according to DIN EN 15978. Data for data acquisition and mass determination of functionally identical LaWiBau are procured and the calculation software LEGEP is adapted accordingly. In the next step, data is collected to form the data basis and enlarge the building data pool. The creation of the data basis takes place by the data acquisition and by the mass determination of functionally identical agricultural buildings. For this purpose, building data from different sources must be obtained, compiled and standardized. Different reference sources, such as the building pool of the LfL, KTBL data sets or also construction plans of already implemented agricultural farm buildings, which contain a proportion of wood in the construction, form the building data pool. The differences in use (e.g. dairy barns, horse barns, machine sheds, etc.) are taken into account in the categorization of the LaWiBau building pools. The LCA of the procured data are calculated over the entire building life cycle using the LEGEP calculation software and subsequently validated via a critical review. The environmental parameters such as GHG emissions, primary energy consumption, raw material use, etc. are worked out and presented for the individual types of use. The existing LaWiBau buildings are mostly formed by hybrid constructions in the existing HolzImBauDat building pool. In a detailed investigation, the environmental influence of the mineral material concept of individual building components on the building will be determined. For example, the influence of individual steel columns (or reinforced concrete columns) in wooden barns on the load-bearing environmental balance is clarified in comparison with an overall structure in wood. The aim is to create economical load-bearing structures while taking environmental aspects into account.

As a result of this work package, the substitution potential in the building sector is presented, which is the savings in greenhouse gas emissions that result when a functionally equivalent wooden building is constructed instead of a conventional building. This is based on standard-compliant calculations of life cycle assessments at product and building level. It also shows the carbon storage, which shows the storage of biogenic carbon in the wood products, represented as global warming potential (GWP) biogenic.

3.3 Resource potential (WP 3, TUM-WS)

In work package 3, resource potentials, in particular of the farmers' own rural forest, are identified for agricultural construction with wood. Existing and potential value chains (Fig. 2) will be analyzed with regard to structure and success factors and evaluated by means of environmental (life cycle assessment) and economic (including value creation) indicators as to whether and how construction with wood can be strengthened, in particular through the involvement of regional actors. Example regions for the analysis of value chains are available through an master thesis of the TUM-HFM (Oberallgäu/Bavaria, Hochsauerlandkreis/North Rhine-Westphalia, Vulkaneifel/Rhineland-Palatinate, here with focus on buildings for dairy farming) as well as further contacts through the LfL (Saxony etc.).

https://doi.org/10.52202/069179-0115

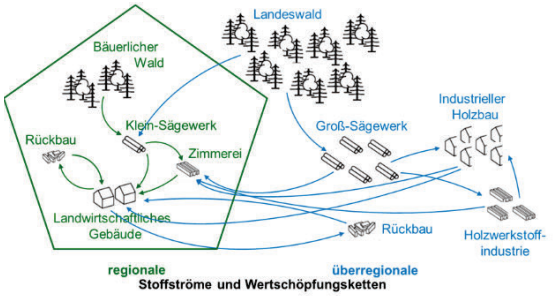

Figure 2: *Illustration of possible value chains for agricultural construction with wood (using Wegener et al. 2010).*

The basic characterization of agricultural farms will be carried out together with WP 1 nationwide with regard to their needs and possibilities of building with wood, using the annual nationwide survey of the test farm network of the BMEL (by means of an additional short questionnaire with regard to characteristic values of forest area, wood types, agricultural building types, priorities in the choice of building material) as well as the annual telephone survey of the small private forest of state authorities in several federal states. From this information, farms in sample regions will be selected and subjected to in-depth quantitative and qualitative analysis. The resource potentials are determined in the example regions, in particular for the farmer with rural forest ownership, by comparing the wood supply (wood species, quantities, assortments), and the previous raw material use with the current raw material/wood use and the wood demand for future construction with wood of the example farms. Data sources are the Federal Forest Inventory (BWI), state statistics, data collections for the small private forest in adherence to the methodology of Wilnhammer et al. [4], as well as queries for realized and planned agricultural buildings (categorization), raw material use of selected building categories (wood species, building materials, components, quantities, costs), and implementation of timber construction (raw material, building material origin, implementing wood processing and timber construction companies). With regard to the analysis of the value chains for agricultural construction, the actors of the value chain used so far as well as the material flows are first determined and interviews are conducted with regard to success factors and obstacles. In doing so, the possibilities of integrating regional actors as well as actors not yet considered are analyzed. For the environmental assessment of the value chains, the regional conditions of the production of the wood products including transport routes are taken into account [5] In this way, possible advantages of the regional value chain can also be considered in the life cycle assessment of the buildings. For the economic evaluation, the cost accounting of local/regional actors (mainly farmers with their own forest, carpentry shops) will be included in cooperation with WP 8 and compared with those of supra-regional actors (mainly state forest, industrial timber construction companies). Based on this, the (supra-)regional value added is calculated [6]. Finally, the potentials of building with own or regional wood will be presented as well as recommendations for an optimization of the value chains especially in the regional context and the feasibility for farmers.

As a conclusion and recommendations for action of this work package, the statement can be made that, in principle, regional, often also farm-owned wood is available for agricultural construction in Germany. The use of other tree species than spruce for the constructive and also non-constructive area offers regionally specific potentials, but due to the regional differences for the promotion of agricultural timber construction a regionally specific approach is necessary.
Furthermore, it can be said that the use of own wood in agricultural construction often shows a cost-efficient and sustainable solution with high potential and especially smaller construction projects can be more easily realized with own / regional wood. In order to ensure the profitability of using own wood, the provision of wood from own forest has to be recognized as eligible. Important success factors in agricultural timber construction are competent and regionally available actors in the value chain as well as support and technical expertise from private and public construction consulting and planning. Building with own / regional wood increases the regional added value by involving a large number of actors, secures jobs and income in rural regions and promotes climate protection by reducing transport distances.

3.4 Wooden products (WP 4, TUM-WS)

Work package 4 compiles the properties for wood products necessary for the special conditions of agricultural construction in a catalog. Existing knowledge as well as experiments and field tests for missing knowledge, especially for hardwood building materials, as well as new materials are used. For the analysis of the suitability of different wood species or wood products and their material properties with respect to specific requirements against gaseous, liquid and, if applicable, mechanical loads in the respective agricultural structures, literature as well as previous experiences of farmers are used for traditional wood products. With regard to the assessment of the use of innovative wood products and materials, not only from spruce, but also from pine (possibly larch and Douglas fir) or hardwood (especially oak and beech), for which no knowledge is yet available with regard to chemical-aggressive stress, laboratory experiments or test methods are used [7]. In worst case scenarios, samples are stored in model atmospheres and the surfaces are examined (e.g. pH, ATR-FTIR or microscopically) or emission measurements are carried out, e.g. by means of chemical sorbers and subsequent pyrolysis GC/MS. Since laboratory tests cannot always represent real-life conditions, field tests (on-site monitoring) are conducted to investigate the durability of wood structures made of selected wood products in agricultural environmental conditions (e.g. glulam, cross-

https://doi.org/10.52202/069179-0115

laminated timber, laminated funicular timber, cement-bonded particleboard or thermowood) under different uses (bay/partition walls as well as exterior walls and ceilings). Based on the results of the laboratory and field tests/monitoring, farmers' previous experience with building with wood, and information from the literature, the advantages and disadvantages of each type of wood or wood-based material and their area of application are compiled in a wood type and product catalog based on selected criteria like the durability class for agricultural construction.

3.5 Hygiene (WP 5, FLI, FUB)

In work package 5, the properties of wood building materials are tested with regard to hygiene requirements. Wood building materials with different surface structures (smoothly planed, rough sawn, etc.) are contaminated with indicator germs (bacteria, fungi and viruses) and with viral animal disease pathogens and the disinfection effect of physical and chemical processes is tested in laboratories of the required biological protection level. Wood products with different surface structure (smoothly planed, rough sawn, etc.) are contaminated with viral animal pathogens (African swine fever virus, foot-and-mouth disease virus, bovine herpesvirus type 1, highly pathogenic avian influenza virus) and the disinfection effect of physical and chemical procedures is tested in laboratories of the required biological protection level. The resistance of the wood products used to the successful disinfection procedures is investigated.

As a result of this work package, the general legal basis as well as the specific legal basis for wood will be presented. In addition, a disinfectant suitable for wooden buildings and their different agricultural use will be proposed, as well as the procedure of barn cleaning and disinfection.

3.6 Durable constructions (WP 6, TUM-TB)

All analyses of damage to buildings in timber construction confirm that the execution of connections has a decisive influence on the durability of timber structures. The main task of this work package is to investigate the connection details used in agricultural timber construction today, which were recorded during the as-built analysis/data collection. The expected damage mechanisms affecting the supporting structure of agricultural buildings can be divided into three categories: mechanical, chemical, and biological-physical attack. Accordingly, topic maps are developed for each category to provide a brief overview of the problems and possible actions. The goal is the same for all topic cards: permanent protection from damage through structural/design measures. The basic hazards and the corresponding structural measures are considered. These topic maps are intended as a first, quick orientation aid, and show that simple and effective measures exist. In the planning process, all corresponding introduced technical building regulations, in particular DIN 68800-2:2022-02, must also be observed.

Other results from this work package include the realization that, regardless of the type of connection, sacrificial boards provide simple and effective protection against all attacks. In conclusion, it can be said that correctly planned and executed agricultural halls made of wood are a durable and sustainable alternative to steel and reinforced concrete halls.

3.7 Design for Reuse (WP 7, TUM-TB, RUB)

Design for recycling and enabling the reusability (= design for reuse) of building materials and permanent connection details are the requirements for the reuse of building components. They enable a cascade use of wood in the first place (Fig. 3). The data necessary for the deconstructability of the connecting materials and their manufacture and static design in relation to the overall structure as necessary basics will be developed in coordination with WP 6. The investigations on the recycling of the agricultural buildings are to prove the nature of this potential. In comparative analyses, open material flow loops of agriculture construction are investigated and modified in feedback with the (building) construction in order to raise the efficiency potential even further, if possible, and thus extend value-added processing to the end of life of product systems. For this purpose, a renewal and extension of the conceptual methods as applied in the investigation of building life cycles (processes) is aimed at.

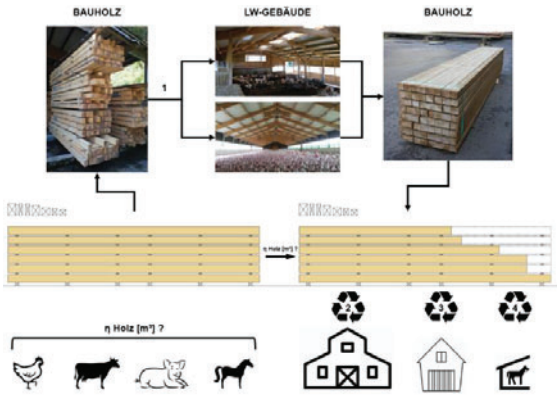

Figure 3: *Concept reuse*

First of all, an investigation of the connection methods of the building pendants takes place on the basis of the previously elaborated data with recording of the components with regard to their assembly and disassembly properties for different building types / materials. Then, the load-bearing structures in timber construction with their components as well as their connection alternatives with their respective manufacturing and assembly methods for the possible improvement of their deconstructability and the assembly

and disassembly and the connections of the components are calculated according to constructional and life cycle assessment methods. The characteristic values about the material stock and to the utilization ways of the wood and wood materials in proportions and geometries are compiled and are available as information for the possible use in a second life cycle or for the cascade use. Finally, an investigation of the economic efficiency and resource efficiency of the hall types through secondary material use and deconstructability over the life cycle takes place. The type of agricultural use results in different heavily used areas in the building. Depending on the type of use, lower loads are present from a certain height in the building, which is addressed here in particular.

3.8 Economical supporting structures (WP 8, LfL)

From the point of view of farmers as building owners, agricultural construction is primarily the manufacture of production facilities, which are subject to high cost pressure due to competition in food production. At the same time, requirements from animal welfare or quality assurance of the stored goods, building physics, optimized work management, expandability, design and the landscape have to be taken into account during planning and construction. In WP 8, first a systematization of typical animal husbandry and storage procedures to characteristic functional, grid and axial dimensions as well as building geometries takes place, and then the development of structural variants, which are previously elaborated building typologies or standardized timber components adapted to an economic utilization, takes place.

Exemplary working drawings are developed for the supporting structures in wood determined from the static pre-dimensioning as a basis for the further investigation steps and supplemented with comprehensive material/parts lists. In the process, the material/parts lists for determining the material consumption (including cross-sections of the load-bearing components, timber requirements, timber fastenings) will be developed and the costs for the design variants will be determined using bills of quantities. The goal is also to develop criteria for estimating the cost consequences of specific design decisions. In addition, the implementation and evaluation of new software add-ons at the interface between CAD work and CNC truss planning for company-specific timber construction projects will be carried out in order to reduce the additional planning effort due to the lack of industry-specific software.

4 RESULTS

The result of the project is a planning guide, which is intended to provide planners and builders with the necessary information from a neutral source. The scientific findings are intended to contribute to implementation in building practice and to show farmers ways in which they can again make greater use of wood as a raw material for their own projects. In addition to a presentation of typical floor plans and load-bearing systems for the majority of agricultural uses, the guide contains reliable information on life cycle assessment, necessary quantities of building materials, individual fraction types and quantities for the reusability of building materials and durable connection details, as well as information on the hygienic properties of wood products as a basis for practice. The preparation of the planning guide is carried out under the condition to enable smaller, regionally working timber companies to participate again in agricultural construction with wood. In addition, politicians as well as industry can use the results, which concern the increase in the use of wood in agricultural construction, resource efficiency and the environmental impact of an overall increase in the use of wood, for an improved basis for decision-making, both in the planning of buildings themselves and in the evaluation of measures in the field of construction.

5 CONCLUSION

The research project "Development of future-oriented concepts for agricultural construction with wood - from planning to deconstruction" will run until the end of 2023. The planning guide mentioned here is currently being compiled and supplemented by a detailed final research report.

ACKNOWLEDGEMENT

This study was carried out on basis of the research project "Development of future-oriented concepts for agricultural construction with wood - from planning to deconstruction" funded by the Federal Ministry of Food and Agriculture (BMEL) under the grant number 2219NR154.

This is a joint project of Ruhr University Bochum, Technical University of Munich, Bavarian State Research Center for Agriculture, Free University of Berlin and Friedrich-Loeffler-Institute.

BUILDING TOWARD ZERO EMBODIED CARBON

Richard Hough[1], Carsten Moeller[2]

ABSTRACT: This paper reviews the factors that determine the contribution of timber buildings to CO_2 emissions abatement, and how they are likely to impact our transition to net zero. Factors include projected volume demands of future building construction; building embodied carbon vs operational carbon; the carbon emissions of different construction materials; the growth and benefits of prefabrication; forests as carbon sinks under sustainable harvesting regimes and the impact of COP26; building end-of-life choices, and political drivers for the increased use of timber for carbon sequestration.

KEYWORDS: embedded, carbon, sequestration, end-of-life

1 INTRODUCTION

With global building floor area expected to double by 2050 [1], demand for raw materials is likely to grow proportionally. Embodied carbon emission from so much new construction will grow similarly unless we act to mitigate its effect.

The contribution of buildings to our global carbon emissions is typically estimated in the range 30-40% [2,3,4]. As a portion of those building emissions, embodied carbon emissions from building construction are typically estimated in the range 10-30% [5]. As efforts to reduce building operational carbon emissions begin to take effect, embodied emissions will continue to increase as a percentage of total building emissions. So the balance of mitigation effort will need to shift - attenuating building embodied carbon will play an increasingly important part in helping achieve net zero carbon by 2050, the goal that is consistent with efforts to limit the long-term increase in average global temperature to 1.5 degC [6].

The cement and steel industries are well aware of the challenge and are ramping up efforts to respond. Meanwhile, timber construction appears to offer an attractive alternative to concrete and steel in climate terms. Depending on availability of sustainably managed forest resource and end-of-building-life strategies, it can provide sequestration of biogenic carbon, or displacement of fossil fuel from current energy generation. For timber to fulfil its potential, government policy regarding the abatement of carbon emissions will be key, at international, national, and local levels. These and other factors affecting timber's likely contribution to climate change mitigation are discussed below.

2 OPERATIONAL VS EMBODIED EFFECTS

Building embodied energy (EE) is the energy consumed during production of a building, ie energy expended in extraction, conversion and transportation of raw materials, and in their processing and manufacture as building components. In terms of EN 15978 boundaries [7], it can be extended across modules A1-A3 ('cradle to gate'), or A1-A5 ('cradle to site') if the building's construction phase is to be included. Embodied carbon (EC) refers to the carbon emissions associated with the embodied energy, plus other emissions associated with the creation of materials, such as calcination in the case of cement, reduction in the case of iron, and photosynthesis in the case of timber.

Operational energy (OE) is the energy consumed in using the building over its lifespan, including heating, cooling, ventilating, lighting, appliances and equipment. Operational carbon (OC) refers to carbon emissions associated with the operational energy, typically deriving from electricity generation or on-site fossil fuel combustion.

Studies vary widely in their assessment of the relative portions of EE (or EC) and OE (or OC) in buildings. At the high end, for an energy efficient apartment block in Sweden with a projected lifespan of 50 years, EE accounted for 45% of total energy [8], with recycling potential estimated at 35-45% of EE. A more modest estimate puts EE at 'usually not more than 30%' [9]. One of the most extensive studies [10] covering 73 sample buildings across 13 countries estimated average EE at 10-20% of total life cycle energy, though changes to the EE/OE balance since publication (2010) would likely have seen that range increase.

[1] *Richard Hough, Senior Consultant, Arup Sydney; Adjunct Professor, University of Sydney, richard.hough@arup.com*
[2] *Carsten Moeller, Structural Engineer, Arup Brisbane, carsten.moeller@arup.com*

https://doi.org/10.52202/069179-0116

Regarding changes to these ratios over time, two effects are at play. Firstly, thanks to the historically greater emphasis on reducing operational energy through more energy-efficient heating and cooling systems, improved building insulation, take-up of 'passive' design strategies, changing user behaviours, regulation, and voluntary ratings schemes, OE continues to reduce, so increasing the EE/OE ratio.

Secondly, the transition to renewable energy has acted to reduce the carbon intensity of OE, whereas much of the carbon emission associated with material production, particularly of cement and steel, is not reducible in a similar way, being inherent in the chemical processes underlying the material's production. So the EC/OC ratio is rising faster than the EE/OE ratio, placing more urgency on attenuation of EC if the construction industry is to play its part in reducing global emissions.

3. CONSTRUCTION MATERIALS

The raw materials we extract from the earth and turn into products for building construction contribute significantly to our annual global greenhouse emissions. Concrete and steel currently dominate the choice of construction materials. Both are the subject of substantial R&D investment to reduce their carbon footprints, but reductions are constrained by the fact that conventional production of both materials involves chemical processes that necessarily off-gas CO2 as a by-product.

Cement is typically cited as contributing around 8% of global carbon emissions [11]. Combustion of fuel for kiln heating accounts for around 40% of that, and calcination of limestone around 60% [12]. Calcination is intrinsic to the production of normal Portland cement, and not amenable to reduction.

Cement substitutes hold much promise, with blast furnace slag, fly ash, and silica fume among the most commonly used. Their use in meaningful proportions raises issues for designers and contractors however in terms of lower early strength. This can translate into longer production cycle times for precast components, longer floor-to-floor cycle times for in-situ construction with delayed de-propping of formwork, and delays in application of prestressing for post-tensioned floors and beams.

Recycling of concrete still offers much scope for implementation [13]. It includes recycling into aggregate for road construction or backfilling, recycling into aggregate for new concrete production, and re-use of precast elements, all of which see more take-up in countries with policies constraining landfill dumping.

The steel industry has made big strides in improving energy efficiency but still accounts for around 8% of global emissions [14]. As with cement, emissions from conventional steel production include an irreducible component inherent in the chemical pathway – reduction of iron oxides generating CO2. Some progress has been made experimenting with alternative reduction environments, including the use of hydrogen [15]. Most promising in the short term however may be increasing the extent of recycling, where studies show plenty of room for improvement globally [16,17].

With the challenges faced by cement and steel in transitioning to low carbon production, construction in timber, or timber composites with concrete or steel, presents itself as an attractive third option.

4. EMBODIED CARBON AND PREFABRICATION

Leaving aside the potential benefits from biogenic carbon storage in wood, embodied carbon to produce a building in timber is typically less than a similar building in concrete or steel [47,48]. Production in timber is typically less energy intensive, typically uses renewable fuel, doesn't involve chemical processes that off-gas CO2, and is well-suited to prefabrication.

Fig. 1. The timber in this prefabricated office building for Sky UK represents -1442 t biogenic CO2, ie sequestered from atmosphere. Emissions from manufacture and transport from Austria represented +200 t, leaving embodied CO2 of -1242 t (Module A1-A5 including biogenic). The alternative structure with steel frame and concrete slabs would have cost +553 t embodied CO2 (A1-A5), ie emitted to atmosphere [44]. Given the building's energy saving features like rooftop PV, LED lighting and CCHP, the -1242 t CO2 represents about 13 years of operational emissions. Even if the sequestered carbon is returned to atmosphere at end-of-life, the 353 t benefit (553 t – 200 t) cf the steel/concrete composite alternative, remains. Photo copyright Simon Kennedy.

Prefabrication can reduce the embodied carbon footprint of a manufactured item by concentrating material resources and equipment at a single location, so reducing the transport costs of diverse materials to distributed construction sites, by encouraging optimisation of material usage and minimisation of waste, and by creating more opportunity for recycling. Precast concrete components for example benefit from indefinite reuse of

https://doi.org/10.52202/069179-0116

steel forms compared to more limited reuse of timber formwork typical of in-situ concrete construction.

Because of its easy machinability, timber is particularly well-suited to prefabrication, and this typically leads to local generation of a valuable biomass energy resource during milling and machining. It is common now for manufacturers of glulam, CLT and LVL to operate plants at or near energy self-sufficiency, with a very small carbon footprint. This is achieved by harnessing all residuals for heat/energy generation – harvesting and sawmilling residuals including bark, and offcuts and sawdust from manufacturing.

At its Varkaus LVL mill for example, Stora Enso operates combined heat and power plants using bio- and recycled fuels and is energy self-sufficient (self-reported [18]). Wiehag's glulam plant at Altheim near Stuttgart generates 38 GWh pa of renewable energy by biomass conversion from 10,000t pa of offcuts and sawdust. This is enough to supply all of the plant's electricity and heating needs, including space heating and kiln drying. Excess offcuts are sold as product and excess power is sold to the grid (self-reported [19]). At Nelson Pine's LVL plant in New Zealand, over 70% of energy requirements are for kiln heating, and are almost entirely accounted for by burning of wood residues from sustainably managed forests (self-reported [20]). According to a Canadian study, two-thirds of the country's total energy consumed in converting logs to dry-dressed lumber is attributable to drying operations, and on average 50% of energy use is derived from renewable biomass fuel [21].

Fig. 2. Wiehag's glulam plant at Altheim near Stuttgart. Photo: Wiehag

5. FORESTS AS CARBON SINKS

For current timber markets to expand, the supply of wood from sustainably managed forests also needs to expand. According to the IPCC, increasing the global resource of sustainably managed forests represents a benefit for global draw-down of CO2 : 'In the long term, a sustainable forest management strategy aimed at maintaining or increasing forest carbon stocks, while producing an annual sustained yield of timber, fibre or energy from the forest, will generate the largest sustained mitigation benefit" [22]. Regarding establishment of new plantation forests, they will be subject to competing land use claims, some of which can also point to carbon benefits, such as planting for biofuel crops. Supply of construction round wood from existing plantations is already subject to competition from biomass energy feedstock markets, which also claim carbon benefits, through fossil fuel substitution. More rigorous life-cycle assessment (LCA) will be an important tool in adjudicating between these competing claims in terms of climate change mitigation potential.

Despite competition for land, Europe's forests have increased in area by 9% over the past 30 years [23], to over a third of the continent's land surface. The associated biomass and stored carbon have grown by 50%, with only three quarters of the net annual wood increment harvested [24], so creating a net carbon draw-down benefit.

Fig. 3. Sweden's plan is to achieve net zero carbon by 2045, with forest carbon storage an important part of the plan. Forest stock has doubled in the past 100 years [45], with harvest rarely exceeding growth in any year. In 2018, CO2 drawdown to forests accounted for 80% of Sweden's 52mt CO2-e emissions [46].

Round wood harvesting in Europe benefits from a long tradition of sustainable forest management. Well-regulated extraction practices have earned European forestry its social licence. The same is not true in other temperate regions however, such as Australia, where harvesting in native forests remains controversial and politically sensitive. Foresters refer to the 'abattoir syndrome', where we enjoy timber products but prefer not to see a tree cut down. That is despite studies favouring managed forests over conservation forests for CO2 draw-down potential [43]. Increasing take-up of forest management certification should help alleviate these concerns. Globally, cumulative forest area managed under the major certification schemes has increased over 30-fold since 2000 [25], to around 30% of worldwide round wood production [26].

https://doi.org/10.52202/069179-0116

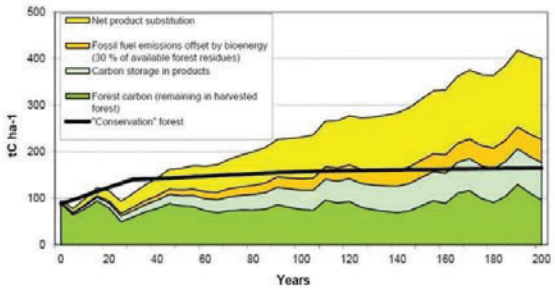

Fig. 4. Native forests in the state of New South Wales, Australia, include 'conservation' forests, with no harvesting, and 'multiple use' forests, with sustainable harvesting. The potential carbon drawdown of each forest type was modelled over a 200 year period. The conservation forest quickly reaches carbon equilibrium (heavy line), as does the multiple use forest. Allowing for potential product substitution benefit and fossil fuel offset benefit from biomass energy conversion of forest residues, the multiple use forest continues to extract carbon from atmosphere (top line) [43].

Deforestation in tropical regions casts a shadow over the timber industry's claims to be contributing to climate change mitigation however. Government responses in temperate regions have included regulation to control importation of illicit product, often with criminal convictions applying. Funding programmes such as UN REDD, the Norwegian Climate and Forest Initiative, the Amazon Fund, and the Billion Tree Campaign have had some effect, and there are now instances of deforestation reversal. Deforestation reached its peak in Costa Rica in the 1980's and has since reversed thanks to legal controls on land use change and stable funding through a PES (payment for ecosystem services) scheme [27]. ITMO's (internationally transferred mitigation outcomes) agreed at COP26 may open the way for funding flows into regions most affected (see 'Political Drivers' below). In the private sector, consumer goods retailers and manufacturers with a combined market value of USD2tr and financial institutions managing USD9tr recently pledged to eliminate deforestation from their supply chains and portfolios [28].

6. END-OF-LIFE CHOICES

LCA allows us to quantify embodied carbon in products and so to encourage behaviours that will move us closer to the circular economy. The challenge with buildings as products is predicting their full life cycle, particularly end-of-life (EOL) scenarios that may occur fifty years or more from construction. That is ambitious if not fanciful, but necessary for the equitable allocation of life-cycle carbon emissions, through fuller application of the LCA toolbox.

Regarding the life cycle of timber buildings, potential EOL scenarios are :

1. *Reuse.* Complete timber components are salvaged for reuse in a future building. Carbon already stored in the timber continues to be stored. Reuse will become more attractive with the increasing use of large section glulam or LVL beams and columns and large CLT floor and wall panels. Elements like these have had enough value added during manufacture to warrant reuse even in the present-day market. A way of quantifying the carbon benefits or disbenefits of reuse is to measure potential outcomes according to Module D of EN 15978 [29], which considers carbon emissions beyond Stage C, End-of-Life. The benefit of reuse is considered to be the emissions difference between reuse of timber components in a hypothetical future building versus the emissions associated with producing a functionally equivalent building using standard practices and market averages.

EOL scenarios are usually uncertain, as are Module D impacts. The benefit of reporting them, even if only qualitatively, is that they offer a measure of 'circularity' of a building project, or its ability to contribute to the low carbon circular economy, which will be key to hastening the decarbonisation of the construction industry. An example is design for deconstruction, which attracts credit in Module D when advantage is taken of reuse.

2. *Recycling*. In this scenario timber is chipped or shredded and repurposed for a variety of potential uses, including OSB or particleboard manufacture, and agricultural uses such as organic mulch for soil nutrition, ground cover for moisture retention and weed suppression, or animal bedding. Depending on the jurisdiction, preservative treated, glued, painted or coated wood may be banned or restricted for some recycling uses.

In LCA terms, recycling of demolition timber into chips for some new use is reported as a C3 transfer of stored carbon to the new product in the same way as for reuse. There are likely however to be additional fossil carbon emissions due to the EOL processing, which is necessary before the new recycled product can be created.

3. *Energy Recovery*. Timber is burned in an energy recovery facility, so the stored CO2 returns to atmosphere, along with small quantities of other greenhouse gases. Applying the EN 15897 Module D approach to the LCA of a timber building where energy recovery is assumed at EOL produces a carbon benefit equal to the difference between the carbon cost of BAU (business as usual) energy production and the carbon neutral cost of the energy retrieved from the timber, assuming of course the equivalent timber is regrown.

Whether the regrowth timber is assumed to have sequestered its carbon before the incineration event or after, raises the question of timelines for biogenic carbon.

https://doi.org/10.52202/069179-0116

'Dynamic LCA' models have been developed to try to account for the relative timings of capture and release of biogenic carbon [30], though they are limited in use by the quality of data available regarding carbon flux in managed forests.

The other uncertainty regarding the calculation of energy recovery from the burning of wood is estimating the Module D benefit in terms of substitution of this carbon-neutral energy for BAU energy. Logically, BAU should refer to conditions likely to prevail at actual EOL, when the substitution occurs. In countries where electricity generation is currently carbon heavy, the future substitution benefit from biomass renewables is likely to be less than currently, assuming progress is made in decarbonising the electricity mix. On the other hand, in countries where hydropower is currently dominant, the substitution benefit would be small both currently and in the future. Less conservative interpretations of Module D calculate BAU energy based on current not future conditions, on the grounds EN 15804:2012 (Sustainability of Construction Works – EPDs) 6.4.3.3 permits this assumption.

Of course when the local grid has converted entirely to renewables, there will be no substitution benefit at all. If CCS (carbon capture and storage) has progressed to commercial feasibility by then, it will open up an alternative means of permanently sequestering the biogenic carbon, by capture and burial of carbon from the flue gases.

Biomass energy conversion raises questions of air pollution, both particulate and gaseous. While incineration of virgin wood is commonly permitted, burning of preservative treated, glued, painted or coated wood is commonly banned or restricted. Scrubbers can neutralise acids in the emission stream; fabric filters and electrostatic precipitators can remove particulates, and higher furnace temperatures can break down combustion chemicals into simpler less harmful compounds, but optimal application of these technologies comes at a price and is far from universal [31].

4. *Storage in Landfill.* While dispatch of EOL timber to landfill is prohibited in some countries and restricted in many others, and while it runs counter to the intention of the circular economy by removing products from circulation, it may nevertheless represent the most effective way of sequestering biogenic carbon from the atmosphere long term in certain circumstances. The landfill scenario in the EN 15804-compliant EPD by FWPA for Australian glulam for example [32] predicts a long-term release from landfill of 62 kgCO2-e/m3, which is just 6% of the biogenic carbon originally sequestered in the wood. The calculation is based on the following assumptions, with technical references provided in the EPD :

Fig. 5. Filbornaverket in Helsingborg, Sweden, is a modern waste-to-energy incineration plant that uses combustible household and commercial / industrial / demolition waste to produce 78MW of electricity and steam for district heating. It was designed to exceed EU standards for cleanliness of exhaust gases [41]. Around half of Sweden's municipal solid waste is burned for energy recovery at end-of-life, the other half is recycled [42]. Photo : Öresundskraft

• Of the gases formed from any degradation of wood in landfill, 50% is methane and 50% is carbon dioxide.
• 36% of the methane is captured, of which a quarter is flared and three quarters is used for energy recovery.
• Of the methane that is not captured, 10% is oxidised and 90% is released to the atmosphere.
• The 'typical' DOCf (degradable organic carbon fraction) is taken as 0.1%, based on bioreactor laboratory research involving testing of various wood waste types in reactors operated to generate maximum methane yields [33], and informed also by excavation of landfill sites to recover old wood samples [34].

Fig. 6. Sections of timber products retrieved from a Sydney landfill site after 46 years of burial [34].

https://doi.org/10.52202/069179-0116

This suggests a remarkable potential for indefinite carbon storage, though assumptions regarding landfill management practices will vary with country and industry practice, particularly regarding methane capture, flaring, and energy recovery. The CO2-e calculation is sensitive to the DOCf assumption, and it relies on the anaerobic conditions commonly found in Australian landfill sites, which will also not be universal.

System Boundaries

In an LCA under EN 15978, a full building system boundary contains Modules A to C, with the 'supplementary' Module D covering the benefits and loads considered to be beyond the system boundary, by giving credit for avoided future use of primary materials and fuels [7]. Module D needs to be reported separately and not aggregated with Modules A to C [49].

Sourced from sustainably managed forests, timber in buildings is generally considered to have biogenic carbon neutrality, meaning biogenic carbon is accounted for when entering (Module A1) and leaving a building (Module C3/C4), producing a net zero effect [29]. In the case of re-use or recycling, carbon benefits are accounted for in the downstream processes of any subsequent product through reduced Module A1-A3 emissions. For European timber products, where Module D energy recovery through incineration is common practice, the benefit is also beyond the system boundary and becomes a broader circular economy benefit. On the other hand, long-term carbon storage in landfill sits in Module C4 and thus within the system boundary of the current project. Adopting the EPD in [32] for example, the landfill option therefore means a considerable biogenic benefit for the current project, compared to the re-use scenario where EN 16485 implies zero benefit, as the captured carbon is passed on. For the current project, landfill therefore wins over re-use, which is at odds with the intent of the circular economy.

The purpose of this discussion about EOL is to highlight the impact that choice of LCA system boundaries can have on allocation of biogenic carbon benefits and therefore the importance of providing a verbal account of project EOL carbon transfer options in addition to the strictly numerical account.

7. POLITICAL DRIVERS

At the international level, a key outcome from the 2021 COP26 in Glasgow was the ratification of Article 6 of the 2015 Paris Agreement, thereby opening the way for international trading of carbon credits via ITMO's (internationally transferred mitigation outcomes), to assist countries in meeting their NDC's (nationally determined contributions) under the Agreement. Applied to forest management for example, this could have big implications for inward investment into countries under pressure to reduce deforestation, such as African countries in the Congo basin, where the world's largest carbon sink is under threat [35,36].

At the national level, governments that have adopted carbon tax or cap-and-trade systems are best placed to monitor and control their progress toward their NDC. Applied to the construction sector, cap-and-trade or other carbon pricing mechanisms will over time favour the transition to greener materials and construction practices [37], providing a market advantage for construction in timber.

Climate Change Conferences (COP's) also host gatherings of regional and city leaders, who continue to advance their own abatement plans alongside national plans. In some local and regional jurisdictions 'timber first' policies have been introduced, including Canada, New Zealand, Germany, Finland, USA, Australia. In most instances there was an active local forest industry advocating, with notable exceptions like the London Borough of Hackney, where the council adopted its policy in 2012 and now has 24 of the UK's largest timber buildings [38].

Some policies have mandated the use of wood in buildings funded with public resources (Canada, France, Sweden); other policies at local government level in Sweden and Finland have required the use of timber on certain sites, and others have funded R&D through public competitions (Austria, Germany, Canada, USA, Norway). Japan introduced its Wood First Law in 2010, which obliges national and local government to use wood for public buildings of three storeys or less [40].

While governments grapple with emissions policy, voluntary green building ratings schemes continue to have a positive effect. These schemes have been evolving too: LEED and BREEAM have moved to recognise LCA as a key assessment tool, thereby allowing more accurate quantification of timber's carbon sequestration potential.

8. CONCLUSION

Construction in timber will not be a primary driver of emissions abatement, but it will make a useful contribution and can also serve as a catalyst for better forest management. The wider adoption of LCA as a criterion for assessing the carbon performance of construction in different materials will be important in maximising the sequestration potential of timber buildings. As part of that, understanding end-of-life choices and their effect on life-cycle outcomes will also be important. LCA conventions that allow credit for biogenic carbon storage to be allocated equitably across building projects will allow clearer present-day choices to be made between the benefits of different construction materials.

Increasingly, an important catalyst for timber building uptake will be government leadership in setting CO2

abatement policy, through stricter implementation of carbon pricing schemes as key platforms for achieving nationally determined contributions under the Paris Agreement.

TRADE-OFFS IN EMBODIED CARBON AND ACOUSTIC INSULATION FOR MASS TIMBER FLOOR ASSEMBLIES

Samantha J. Leonard[1], Mohamad B. Eddin[2], Morgan K. Prichard[3], Jonathan M. Broyles[4], Nathan C. Brown[5], Sylvain Ménard[6]

ABSTRACT: Mass timber structural systems are increasingly used in the design of low and mid-rise buildings. One of the primary motivators for using mass timber structures is their low embodied carbon emissions (EC), which reduces a building's carbon footprint. Despite this advantage, a criticism of mass timber structures in multi-story buildings is often poor air-borne and impact sound insulation. In response, this paper studies common mass timber floor assemblies for their EC and sound insulation performance. EC data is used along with previous experimental acoustic data to evaluate how acoustic insulation affects the sustainability of mass timber floors. This study found that there is no clear relationship between EC and acoustic insulation; while high-EC assemblies exist, there are many low-EC assemblies at all levels of acoustic insulation. Trade-offs instead occur in the types of assemblies that can achieve performance goals and their depth or visible finish. While other factors such as cost or structural requirements may control assembly selection, designers seeking to reduce EC should consider room design needs and select acoustic insulation strategies with favorable EC-to-acoustic insulation ratios.

KEYWORDS: Mass Timber Floors, Sound Transmission Class, Impact Insulation Class, Embodied Carbon Emissions

1 INTRODUCTION

Mass timber structures are increasingly gaining interest among building owners and developers due to their potential to positively affect the triple bottom line: sustainability, society, and economy [1]. Mass timber structural elements have been shown to require less energy during manufacturing compared to traditional structural materials such as steel and concrete [2], can improve occupant wellness [3], and have the potential to revitalize local economies in forested regions [4].

However, the relatively lightweight mass timber floor structures often pose challenges for serviceability requirements such as sound insulation [5, 6]. The 2021 IBC requires that projects meet specific acoustic performance standards for floor and wall assemblies separating dwelling units [7]. The two main acoustic insulation performance quantifiers in North America are Sound Transmission Class (STC), a measure of a floor or wall assembly's ability to prevent airborne-based sound transmission between spaces, and Impact Insulation Class (IIC), a measure of a floor assembly's ability to insulate a space from impact noise (i.e., footfall) from above [8].

Lab-based measurements for mass timber floor systems constructed using Cross Laminated Timber (CLT), a panelized mass timber product, have demonstrated that bare CLT alone cannot meet typical code requirements for acoustic insulation [9]. While several recommendations exist to improve the acoustic performance of a CLT floor system, not every recommendation improves the same acoustical phenomena. Common examples of acoustical treatments include using dense-porosity surfaces that reflect sound, adding mass to reduce vibration amplitudes, including sound-dissipating layers in the assembly to absorb sound, and providing acoustic separation between finishes and the structure to improve sound insulation [5, 10]. These strategies complicate how acoustical performance can be improved for mass timber structures. As sound insulation performance requirements can have significant effects on the floor assembly construction, designers require guidance during project decision-making. Many organizations offer resources with data on mass timber floor assembly acoustic performance, such as the FPInnovations CLT Handbook chapter on acoustics and the WoodWorks Inventory of Acoustically-Tested Mass Timber Assemblies (WW Inventory herein) [5, 11].

However, there is limited guidance on how decisions related to sound insulation performance affect a mass timber floor system's carbon produced during material extraction, transportation, and manufacturing, also known as embodied carbon (EC).

Salles E Portugal et al. studied concrete versus cork flooring materials for their environmental impact [12]. Broyles et al. conducted design optimization of concrete floor slabs for embodied carbon and acoustic performance [13, 14]. Tomas M. Echenagucia et al. researched the acoustic optimization of a concrete structure for a concert hall space [15]. Mirdad et al. analyzed 28 mass timber-concrete composite floors for EC and STC and found that increasing timber thickness is generally more beneficial for sound insulation and EC than increasing concrete thickness; however, IIC was omitted, and the types of assemblies are limited [16]. Ilgin et al. reviewed 13 tall mass timber building case studies for various architectural design features, including finding an average floor-to-floor height of 3 m, which is affected by floor assembly construction [17]. Beyond these papers, current literature review did not find a comparison of acoustic performance and embodied carbon for a wide range of mass timber floor assembly types. This study builds on the existing WW Inventory by adding EC data for each assembly. By pairing acoustic insulation ratings and EC data sets, these performance objectives can be compared for a range of assembly types and configurations. Resulting findings are intended to aid early design decision making.

2 METHODS

The studied assemblies for this research come from the WW Inventory, which is the most comprehensive database of mass timber assembly acoustic performance test results found during the literature review process. This study calculated EC for the assemblies based on the inventory's description of their construction, and EC is compared to the inventory's acoustic performance test ratings during the data analysis process.

2.1 ASSEMBLY CONSTRUCTION

The WW Inventory included descriptions and test data for 349 mass timber floor assemblies. The inventory organized floor assemblies into six categories, which was further divided into twelve total categories in this study. The categories included in this study are summarized in Table 1. Assemblies include features such as: structural or non-structural toppings, exposed mass timber panel ceilings, suspended acoustic ceilings, and raised access floors. A variety of materials and products appear in the assemblies, including those of the following types: mass timber panel, concrete or gypsum topping, acoustic mats or systems, acoustic accessories, board-type products such as gypsum board and plywood, insulation, flooring, and acoustical underlayment. Assembly descriptions and typical material properties are used to estimate total assembly depth. In the final EC database, 92 out of 349 assemblies meet the 2021 IBC requirements, have both STC and IIC data, and have sufficient information to estimate EC.

Table 1: *Categories used in this research, based on the WW Inventory. Symbols are referred to later in the results plots. The final main EC database is discussed further in section 2.3.*

Symbol	Assembly Category & Symbol	Typical Assembly Construction	Number of Assemblies	Code-compliant w/ STC/IIC data	In Final Main EC Database
●	Mass timber with ceiling side concealed, with or without finish floor		59	39	25
●	Mass timber with ceiling side concealed, with or without finish floor, no topping		31	22	17
▼	CLT-concrete composite		10	10	6

		Total	349	137	92

https://doi.org/10.52202/069179-0117

Most assemblies in the full WW Inventory (266 out of 349, or 76 percent) use five-ply CLT panels, which can typically span about 4 to 5.5 meters [18]. Table 2 shows typical maximum allowable spans for the mass timber panels which appear in the inventory. Spans are based on IBC 2021 residential occupancy loads but can vary depending on factors such as wood species, structural loading requirements, and project-specific fire resistance rating requirements. Mass timber panel structural spans are often controlled by criteria to limit walking-induced floor vibrations. More in-depth calculations of span limits for individual assemblies are out of this paper's scope.

Table 2: *Typical allowable spans for mass timber panels appearing in the WW Index, based on publicly-available manufacturer technical guides* [18–20] *STC and IIC data is from the WW Inventory* [11].

Mass Timber Panel	Panel Depth (mm)	Span (m)	Assumed Panel Construction	STC	IIC
3-ply CLT	104.8	4.0		38	22
5-ply CLT	131.8	4.8		39	22
5-ply CLT	137.2	4.8		41	27
5-ply CLT	174.6	5.5		41	25
7-ply CLT	228.6	7.0		44	30
GLT	88.9	3.7		35	20
2x4 NLT w/ Plywood	88.9	3.7		29	-
2x6 NLT w/ Plywood	139.7	5.2		34	33

2.2 ACOUSTIC PERFORMANCE DATA

Acoustic performance test data for most assemblies consists of one STC rating and one IIC rating (270 assemblies). Some assemblies include only STC or IIC (57 assemblies), while 33 assemblies include one or more of the following ratings: Apparent Sound Transmission Class (ASTC), Apparent Impact Insulation Class (AIIC), Field Impact Insulation Class (FIIC), Field Sound Transmission Class (FSTC), and Normalized Noise Isolation Class (NNIC). Where ASTC, AIIC, FSTC, FIIC, or NNIC ratings are provided in lieu of STC and IIC, an estimated STC and IIC rating were calculated to provide a comparable rating to other assemblies. It is assumed that these metrics generally result in a lower rating by about five points due to field conditions [21], and therefore five points were added to these values to estimate equivalent STC and IIC ratings. The WW Inventory assembly ratings are obtained from various manufacturer and third-party test reports for testing performed in accordance with the ASTM E 90 and ASTM E 492 test standards [22, 23]. A limitation of this data is that there are often rating discrepancies between labs, bringing into question the expected sound insulation performance of an assembly [24]. Additionally, construction quality can vary the acoustic insulation performance [25], as air leaks can reduce performance [26]. Table 3 summarizes the standards and methods used in the WW Inventory assembly data.

Table 3: *Test standards and methods used to quantify sound insulation of assemblies in the WW Inventory.*

Standard (Short Name)	Standard (Long Name)	Number of Assemblies
ASTM E 492 [23]	Standard test method for laboratory measurement of impact sound transmission through floor-ceiling assemblies using the tapping machine	176
ASTM E 90 [22]	Laboratory measurement of airborne sound transmission loss of building partitions and elements	170
Modified ASTM E 90/E 492 [22, 23]	Floor zone testing procedures	68
ISO 12354 (ISO 15712-1) [27]	Building acoustics — Estimation of acoustic performance of buildings from the performance of elements — Part 1: Airborne sound insulation between rooms	36
ASTM E 1007 [28]	Standard test method for field measurement of tapping machine impact sound transmission through floor-ceiling assemblies and associated support structures	26
Multiple Methods	Combination of ASTM E 492 and ASTM E 1007 [23, 28]	20
ASTM E 336 [29]	Standard test method for measurement of airborne sound attenuation between rooms in buildings	19
Legacy from CLT handbook [30]	Various European standards	11

For the purposes of evaluating and comparing designs, levels of acoustic performance are defined per Table 4, based on the performance divisions used by Long [21].

Table 4: *Acoustic performance tier requirements*

Performance Tier	STC/ IIC	Description
Non-code-compliant	<50	Clearly hear normal activities of neighbor
Code Minimum	50	Normal activities of neighbors somewhat muted
Good	55-59	
Better	60-64	Cannot hear normal activities of neighbors
Best	65+	

2.3 EMBODIED CARBON ESTIMATION

The assemblies studied include between 1 and 9 floor materials and components. Embodied carbon material values are obtained for each material from either the Inventory of Carbon and Energy (ICE) V3.0 database [31], product environmental declaration (EPD) sheets, or industry wide EPDs. The ICE database is a collection of EC factors that relate a construction material quantity to its corresponding carbon emissions, using a cradle-to-gate life cycle assessment (LCA). EPDs are often created by manufacturers or third-party groups and are independently validated per ISO 14025:2006. Additionally, technical product data sheets and NRC test reports were referenced to clarify typical information about some material types, and to help inform property assumptions. Note that the analysis includes only the cradle-to-gate LCA boundaries (A1-A3).

From the perspective of calculating embodied carbon, all the materials included in the studied assemblies can be classified based on their coverage, resulting in three coverage categories: area, linear, and discrete. Each material in the WW Inventory had typical properties such that EC per area could be calculated for each material. Most materials in the inventory are area-based, meaning they are installed to cover the full area of the floor. EC per area for these materials is calculated per Equation 1:

$$EC_i = EC_f * t_{i,typical} * \rho \quad (1)$$

Where:

EC_i = EC per area for a given assembly layer of typical thickness [kg CO_2 eq./m^2]

EC_f = EC factor per mass for a given assembly component [kg CO_2 eq./kg]

$t_{i,typical}$ = the baseline layer thickness assumed for the EC_i value [m]

ρ = component density [kg/m^3]

Acoustic accessories include both linear- and discrete-based materials, where linear includes items like wood furring or resilient channels, and discrete includes those such as acoustic clips or rubber isolators. EC for linear and discrete materials can be calculated per Equations 2 and 3, respectively, to determine an equivalent EC per area. Based on Equations 1 through 3, representative assembly material values are summarized in Table 5.

$$EC_i = \frac{EC_f * A_{i,typical} * \rho}{S} \quad (2)$$

Where:

$A_{i,typical}$ = the baseline component cross sectional area assumed for the EC_i value [m^2]

S = component spacing [m]

$$EC_i = \frac{EC_f * m_{i,typical}}{S_\perp * S_\parallel} \quad (3)$$

Where:

$m_{i,typical}$ = the baseline component mass assumed for the EC_i value [kg]

$S_\perp$ = spacing perpendicular to a reference span direction [m]

$S_\parallel$ = spacing parallel to a reference span direction [m]

Table 5: *Embodied carbon of representative mass timber assembly materials (kg CO_2 eq. per m^2 per typical thickness/unit/spacing)*

Coverage Category	Material Type	Material	EC_i	Ref
Area	Mass Timber Panel	CLT (5-ply)	23.9	[32]
		GLT (88.9 mm)	14.3	[33]
	Concrete or Gypsum Topping	NW Concrete (38.1 mm)	12.4	[31]
		LW Concrete (76.2 mm)	12.0	[34]
	Acoustic Mats or Systems	Dimpled Rubber Mat (25.4 mm)	13.7	[35]
		Raised Access Floor	52.5	[36]
	Board-type Products	Gypsum (15.9 mm)	1.79	[37]
		Plywood (19 mm)	7.3	[31]
	Insulation	Fiberglass (92 mm)	0.90	[38]
		Mineral Wool (30 mm)	1.1	[39]
	Finish Flooring	Carpet	12.9	[40]
		Hardwood Flooring	3.5	[31]
	Acoustical Underlayment	Flat Rubber Mat (17 mm)	21.8	[35]
		Foam Mat	3.5	[41]
Linear	Acoustic Accessories	Resilient Channels	1.66	[42]
		Wood Furring	0.35	[31]
Discrete		Sound Isolation Clips	5.35	[31]

https://doi.org/10.52202/069179-0117

In some cases, EC information was not available for materials or products, or there was not enough information in an assembly description to reasonably estimate EC. As a result, only 217 out of 349 assemblies were included in the EC database. 92 of those 217 assemblies meet the 2021 IBC and have both STC and IIC data. Each studied assembly is evaluated for EC by a summation of each material's EC material value. The unit of comparison is kg CO_2 eq. per m^2. Because the layer EC values were first calculated based on typical properties per Equations 1-3, atypical conditions must be accounted for in each assembly estimate. While some modifications were made as needed depending on whether a layer was area, linear, or discrete-based, the general equation to estimate the full assembly EC is summarized and simplified in Equation (4):

$$EC = \sum_{i=1}^{n} EC_i * \frac{d_{i,actual}}{d_{i,typical}} \quad (4)$$

Where:

EC = total assembly EC per area [kg CO_2 eq./m^2]

$d_{i,actual}$ = the actual property (thickness, density, area, spacing, or mass) of the given component if different than typical [mm, kg/m^3, mm^2, m, kg]

$d_{i,typical}$ = the baseline property assumed for the EC_i value [mm, kg/m^3, mm^2, m, kg]

3 RESULTS AND DISCUSSION

3.1 RESULTS

After obtaining the total EC for the corresponding timber floors in the WW Inventory, the EC is plotted against the air-borne (STC) and structure-borne (IIC) acoustic performance. Figure 1 shows STC versus EC, assigning to each data point a hue based on assembly depth and a marker style based on whether the mass timber panel is exposed aesthetically to the underside. Similarly, Figure 2 compares the same data set, but for IIC versus EC. Horizontal lines in both Figures 1 and 2 depict the lowest rating of each acoustic performance tier per Table 4.

Figure 1 shows that there is no clear relationship between STC and EC; all STC performance tiers can be achieved with similar levels of EC (between about 30 to 50 kg CO_2 eq./m^2) if the right assembly is selected. While low-EC options exist, there are numerous assemblies with significantly higher EC (by 2 to 4 times, upwards of 100 to 125 kg CO_2 eq./m^2) which should be avoided if possible. Interestingly, these high-EC assemblies occur more frequently in the lower performance tiers for this data set. Figure 1 also finds that while low-depth options exist at all performance tiers (200 to 300 mm), the highest STC-rated assemblies made use of deep assemblies (of 400 to 450 mm) and concealed ceilings (i.e. underside acoustic treatment is required such that the ceiling cannot be exposed aesthetically.) Some assemblies with exposed ceilings achieve great STC performance but are limited to a maximum of STC-66 within this data set.

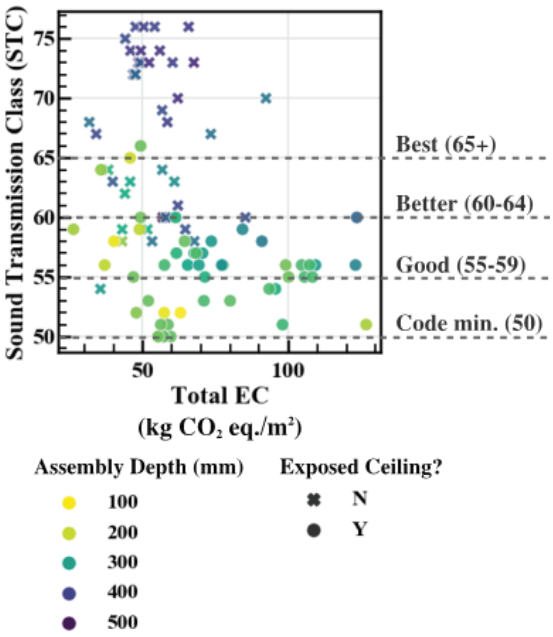

Figure 1: *STC versus EC for all studied code-compliant assemblies. Horizontal lines depict acoustic performance tiers.*

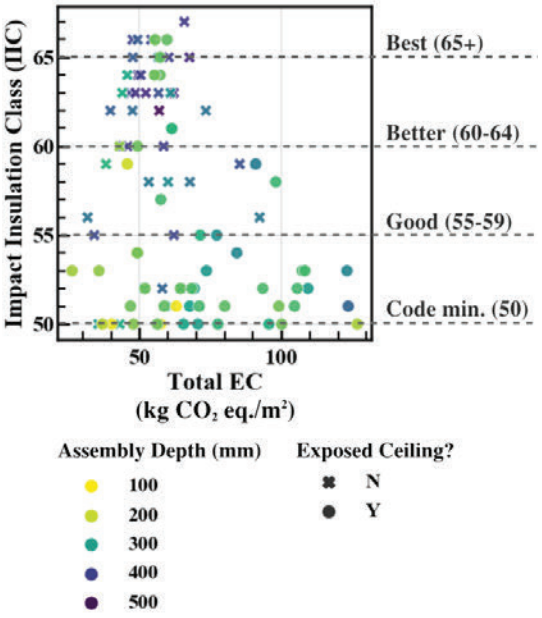

Figure 2: *IIC versus EC for all studied code-compliant assemblies. Horizontal lines depict acoustic performance tiers.*

Figure 2 shows some trends for IIC versus EC similar to those for STC versus EC. There is again no clear relationship between IIC and EC, and while high-EC options exist especially at lower performance tiers, there are low-EC options at all performance tiers. Further, there

are similarly relatively low-depth options (200 to 300 mm) at all performance tiers; however, the highest IIC-ratings are not limited to the deepest assemblies. Note that maximum IIC ratings are lower than the maximum STC ratings for assemblies in this data set, which is consistent with the difficulty of achieving higher IIC ratings in general. Figures 1 and 2 show several assemblies at a given performance rating with different EC values. While designers should attempt to select the lowest-EC option that meets their project's IIC and STC requirements, other factors out of the scope of this study, such as structural requirements, cost, aesthetics, and scheduling, may restrict assembly selection.

Figures 3 and 4 use the full database of assemblies with both STC and IIC test data and sufficient EC data, including non-code-compliant assemblies. These were included here to better understand the relationship between STC and IIC amongst the assemblies included in the WW Inventory, as well as to visualize how estimated EC (Figure 3) and approximate allowable span (Figure 4) are represented within the data set.

Figure 3 shows that STC and IIC have a hyperbolic relationship. Many more of the assemblies in this data set met code for STC than for IIC, as it is often more difficult to achieve higher IIC ratings. The lowest-EC assemblies with 15 to 20 kg CO_2 eq./m^2 often do not meet code. Relatively low-EC assemblies of 40 kg CO_2 eq./m^2 occur at all combined STC and IIC performance tiers (i.e. both STC and IIC are rated at the same performance tier for an assembly.) Assemblies with concealed ceilings generally achieve the best combined STC and IIC performance.

Figure 4 shows the same data as Figure 3, but with data points assigned a hue based on approximate allowable span per Table 2 and a marker based on the presence of a topping. All acoustic performance tiers for STC and IIC have options that can span upwards of 6 meters. Longer spans are likely possible at higher acoustic performance using similar assemblies to the 6-meter-spanning assemblies; however, the number and types of longer-spanning assemblies was limited in the WW inventory.

Figures 5 and 6 take the data from Figure 3 and removes the non-code-compliant assemblies for closer analysis of STC versus IIC (Figure 5) and Depth versus EC (figure 6). In each plot, both marker hue and style are assigned based on the assembly category per Table 1. Per Figures 5 and 6, although many concealed-ceiling assemblies are the deepest assemblies, averaging around 400 mm, these represent most of the best-performing assemblies for STC and IIC while maintaining relatively low EC, with several options in the range of 45 to 50 kg CO_2 eq./m^2.

Figure 5 and 6 also show that for categories that include versions both with and without a concrete or gypsum topping (Ceiling Side Concealed and Raised Wooden Sleepers), those with a topping tended to achieve higher STC and IIC ratings with limited impact to EC. This is likely because the concrete and gypsum toppings are most often paired with an acoustical mat, which together can be a relatively efficient use of material to improve acoustic insulation. While STC and IIC are generally related in Figure 5, some assemblies with flooring can have a high IIC rating even if STC is low.

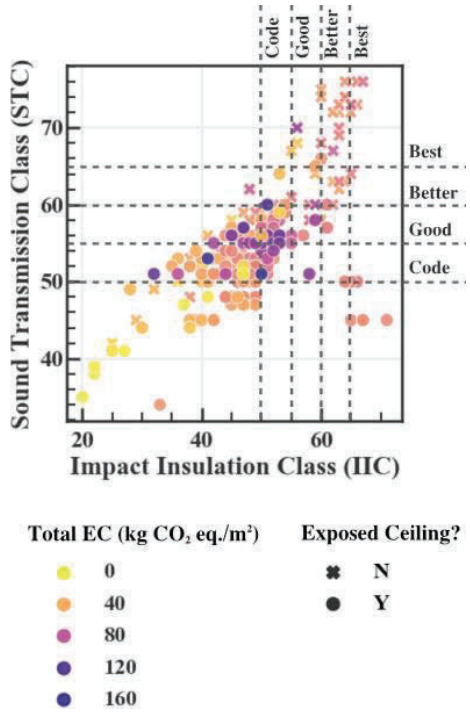

Figure 3: *STC versus IIC for all studied assemblies, including non-code-compliant assemblies.*

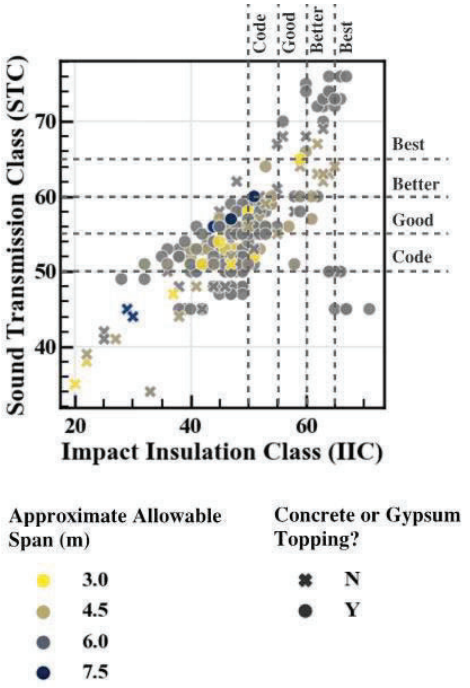

Figure 4: *STC versus IIC for all studied assemblies, including non-code-compliant assemblies.*

https://doi.org/10.52202/069179-0117

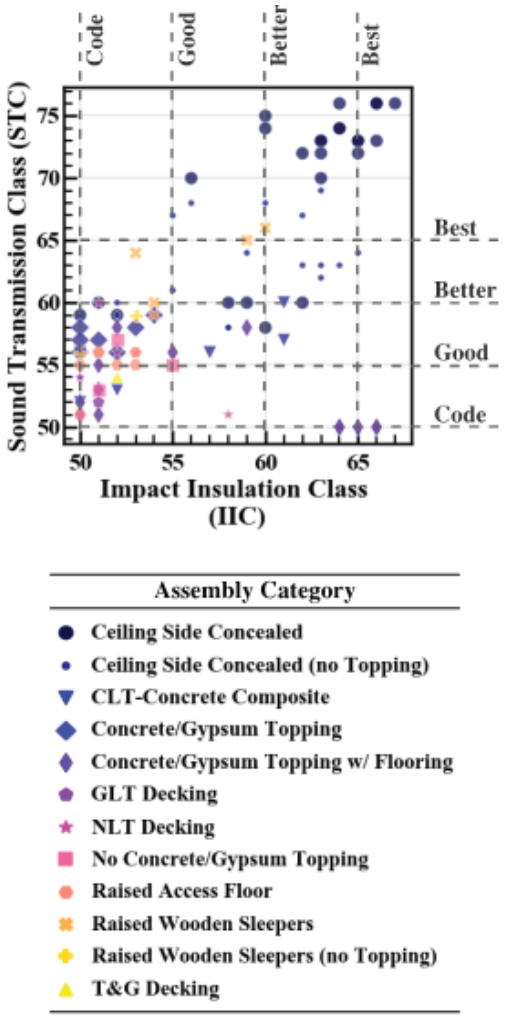

Figure 5: *STC versus IIC for all studied code-compliant assemblies*

Further, there is no relationship between EC and assembly depth, according to Figure 6. Low-EC options of 30 to 40 kg CO_2 eq./m^2 occur at a variety of assembly depths. This is likely because many assemblies use separation and air gaps between assembly components to improve acoustic performance, which makes efficient use of the materials in such assemblies.

Although Figures 1 through 6 indicate no clear relationship between sound insulation and EC, or between assembly depth and EC, options exist with higher EC. While it may be possible for designers to simply select the lowest-EC option that meets their project's STC and IIC requirements, there are most likely other factors that have the potential to control assembly selection, such as structural performance requirements, cost, scheduling, and material availability. Except for the approximate allowable spans shown in Figure 4, these factors are out of the scope of this research. However, by understanding the material efficiency of the components and systems used to improve sound insulation versus their EC, general recommendations and guidance can be provided to help reduce EC during early design decisions. Approximate component and system contributions to EC, STC, and IIC are shown in the bar chart in Figure 7.

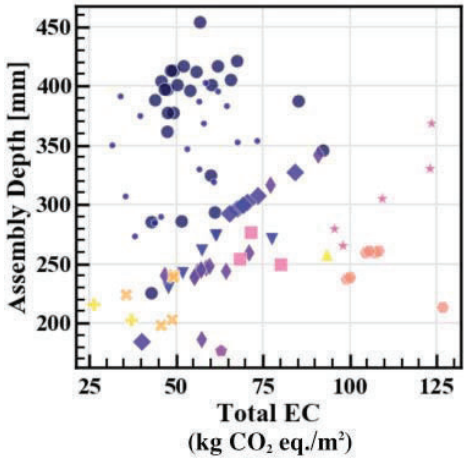

Figure 6: *Assembly depth versus EC per unit of floor area for all studied code-compliant assemblies*

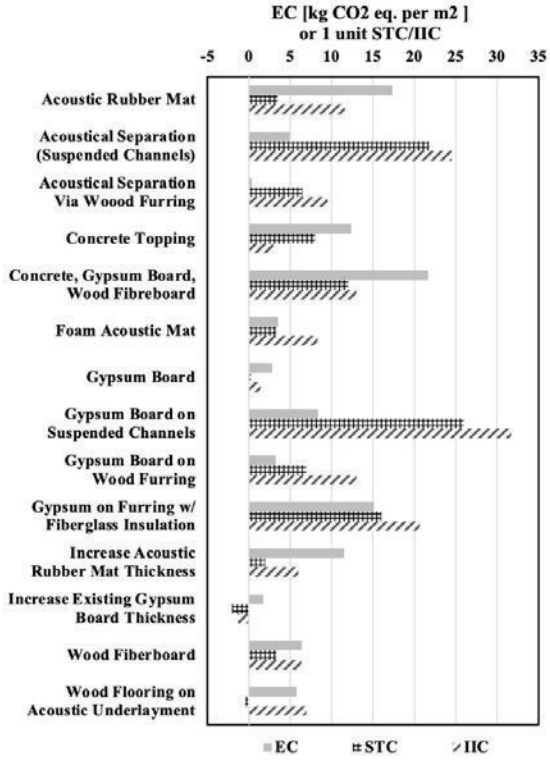

Figure 7: *EC per floor area of various materials or systems of materials and the difference in STC and IIC as compared to existing baseline assemblies without the given material or system. (Based on a selective set of assemblies with 5-ply CLT panel and 38-mm concrete topping)*

https://doi.org/10.52202/069179-0117

Figure 7 shows that increasing gypsum in an assembly that already has some gypsum does not add much EC but does not help STC or IIC either. Additionally, adding a separation between layers via wood furring provides the best STC and IIC improvement per amount of added EC. However, the most significant takeaway is that suspended channels and other means of providing acoustical separation between assembly layers provide high improvements to STC and IIC with relatively low EC impact to the assembly. This further validates that the typical recommendation of providing acoustic separation between layers is a materially-efficient and effective approach to improving sound insulation in an assembly.

3.2 DISCUSSION

Previous studies have shown that many mass timber floor systems without acoustic treatments have unsatisfactory air-borne and structure-borne sound insulation performance. However, adding materials and components to improve sound insulation can affect the EC of mass timber floor assemblies. By combining existing acoustic test results with EC data for a variety of assemblies, comparisons can be made to understand different assembly types and trade-offs with improved sound insulation. Because of data limitations due to lab-to-lab differences in STC and IIC results, as well as the limited availability of EC data, the findings of this research are most helpful during early design when more general and broad design decisions occur. Further analysis is needed to refine a design in the later stages of a project. This research finds that:

- Although adding acoustic treatments or systems to assemblies results in many with high EC, there is no clear relationship between STC and EC or between IIC and EC; relatively low-EC options exist at all acoustic performance tiers.
- In this data set, deeper assemblies are needed to achieve the best STC values, but low-depth options exist for all IIC tiers.
- One trade-off to achieve the best acoustic performance is that a designer may need to sacrifice exposed timber ceilings for underside acoustic treatment, which affects the architecture and results in greater assembly depth. However, because separations and air gaps are often used to achieve improved IIC and STC, these assemblies can still have relatively low EC.
- The best EC per STC or EC per IIC from separating components aligns with typical recommendations to improve sound insulation per the CLT handbook [5].
- An in-depth structural analysis was excluded; however, there are a wide variety of assemblies in this data set that can span up to 6 meters at all acoustic performance tiers.
- Experimental measurements were not taken from the same lab, which could have significant variability in results from lab to lab.
- More holistic studies including other building disciplines (for example, fire proofing, thermal insulation, cost, scheduling, etc.) may continue to reveal what the best assemblies are and for what design scenarios are best.
- There are many buildings for which code will not allow exposed timber ceilings depending on the Construction Type per the 2021 IBC, and in most cases, a non-combustible topping is required for mass timber floors [7].

4 CONCLUSIONS

This study extended the WW inventory that compiled the sound insulation performance of mass timber assemblies by extracting material information and adding EC data. The results showed that there was no direct correlation between EC and acoustic insulation. As a result, designers may select a floor assembly which meets project-specific goals for EC, STC, and IIC. Where several assemblies have similar acoustic performance, but different EC, other factors not in this study's scope may control the design selection. These additional factors include, but are not limited to, structural design requirements, cost, scheduling, and fire resistance requirements. Although this study helps extend existing research on the performance of mass timber assemblies within the built environment, a comprehensive database including additional considerations could improve initial assembly selection.

DATA AVAILABILITY

The WoodWorks Inventory of Acoustically-Tested Mass Timber Assemblies is publicly available at no cost from https://www.woodworks.org/resources/inventory-of-acoustically-tested-mass-timber-assemblies/. EC data generated for this paper, building on the WW Inventory data, is available by request from the corresponding author. Components and data sources in Table 5 are only representative. Data available from the corresponding author includes EPDs, technical data sheets, and reports for the components listed below. Most EPDs are manufacturer-specific, and as such, a multitude of manufacturers are listed below as data sources for this research; however, it is not the authors' intent to promote specific manufacturers or products.

- CLT – average of Product EPDs from various North American manufacturers: Smartlam, [smartlam.com], Structurlam [structurlam.com], Nordic Structures [nordic.ca/en/products], Vaagen [vaagentimbers.com], Kalesnikoff [kalesnikoff.com]
- Glue Laminated Timber (GLT) – Industry-wide EPD, [awc.org/wp-content/uploads/2021/11/AWC_EPD_NorthAmericanGluedLaminatedTimber_20200605.pdf]
- Mass Plywood Panel (MPP) – Product EPDs from Freres, [frereswood.com]

- Bamboo Plywood – Product EPD by Plyboo, [plyboo.com]
- Roof Board – Product EPD by Georgia Pacific, [buildgp.com/densdeck]
- Sand – Report by the National Stone Sand & Gravel Association [44].
- Flooring – Product EPDs by Mannington Commercial [manningtoncommercial.com] and Tarkett [home.tarkett.com/en_EU]; Industry-wide EPDs by TCNA [tcnatile.com] and RFCi [armstrongflooringpartner.force.com/ArmstrongConnect/s/article/Environmental-Product-Declaration-EPD-Luxury-Vinyl-Tile].

The ICE v3.0 database values were used for Nail Laminated Timber (NLT), tongue and groove (T&G) decking, wood subfloor, cement mortar, normal weight concrete, sound isolation clips, wood furring, wood board products such as plywood, hardwood flooring, and laminate flooring [31]. Finally, NRC reports on sound insulation research and assembly test results were used to clarify assembly construction where relevant [45],[46].

ACKNOWLEDGEMENTS

The authors would like to thank Ryan Solnosky, Kevin Parfitt, Dr. Ali Memari, and Corey Gracie-Griffin for their advisement on this work. This research is supported in part by the Graduate Assistance in Areas of National Need (GAANN) Fellowship and the J. Roger Glunt Graduate Fellowship in Housing, hosted by the Pennsylvania Housing Research Center (PHRC). Neither fellowship had any role or input in the planning and implementation of this research, and the included results do not reflect the views of these organizations.

ECOLOGICAL PERFORMANCE AND RECYCLABILITY OF TIMBER-BASED CONSTRUCTIONS

Alireza Fadai[1], Daniel Stephan[2]

ABSTRACT: The growing importance of large-volume timber construction in European metropolitan areas leads to the investigation of a possible optimization potential in the use of timber in combination with other materials. This results in further investigations to gain synergies from a combination of the individual composite systems. For this reason, different types of combined timber composite constructions are developed and evaluated with regard to structural implementation and environmental optimization. Through a suitable combination, a construction-optimized design with increased resource efficiency can be achieved both at the component level and at the level of the overall structure.

For a holistic ecological assessment of building structures, the whole life cycle of the construction system needs to be investigated. Sustainable recycling means employing the materials used for the construction and operation of a building after the initial use for a new purpose. In a progressive design process, recyclability of the materials has to be considered in the planning stage of construction projects. If possible, recyclable components or already recycled components should be used. The factors separability and absence homogeneity are particularly decisive for the assessment of the possible recyclability of materials. For this reason, various life cycle phases and exploitation scenarios beyond the production phase of the building materials ("from cradle to gate") are evaluated. Especially the timber-wood lightweight concrete-glass-façade, developed and further investigated at the research department "Structural Design and Timber Construction" at the Vienna University of Technology, is set in context to standardized exterior façades to demonstrate a sensible design process regarding recyclability, resource efficiency and ecological advantages.

In addition, the thermal behavior is assessed in multiple studies. In the process, different construction methods, including timber, reinforced concrete and brick construction, are investigated and impact factors such as the orientation and size of the windows, the total solar energy transmittance of the glazing and solar shading devices are evaluated.

KEYWORDS: Wood-based construction, Sustainable building, Environmental impacts, Recyclability, Energy efficiency

1 INTRODUCTION

The growing importance of large-volume timber construction in European metropolitan areas leads to the investigation of a possible optimization potential in the use of timber in combination with other building materials. This results in further investigations to gain synergies from a combination of the individual composite systems.
For this reason, different types of combined timber composite constructions are developed and evaluated with regard to structural implementation and environmental optimization. Through a suitable combination, a construction-optimized design with increased resource efficiency can be achieved both at the component level and at the level of the overall structure.
Within the scope of subprojects, material-specific potentials could be identified for the respective materials used, which combine timber in the form of integrated timber ribbed panels (HCLTP elements [1]), wood lightweight concrete (WLC) and glass to increase the overall resource efficiency. This construction is in the focus of the current research project (cf. Figure 1 and [2, 3]).
When timber-WLC-glass-façades are used, the combined panel and ribbed component geometry offers an ideal basis for the execution of a multi-layer polyvalent composite construction.

The ribbed structure makes it possible to mount stiffening glass elements on the outside of the ribs and to create a buffer plane in the space between the ribs. By using an additional adaptive planking made of WLC, this gap can contribute to the structural optimization of the supporting structure [4].

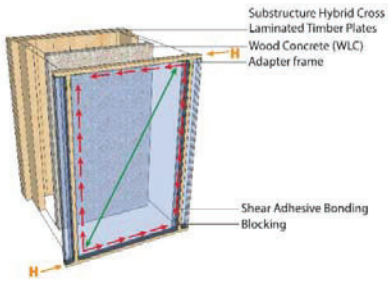

Figure 1: *Timber-wood lightweight concrete-glass façade*

The amount of glass used in this façade not only increases the resource efficiency of the construction, it also gives the opportunity to design optimal ratios of opaque and transparent elements. Nowadays the people feel the consequences of climate change very clearly. Especially in dense city areas the importance of climate resistant planning is invaluable. One of the key elements of climate resilient planning is designing glass façades to increase solar gains in the winter to reduce the heating demand but to look out for overheating in the summer.
To figure out clear factors for the design process, various simulations of different construction methods are carried out and put in context to the timber-WLC-glass-façade design decision. In the process, impact factors like orientation, window size, total solar energy transmittance (g-value) and solar shading devices are valuated.

2 LIFE CYCLE ASSESSMENT

Sustainable recycling means employing the materials used for the construction and operation of a building after the initial use for a new purpose. Waste products turn into secondary raw material. Easier dismantlability of an object into its components means that this object shows a better deconstruction. [5].
In a progressive design process, recyclability of the materials has to be considered in the planning stage of construction projects. If possible, recyclable components or already recycled components should be used. The factors separability and absence homogeneity are particularly decisive for the assessment of the possible recyclability of materials.
In consideration of their recyclability the lifecycle of different construction alternatives with a focus on timber and glass as building material is being analyzed and evaluated. For a holistic ecological assessment of building structures, the whole life cycle of the construction system needs to be investigated. For this reason, various life cycle stages and exploitation scenarios beyond the production phase of the building materials ("from cradle to gate") are evaluated according to the European standards EN 15804 [6] and EN 15978 [7], including the use and end of life cycle stages, such as energy consumption, maintenance and repair, respectively deconstruction, disposal and recycling ("from cradle to grave").

Thereby considered assessment criteria are the renewable **P**rimary **E**nery **I**nput (PEI_e), the non-renewable **P**rimary **E**nergy **I**nput (PEI_{ne}) and the **G**lobal **W**arming **P**otential over 100-year time horizon (GWP_{100}).
With these environmental computations, the ecological properties and impacts of wood-based construction systems can be shown. Furthermore, decisively design criteria for sustainable structural systems can be derived thereof [8].
The ecological assessments are calculated with integration of the databases "IBU-EPD" [9] and "ÖKOBAUDAT" [10], both managed by the German Federal Ministry of Housing, Urban Development and Building (BMWSB). In the last years the database updated from EN 15804 (now called EN 15804 + A1) [6] to the new system EN 15804 + A2 [11] because the new standard DIN EN 15804 + A2 [11] is introduced. With this change the ecological parameters differ a lot from the old ones and must not be mixed in the calculation process. The new system will be the basis of future calculations, especially within the Assessment System for Sustainable Building (BNB) [12]. The ecological assessment in this paper focuses in the comparison of different materials and the timber-WLC-glass-façade from before the change, so the used data is based on the system according to EN 15804 + A1 [6].
To put the decision to use wood- and glass-based materials as primary investigation in the timber-WLC-glass-façades in a clear context, different building materials and components are compared [13].

Figure 2 compares the primary energy demand, categorized in renewable and non-renewable (grey energy), of different building materials per m³ for the life cycle stages A-D (production, construction process, use and end of life stage as well as supplementary beyond the building life cycle).

The comparison of the materials concrete (different compressive strength classes), brick (insulating and non-insulating), timber (coated, structural and medium density fiberboard) and glass panels shows that timber and glass have high primary energy values. Nevertheless, most of the primary energy of timber is the renewable part (mostly solar power in the production phase) and glass is calculated as 1 x 1 x 1m block (of glass) to ensure comparability. Concrete with low compressive strength (C25/30) has lower primary energy demand than concrete with higher compressive strength (C50/60). Bricks without insulation and lower density of 740kg/m³ lead to lower environmental impact than its perlite filled version with 800kg/m³. In need of insulation material later on in most cases, the low-density version is more likely to be used within a solid brick construction.

https://doi.org/10.52202/069179-0118

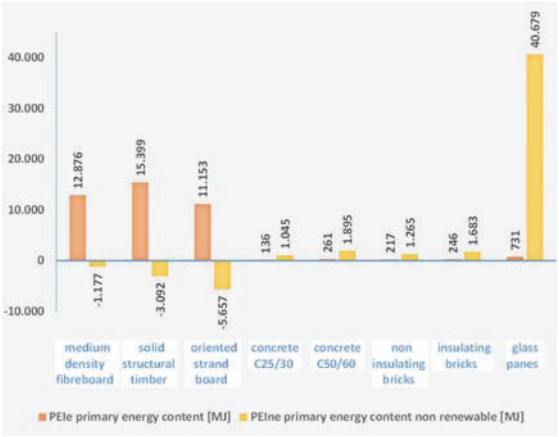

Figure 2: *Primary energy demand of building materials per m³ for the life cycle phases A-D*

Figure 3 illustrates one of the great advantages of timber-based materials. With a negative input for the global warming potential, wood has a considerable environmental balance. In contrast, concrete and brick materials cause more environmental impacts depending on density and compressive strength, similar to the calculations of the primary energy demand. Glass materials again cause the most GWP value due to the framework conditions, but have a high potential when used as individual panes.

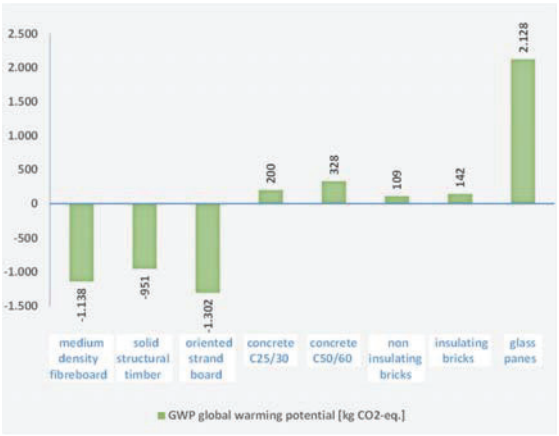

Figure 3: *Global warming potential of building materials per m³ for the life cycle phases A-D*

In a comparison of different exterior walls with concrete and brick materials (cf. Figure 4), vertically perforated brick and monolithic concrete require the most primary energy. Monolithic brick, perlite-filled brick and concrete with **e**xternal **t**hermal **i**nsulation **c**omposite **s**ystem (ETICS) roughly tie here.

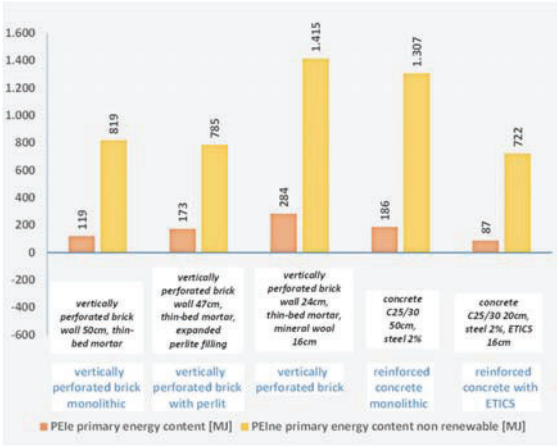

Figure 4: *Primary energy demand of brick and concrete exterior walls per m² for the life cycle phases A-D*

As can be seen in Figure 5, the perlite-filled brick in particular stands out in comparison, because of its high GWP value due to its filling. The GWP data of the other exterior walls are similar, with the ETICS concrete and the monolithic brick having the lowest GWP values.

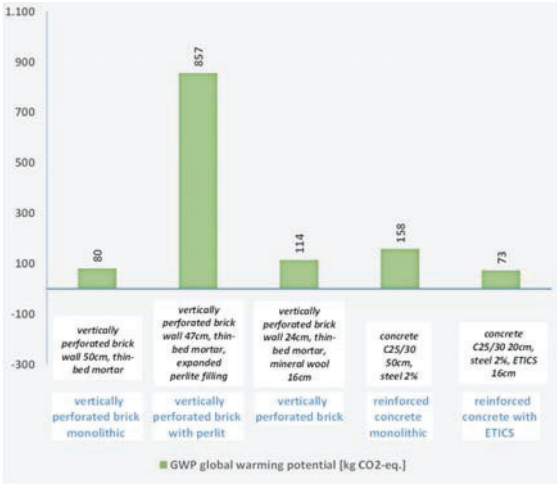

Figure 5: *Global warming potential of brick and concrete walls per m² for the life cycle phases A-D*

The analyzed timber exterior walls perform significantly better in terms of primary energy demand, especially the non-renewable part (cf. Figure 6).

https://doi.org/10.52202/069179-0118

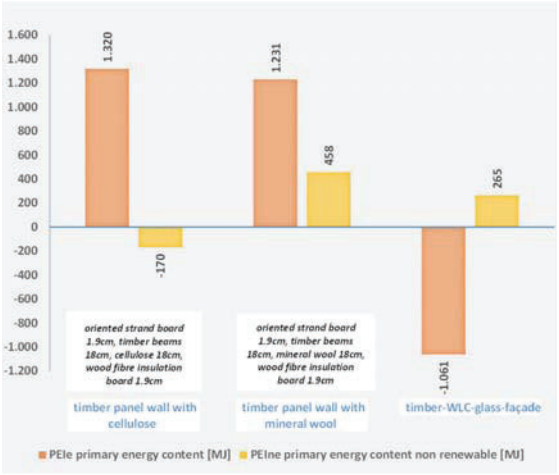

Figure 6: *Primary energy demand of timber exterior walls per m² for the life cycle phases A-D*

The results of the timber-WLC-glass-façade are particularly interesting and noteworthy. In the calculations per m² of façade, the strength of a mixed construction method from an ecological point of view is clearly shown by the very low primary energy values.

The same tendency is just as evident when considering the global warming potential. The timber exterior walls have a lower GWP value than the concrete or brick walls, especially the timber panel with cellulose and the timber-WLC-glass-façade (cf. Figure 7).

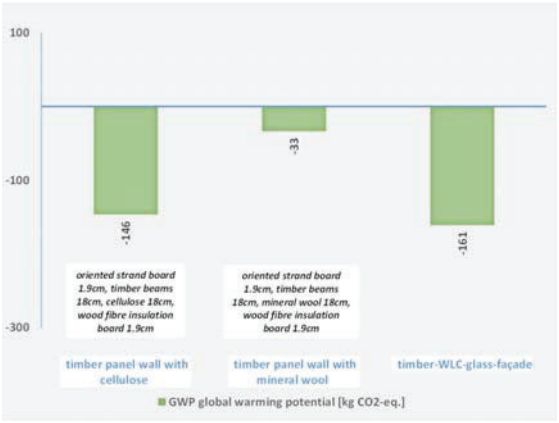

Figure 7: *Global warming potential of timber exterior walls per m² for the life cycle phases A-D*

A sensitive mixture of building materials (including glass) in a façade can therefore lead to ecological advantages if connected correctly. These studies show the potential of hybrid timber façades especially in case of the overall resource efficiency and recyclability potential.

3 ENERGY EFFICIENCY

At the present time, the required energy standard of buildings according to building regulation is at the level of a low-energy house. By introducing the "Energy Performance of Buildings Directive", the European council established the basis for uniform valuation. These guidelines indicate that a building has to be sustainable, the used construction materials and components have to be recyclable and the use of environmentally friendly resources and secondary materials is welcome [14].
Coherences of sustainability and energy efficiency on component and on overall system level can most suitable be shown by the assessment of a building model with a maximum geometrical simplicity. Consequently, a quadratic one-storied simulation model in different variations (wood-based and conventional building structures) is defined (cf. Figure 8) and subsequently investigated and compared with regard to its thermal behavior (heating energy demand and operative room temperature).

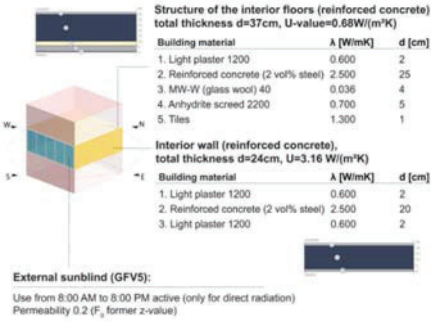

Figure 8: *Isometric view of the simulation model*

The simulations are carried out with the 3D online tool Thesim 3D [15]. Thesim 3D simulates the thermal behavior of a room in a steady-state, periodic condition (period length: 1 day). It is therefore particularly suitable for standardized summer overheating tests according to EN ISO 13791 [16] or ÖNORM B 8110-3 [17].
To evaluate these assessments, different types of conventional constructions are compared with the timber-WLC-glass-façade. The comparison is made with respect to materialization at the component level as well as at the overall structure level, which allows a scale-independent evaluation of the investigated types of construction to be achieved. This evaluation is made possible by a broad spectrum of calculations, ranging from static and dynamic thermal simulations for annual heating-up and overheating periods to the resulting various ecological impact calculations.

As a starting point for the simulations, a critical room with the dimensions 4 x 4 x 6m is defined (cf. Figure 9), which is initially calculated with the timber-WLC-façade in Vienna, Austria (average temperature is 24.9°C ± 7K). In the first calculation neither shading nor night ventilation is applied, the windows are triple glazing (U-value = 0,5; g-value = 0,48).

https://doi.org/10.52202/069179-0118

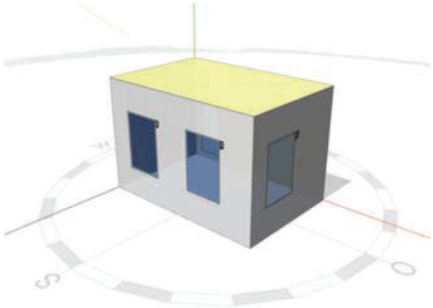

Figure 9: *Isometric view of the critical room model*

As shown clearly in Figure 10, the operative room temperature far exceeds the 27°C limit according to ÖNORM B 8110-3 [17]. Due to the closed windows facing south and lack of ventilation, the heat in the critical visibly accumulates and cannot escape.

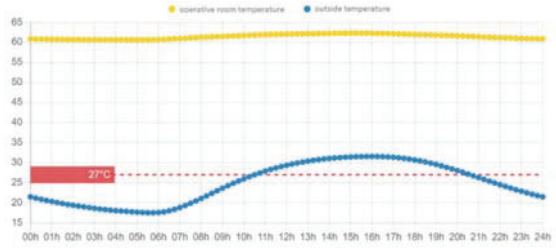

Figure 10: *Thermal simulation of the critical room*

Therefore, some optimization measures has to be taken (cf. Figure 11). This time shading (F_c = 0.2) in direct sunlight and night ventilation from 08:00 PM to 08:00 AM (tilted window) is applied.

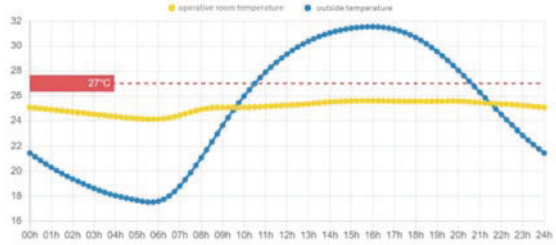

Figure 11: *Thermal simulation of the critical room with optimization measures*

As a result, the critical room does not exceed an operative room temperature of 25.8°C even during the hottest summer days.

Furthermore, to evaluate other influencing factors several thermal simulations of existing buildings in the cities Vienna and Wels (Austria), Bochum (Germany) as well as London (England) are carried out. The critical room dimensions are congruent, but other framework conditions are unquestionably different in these European cities. The wide range of climatic conditions and various construction made out of timber, reinforced concrete and brick should lead to nuanced solutions. To save energy on the one hand and to avoid summer overheating on the other hand the factors "orientation and size of windows", "g-values of window panes" and "awnings" are identified.

As the studies show, the building design contributes significantly to the desired indoor climate in summer. Independent of the location the highest solar radiation occurred in the south and west zones of the buildings and has no shading available. Consequently, the placement and size of windows as well as the use of balconies and shading devices are crucial for the overheating aspect.
In terms of g-value of window panes the case study in London with a solid wood building (daily average exterior temperature: 16.3°C) shows that a lot of emphasis must be placed on orientation and the g-value during the planning phase.
Especially in this context, the question between double and triple glazing arises. In winter, triple glazing (U-value = 0.7; g-value = 0.48) is more advantageous than double glazing (U-value = 1.4; g-value = 0.27) because of its low U-value. In summer, however, low U-values and higher g-values are counterproductive, as less heat is lost through the windows and overheating occurs (cf. Figure 12).

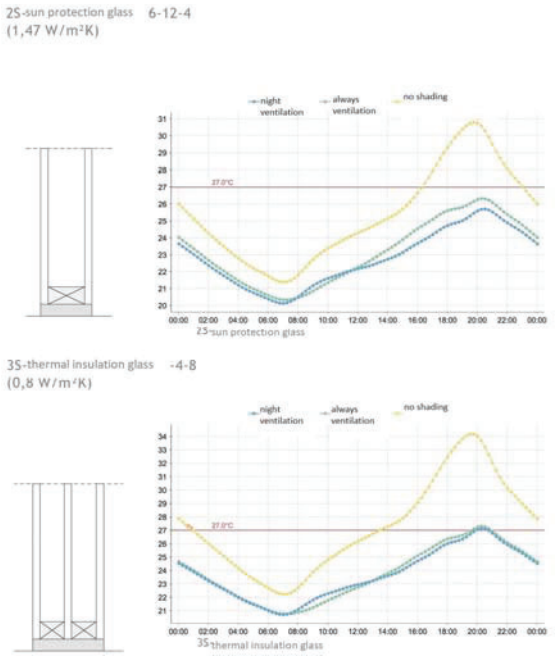

Figure 12: *Thermal dynamic building simulations with double and triple glazing, building in London (© ITI/TU Wien)*

4 CONCLUSIONS

This paper illustrates how timber-based structures can be used both optimally and sustainably in terms of their ecological value, recyclability and energy efficiency. On the basis of these investigations, the competitiveness of timber construction compared to conventional construction methods is demonstrated. Especially the timber-WLC-glass-façade, developed and further investigated at the research department "Structural Design and Timber Construction" at the TU Wien is set in context to standardized exterior façades to demonstrate a sensible design process regarding recyclability, resource efficiency and ecological advantages.

When looking at the ecological values of individual building materials, it is apparent that in terms of non-renewable primary energy input (primary energy necessary to construct a building; so-called "*grey energy*") and global warming potential, timber-based materials have a good environmental balance. Nevertheless, building materials such as concrete or even glass can also offer an ecological advantage in certain building components. The timber-WLC-glass-façade is an example of the environmental benefits that mixed construction can have, as long as it meets the structural requirements.

Furthermore, multiple studies are carried out to assess the thermal behavior of the timber-WLC-glass-façade and other materials. In the process, different construction methods, including timber, reinforced concrete and brick construction, are investigated and impact factors such as the orientation and size of the windows, the g-value of the glazing and solar shading devices are evaluated. In conclusion a thermal sensitive design should always consider structural sun protection, the situational number of glass layers in windows, appropriate ventilation behavior and orientation of the most critical room in the given location.

Ultimately, a well-thought-out planning process requires many factors. In order to move towards a sustainable circular economy, the issues of environmental sustainability, recyclability and resource efficiency must be considered in particular.

EMBEDMENT STRENGTH OF RECOVERED SPRUCE AND OAK

Caitríona Uí Chúláin[1], David Gil-Moreno[2], Daniel F. Llana[3], Mitja Plos[4], Goran Turk[5], Paul Hogan[6], Annette M. Harte[7]

ABSTRACT: The circular use of construction materials is an essential step in the drive to reduce the environmental impact of the construction sector. One of the factors that currently limits the ability to reuse timber recovered from demolition in structural applications is the lack of data relating to its structural performance, which would allow for the certification of its characteristics and the development of design guidelines.

This paper presents a study on the embedment performance of recovered timber by determining the embedment strength of spruce and oak specimens recovered from demolition sites in Ireland and Slovenia. Tests were carried out in the parallel and in the perpendicular to the grain directions using three different dowel diameters. The results were comparable with mean values reported in the literature and with the empirical Eurocode 5 predictions. Based on these findings, it can be concluded that the embedment performance of the recovered spruce and oak is equivalent to that of new timber. Further studies on recovered timber of different origin, species, ages and history of use are needed to confirm these findings.

KEYWORDS: Embedment strength, connections, circular construction, recovered timber, spruce, oak

1 INTRODUCTION

More than a third of all waste within the EU comes from construction and demolition [1]. This waste contains valuable natural resources with significant potential for reuse and recycling. In Europe, timber recovered from buildings at the end of life, often referred to as recovered or secondary timber, is, for the most part, converted into chips for use in energy production and, to a lesser extent, for the manufacture of particle boards or pallet blocks [2-4].

Recovered timber is considered to have great reuse potential [5] with maximum environmental benefits achieved through reuse in products with long lifespan, such as those for structural applications in buildings. However, the realisation of this potential is currently inhibited by the lack of grading standards and design guidelines for use of this resource. Recent European projects have begun to address this issue including the Buildings as Material Banks project (BAMB2020) [6], the CaReWood project [7] and the InFutUReWood project [8]. These projects have identified problem areas and proposed technical and methodological solutions to maximise reuse of timber from current buildings especially as a structural material. The most important issue to be addressed is of lack of knowledge of the material properties after the end of its first life.

Some recent studies have applied visual grading and non-destructive testing to characterise the flexural properties of recovered softwoods and hardwoods. Nakajima and Nakagawa [9] developed a visual grading approach for recovered timber boards which acocunts for holes and fissures. Non-destructive evaluation of recovered softwood [10-13] and hardwood [14] timber boards using acoustic methods was used to sort timber for the manufacture of CLT panels, which were subsequently tested in bending.

The issue of connections between recovered wood members has not been addressed to date and the development of design guidelines for such connections will be key to the successful implementation of the circular use of wood in construction.

Dowel-type connections are commonly used to connect structural timber members. For laterally-loaded fasteners, Eurocode 5 (EN1995) [15] provides guidelines derived from the Johansen yield model [16] for the connection capacity. The embedment strength of the timber elements being connected is a required property. For this, the embedment strength may be determined by test or calculation. The embedment strength may be established from experimental tests in accordance with standards, which for Europe is EN 383 [17]. Many studies have reported on embedment strength tests on new timber. Ehlbeck and Werner [18] tested seven different wood

species (including softwood and hardwoods) using dowel diameters ranging from 8 mm to 30 mm under different load to grain angles. The tests were made in accordance with the then proposed standardised European embedment test method prEN 383 in compression and in tension. The test findings indicated that the embedment strength increases linearly with increasing wood density and that results depend significantly on the fastener diameter. A formula was proposed where the strength is proportional to the timber density with a correction depending on the diameter of the dowel. Sawata and Yasumura [19] tested four grades of Japanese softwood under loading parallel and perpendicular to grain using dowel diameters ranging from 8 mm to 20 mm. The study found that there is significant correlation between embedding strength and density but found that the dowel diameter did not significantly influence results. Sandhaas *et al*. [20][21] compiled a data set of softwood and hardwood embedment tests. Six different wood species with densities ranging from 465 kg/m^3 to over 1200 kg/m^3 were tested, using 12 mm and 24 mm diameter dowels of two different steel grades. All embedment tests were carried out in compression. The influence of the dowel diameter on the embedment strength was found to be of low significance. They presented a simplified formula, discounting any influence of the dowel-to-wood surface area, that gave a more straight-forward design equation to that proposed by Ehlbeck and Werner [18]. Santos et al. [22] found that results of embedment testing to European EN 383 [17] and American ASTM D5764 [23] standards were comparable.

As an alternative to testing, embedment strength may be determined by calculation. Eurocode-5 [15] provides expressions for the embedment strength of new timber, which are a function of the characteristic timber density (the 5th percentile), the dowel diameter, the angle between the load direction and the timber grain, and the timber type. These empirical equations were adapted from those proposed by Ehlbeck and Werner [18] and were derived based on tests on new timber. Their applicability to recovered timber has yet to be established.

This paper presents a study carried out as part of the InFutUReWood project [8] to determine the embedment strength of recovered softwood and hardwood timber. The test programme includes the determination of embedment strength of timber from demolition projects in Ireland and Slovenia. Recovered spruce and oak specimens were tested in compression using dowels of three different diameters in the parallel and perpendicular to the grain directions in accordance with EN 383 [17]**.** Values obtained are compared with published data for new timber and with values from the Eurocode 5 empirical equations [15].

2 MATERIALS AND METHODS

2.1 RECOVERED TIMBER SAMPLES

The three types of recovered timber samples were investigated in the study were: Irish-sourced spruce, Slovenian-sourced spruce, and Slovenian-sourced oak. The Irish-sourced spruce sample was recovered from the roof trusses of a 1970s office block in Dublin, which had been vacant for over two years before its demolition. Grade stamps were visible on some of the boards indicating that the timber was grade TR26 imported spruce. This timber grade is commonly used in Ireland and the UK for roof trusses. TR26 grade timber has characterisitic and mean densities of and 370 kg/m^3 and 444 kg/m^3, respectively [24]. The moisture content of the timber boards at the time of recovery was estimated using a hand-held moisture meter to be between 18% and 23%. This high moisture content was attributed to water ingress onto the structural timber through damaged slates and sarking felt in the roof envelope for a period of time prior to demolition.

The Slovenian spruce was recovered during the refurbishment of the roof of a faculty building at Ljubljana University. The building is estimated to have been built in the years from 1947 to 1949 so the specimens were about 70 years old. The strength grade of the timber is unknown as at that time the JUS (Yugoslavian) norms were not yet in use. During their use in the building the specimens were protected against rain and not insulated. Therefore, they were not exposed to water, but were subjected to varying temperature estimated between -20° C and 50° C. The moisture content estimated with a resistance moisture meter was between 6.5 % and 12.4 %, with an average of 8.9 %. The density of the specimens at moisture equilibrium was between 362 kg/m^3 and 526 kg/m^3, with an average of 426 kg/m^3.

The Slovenian oak sample was recovered during the reconstruction of an external vehicle bridge over the river Sava, which was constructed between 1930 and 1935. During their use on the bridge, the specimens first served as the driving surface, and later they were covered with a new driving surface also made from wood. At first the water and salt from the vehicles would drip onto the specimens directly, and later only partially. The whole time they were exposed to moisture from the surrounding moist air over the river, but they were protected from direct rain by the roof of the bridge. The moisture content of the beams was between 9.1 % and 11.2 % at the time of recovery. The density of the specimens at moisture equilibrium was between 609 kg/m^3 and 860 kg/m^3, with an average of 739 kg/m^3.

Before preparation of the embedment specimens, the timber was conditioned in a chamber with a relative humidity of 65 ± 5% and temperature 20° ± 2° C. The specimens were then cut to the dimensions outlined in EN 383 [17] where the size of the specimen varies with the dowel size used, and with the load direction relative to the wood grain. The cut specimens were returned to the conditioning chamber until testing. The moisture content of all the timber specimens at the time of embedment testing was determined in accordance with EN 13183-1:2002 [25].

2.2 EMBEDMENT TESTING

Specimens for embedment testing were prepared in accordance with EN383 [17] (Figure 1). Smooth high strength steel dowels with diameters of 10 mm, 12 mm and 14 mm were used. A minimum of 10 specimens were tested for each combination of timber source, dowel diameter and loading direction where possible giving a

total of 191 specimens tested (Table 1). The exception was the 14 mm dowel tests perpendicular to the grain on the Irish-source spruce where only 8 specimens could be manufactured from the available resource. In all, 59 and 65 specimens of Irish-sourced and Slovenian-sourced recovered spruce were tested along with 67 specimens of Slovenian recovered oak.

Each dowel was loaded perpendicular to its axis in accordance with the loading procedure outline in EN 383 [17] and EN 26891 [26]. The dowel deformation was measured using two LDVTs. Tests were terminated when the deformation reached 5 mm or when the specimen failed due to splitting.

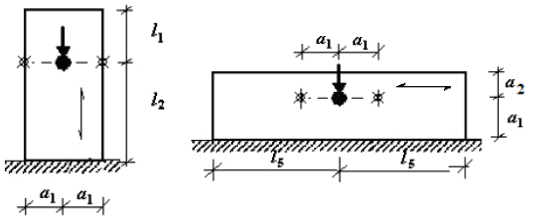

Figure 1: *Test set up for embedment tests parallel to the grain (left) and perpendicular to the grain (right) [2]*

Table 1: *Embedment test series by dowel diameter (dia)*

Series	Dowel dia (mm)	No. Tests Parallel	No. Tests Perpendicular
Spruce Ireland	10	11	10
	12	10	10
	14	10	8

	12	11	10
	14	10	11
Oak Slovenia	10	12	13
	12	10	10
	14	11	11

3 RESULTS

3.1 LOAD-DISPLACEMENT RESPONSE AND FAILURE MODES

The mean load-displacement responses for tests carried out using 10 mm dowels in the parallel to grain and 14 mm dowels in the perpendicular to grain directions are shown in Figures 2 and 3, respectively. Similar trends were found with other dowels diameters in the respective loaded directions. For all tests, no significant difference was found between the Irish-sourced and Slovenian-sourced spruce. The higher density oak sample was clearly stiffer than the two spruce samples. For the parallel to the grain tests, the peak load was reached before the 5 mm displacement limit specified in EN 383 [17]. This occurred at a displacement of 2 mm for the spruce and 3.5 mm for the oak specimens. As previously reported [21], specimens tested in the parallel to the grain direction are prone to splitting. For the present study, the proportion of specimens failing by splitting reduced with increasing dowel diameter as seen in Table 2. The occurrence of splitting failures occurred for the most part after the peak load had been reached in the tests and therefore does not impact on the embedment strength. This agrees with the findings of Sandhaas *et al*. [21] who found that there was no difference in embedment strength for unreinforced specimens and those reinforced to prevent splitting.

For the perpendicular to the grain tests, the load continued to increase up to the 5 mm displacement limit without reaching a steady state. All of the 94 specimens except one of the 10 mm Slovenian spruce specimens failed in embedment without splitting.

	12	20	0
	14	18	0

https://doi.org/10.52202/069179-0119

3.2 EMBEDMENT STRENGTH

The embedment strength for each specimen was determined from the maximum load divided by the area of contact between the dowel and the timber element using Eq. (1).

$$f_h = \frac{F_{max}}{dt} \quad (1)$$

where f_h, in N/mm^2, is the embedment strength, F_{max}, in N, is the maximum load at 5 mm dowel embedment (or failure load due to splitting), d, in mm, denotes the dowel diameter and, t, in mm, represents the thickness of the timber specimen. The mean values of embedment strength and density of the test specimens in each series together with their respective coefficients of variation (COV) are given in Tables 3 and 4 for the parallel to and perpendicular to the grain tests, respectively.

Table 3: *Mean density and embedment strength parallel*

Series	Dowel diameter (mm)	Density kg/m^3 (COV %)	Embedment strength N/mm^2 (COV %)
Spruce Ireland	10	426 (18)	30.2 (30)
	12	408 (6)	26.8 (14)
	14	424 (9)	29.2 (18)
Spruce Slovenia	10	368 (5)	28.7 (10)
	12	374 (12)	27.8 (15)
	14	371 (7)	28.6 (12)
Oak Slovenia	10	628 (9)	55.5 (16)
	12	581 (12)	47.3 (18)
	14	609 (9)	51.5 (14)

Table 4: *Mean density and embedment strength perpendicular*

Series	Dowel diameter (mm)	Density kg/m^3 (COV %)	Embedment strength N/mm^2 (COV %)
Spruce Ireland	10	416 (6)	20.5 (9)
	12	378 (6)	17.4 (23)
	14	399 (8)	16.5 (12)
Spruce Slovenia	10	407 (6)	25.6 (45)
	12	367 (3)	16.4 (13)
	14	393 (8)	17.6 (21)
Oak Slovenia	10	631 (10)	46.2 (29)
	12	653 (10)	50.3 (22)
	14	669 (7)	48.6 (19)

For the parallel to grain direction, the mean embedment strength varied between 26.8 and 30.2 N/mm^2 for the recovered spruce specimens and between 47.3 and 55.5 N/mm^2 for the recovered oak. The COV was 18% or less except for the 10 mm Irish spruce series which was 30%. For the perpendicular to the grain tests, the embedment strength for the recovered spruce specimens varied between 16.4 and 25.6 N/mm^2 while the values for the recovered oak varied from 46.2 to 50.3 N/mm^2. Overall, there was greater variability in the perpendicular to grain results with COV of over 20% in five of the nine series with the largest COV in the 10 mm Slovenian spruce series at 45%.

Boxplots of the embedment strength for the parallel to grain tests by diameter and species are given in Figure 4.

There was no significant difference between the embedment properties of the spruce recovered in Ireland and that in Slovenia, regardless the diameter. The higher embedment strength of the oak specimens is likely to be due to their higher density. Similar conclusions can be drawn for the perpendicular to the grain direction.

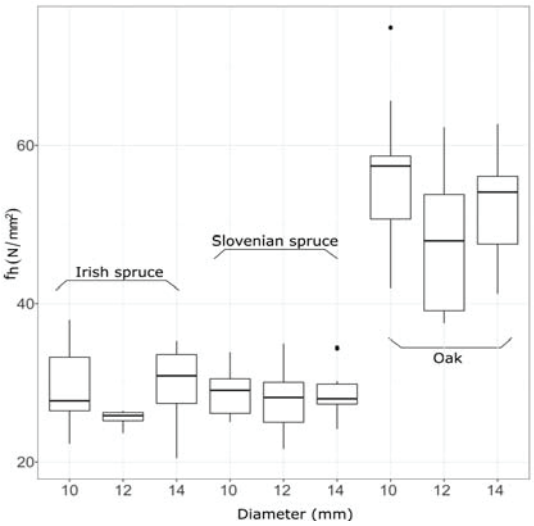

Figure 4: *Box plots of embedment strength parallel to the grain results*

Embedment strength results in the parallel and perpendicular to grain directions were strongly influenced by density as can be seen in Figure 5.

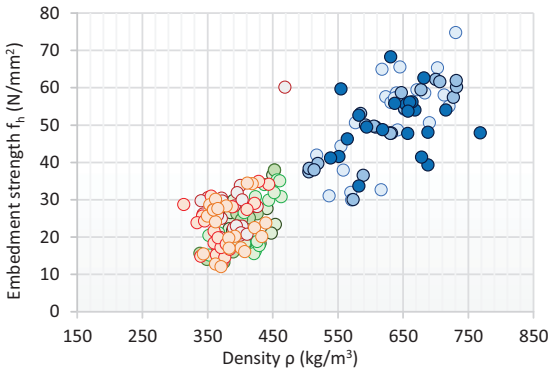

Figure 5: *Embedment strength v density – all specimens (Irish spruce-green; Slovenian spruce –red; Oak – blue)*

For the full dataset of parallel to grain data, the linear relationship between density and embedment strength was very strong (R^2 = 0.90). Including diameter as an additional explanatory variable in the linear regression had a negligible effect on the overall fit of the regression (R^2 = 0.91). The effect of the diameter on the slope and intercept of a linear regression was investigated with ANOVA. The results showed that the diameter affects the intercept ($F_{2\ 94}$ *=3.99, P= 0.02*) but not the slope ($F_{2\ 92}$ *=0.78, P= 0.46*). A multiple comparison at the 95% confidence level showed that 12 mm diameter had an intercept term 3 kN/mm^2 lower than the other two

diameters, with no significant differences between the intercept for the 10 mm and 14 mm diameters. It is important to note that these findings are based on the limited dataset in the study and more testing of recovered timber will be needed before any definitive conclusions can be reached.

The overall relationship between density and embedment strength in the perpendicular to grain direction was also very strong ($R^2 = 0.90$). An ANOVA of the softwood data showed that the diameter affects the intercept ($F_{2\,55} = 9.01$, $P < 0.001$) but not the slope ($F_{2\,53} = 1.32$, $P = 0.28$). In the softwoods, the 10 mm diameter was about 3 kN/mm^2 higher than those of the 12 mm and 14 mm. The differences between the latter were not statistically significant. For the hardwood, the effect of diameter in the relationship was not significant ($F_{2\,30} = 1.57$, $P < 0.23$), but the number of tests was roughly half that of the softwoods. Figure 6 shows the relationship of perpendicular to the grain strength by timber type. Even though the effect of the diameter was significant for the embedment strength calculation parallel to the grain and in softwoods tested perpendicular to the grain, trends could not be established. As mentioned earlier, the size of the dataset in the current study does not allow for definitive relationships for the embedment strength of recovered timber to be established. Nevertheless, some trends can be identified.

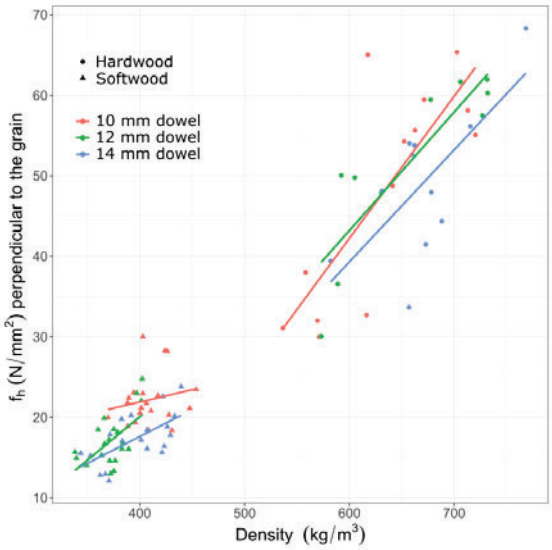

Figure 6: *Relationship between density and embedment strength perpendicular to the grain by dowel diameter*

3.3 COMPARISON WITH PUBLISHED DATA FOR NEW TIMBER AND EC5

The embedment strength values for recovered timber reported here agree reasonably well with values published in the literature from tests on new timber of similar species. Figure 7 shows a comparison of the results for 12 mm dowel parallel to grain tests from the current study compared to data presented by Glišovíc *et al.* [27] and Sandhaas *et al.* [21] for spruce, pine, oak and beech. No impact of aging can be seen in the recovered timber results.

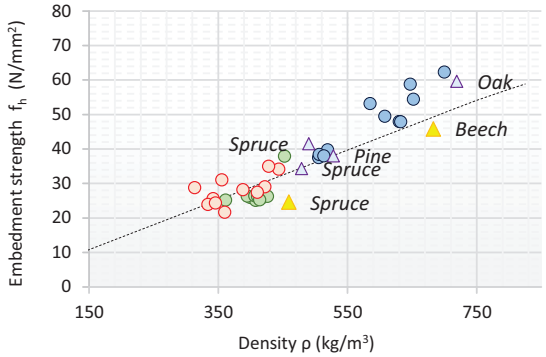

Figure 7: *Embedment strength v density – 12 mm specimens parallel-to-grain (Irish spruce-green; Slovenian spruce – red; oak – blue; Glišovíc et al. [27] – purple; Sandhaas et al. [21] - yellow)*

EC5 [15] provides an empirical equation for embedment strength as a function of density, dowel diameter and angle to grain (Equation (2)).

$$f_{h,\alpha,k} = \frac{0.082\,(1 - 0.01\,d)\rho_k}{k_{90}\,sin^2\alpha\, +\, cos^2\alpha} \qquad (2)$$

where $f_{h,\alpha,k}$, in N/mm^2, represents the characteristic embedment strength, ρ_k, in kg/m^3, denotes the characteristic timber density, d, in mm, represents the dowel diameter, and α, represents the angle of the load to the grain. k_{90}, may be taken as $1.35 + 0.015\,d$ for softwoods, and as $0.90 + 0.015\,d$ for hardwoods. The line representing this equation with the characteristic value replaced by the actual density is shown in Figure 7. For the spruce specimens, the data points are closely aligned with this equation. The equations underpredict the embedment strength of the recovered oak. In general it can be said that the EC5 equation can be used to predict the embedment strength of the recovered timber specimens in the current study. Further work is required to determine its applicability to recovered timber in general.

4 CONCLUSIONS

To support the understanding of the behaviour of recovered timber and support its reuse in new construction, a study was carried out as part of the InFutUReWood project [8] to determine the embedment strength in the parallel and perpendicular to grain directions of recovered spruce and oak. Spruce was recovered during the demolition of roof structures in Ireland and Slovenia and the oak was recovered from the renovation of a vehicle bridge in Slovenia.

Specimens were tested in accordance with EN383 [17] using smooth high strength steel dowels of three different diameters. A total of 191 tests were performed of which 97 were in the parallel to grain direction and 94 perpendicualr to the grain.

For the two spruce series, no significant difference in the embedment strength was found despite the fact that the environmental conditions during the life of the two roof

https://doi.org/10.52202/069179-0119

structures from which the material was recovered was quite different. For the tests in the parallel to grain direction, the peak load was reached at an embedment of approximately 2mm. A high percentage of specimens failed in splitting before reaching the 5 mm embedment value specified in the standard. For the perpendicular to grain tests, only one specimen failed in splitting.

The embedment strength of the recovered oak specimens was significantly higher that that of the spruce, which is likely due to the higher density. Again, splitting occurred in a high proportion of the parallel to grain tests with no evidence of splitting perpendicular to the grain.

A strong linear relationship was found between embedment strength and density for all tests. The influence of dowel diameter on strength was less clear and will require further testing to establish it.

The results were compared with mean values for new softwood and hardwood timber specimens reported in the literature and were found to be generally in line with these values. The empirical Eurocode 5 predictions for the embedment strength of softwoods and hardwoods were good predictors of the embedment strength of the recovered timber specimens investigated in this study.

Based on these preliminary findings, it can be concluded that the embedment performance of recovered spruce and oak seems to be equivalent to that of new timber. However, further studies on recovered timber of different origin, species, ages and history of use are needed to confirm these findings for recovered timber in general.

ACKNOWLEDGEMENTS

This work was carried out in Ireland and Slovenia as part of the InFutUReWood project supported under the umbrella of ERA-NET Cofund ForestValue by the Department of Agriculture, Food and the Marine for Ireland and the Ministry of Education, Science and Sport for Slovenia. This is supported under the umbrella of ERA-NET Cofund ForestValue, and ForestValue has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 773324.

The authors would like to acknowledge the contribution of Colm Walsh and Peter Fahy, senior technical officers in the School of Engineering, University of Galway, for their assistance with the laboratory test programme.

PROPOSAL OF A METHOD FOR ESTIMATING THE RESIDUAL STRENGTH FROM THE DEPTH OF PILODYN PENETRATING FOR A CYLINDRICAL MEMBER

Makoto Imai[1], Hironobu Kobayashi[2], Tadashi Hara[3]

ABSTRACT: A method for estimating the residual strength from the depth of Pilodyn penetrating for a cylindrical member (thereafter, Pe) was investigated. Conventionally, a relational expression for estimating the residual strength from the results of Pe and the strength test has been sought. However, it is not always possible to carry out a fracture test, and the residual strength should be theoretically derived from Pe and the like. The defect model by Pe was generally a circular cross-section model based on the average value, but since the decay was not uniform, it was thought that the elliptical model could estimate the residual strength more realistically. We acquired Pe and conducted strength tests on members used outdoors, and verified the fit between the residual strength estimation results based on the elliptical model and the actual strength test results. With this method, it is possible to estimate the residual strength simply by acquiring Pe, and it is expected that it will be easier to determine the renewal time of the structure.

KEYWORDS: Pilodyn penetration, Section modulus, Elliptical approximation, Estimating the residual strength

1 INTRODUCTION

Japan is a hot and humid environment that is unfavorable for wood, which is very different from the dry summer conditions in Northern Europe and Canada [1]. Wood and wood products used outdoors are constantly exposed to wind and rain and wood-rotting fungi in such an environment, and deterioration over time such as decay is inevitable. Aging causes not only a deterioration in appearance, but also a reduction in the strength of materials and joints. As a preventive measure against deterioration, treatment with antiseptic agents, protection using other materials, etc. are performed, but deterioration cannot be completely prevented. Therefore, it is necessary to periodically diagnose deterioration.

Deterioration is generally diagnosed by visual observation or palpation, and if any abnormality is confirmed, secondary diagnosis using dedicated equipment is performed to acquire quantitative data [2]. Dedicated equipment used for secondary diagnosis is mainly non-destructive diagnostic equipment such as FFT Analyzer (Hammering sound frequency analyzer) and FAKOPP (Stress wave measuring device), and micro-destructive diagnostic equipment such as RESISTOGRAPH (Penetration resistance measuring instrument) and Pilodyn (Figure 1).

Pilodyn is a device that ejects a steel pin with a diameter of 3 mm and a length of 40 mm by the force of a spring and measures the depth of the pin driven into wood. This equipment diagnoses deterioration by estimating the density from the obtained penetration depth. Since the density has a high correlation with the bending strength, the method of estimating the residual strength by deriving the relational expression between the Pilodyn penetration depth *Pe* and the bending strength σ by strength test is generally performed [3].

Figure 1: A scene of driving a Pilodyn pin into a pillar

Simply put, when Pe exceeds 30 mm, it is considered to be the service life limit [4], but since Pe is affected by the moisture content [5][6], the evaluation may differ depending on the condition of the material to be driven.

Since Pe fluctuates depending on the moisture content, it is difficult to judge the initial deterioration from Pe within the range of 30 mm from sound material (approximately 15 mm). The authors are also working on an initial deterioration detection method that applies the preventive design technology of quality engineering (MT system) [7]. Mori et al. [4] regarded the rotten part of the processed material as a defect, and defined the ratio of the sound part other than the defect in the cross-sectional area as the cross-sectional survival rate. As a result of the strength test, it was shown that the relationship between the section survival rate and the bending strength fits well when it is hypothesized that decay progresses uniformly from the outer periphery. Based on this result, the average thickness of the cross-sectional loss due to decay (hereinafter referred to as the defect depths) was estimated from the average *Pe* values at multiple points on the outer circumference, and we devised a method to evaluate the residual strength by calculating the section modulus of the remaining circular cross section from the defect depths (hereinafter referred to as the circular approximation method) (Figure 2).

However, in actual wood, it is thought that decay progresses locally from the part where the efficacy barrier of antiseptic agents is weak, and the hypothesis that "decay progresses uniformly from the outer periphery" does not necessarily hold. Therefore, it is necessary to examine the appropriateness of simply averaging the defect depths. In addition, for structures such as fences, it is important to evaluate the soundness against external forces from outside the plane to prevent overturning. If the defects are concentrated in the direction of the external force, the circular approximation method may give a poor evaluation of the out-of-plane external force, resulting in a dangerous judgment result.

Therefore, we devised a method to calculate the residual strength from *Pe* by assuming that the residual cross section is elliptical rather than circular, and using the section modulus that reflects the anisotropy of the defect (Figure 3). This method is hereinafter referred to as the elliptical approximation method.

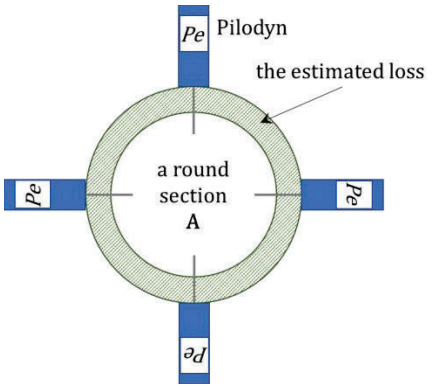

Figure 2: *The method of Mori et al. (Circular approximation)*

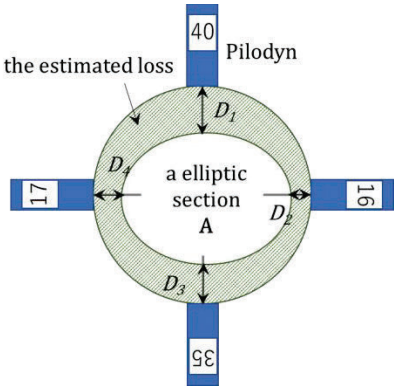

Figure 3: *The new idea of ellipse approximation (Pilodyn values are examples)*

2 SPECIMEN AND TEST METHOD

2.1 OVERVIEW OF THE SPECIMEN

The object of the investigation is a column material (φ150 mm) made of Japanese larch, which has been preserved with antiseptic chemicals for more than 10 years since it was installed as access prevention fences on a high-standard road (Figure 4).

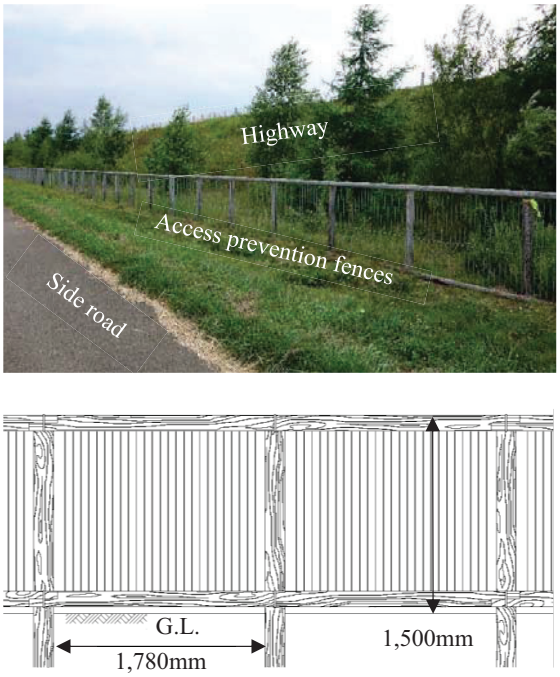

Figure 4: *Access prevention fences on a high-standard road*
Upper: Fences seen from side road, Lower: Fences front view

Two types of bending strength tests were conducted: a full-scale test and a sample test. A full-scale test specimen (n=10) was used for the test with the original cross-sectional dimensions (φ150 mm × 2,900 mm) of the cylindrical material. Sample specimens (n = 307) were prepared by cutting a cylindrical material into rectangular

https://doi.org/10.52202/069179-0120

cross sections of 25 mm × 25 mm × 550 mm. In addition, the samples were taken from the outer part without the heartwood so as to include the rotten part as much as possible (Figure 5).

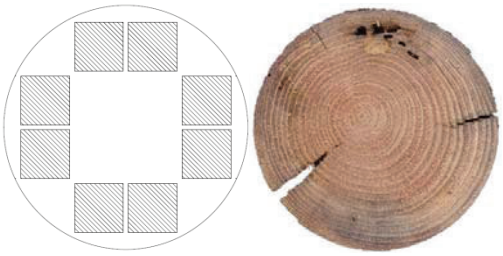

Figure 5: *Image of cutting out sample specimens from a cylindrical material (The shaded area is the sample specimen)*

2.2 BENDING STRENGTH TEST METHOD

The bending strength test was carried out by the trisecting four-point loading method with the bending span set to 18 times the height of the specimen for both the full-scale test and the sample test. In both tests, the decayed surface was taken as the upper surface (Figure 6).

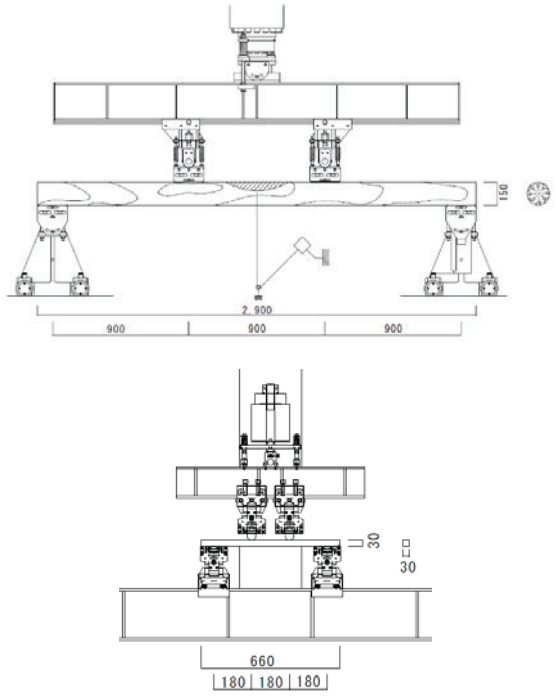

Figure 6: *The trisecting four-point loading method (The shaded area is the decayed area), Upper: full-scale test, Lower: sample test*

For the full-scale test specimen, the presence or absence of decay was visually observed before the test was conducted, and the average *Pe* was calculated from the *Pe* obtained by injecting Pilodyn into four points on the outer periphery of the center of the span.

For the sample specimen, both butt ends were observed before the test, the defect depths *D* due to decay was actually measured (Figure 7), and the section modulus Z_1 was calculated from the remaining cross section. The section modulus reduction rate R_d was calculated from the ratio to the original section modulus Z_0 without defect (Equation(1)).

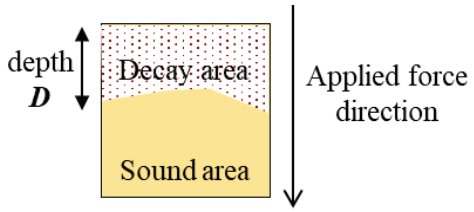

Figure 7: *The cross-sectional defect depth D of the sample specimen*

$$R_d = 1 - \frac{Z_1}{Z_0} \tag{1}$$

The bending strength σ was calculated from the maximum load values P_{max} obtained from the bending test and Z_0. (Equation(2)).

$$\sigma = \frac{aP_{max}}{2Z_0} \tag{2}$$

Here, a = Distance between fulcrum to load points.
Considering the average bending strength of specimens without cross-sectional defects as the bending strength of sound material σ_0, the ratio of the bending strengths σ_1 and σ_0 of each specimen with cross-sectional defects was used to calculate the residual rate of bending strength R_σ (Equation(3)).

$$R_\sigma = \frac{\sigma_1}{\sigma_0} \tag{3}$$

Imai et al. [8] obtained *Pe* by penetrating Pilodyn into larch columns. After that, the material was cut at the place where the pin was driven, the defect depths *D* was measured from the cross section (Figure 8), and the relationship between *Pe* and *D* was derived as Equation(4). This indicates that Pilodyn has enough energy to allow the pin to penetrate the sound larch wood by an average thickness of 14.5 mm. It also indicates that the driving depth of the pin increases as the sound portion and density decrease due to decay or the like. In other words, by using this equation, it is possible to estimate the defect depths (degree of decay) at that location from the measured Pilodyn penetration depth.

$$D = 0.94Pe - 14.5 \quad (\text{n} = 664, \text{R} = 0.946) \tag{4}$$

https://doi.org/10.52202/069179-0120

Using these Equations (1) to (4), a method for estimating residual strength from measured *Pe* is examined.

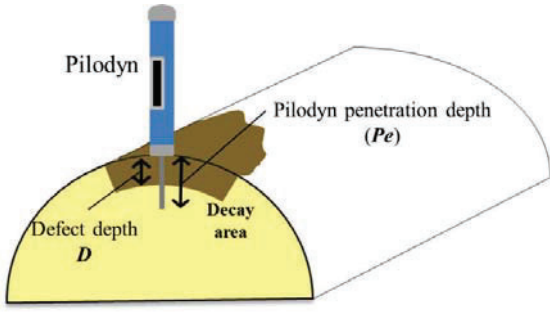

Figure 8: *The defect depth D observed by cutting at the Pilodyn penetration position*

3 VALIDATION OF THE ESTIMATION METHOD

3.1 RELATIONSHIP BETWEEN BENDING STRENGTH AND DRIVING DEPTH OF FULL-SCALE SPECIMEN

As a result of visual observation of full-scale test specimens, decay was confirmed in 5 out of 10 specimens. Table 1 shows the bending test results. The average bending strength σ_d of the 5 specimens with decayed parts is 12.2 N/mm^2 (standard deviation 6.3 N/mm^2), and the average bending strength σ_h of the remaining 5 specimens is 16.1 N/mm^2 (standard deviation 2.4 N/mm^2).

Table 1: *A result of the full-scale specimens bending test*

Specimens	P_{max} (kN)	Bending Strength σ (N/mm^2)
Decay_1	7.6	10.3
Decay_2	14.5	19.7
Decay_3	10.3	14.0
Decay_4	1.9	2.6
Decay_5	10.5	14.2
Ave. (S.D.)	**9.0**	**12.2 (6.3)**
C.V.	**52.0**	**51.6**
Sound_1	12.5	16.9
Sound_2	11.3	15.3
Sound_3	10.1	13.7
Sound_4	10.7	14.5
Sound_5	14.6	19.9
Ave. (S.D.)	**11.8**	**16.1 (2.4)**
C.V.	**15.2**	**14.9**

Table 2 shows the Pilodyn measurement results. Figure 9 shows the relationship between the bending strength σ calculated from the results of the full-scale test and the average value of *Pe*, and the regression equation is shown in Equation(5). A strong correlation was found between σ and the average *Pe* (R = 0.887).

$$\sigma = 125.37e^{-0.146Pe} \quad (R^2 = 0.760,\ P < 0.01) \qquad (5)$$

Table 2: *A result of Pilodyn measurement results*

Specimens	Pe_1 (mm)	Pe_2 (mm)	Pe_3 (mm)	Pe_4 (mm)	***Ave.* (mm)**
Decay_1	12.0	40.0	14.0	17.0	**20.8**
Decay_2	11.0	11.0	13.0	13.0	**12.0**
Decay_3	14.0	13.0	16.0	13.0	**14.0**
Decay_4	40.0	23.0	14.0	11.0	**22.0**
Decay_5	13.0	23.0	16.0	14.0	**16.5**
Sound_1	13.0	15.0	17.0	13.0	**14.5**
Sound_2	13.0	14.0	18.0	13.0	**14.5**
Sound_3	12.0	14.0	14.0	13.0	**13.3**
Sound_4	17.0	15.0	18.0	17.0	**16.8**
Sound_5	12.0	13.0	15.0	11.0	**12.8**

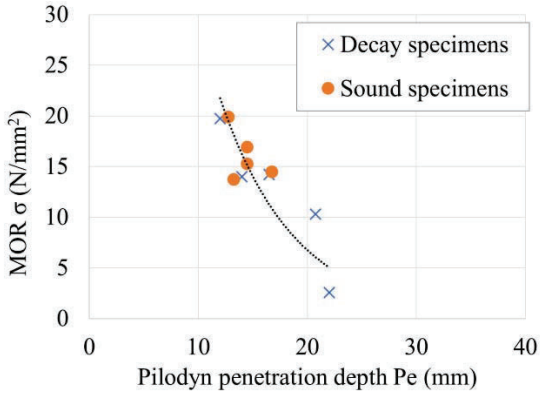

Figure 9: *A relationship between bending strength and Pilodyn penetration depth*

3.2 RELATIONSHIP BETWEEN SECTION MODULUS REDUCTION RATE AND BENDING STRENGTH RETENTION RATE

As a result of observing the butt end of the sample specimen, 224 specimens out of 307 specimens were sound specimens without defects. Table 3 shows the bending test results. The average bending strength σ_0 of the sound body was 56.4 N/mm^2 (standard deviation 12.5 N/mm^2).

The section modulus reduction rate R_d was calculated from the specimen in which defects were observed, and the relationship between the bending strength residual rate R_σ calculated from the bending strength obtained in the test and R_d is shown in Figure 10, and the regression equation is expressed by the Equation(6). A strong negative correlation was observed between R_σ and R_d (R = 0.755).

$$R_\sigma = 1.1015e^{-2.75R_d} \quad (R^2 = 0.565,\ P < 0.01) \qquad (6)$$

https://doi.org/10.52202/069179-0120

Table 3: *A result of the sample specimens bending test*

Specimens	Quantity	Ave. D (mm)	**Ave. σ** (S.D.) (N/mm^2)
Decay	83	3.7	**40.0** (23.3)
Sound	224	0.0	**56.4** (12.5)

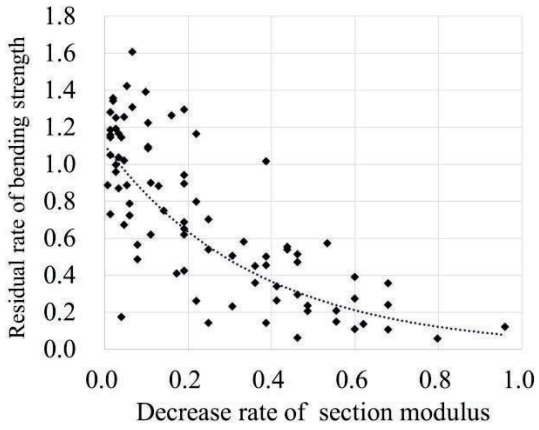

Figure 10: *A relationship between Residual rate of bending strength and decrease rate of section modulus*

3.3 EXAMINATION OF APPROXIMATION METHOD OF RESIDUAL CROSS-SECTIONAL SHAPE

First, Pe_1 to Pe_4 obtained from four points on the circumference of the full-scale specimen were substituted into Equation(4) to estimate the cross-sectional defect depths D_1 to D_4. The section modulus was obtained using the Equation(7) for the circular approximation method and the Equation(8) for the elliptical approximation method, and the section modulus reduction rate was calculated from the Equation(1). R_σ was estimated from the calculated R_d using Equation(6).

$$Z_{CA} = \frac{\pi(r - D_{ave})^3}{4} \quad (7)$$

$$Z_{EA} = \frac{\pi(2r - D_1 - D_3)(2r - D_2 - D_4)^2}{32} \quad (8)$$

Here, r = original cross-sectional radius of the cylindrical material, D_{ave} = average value of D_1 to D_4, D_1 and D_3 are cross-sectional defect depths in the width direction, and D_2 and D_4 are cross-sectional defect depths in the external force direction.

Using the average bending strength σ_h of sound materials, the initial strength σ_0 is assumed to be 16.1 N/mm^2, and the estimated R_σ is substituted into Equation(3) to estimate the bending strength (remaining strength). Figure 11 shows the relationship between the estimated residual strength and the residual strength obtained from the full-scale strength test.

If the circular approximation plot is higher than the elliptical approximation plot, it means that the circular approximation method underestimates the effects of decay. 6 out of 10 specimens corresponded to this, but the remaining 2 out of 4 specimens were clearly underestimated by the elliptical approximation method rather than by the circular approximation method. In the elliptical approximation method, the major axis of the ellipse is in the direction of less decay, and the minor axis is in the direction of more decay, but there are cases in which there is less decay in the direction of applied force. In other words, it is thought that decay was concentrated in the areas perpendicular to the direction of the applied force in these two bodies, and it was found that the elliptical approximation method does not always result in a safer evaluation than the circular approximation method. In addition, almost all approximation methods lead the residual strength from *Pe*, but the estimated value exceeded the measured value. This is because, in the case of cylindrical timbers with heartwood, unlike rectangular sample specimens with small cross-sections, there are areas with high strength on the outside (mature timbers, etc.) [9]. In this case, it is considered that the reduction in strength is greater than the defect thickness estimated from Equation(4).

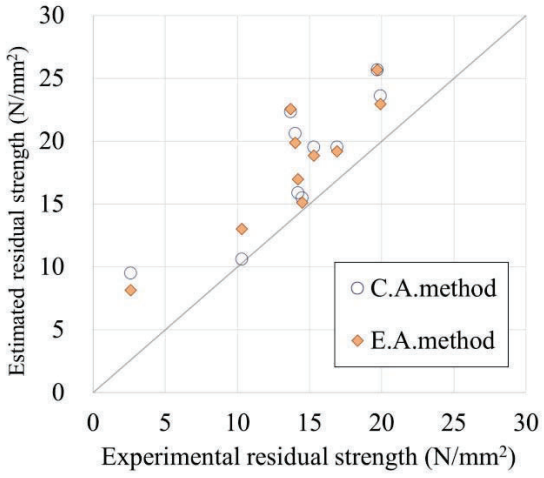

Figure 11: *A relationship between estimated residual strength and experimental residual strength*

4 CONCLUSION

The proposed method for estimating the residual strength by elliptical approximation of the residual cross section is

to calculate the section modulus appropriately from the defect depths estimated by driving Pilodyn, considering the direction of the external force applied to the structure, and to calculate the residual strength against the external force. It is a method to estimate the intensity, and it was found that it is possible to make a sufficient estimation. In this test, the number of subjects was limited to 10, so it was not possible to fully confirm the merits of the elliptical approximation method. However, it is clear that it is a residual strength estimation technique that takes into consideration.

In the future, we would like to recommend the elliptical approximation method by proving the usefulness of the method through the enrichment of empirical data.

We are also considering applying this method to a diagnostic method at the field level. The elliptical approximation method requires calculation of the section modulus once, and is not suitable for diagnosing the state of deterioration immediately on site. Therefore, it is considered preferable to utilize *Pe* directly as a diagnostic parameter while maintaining the concept of the elliptical approximation method, that is, the concept of section modulus. In other words, this is a method of giving weight to *Pe* in the direction of force application for evaluation. For example, *Pe* in the applied direction is squared, and Pe in the orthogonal direction is treated as it is.

If it is possible to derive the relationship between the value calculated by this method and the state of deterioration (for example, residual bending strength, etc.), it will be possible to diagnose the state of deterioration without complicated calculations even at the site level.

ACKNOWLEDGEMENT

This research was carried out by the 2016-2018 Hokkaido Research Organization Priority Research and 2022-2023 Ordinary Research. We received cooperation from the Performance Department of the Forest Products Research Institute and research support staff in preparing sample specimens and assisting in bending tests. I would like to take this opportunity to express my deep gratitude.

In addition, Mr. Kasama, Researcher of the Regional Landscape Unit of the Civil Engineering Research Institute for Cold Region, provided valuable advice on the provision of the site, the provision of the full-scale test specimen, and the construction method. Thank you from the bottom of my heart.

BENDING CHARACTERISTICS OF CLT FROM RECOVERED SPRUCE

Caitríona Uí Chúláin[1], Daniel F. Llana[2], Paul Hogan[3], Patrick McGetrick[4], Annette M. Harte[5]

ABSTRACT: The circular use of construction materials is an essential step in the drive to reduce the environmental impact of the construction sector. Structural materials, such as timber, recovered from demolition of buildings is a valuable resource. Reuse or recycling these materials in new buildings products reduces waste and the overall carbon footprint of the build environment. This paper investigates the use of spruce recovered from demolition of a roof structure in the manufacture of CLT panels. Bending tests are performed on 3-layer panels made from this recovered material and also on panels made from new timber and hybrid panels with mixed new and recovered timber. Results show that the performance of CLT panels using recovered timber is equivalent to that of panels from new timber in terms of bending strength and stiffness.

KEYWORDS: recovered timber, circular construction, mass timber, spruce, Douglas fir, secondary timber, salvaged, reclaimed

1 INTRODUCTION

The construction sector is the largest consumer of raw materials and accounts for about 50% of all extracted materials [1,2] and the built environment is responsible for 25-40% of global carbon emissions [1]. At the same time, the OECD has predicted that the world's consumption of raw materials will more than double over the period 2017-2060 [3] and the construction sector will account for much of this increase.

To address this, policy initiatives aimed at enhancing the sustainability of the construction sector have been introduced as a key priority for Europe. As part of the European Green Deal, the European Commission in 2020 adopted a new Circular Economy Plan [2], which promotes circularity principles throughout the lifecycle of buildings. It is addressing the sustainability performance of construction products through revision of the Construction Product Regulation, including the possible introduction of recycled content requirements for certain construction products and revising material recovery targets set in EU legislation for construction and demolition waste.

As construction and demolition is currently responsible for more than a third of all waste within the EU [4], reuse and recycling of building materials has the potential to significantly reduce this waste and also reduce the carbon footprint of the built environment through extending the life span of building components.

Timber recovered from buildings at the end of life, often referred to as recovered or secondary timber, is a valuable natural resource with significant potential for reuse and recycling. To optimise the environmental benefits of reuse and recycling and support the circular economy, recovered timber should be used in long-life products, such as structural products for buildings. However, in most European countries timber construction and demolition waste is, for the most part, converted into chips for use in energy production with smaller amounts used for particle board or pallet block manufacture and for composting [5-7]. Key factors inhibiting reuse of recovered timber in the manufacture of structural products are the fact that it is currently prohibited by regulations and that grading standards are not available. To support the development of standards on the reuse of timber, further research is necessary concerning the properties of recovered timber and identification and characterisation

of new engineered timber structural products suitable for use of this material.

This work has already begun with a number of European projects focussing on circular use of building materials. The Buildings as Material Banks project (BAMB2020) [8] investigated ways to increase the value of building materials through flexible, circular building design. The CaReWood project [9] introduced an upgrading concept for recovered solid timber as a source of clean and reliable secondary wooden products. In the InFutUReWood project, [10] key problem areas were identified and technical and methodological solutions were proposed to maximise reuse of timber from current buildings especially as a structural material.

The recent growth in interest in timber construction across the globe can be credited not only to the necessity to reuse the embodied carbon of construction materials but also to the development of cross-laminated timber (CLT), which is a high-performance panel product that can displace reinforced concrete and steel in demanding structural applications [11]. CLT was first commercialised in Austria in the 1990s [12] and production in Europe has grown exponentially in the intervening years. While most European CLT is manufactured from Norway spruce, many studies have been carried out to investigate the potential use of locally-grown timber, including lower grade species, for CLT production [13-15]. In the future, it will be challenging to meet the growing demand for timber to produce CLT and other products from the finite supply of new timber from our forests. Supplementing the new timber with suitable material recovered from buildings at the end of life offers a potential solution.

Some recent studies have started to investigate the potential use of recovered timber for CLT production. Llana *et al.* [16] investigated the flexural performance of three-layer CLT panels manufactured using 200-year-old recovered oak. Four different designs were investigated: all new oak, all recovered oak, outer lamina recovered oak with new oak core and outer lamina new oak with recovered oak core. Based on results from tests on three replicates of each design, they found no significant different in the flexural stiffness of the four designs. However, the bending strength of the panels with new oak on the outer layers was about double that of the panels with recovered oak on the outer layers. Rose *et al.* [17] compared the properties of three-layer CLT panels manufactured from recovered mixed-species softwoods with those made from new Scandinavian pine timber. Comparing results from bending tests of three specimens of each type, the modulus of elasticity of the panels made from recovered timber were found to be double that of the panels from new timber. However, the bending strength of the recovered timber panels was only 60% of those from new timber. The fact that 70% of specimens failed at finger joints may have contributed to the difference in strength values.

In a Norwegian study, Stenstad *et al*. [18] used recovered timber with a variety of defects, such as holes, in the cross-layer of three-layer CLT panels. All the boards had their original grade stamps indicate that they were C24. New timber of grade T22 was used in the outer layers. The bending stiffnesses of these panels were found to be the same as those manufactured using new timber in all layers. Arbelaez *et al.* [19] also found similar bending stiffness in 3-layer panels manufactured from new and recovered Douglas fir.

Within the InFutUReWood project [20], the recycling potential of recovered timber in new mass timber products has been investigated. This paper presents results of a study carried out as part of this project to investigate the processing of recovered spruce onto cross-laminated timber panels and to compare their structural performance with equivalent products from new timber.

2 MATERIALS AND METHODS

Norway spruce (*Picea abies* (L.) Karst.) timber boards were recovered from the roof trusses of an office building in Dublin, Ireland. The building was constructed in the 1970s and had been unoccupied for over two years before its demolition. The building was demolished mechanically and materials were sorted at ground level (Figure 1). A sample of 78 boards was recovered, most of which had cross-sectional dimensions of 142 mm x 35 mm. Grade stamps visible on some of the boards indicated that the timber was imported grade TR26 spruce. This timber grade is commonly used in Ireland and the UK for roof trusses. TR26 grade timber has a mean modulus of elasticity in bending of 11000 MPa and a characterisitic bending strength of 28.3 MPa [21].

Using a hand-held moisture meter, the moisture content of the timber boards at the site was estimated to be between 18% and 23%. This high moisture content is attributed to rain penetration of the roof through damaged slates and felt over an extended period of time prior to demolition. Punched metal plates and other metal content were removed on site where possible.

Figure 1: *Recovered timber on site awaiting collection.*

The material was moved to the Timber Engineering Laboratory at the University of Galway where all remaining detectable metal content was removed and it was stored in a conditioning room at 65% relative humidity and 20°C until it reached the equilibrium moisture content.

2.1 NON-DESTRUCTIVE TESTING

Non-destructive testing based on acoustic measurements is widely used for the evaluation of timber mechanical

https://doi.org/10.52202/069179-0121

properties [22]. In this study, non-destructive evaluation of the recovered timber boards was carried out using a handheld acoustic grader (MTG, Brookhuis, Netherlands) to record the longitudinal vibration frequency *f*. The dynamic modulus of elasticity E_{dyn} was then determined using Equation (1), where the density ρ for each board was determined based on measurements of mass and dimensions and *L* is the board length. Values were then adjusted to a reference moisture content of 12% in accordance with EN 14081-2 [23].

$$E_{dyn} = 4\,\rho\, f^2 L^2 \quad (1)$$

For the boards, the adjusted values, $E_{dyn,12,adj}$, ranged between 8000 N/mm^2 and 15000 N/mm^2. To reduce variability between specimens, from the full sample boards with $E_{dyn,12,adj}$ values between 11000 N/mm^2 and 13900 N/mm^2 were selected for the manufacture of CLT panels.

A matching sample of new timber was sourced for manufacturing reference CLT panels and hybrid panels. As Irish-grown spruce is normally graded to C16, its properties are not equivalent to TR26 material and so it deemed unsuitable as reference new timber. The most suitable available material was Irish grown Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco). Based on acoustic measurements of 101 new boards, a batch of timber boards with $E_{dyn,12,adj}$ values between 10600 N/mm^2 and 14600 N/mm^2 was chosen for processing into CLT panels. The nominal cross-section of these boards was 110 mm x 45 mm.

2.2 CLT MANUFACTURE AND TESTING

Three-layer 60 mm thick CLT panels were manufactured using recovered and new timber, as shown in Figure 2. Three different material combinations were used: recovered timber in all layers, new timber in all layers, and hybrid with new timber in top and bottom layers and recovered timber in the core. Three panels of each material combination were manufactured for testing. All boards were planed to a final cross-section of 90 mm x 20 mm. Additional nails that had not previously been detected in the recovered timber were removed at this stage. Panels were bonded using a one-component polyurethane adhesive using a pressure of 0.6 MPa for a minimum of 2 hours. The adhesive selection and processing parameters were based on previous studies carried out in the University of Galway using new spruce timber [24, 25]. The final panel dimensions were 1620 mm x 360 mm.

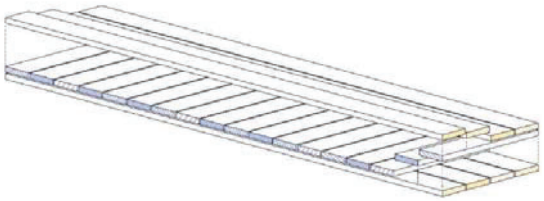

Figure 2: *60 mm x 360 mm x 1620 mm three-layer CLT panel*

All panels were conditioned at 65% relative humidity and 20°C prior to testing in out-of-plane bending in accordance with EN408 [26] and EN 16351 [27]. The four-point bending tests were carried out over a span of 1560 mm (equivalent to 26 times the depth *h*) with the load heads spaced at 6*h*. Global deflection of the panels was measured at each edge at midspan using two 100 mm linear variable differential transformers (LVDTs).

The global modulus of elasticity was calculated from Equation (2) [adapted from EN 408 [26] 10.3 Equation (2)].

$$E_{m,g}\, I = \frac{3al^2 - 4a^3}{24\left(2\frac{w_2 - w_1}{F_2 - F_1} - \frac{6a}{5Gbh}\right)} \quad (2)$$

where l, b, h , in mm, represent the span, panel width, and depth, respectively. The mean shear modulus *G* is taken as 650 N/mm^2 in accordance with EN 408 [26] and EN 16351 [27].

The bending strength was calculated using Equation (3)

$$f_m = \frac{F_{max}\, a h}{4\, I_{tr}} \quad (3)$$

where F_{max} is the failure load, I_{tr} is the transformed second moment of area and other terms are as defined above and in EN 408 [26].

3 RESULTS AND DISCUSSION

3.1 LOAD-DISPLACEMENT RESPONSE

The load-displacement response of the recovered, new and hybrid CLT panels are presented in Figures 3, 4, and 5, respectively. The displacement in each case is the average of the displacement measurements from the two LVDTs mounted at the panel edges.

Similar linear responses until close to failure are seen in each panel type.

https://doi.org/10.52202/069179-0121

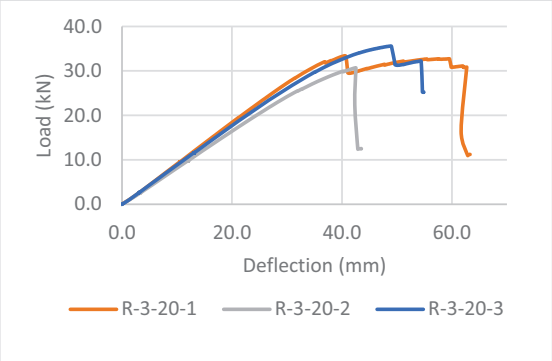

Figure 3: *Load-deflection response – recovered timber panels*

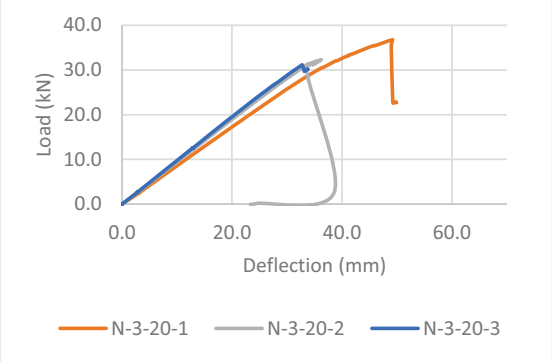

Figure 4: *Load-deflection response – new timber panels*

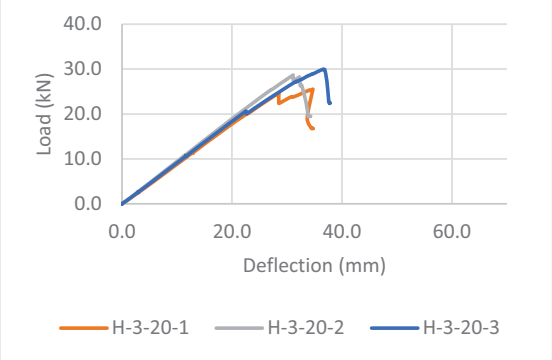

Figure 5: *Load-deflection response – hybrid timber panels*

All panels failed in bending, which initiated at the location of a knot or large slope of grain on the underside of the panel and then propagated through the thickness of the panel as seen in Figure 6.

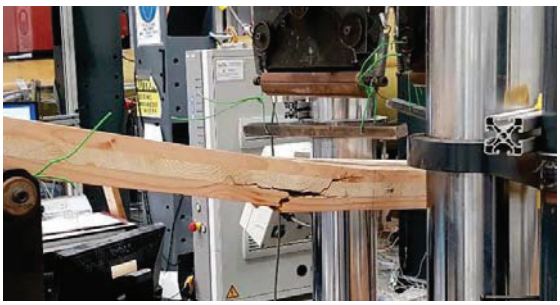

Figure 6: *Bending failure of hybrid CLT panel*

3.2 MODULUS OF ELASTICITY

The mean global modulus of elasticity and bending strength for each test series together with the coefficients of variation are given in Table 1. The mean modulus of elasticity was 10300 N/mm^2, 10900 N/mm^2 and 10800 N/mm^2 for the recovered, new and hybrid panels, respectively. There is no significant difference between the means of each group as can be observed visually in Figure 7. This is to be expected as the panels were manufactured with timber boards with similar dynamic modulus of elasticity values. This finding is consistent with other studies [16, 18, 19].

As the modulus of elasticity values of the CLT panels are consistent with the modulus of elasticity of the boards used in their manufacture, it indicates that the bonding of the layers was successful for both recovered and new timber.

Table 1: *Bending test results*

Panel type	Panel #	$E_{m,g}$ N/mm^2	f_m N/mm^2
Recovered	R-3-20-1	10900	50
	R-3-20-2	9700	46
	R-3-20-3	10420	53
	Mean	*10300*	*49*
	COV %	*5.9*	*7.5*
New	N-3-20-1	10100	55
	N-3-20-2	11100	48
	N-3-20-3	11400	46
	Mean	*10900*	*50*
	COV %	*6.1*	*8.7*
Hybrid	H-3-20-1	10500	38
	H-3-20-2	11100	43
	H-3-20-3	10800	45
	Mean	*10800*	*42*
	COV %	*2.8*	*8.2*

https://doi.org/10.52202/069179-0121

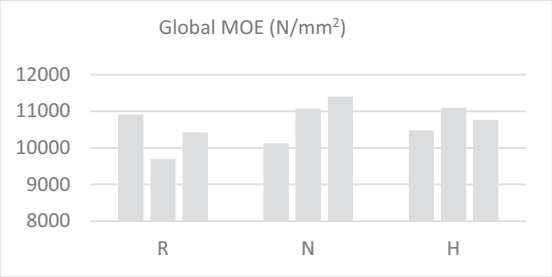

Figure 7: *Global Modulus of elasticity – all panels*

3.3 BENDING STRENGTH

The mean bending strength was 49 N/mm^2, 50 N/mm^2 and 42 N/mm^2 for the recovered, new and hybrid panels, respectively (Table 1), with low coefficients of variation in the range 7.5%-8.7%. The strength values for the hybrid panels were consistently lower than those of the recovered and new panels (Figure 8). There was no obvious reason for this detected during testing. However, as only three panels were tested in each series and significant variability is expected in timber strength due to the influence of features such as knots, these differences in strength values may not be significant.

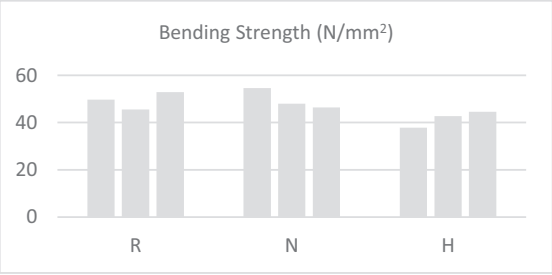

Figure 8: *Bending strength – all panels*

This finding is different to that reported by Rose *et al.* [17] who reported a 60% lower bending strength for recovered softwood panels compared to new panels. These panels had a different failure mode to the current study which may be a factor in the different outcomes. For hardwoods, Llana *et al.* [16] recorded a 50% reduction in bending strength for panels using recovered oak compared to those made from new oak. Kránitz *et al.* [28] in their extensive literature review on the effects of aging on wood, reported a decrease in bending strength for hardwoods. However, this review indicated that for softwoods there was no difference in the bending strength between new and wood up to 400 years old. For the present study, the age of the recovered timber was about 50 years so no deterioration would be expected based on the conclusions of five different studies.

While bending strength and stiffness do not appear to be adversely affected by being under load for 50 years, other properties need to be investigated. Kránitz *et al.* [28] reported an increase in brittleness, which may affect the properties perpendicular to the grain.

4. YIELD OF CLT

Regarding the yield from the recovered timber, the recovered timber cross-section (142 x 35 mm^2) was significantly larger than the board dimensions required for panel manufacture (90 x 20 mm^2) and this resulted in a yield of about 28% when length reductions are included. The yield would be greatly increased if recovered timber dimensions closer to the final board dimension were available. For example, using 130 mm x 30 mm boards to produce a 90 mm thick panel would have increased the yield to 70%. The commercial availability of recovered timber in a range of sizes close to those required for panel manufacture will be necessary to ensure efficient reuse of the material.

5. CONCLUSIONS

Spruce members were recovered from the demolition of a timber roof truss that had been under load for about 50 years and which was exposed high relative humidity during its later years. A sample of new timber with a similar range of dynamic modulus of elasticity values was source. CLT panels of three different designs were successfully manufactured and tested in bending from this material. These included panels made entirely from recovered timber, panels from new timber and hybrid panels with new timber in the outer layer and recovered timber in the cross-layer. Overall, this study has found no difference in the mechanical properties in bending of CLT manufactured from recovered and new softwood timber.

While these results are very positive, it should be borne in mind that the number of specimens tested was small and used recovered timber from a single source. Further testing of panels manufactured from a wide range of sources is recommended to confirm these findings.

In terms of yield, mass timber products are a good option for recycling of recovered timber subject to availability of boards with cross-sections close to the final size required.

ACKNOWLEDGEMENTS

This work was carried out in Ireland as part of the InFutUReWood project supported under the umbrella of ERA-NET Cofund ForestValue by the Department of Agriculture, Food and the Marine. ForestValue has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 773324.

The authors would like to acknowledge the contribution of Colm Walsh and Peter Fahy, senior technical officers in the School of Engineering, University of Galway, for their assistance with the laboratory test programme.

COMPARISON OF ENERGY EFFICIENCY BETWEEN WOODEN-BASED HYBRID STRUCTURE SYSTEM AND RC STRUCTURE SYSTEM IN SUBTROPICAL AND TROPICAL AREA

Cheng-Chieh Hsu [1], Meng-Ting Tsai [2], Shao-Chi Wu [3]

ABSTRACT: In response to the environmental problems of global warming, the need to save energy and carbon emissions, the energy usage in building sector accounts for 40% of global energy consumption, and its greenhouse gas emissions account for more than three-thirds of its global emissions. It is the largest source of emissions in most countries. However, previous research has mostly focused on comparing the energy-saving efficiency between wooden and RC structures in high-latitude regions, energy-saving efficiency between wooden and RC structures in low-latitude regions, especially in sub-tropical or tropical area in Asia, has not been focused. In this study, in order to examine the energy consumption differences in sub-tropic and tropic area, the energy consumptions in Taipei, Kaohsiung, Hochimin City and Singapore were compared. Moreover, considering the common-used construction materials in buildings in the selected Asian cities, hybrid structure system comprises RC beams/columns and various floors and walls system such as brick, wood and so on was used for the comparison. Simulation method was used to compare the energy efficiency of the four-story and ten-story wooden structures, RC structures, and other types of hybrid system focusing on the usage phase of the building in this study. The research method is to establish a simulation model based on the literature review to set the basic building parameters for analysis. The software called Green Building Studio in Revit was used to simulate the energy consumption in different types of buildings. The carbon emission was calculated to compare the difference in energy efficiency between different structures. Moreover, the combination of different wooden based structural system which was influenced by the energy consumption was evaluated as well, in order to understand the advantage of applying wooden components. The results of the study show that, the use of CLT in four-story and ten-story buildings has a common energy-saving trend in the energy consumption. For the hybrid structural system, the average energy saving are up to 7.49% to 8.12%, depending on the different types of wooden based hybrid system, when the numbers of the original RC buildings were replaced by wooden buildings.

KEYWORDS: Wood structure, RC structure, building energy use, building energy simulation

1 INTRODUCTION

Due to the environmental problems caused by global warming, energy consumption and carbon emissions must be reduced. The building density in an area rapidly increases with increasing population. A report of the United Nations Environment Program indicates that the energy consumption of the construction sector accounts for 40% of the global energy consumption. In addition, the greenhouse gas emissions of the construction sector account for over 33% of the total global emissions, and the construction sector is considered the largest emission source. Consequently, to reduce their environmental impact, construction-related industries should aim to reduce their energy consumption and carbon dioxide emissions in the usage stage of the building life cycle.

Wood construction is becoming increasingly popular internationally, and various new types of wooden building materials and wood construction methods are constantly emerging. From the environmental perspective, wooden structures are favorable insulators that are suitable for carbon fixation. The thermal conductivity of concrete is 1.4 w/m·k, which is 10 times the conductivity of wood. In this study, in order to examine the energy consumption differences in sub-tropic and tropic area, the energy consumptions in Taipei, Kaohsiung, Hochimin City and Singapore were compared. Moreover, considering the common-used construction materials in buildings in the selected Asian cities, hybrid structure system comprises RC beams/columns and various floors and walls system such as brick, wood and so on was used for the comparison. The amounts of the carbon emission was calculated to compare the difference in energy efficiency between different structure systems. Moreover, the power reserve capacity (rate) in the power station which was influenced by the energy consumption was evaluated as well, in order to understand the advantage of applying wooden components in to the wooden-based hybrid structure system in tropical and subtropical area.

2 METHODOLOGY

2.1 ASSESSMENT OF ENERGY CONSUMPTION

Autodesk Green Building-rating System (GBS) was used for simulating the structure energy consumption in this study. GBS can be used as an independent cloud-service-based program or a plug-in component of the Revit program for energy analysis. GBS comprises the DOE-2.2 analysis core and can provide extremely detailed analysis. As a cloud-based tool, GBS can facilitate rapid computation on the Autodesk server. In general, the DOE-2.2 analysis core requires extremely detailed information on the building envelope and electromechanical system for computation. However, GBS presets numerous building envelope and electromechanical system parameters according to the ASHRAE standard. Thus, architects can focus more on the design factors that have decisive influences on the overall energy consumption of buildings and can ignore technical details. In addition to the building energy consumption, electricity consumption, and annual carbon emissions, GBS can calculate the Energy Star score of buildings. It can also evaluate the glass property and water usage efficiency scores according to the LEED evaluation system published by the U.S. Green Building Council. GBS can even determine the solar energy usage potential.

2.2 ASSESSMENT OF CO2 EMISSION

The Guidelines for National Greenhouse Gas Inventories published by the Intergovernmental Panel on Climate Change were used for the assessment of carbon dioxide emissions. In this study, the calculation method for the emissions of carbon dioxide, methane, and nitrous oxide was adopted to calculate the carbon emissions of different countries. GBS calculates the energy consumption of buildings according to two major parameters: electricity consumption and fuel consumption. The calculated carbon emission of electricity consumption differs according to the electricity carbon emission coefficients of different countries. The carbon emissions can be calculated using equation (1). The emission coefficients of different countries are listed in Table 1. For calculating the carbon emission of fuel consumption, the fuel volume (m3) is first converted into energy units. An energy of 38 MJ or 10.6 kWh can be generated by burning 1 m3 of natural gas. The carbon emission of fuel consumption can then be calculated using equation 2. The carbon emissions coefficient of fuel is listed in Table 2, and all the compared countries have the same carbon emissions coefficient of fuel. The carbon emissions of the total energy consumption of a building can be obtained by summing the carbon emissions of electricity and fuel.

(A) Electricity consumption is converted into carbon emissions by using the following formula:
Electricity usage (kWh) × electricity emissions coefficient (kg CO_2e/kWh) = carbon dioxide emissions(kg) (1)

(B) Fuel consumption is converted into carbon emissions by using the following equation:
Fuel usage (m^3) × natural gas emissions coefficient (kg CO_2e/m^3) = carbon dioxide emissions (kg) (2)

(C) The carbon emission of total energy consumption is calculated as follows:
Carbon emission of total energy consumption (kg)
= equation (1) + (2) (3)

3 SIMULATION MODELING

To determine the energy usage efficiencies under different conditions, the energy consumption and carbon emission were compared for different numbers of stories (4 and 10), different construction materials (RC and CLT), and cities with different latitudes (from north to south, Taipei, Kaohsiung, Hochimin City and Singapore). The related structure usage situations and air admission timing of the air-conditioning system were set. In addition, the energy simulation was only conducted for the daily usage stage in the structure life cycle. When GBS was used for structure energy simulation, the basic settings, simulation parameters, weather data, electromechanical system, indoor load, and operation schedules had to be input in the simulation process. The basic parameters and settings of this study are as follows:

1. According to the descriptions on the official website of Autodesk, the data on weather stations were obtained from the World Meteorological Organization.
2. For concrete materials, the pre-existing data in the program were used. The parameters of CLT walls were obtained from relevant research.
3. For the electromechanical system and indoor load, detailed data were required from the DOE-2.2 analysis core to the electromechanical system for the operation. However, the building envelope and electromechanical system parameters were preset in GBS according to the ASHRAE standards. Different air-conditioning systems are used in different countries. The preset parameters were used for the mechanical system and indoor load in this study. The preset parameters of heating, ventilation, and air-conditioning (HVAC) systems were a central variable air volume system, hot-water heating, a performance coefficient of 5.96 for the freezer, and a boiler efficiency of 84.5.

Because this study was a preliminary study, a 24/7 operation schedule was set. Thus, simulations were conducted 7 days a week and 24 hours a day. Then, GBS was used to analyze the simulated building energy consumption. In the comparison of the energy consumptions of different building materials (RC and CLT) in cities at different latitudes, only the energy consumption in the operation stage was considered. In

https://doi.org/10.52202/069179-0122

addition, the following assumptions were made in the simulation process for the energy consumption:
(1) The window positions remained the same when switching from an RC structure to a CLT structure; thus, the illumination demands remained the same.
(2) Except for the balcony, the indoor temperatures of all the rooms were controlled between 18 and 26 °C.
(3) No heating or cooling was conducted in the stair areas.
(4) Electricity was used for the air-conditioning system and illumination, and fuel was used for heating.

3.1 TARGET BUILDING

To determine the energy usage efficiencies for different numbers of stories and different weather conditions, the standard floor of social housing in Taipei City was used as the standard floor in this study. The layouts and basic information of a four-story building and a 10-story building are listed in Table 3.

3.2 BUILDING MATERIALS

The influence of the floor height on the energy-saving efficiency was examined. In addition, the energy consumption efficiencies of the RC and wooden-based hybrid structures were compared. In this study, only the energy consumption in the daily life stage of the building was examined. The simulated building was an RC structure with fixed floor plans on different floors, the building height, building direction, total area, and opening such as windows and doors were fixed for the building simulation. The layout and the structure of the other types of buildings follow the RC structure, which was the target building, however, the material of structures floors and walls, was replaced with wooden components. The building types are illustrated and as shown in Fig 2.

Table 1. Electricity carbon emission coefficients of different countries.

Country	Electricity carbon emission coefficient (kg CO2e/kWh)
Taiwan (Taipei/Kaohisung)	0.53
Vietnam (Hochumin City)	0.57
Singapore	0.41

The physical properties of RC and CLT, including their heat transfer coefficient, specific heat, and density, were also determine for complete analysis. As presented in Table 4, RC has a higher heat transfer coefficient, specific heat, and density than CLT does. Thermal resistance and heat loss are inversely correlated. Thus, an increase in the thermal resistance of the wall material between the interior and exterior of a building can reduce the heat loss of the building (equation 4). As presented in Table 4, CLT walls have a higher thermal resistance than RC walls do. The thermal resistance of a 300-mm-thick external CLT wall is up to 3.3 m2·K/W. The thermal resistance of a 300-mm-thick RC external wall is only 0.25 m2·K/W, which is approximately 1/13th the thermal resistance of a 300-mm-thick CLT external wall. Table 5 lists the physical properties of RC and CLT walls of different thicknesses. Fig. 2 displays the models of numerical analysis. Four- and Ten-story CLT and RC buildings were constructed for comparing the energy consumptions in their daily life stages.

$$\text{Heat loss} = (A/R) \times (T_{indoor} - T_{outdoor}) \quad (4)$$

A : external surface area of the building
R : thermal resistance (R value)
T_{indoor}: indoor air temperature
$T_{outdoor}$: outdoor air temperature

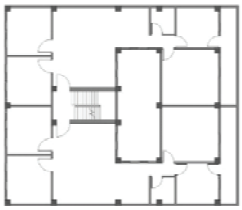
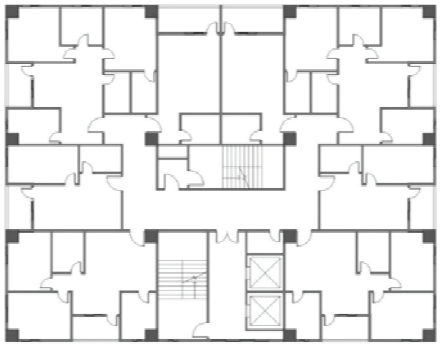
3.3 CITIES IN SUB- AND TROPICAL AREA

Cities at different latitudes have different climates, which influence the energy consumption of buildings. The climate includes the highest and lowest outdoor temperatures and humidity.



(a) 4-story building



(a) 10-story building

(b) Analysis models of the 10-story RC and CLT structures.

Fig. 3. Simulation modelling.

In this study, the energy consumptions of buildings in cities at different latitudes were also simulated to determine how the overall energy usage efficiency varied with the latitude. The latitude of Taipei was selected as the standard. The other cities selected for comparison were Tokyo and Harbin, which are located to the north of Taipei, as well as Singapore, which is located close to the equator and to the south of Taipei. These cities were selected for comparing the energy-saving efficiencies of RC and CLT buildings of different heights in different environmental conditions. The monthly average temperatures of the aforementioned cities in 2021 are presented in Fig. 4. The lowest monthly average temperature in Taipei, which is located at a high latitude of subtropical zone, was 17.7 °C in January, and the highest monthly average temperature in Taipei was 30.6 °C in July. Thus, the largest monthly average temperature difference was approximately13 °C in Taipei. The lowest monthly average temperatures in Singapore, which is located at a low latitude, near Equator, were 27 °C in December, and the highest monthly average temperatures in Singapore were 29 °C in August and September, respectively. The highest monthly average temperature difference in Singapore was only 2 °C. The highest monthly average temperatures of Kaohisung and Hochimin City, which are located inbetween the tropical zone, were 28.6 °C in August and 30.6 °C in April, respectively. These temperatures were comparable to the high temperatures in Singapore, which is located in the tropics as shown in Fig. 4 and Fig. 5.

4 RESULT AND DISCUSSION

4.1 ENERGY CONSUMPTION

In the simulation, electricity was used by the HVAC system, illumination equipment, and other equipment. Fuel was used by the HVAC and domestic water heating systems. Table 6 presents the simulation results for the 4- and 10-story building made of different building materials and located in cities at different latitudes.

Taking10-story building in Taipei for example, which is located at the highest latitude among the considered cities, the annual electricity consumptions of the RC and CLT structures were 157 and 151 kWh/m^2, respectively. For Singapore, which is at the lowest latitude, the annual electricity consumptions of the RC and CLT buildings were 202 and 190 kWh/m^2, respectively. For both 4- and 10-story building, the simulation results indicated that the electricity consumption of RC buildings was considerably higher than that of CLT structures at higher and lower latitudes. However, at low latitudes, the difference in the electricity consumptions of RC and CLT buildings was relatively higher. The different trend was observed for the fuel energy usage though. Overall, the energy-saving efficiencies of CLT buildings were higher than those of RC structures. The differences in the energy-saving efficiencies considering both electricity and fuel of CLT and RC buildings were higher at higher latitudes.

A comparison of the total energy consumptions of RC and CLT buildings is presented in Table 6 as well. For four-story buildings, the total energy consumptions of the CLT buildings were approximately 98.7%, 99.6%, and 98.7% those of the RC buildings in Kaohsiung, Hochimin City, and Singapore, respectively. No significant difference was observed in the total energy consumptions of the four-story CLT and RC buildings in these cities. Greater difference of the total energy consumptions of RC and CLT buildings is observed in Taipei, which is approximately 89.6% difference. For 10-story buildings, the total energy consumptions of the CLT buildings were approximately 95.9%, 97.3%, and 96.1% those of the RC buildings in Kaohsiung, Hochimin City, and Singapore, respectively. For Taipei, the difference between the total energy consumptions of the 10-story CLT Buildings and RC buildings was marginally higher than that of the four-story CLT and RC structures, which is 88.8% of the difference.

4.2 CO2 EMISSION

Table 7 presents the carbon dioxide emissions per unit area for 4- and 10-story RC and CLT structures in cities at different latitudes. The carbon emissions of electricity energy consumption mainly originate from air-conditioning systems, illumination systems, and basic facilities of the structure. The carbon emissions of fuel energy consumption mainly originate from the use of heating systems. Electricity carbon emissions were calculated according to the electricity emission coefficients of the countries in which the considered cities are located (Tables 1 and 2). Thus, the carbon emissions from the same electricity energy consumption were different in different countries.

The electricity carbon emissions of four-story RC and CLT buildings were 95 and 93 kg/m^2·yr, respectively, in Taipei; thus, the difference in the electricity carbon emissions of the two types of four-story structures was only 2 kg/m^2·yr in Taipei. In Singapore, the electricity carbon emissions of four-story RC and CLT buildings were 157 and 153 kg/m^2·yr, respectively, which represents an electricity carbon emission difference of 4 kg/m^2·yr. The difference in carbon emissions was small because the monthly average temperature in every month

https://doi.org/10.52202/069179-0122

in Singapore was higher than 26 °C, which was the temperature set in this study for the air-conditioning system to be turned on. The air-conditioning system demands were high. Thus, the demands for carbon emissions from electricity energy consumption were high for both RC and CLT buildings. For Taipei, in addition to the air-conditioning system demands, the heating system demands were slightly high. The carbon emissions of fuel energy consumption for four-story RC and CLT buildings in Taipei were 38 and 30 kg/m^2·yr, respectively, which represents a fuel carbon emission difference of 8 kg/m^2·yr. In Singapore, the fuel carbon emissions of four-story RC and CLT buildings were both 19 kg/m^2·yr. In cities at higher latitudes, the heating system needs were higher. Thus, the fuel carbon emissions and fuel carbon emission differences increased considerably with the latitude. Table 7 indicate that the 10-story buildings had better carbon emission reduction effects to those of the four-story buildings for electricity and fuel energy consumption. For regions at higher latitudes (Taipei), the differences in electricity carbon emissions of 10- and 4-story structures were not significant. However, the carbon emissions reduction efficiencies of buildings with more stories could be shown in the differences of fuel carbon emissions. Thus, greater differences were observed in the carbon emissions of total energy consumption for RC and CLT buildings in Taipei and Singapore for 10 story building.

4.3 HYBRID BUILDING SYSTEM

The results of this study indicate that CLT buildings have higher energy-saving and carbon reduction efficiencies than RC buildings do at different latitudes. These efficiencies increase with the number of floors. Moreover, the differences in the energy consumption efficiencies of CLT and RC buildings increase with the latitude. All the East Asian cities selected in this study have high degrees of urbanization and concentrated high-rise buildings. The existing high-rise buildings in these cites face the problem of aging. For example, in Taipei, most buildings are RC structures that are approximately 30–50 years old. These structures are still usable; however, their overall energy consumption is high because of the RC building material. Consequently, in this study, few strategies are proposed for the renewal of these buildings in the future. The proposed strategy involves preserving existing RC beam structures and renewing the floors and walls with CLT for renovation type 1. Replacing the top 4 floors of the building with wooden system is the renovation type 2 in this study. For renovation type 3, the original service core with RC as major construction material is preserved, while the rest of the living space is replaced by wooden construction. On the basis of this concept, three wooden based hybrid building systems are defined, and the analysis model was established in this study. Fig. 6 illustrates the models of preserving the RC beam structures and replacing the floors and walls with CLT, replacing the top 4 floors of the building with wooden system, and the original service core with RC as major construction material is preserved. The energy consumptions of CLT and RC structures of the same size were also compared. The analysis and simulation conditions were the same as stated previously as shown in Section 3. The simulation results are concluded and as shown in the next section.

4.4 SIMULATION RESULTS FOR HYBRID BUILDING SYSTEMS

The analysis results presented in Table 8 indicate that 3 types of different hybrid buildings have better electricity energy consumption performance to the RC structure. The electricity energy consumption performance of the hybrid buildings is only marginally worse (3%–7% lower) than that of the CLT buildings. Thus, the proposed hybrid buildings are close to the CLT buildings in terms of electricity energy consumption. For fuel energy consumption, no significant difference was observed between the different building in Singapore and Hochimin City and Kaohsiung, which is located at a lower latitude. In Taipei, which are located at relatively higher latitudes, the fuel energy consumption of the hybrid buildings is higher than that of the RC buildings and not significantly different from that of the CLT buildings. The CLT and wooden based hybrid buildings exhibited no significant difference in their total energy consumptions. The aforementioned buildings exhibited lower total energy consumptions than the RC buildings did. The energy-saving efficiency of the proposed wooden hybrid structure system, which comprises RC beam structures and CLT floors and walls for hybrid type 1, replacing the top 4 floors of the building with wooden system for hybrid type 2, and original service core with RC as major construction material preserved for hybrid type 3, are close to that of CLT buildings. The advantage of the hybrid building system is obvious if the weight of the material is compared. The total building weight is potentially reduced if part of the building material is replaced from reinforced concrete to wood, due to the light weight property for wood comparing to concrete. In the region with high frequent earthquake, especially in Taipei or Kaohsiung, the reduction of building weight means the seismic force can be potentially reduced, improving the resilience of the building.

5 CONCLUSIONS

In this study, the differences of energy consumption and carbon emission at sub-tropical and tropical area such as Taipei, Kaohsiung, Hochimin City and Singapore, were compared. The preliminary study clarified that the energy-saving efficiency is higher in the cities in the higher latitude when the construction materials are substituted from RC structure to CLT structure. Generally, the performance of wooden buildings is better than RC buildings and the following results are conclude.

(1) For 10-story buildings, the total energy consumptions of the CLT buildings were approximately 95.9%, 97.3%, and 96.1% those of the RC buildings in Kaohsiung, Hochimin City, and Singapore, respectively. For Taipei, the difference between the total energy consumptions of the 10-story CLT Buildings and RC buildings was marginally higher than that of the four-story CLT and RC structures, which is 88.8% of the difference. For cities located in Subtropical area such as Taipei, archiving a better energy consumption efficiency than the cities located in tropical cities, such as Kaohsiung, Hochimin City, or Singapore.

(2) The greater differences were observed in the carbon emissions of total energy consumption for RC and CLT buildings in Taipei and Singapore for 10 story building, indicating that the 10-story buildings had better carbon emission reduction effects to those of the 4-story buildings for electricity and fuel energy consumption.

(3) The electricity energy consumption performance of the hybrid buildings is only marginally worse (3%–7% lower) than that of the CLT buildings, indicating the energy-saving efficiency of the proposed wooden hybrid structure system, which comprises RC beam structures and CLT floors and walls for hybrid type 1, replacing the top 4 floors of the building with wooden system for hybrid type 2, and original service core with RC as major construction material preserved for hybrid type 3, are close to that of CLT buildings. Thus, it is understood that the proposed hybrid buildings are close to the CLT buildings in terms of total energy consumption.

In conclusion, the proposed hybrid building system, which comprises RC beams, columns and CLT floors and walls, replacing the top 4 floors of the building with wooden system, and original service core with RC as major construction material preserved have less building weight compared to the original RC building, and less energy required for the manufacturing of building materials in the renovation of the aged building, has an energy-saving efficiency close to that of a CLT building. For the cities selected in this study, the proposed hybrid building systems can be effectively used for old building renewal.

ENVIRONMENTAL PERFORMANCE OF NEXT-GENERATION TIMBER SCHOOLS FOR CLIMATE ACTION: A SIMULATION APPROACH

Ramit Debnath[1], Antiopi Koronaki[1*], Dario Marino[1], Yiping Meng[1], Darshil U. Shah[1], Peter Hazzard[2], Simon Smith[3], Kirsten Haggart[4], Michael H. Ramage[1]

ABSTRACT: As the global response to climate change intensifies, timber buildings will play an essential role in reducing carbon emissions from the built environment. This study provides a simulation-driven approach to estimating the environmental performance of timber buildings. In doing so, we present a case study of the UK's next generation of timber school buildings, the New Model School (NMS-timber). We perform a sensitivity analysis of the timber school building to concrete construction (NMS-concrete). The methodology involves an environmental performance estimation of the two building cases' operational energy and thermal comfort characteristics. The results show that NMS-timber has an annual energy usage intensity (EUI) of ~132kW/m^2 and ~146kW/m^2 for NMS-concrete, demonstrating a ~9.6% more energy efficiency per square metre for the timber building. We also find that the timber school building will save ~34.30% heating energy compared to the concrete construction while almost eliminating the cooling energy needs. We conclude that the NMS-timber can offer significantly better environmental performance to concrete buildings. When applied in early stages of the design development, the digital workflow presented promotes informed decisions during the project development stages and enhances the construction of energy-efficient structures.

1 INTRODUCTION

With the building and construction sector contributing around 38% of global carbon dioxide emissions [1], natural materials like timber and advancements in their structural applications have been at the forefront of decarbonising the embodied emissions of the built environment [2]–[4]. However, there are several policy and operational challenges to integrating engineered timber structures in the current built environment which hinder the seamless collaboration and material flow across the supply chain [5].

This study contributes to current discussions on the suitability of engineered timber in decarbonisation of the built environment with a focus on school buildings. The significant shortage of school places in the UK and the government's commitment to deliver a platform for low-carbon schools highlight the importance of reducing their embodied and operational emissions [6, 7]. This study explores the potential of engineered timber to address this challenge by evaluating a timber school case-study using environmental performance analysis metrics. In doing so, the novel aspect of this study is the data-driven and computational simulation-based approach that compares the energy-use demand, environmental characteristics, and occupancy-based optimisation of spaces in a proposed timber building in the UK.

This paper generates a comparative basis for engineered timber buildings like schools with their concrete counterparts. The main objectives of this research are, first, to establish a simulation-driven comparative basis for evaluating the environmental performance of engineered timber buildings and enable its reproducibility for architects, designers, policymakers, and researchers, thus contributing a critical step towards developing a digital twin model of timber buildings. Second, to evaluate characteristic environmental factors that differentiate timber schools from existing concrete schools. When carried out in early stages of the design development, such studies promote informed design decisions and the construction of energy-efficient structures.

2 CONTEXT

The case-study analysed in this paper is the New Model School (NMS), a modular engineered timber school building designed as an extension to the Fawcett Primary state school in Cambridge, UK. The existing school is a concrete structure including teaching spaces, a dining hall, sport facilities, offices, and services. The New Model

https://doi.org/10.52202/069179-0123

School (NMS) extension was developed in collaboration between academia and industry, aiming to demonstrate the potential of a modular kit-of-parts of engineered

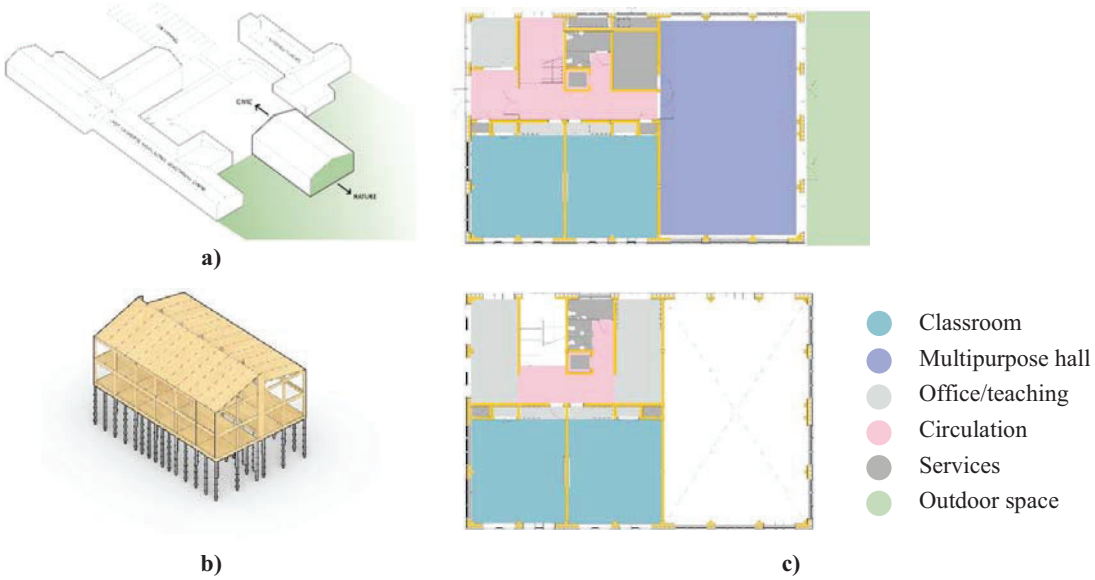

Figure 1: *a) The proposed two-storey engineered timber school extension and its relationship with the existing school building on site. b) The structure of the New Model School, made from engineered timber components. c) Programme distribution on the two storeys.*

timber [8]. The goal of the project was to develop a set of building components that can be combined to create healthy indoor environments and that can then be fully demounted and reconfigured to address a diverse set of programmes and scales. The NMS building is an extension to the existing primary school and has received approval from planning.

The NMS forms a stand-alone two-storey structure of 660m^2 and its design is based on a repeatable grid of size *ca* 56m^2 that meets the spatial and programmatic requirements for primary schools according to the Department for Education, as shown in Fig. 1 [9]. It is a lightweight glulam frame-based structure with composite CLT and ribbed glulam beam components for the roof and first floor slabs. The substructure uses a suspended softwood timber cassette sat atop glulam ground beams supported on recycled steel screw piles. The façade is made of modular insulated timber panels, while a vertical service wall traverses the building and incorporates natural ventilation shafts and service risers.

3 METHODOLOGY

The aim of this study is to assess the impact of the building envelope on the environmental performance of school buildings. The New Model School is used as a case-study and by maintaining the building orientation, programme, and openings identical, we generate two digital models of the school: one using the proposed engineered timber structure and envelope of the New Model School (*NMS-timber*) and one using the conventional construction of the existing school building with a concrete structural frame and brick infill walls (*NMS-concrete*). Since the focus of this study is placed on the impact of the building envelope, the two structural systems are applied interchangeably, without accounting for potential changes in the sizing and configuration of structural elements.

We adopt a simulation-driven methodology to evaluate and compare the environmental performance of the two school models. The simulation has three main components. First, setting up the site parameters and calibrating with climatic parameters; second, setting up the building parameters; third, setting up the energy simulation parameters to evaluate annual thermal comfort variations in the NMS using two variables: operating temperature and mean radiant temperature. These act as guides to assess the thermal comfort of users within the space. Finally, we estimate and compare the annual energy use intensity (EUI, kW/m^2) for heating and cooling demands in the NMS-timber and NMS-concrete, which provide an insight to the operational energy required.

3.1 SITE AND CLIMATE

The historical climate data is accessed from University of Cambridge's Digital Technology Group [10] and diurnal weather data from Cambridge Airport's weather monitoring station [11]. The actual NMS-site is within a 5km radius from these data locations.

https://doi.org/10.52202/069179-0123

3.2 BUILDING DESIGN PARAMETER SETUP

The NMS-timber envelope is an insulated timber frame with air-tight and well-insulated façade panels. Designed for high energy efficiency, it has low U-values (walls: 0.05 W/m2K; windows: 1.36 W/m2K; roof: 0.26 W/m2K; ground: 0.08 W/m2K). The concrete building envelope, on the other hand, is made of brick infill walls with layers of insulation and air gap, concrete floor slabs and an insulated lightweight concrete roof. When applied to the digital model, the respective U-values increase (walls: 0.42 W/m2K; windows: 1.36 W/m2K; roof: 0.39 W/m2K; ground: 0.52 W/m2K). Each classroom is 7.2x7.8m and has four south-facing windows (30% of total surface area), which are partially operable for free cooling in the summer and cross-ventilation through natural ventilation shafts on the service wall. The occupancy ratio of the building is defined according to government guidelines for schools [12]. It is assumed that the local community will use the building for extra-curricular activities; hence the analysis period spans the whole calendar year.

3.3 SIMULATION SETUP

The computational models of NMS were set up as a multizonal energy simulation (MES) using EnergyPlus v22.2.0 [13] and OpenStudio v3.5.1 [14] to estimate energy usage intensity (kW/m^2), season sensitive energy demand, heat balance and thermal comfort estimations (operational and radiant temperatures, and relative humidity (%)), heating and cooling energy demand.

Occupancy scheduling was done on a whole-year basis instead of following a typical UK school term, as the timber school is also designed for community events and activities, apart from the regular classroom services.

3.4 BENCHMARKING

The simulation results of NMS-timber and NMS-concrete are benchmarked against recent studies that used the Non-domestic National Energy Efficiency Data (ND-NEED) [15], the Display Energy Certificates (DEC) database [16] and CIBSE TM46 standards [17]. The ND-NEED provides standards for energy use in non-domestic buildings in Great Britain, based on actual readings. Similarly, the CIBSE TM46 and DEC databases include national-scale statistical data and benchmarks of energy consumption for educational buildings.

4 RESULTS

The analysis was run for a one-year period and the results presented focus on the environmental performance of the four classrooms (c1; c2; c3; c4) to evaluate the impact of building fabric, mainly concrete (NMS-concrete) and engineered timber (NMS-timber). Results show that NMS-timber has higher operating temperature values across all months, especially peaking in July (see Fig 2a). The NMS-timber demonstrates ~2°C higher operating temperature in peak summer months (July) compared to the NMS-concrete model. Similarly, for peak winter (Dec-Feb), NMS-timber shows ~1.8 - 2.2°C higher operating temperatures than NMS-concrete (see Fig 2a). In addition, the relative humidity levels were ~0.9% higher (on average) in the NMS-timber than in NMS-concrete, as shown in Fig 2c. While the peak temperatures in the summer months are on the limits of thermal comfort levels, a more detailed digital model of the school's environmental performance is needed to better understand

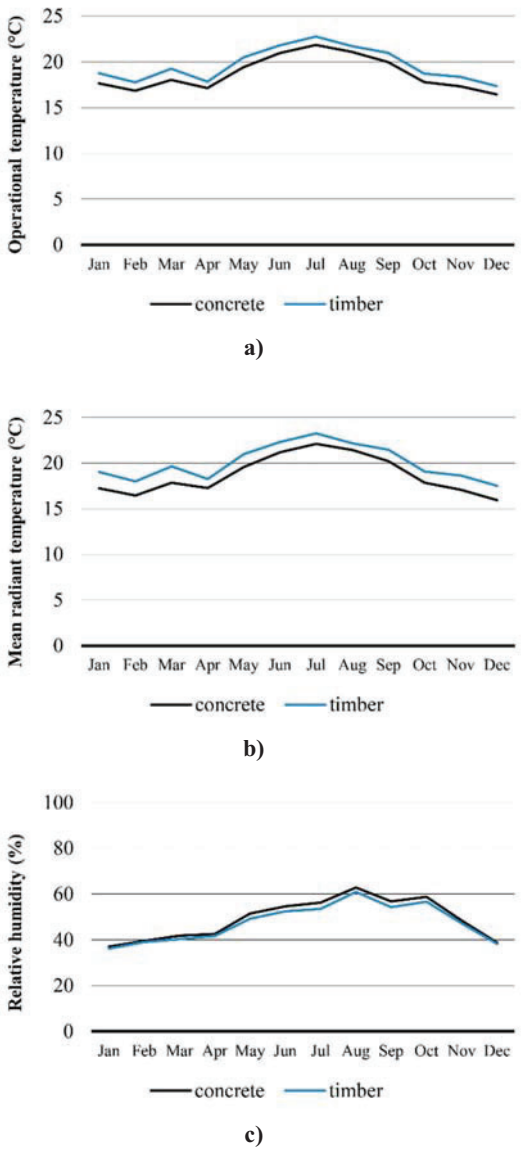

Figure 2: *Simulated annual environmental parameters for NMS-timber and NMS-concrete a) Operational temperature (°C); b) Mean radiant temperature (°C), and c) Relative humidity (%).*

https://doi.org/10.52202/069179-0123

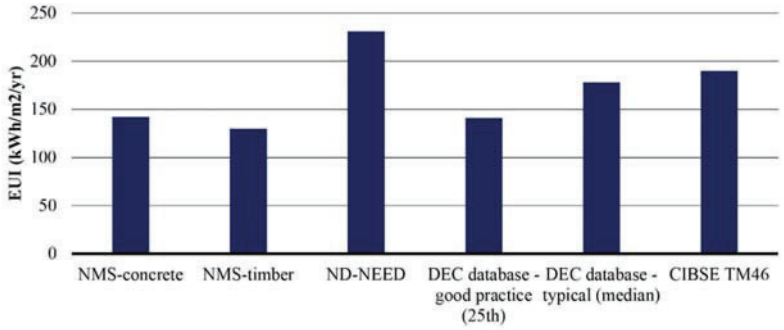

Figure 3: *Energy consumption in kWh/m²/year of the timber and concrete models of the school in comparison to benchmarks from literature.*

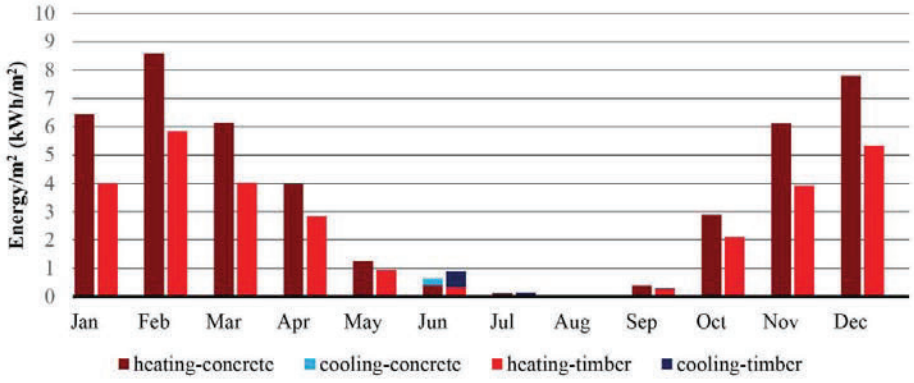

Figure 4: *Monthly energy demand per square metres for cooling and heating of all 4 classrooms for the engineered timber (NMS-timber) and concrete school (NMS-concrete).*

the internal environment, considering airflow characteristics and their impact on temperature and thermal comfort.

However, in terms of mean radiant temperature, the simulated temperature differences were significantly higher in peak winter months ~4°C (see Fig2b) for the timber building compared to the concrete structure. Therefore, NMS-timber can offer greater thermal comfort in winter than NMS-concrete. Similarly, simulated results show that the temperature difference for peak summer months (June - August) is in the range of ~1.9 - 2.1°C, offering NMS-concrete to be cooler. Our ongoing study will use on-site environmental performance measurement to confirm this trend and verify with occupant-led subjective comfort ratings.

The results from the energy performance analysis show that NMS-timber has an annual energy usage intensity (EUI) of ~132kW/m2 and ~146kW/m2 for NMS-concrete (see Fig 3). Therefore, this demonstrates that the timber building is ~9.6% more energy efficient per square metre than the concrete construction of similar configurations. Furthermore, in the benchmarking tests, we find the NMS-timber to be 40%, 9%, 20% and 30.5% less energy intensive per m2 compared to ND-NEED, DEC-good practice, DEC-typical and CIBSE TM46 standards, respectively (see Fig 3).

Fig 4 shows the simulated heating and cooling energy demand for the NMS-timber and NMS-concrete buildings. The timber building in general has less heating and cooling energy demand per square metre by 29.22%. More specifically, the heating energy demand for November - February is 34.30% less in NMS-timber than in NMS-concrete. Similarly, the cooling energy demand for NMS-timber is negligible (~0.08kWh/m^2) between June - August, as compared to NMS-concrete (~0.8kWh/m^2). Thus, emphasising that timber school building has better winter and summer energy performance characteristics.

5 CONCLUSION

This paper presents an environmental performance basis for engineered timber buildings like schools (NMS-timber) with an existing concrete school structure (NMS-concrete). We used an environmental performance simulation approach to estimate the two building cases' operational energy and thermal comfort characteristics. The results from the energy performance analysis show that NMS-timber has an annual energy usage intensity (EUI) of ~132kW/m^2 and ~146kW/m^2 for NMS-concrete, demonstrating a ~9.6% more energy efficiency per square metre for the timber building. Moreover, when benchmarked against recent studies, our results showed the NMS-timber to be 40%, 9%, 20% and 30.5% less

https://doi.org/10.52202/069179-0123

energy intensive per m2 compared to ND-NEED, DEC-good practice, DEC-typical and CIBSE TM46 standards, respectively.

We also find that the timber school building will save ~34.30% heating energy annually compared to the concrete construction while almost eliminating the cooling energy needs. Thus, the NMS-timber building developed can offer significantly better environmental performance to concrete buildings.

Our future work will expand the verification and validation of this study's simulation approach using in-site environmental sensors and establish an experimental protocol for streamlining such measurements for upcoming timber building stocks. It also includes a detailed analysis of the school's Building Integrated Photovoltaics (BiPV) systems that need to be integrated into the timber school, per UK government norms. Moreover, further optimization of the building parameters, BiPV and school ancillary services will be performed to improve the accuracy of the energy simulation. This will include estimating airflow characteristics using a computational fluid dynamics (CFD) workflow, which, when overlaid with the MES analysis, gives a comprehensive insight to the school's environmental performance, In this manner, this study intends to set a workflow for a digital twin model of the school where different materials and emission reduction scenarios can be used to measure its sustainability over the long run.

As the global response to climate change intensifies, timber buildings will play an essential role in reducing embodied carbon emissions of the built environment. Our study proposes a digital workflow that enables the comparative assessment of alternative construction materials based on their environmental performance in a robust and resource-efficient manner. When carried out in the early stages of a project, this approach can promote informed design decisions during the project development stages, improve the environmental performance of new buildings and act as a guide to policymaking.

DEVELOPMENT OF MATERIAL FOR CIVIL CONSTRUCTION WITH BABASSU PALM FIBERS

Antonio da Silva[1], Francisco Lahr[2], Antonio Costa[3], Joaquim Costa[4]

ABSTRACT: Present in the transition space of the Caatinga, Cerrado and Amazon biomes, distributed between the north and northeast regions of Brazil, it hosts a species that carries with it an economic potential already known by local populations: the babassu (Attalea speciosa).This palm is a source of income for families that depend on babassu extraction in the Brazilian states of Maranhão, Piauí and Tocantins. According to studies by Embrapa, the exploitation of babassu coconut (the most used part of the babassu) is just one of the possibilities involving this native raw material. It is for this reason and for its favorable environmental repercussion, in view of the sustainability of its material, that we aim with this research to enable a new application for babassu, using fibers from its leaf, whose characteristics allow its use in civil construction for internal use and environments exteriors in buildings. Thus, this work intends to evaluate the technical viability of manufacturing, on a laboratory scale, a compact sawn wood board, similar to the Oriented Strand Board (OSB), making a considerable reduction in the final value of the work, as it is an abundant material in the region, easy to produce, sustainable and ecological.

KEY WORDS: Plate, Babassu, Civil Construction, Sustainable

1 INTRODUCTION

The generalities about the Palm of Babassu, its impact on the economy with the products already known, research for its use in civil construction and objectives of this research will be addressed.

1.1 GENERAL CHARACTERISTICS OF THE BABASSU PALM TREE

The Babassu Palm is a species that dominates the ecotonal landscapes, which are areas resulting from the contact between two or more border biomes, in the mid-north region of Brazil (Transition between the Amazon, Cerrado and Caatinga), traditionally exploited in an extractive way by thousands of families, mainly in the states of Maranhão, Piauí and Tocantins. The adult babassu palm can reach between 10 and 30 meters in height and its leaves can reach up to 8 meters in length.

Babassu is still used as a source of raw material for the production of charcoal, fibers for basketry, fences, housing roofs, and even for the preparation of porridge and cakes (Silva et al., 2001). Its importance for the family farmer, the socioeconomic issues and land conflicts arising from its exploitation are widely described in the works of May (1990) and Anderson et al. (1991).

1.2 THE IMPORTANCE IN THE ECONOMY

Several economic activities can be developed from babassu, since the tree is fully utilized, and the fruit has the greatest economic potential for technological and industrial use, being able to produce about 64 products, such as coal, ethanol, methanol, cellulose, flour, fatty acids, glycerin, among others.

The babassu almond, due to the quality of its oil, is the part of the plant that currently has the greatest economic importance, although it represents a small proportion in relation to the total mass of the fruit, having produced a quantity of 48,706 tons in 2019 throughout Brazil, with the state of Maranhão responsible for the production of 45,166 tons, corresponding to 92.73% of the total, and moving about 89,363 thousand reais, according to data provided by the Brazilian Institute of Geography and Statistics (IBGE)..

The above demonstrates that babassu stands out as an important species not only for the subsistence of poor families in a wide geographic region of the country, but also as a non-timber extractive product of enormous value for the industry. In addition, because it spontaneously occupies landscapes with little economic expression in the

https://doi.org/10.52202/069179-0124

national agricultural scenario, babassu is of strategic-territorial importance for the country.

1.3 USE OF THE PALM TREE IN THE CONSTRUCTION SECTOR AND RESEARCH INCENTIVES

Despite its importance as a non-timber extractive product and its potential for generating energy and co-products, in the field of civil construction, which has been reinventing itself and increasingly seeking sustainable materials, there is little published literature, as well as a scarcity of research in order to use this promising material. In the literature, there are only reports of the use of babassu palm leaves being used to form the roofs of low-income families' houses. In recent years, some actions have been initiated aimed at using babassu parts in civil construction, however, there has been discontinuity of work, lack of integration between different areas of knowledge and lack of long-term research and development policies.

In 1980, the State Institute of Babassu (INEB) was created, an agency of the Government of the State of Maranhão. During its four years of existence, INEB coordinated a research program on babassu, in collaboration with what was then CENARGEN (now Embrapa Genetic Resources and Biotechnology) and the New York Botanical Garden (NYBG) (Pinheiro et al., 2005).

Research on babassu was intensified by the creation of the National Research Program (PNP) on Babaçu, coordinated by EMBRAPA, in 1982. The PNP-Babaçu was organized with the aim of contributing to rationalizing and accelerating the use of babassu. The program's long-term goal would be “the gradual transformation of current babassu extractivism into an economically exploitable crop” (EMBRAPA, 1984), but clearly this goal has not yet been reached.

1.4 OBJECTIVE OF THE ARTICLE

Emphasize research on the technical feasibility of manufacturing, on a laboratory scale, particulate panels similar to OSB (Oriented Strand Board), derived from fibers using babassu leaf or coconut bunch cover as input, a residue originating from the removal of The palm leaf or the top of the bunch falls off the palm tree on its own, together with the fruits when they mature, with the aim of manufacturing a low-cost product with a quality equivalent to products that are at the top of the market today, in addition to providing a new product from the babassu palm tree intended for the civil construction area, using engineering to develop ecologically sustainable materials with low environmental impact, and finally, making available and encouraging studies on an endemic palm tree in Brazil with great economic potential.

2 MATERIALS AND MODEL USED

The main material used in the manufacture of the particulate plate was the babassu leaf, representing about 98% of the product composition and the other 2% correspond to the centrifuged latex that was used as a binder to make the product similar to OSB. A hydraulic press, model SL 10/5, was also used to press the layers of sheets and give better compactability to the plate.

2.1 BABASSU

Babassu is a highlight among the palm trees present on Brazilian soil, it is a large species, reaching up to 30m in height, has leaves up to 8m long, slightly arched and pointed in the vertical direction, which fall when reaching their apex. giving way to new ones (Figure 1), it also has cream-yellowish flowers, clustered in long bunches protected by peduncular bracts, which are foliaceous structures associated with the inflorescence of the palm tree that are highly resistant to humidity and fire, and later give rise to origin to oval and brown fruits, with an almond inside.

Figure 1: *Babassu palm trees located in the parking lot of the Federal Institute of Maranhão (IFMA). (Source: Author)*

The occupation of the landscape by babassu occurs vigorously (Figure 2), and seems to be favored by slash-and-burn family farming systems, as well as the formation of pastures (Anderson et al., 1991). Strongly associated with the local culture, babassu is part of the life history of hundreds of communities that collect and break coconuts in a rudimentary way, to sell the almond, an important complement to their income.

Figure 2: *Great density of palm trees in nature. (Source: Flickr)*

2.2 CENTRIFUGED LIQUID LATEX

Latex is a material extracted directly from the rubber tree, a tree of the genus Hevea, of the Euphorbiaceae family, native to the Amazon rainforest, which stands out for its ability to produce this material (Figure 3). The extraction process begins when the tree trunk reaches a perimeter of 45cm, being measured at a distance of 1 meter over the graft, only then is an incision made in the stem with a special knife, without going beyond the part where the lactiferous vessels, so as not to impair the radial growth of the trunk. When harvested from the tree, latex has an average of 30% rubber, 68% components such as water and substances such as proteins, mineral salts, etc.

Figure 3: *Latex extraction process. (Source: wandee007/shutterstoch.com)*

In this research, Centrifuged Latex 60%, from RICLA colas e resins, a Brazilian company that has been manufacturing adhesive gums since 1989, was used. a) Practicality in use: based on its elasticity and flexibility, practicality is guaranteed in carrying out different types of work, including the manufacture of OSB boards; b) Impermeability: as it is a water-resistant adhesive, latex glue can be used to glue parts that will be exposed to moisture; c) Excellent cost-benefit ratio: it is a material that yields a lot; and d) Ease of adhesion: it showed good adhesion with laminated profiles of babassu leaves.

Figure 4: *Binding material used. (Source: Company catalog).*

2.3 ORIENTES STRAND BOARD (OSB)

The industrial scale production of structural particle boards began in the 1970s, in the United States, under the trade name “waferboard”.

The sheets were produced with particles of larger dimensions, in relation to the particles used in “conventional” agglomerates, but with the same random distribution in the mattress formation process.

The width and length of “OSB” sheets are determined by the production technology and not according to the length of the logs, as in the case of plywood. The current context of the Brazilian forest sector demonstrates the consequences of the predatory exploitation of natural forests, mainly caused by the expansion of the agricultural frontier, by mining activities, by the production of charcoal and others. The lack of an exploitation monitoring policy, via sustained management, also contributes to worsening the situation. Within this context, it seems, more and more, that the logical tendency is to use reconstituted wood from the furniture industry and alternative materials of lignocellulosic fibers.

The OSB panel offers resistance for multiple uses and has a wide application in the field of housing construction, in all existing types, and other applications, among which stand out: floors, walls, I-beams, stairs, ceilings, roofs, fencing, sheds, protective trays. Other applications: furniture, loudspeakers, dividers, packaging (Bins and Paillets), finishing in general and design, according to quotes from Revista de madeira, year 16, nº 97, June/2006.

As it is a product recently produced in Brazil, it can be considered that there is little information available on the market about the variables of its processing, mainly in relation to alternative materials not yet explored in the production process.

https://doi.org/10.52202/069179-0124

3 METHODOLOGY

Analyzing the babassu palm, intriguing characteristics were noted, due to its natural state it presents great resistance to fire and water, making it a very promising material for use in civil construction and in the manufacture of materials used in contact with humidity and temperatures high.

In a field work, the senescent leaves of the palm tree were collected, being removed from the thickest stalk that supports the leaves with the aid of a machete and accommodated in bales that were transported to the Federal Institute of Maranhão (IFMA), Campus Monte Castelo, São Luís (Figure 5).

Figure 5: *Conditioning the raw material in bales for transport to the laboratory. (Source: Author).*

In the civil construction laboratory belonging to the institution, the samples were placed in an oven for drying at a temperature of around 60ºC, during a period of 48 hours. After drying, the material was cut into 14 cm sheets with a natural leaf width of approximately 4 cm, and then we used a brush to spread the 60% centrifuged latex over the leaves, beginning the assembly of the layers that form the panels. After organizing the sheet blades, similar to OSB, the first layer of the panel was taken to the Hydraulic Press SL 10/5, where it was pressed at a pressure of 1.5 ton/cm², for a time of 24 hours. This process was repeated 10 times, forming 10 layers with a thickness of approximately 1 mm (natural thickness of the sheet), which were successively glued and pressed overlapping one by one in crossed directions, respecting the same pressure and time mentioned above, resulting in a plate final with a thickness of 1 cm and dimensions of 50 x 50 cm, weight of 499.28g, total volume of 1250 cm³ and density of 0.399 g/cm³.

Figure 6: *Material cut into 14 cm sheets and natural leaf width of approximately 4 cm. (Source: Author)*

4 RESULTS AND DISCUSSIONS

Babassu is indisputably a raw material of immeasurable value that is still little researched and used. The plate made with the leaf of this palm tree is light, has an excellent design, has low degradation over time, in addition to having a low modulus of elasticity, facilitating its molding. In the initial stage of the first layer, with fibers oriented only in one direction, good flexural strength was observed, being able to significantly support its own weight without excessive deformation. After pressing the ten layers, positioning the fibers crosswise, we obtained a panel with greater resistance than imagined and with very attractive aspects, combining quality and good value for money in a single piece, which will provide satisfaction and pleasure to the consumer public. Due to its characteristics (Table 1), it can be used in civil construction to cover walls in internal and external environments (reconciled with additives), in linings, in decorative details of rooms, in baseboards, among others, making a considerable reduction in the final value of the work because it is a material that is easy to produce, sustainable, renewable and ecological, in addition to collaborating with the preservation of the environment by reducing construction waste, and having the raw material with vast density in the Brazilian territory.

Table 1: *Characteristics of the plate made in the laboratory.*

Material /Character	OSB of Babaçu
Weight	499,28g

Área	2500cm²
Volume	2500cm³
Density	0,199g/cm³

.

5 CONCLUSIONS

For the realization of the plate similar to OSB, we can emphasize that this new material based on leaves of the Babassu Palm tree as the main raw material has a great benefit in the environmental field and a good use for the most diverse purposes, since it is a material low cost to operate and sustainable, in addition to being a renewable raw material, causing the satisfaction of all who come to use these panels (Figure 7). Observing the need to protect the environment, which is suffering a lot with the development of humanity, both with the production of garbage and pollution, and with the exploitation of finite resources in an unbridled way, the importance of studies and discoveries of ecologically sustainable products and low impact on nature is vital for reducing environmental degradation and increasing people's quality of life in the future. Based on this, the exploitation of babassu palm leaf fibers for the preparation of pressed wood panels similar to OSB, with the intention of being used in the field of civil construction, can have a positive impact because it is an ecological product, without generating toxic waste in its manufacture and revolutionizing the means of producing materials for this branch of engineering that is essential for human development and which is currently one of the main degraders of the environment.

The social aspect of this new product can also be emphasized, as there is the possibility of building houses using these panels, thus lowering their final value and contributing to a more sustainable world.

Therefore, Brazil, as the sole owner of this raw material, will be able to take advantage of this product, which at the moment is unexploited, making it a great benefit both for society and for the economy, which will gain a new production line, generating jobs and influencing the GDP (Gross Domestic Product) of this country.

EXPLORING THE STRUCTURAL DESIGN, COST AND DURABILITY OF MASS TIMBER NOISE BARRIER FOR HIGHWAY APPLICATIONS

Weichiang Pang[1], Michael Stoner[2], Harsh Bothra[3], Laura Redmond[4], Patricia Layton[5]

ABSTRACT: The sound generated from vehicular traffics on highways cause noise pollution. To deal with the traffic noise coming from these highways, noise barriers have been erected across major highways. Currently, the primary material used for highway noise barrier is concrete. This paper explores the use of mass timber as highway noise barrier from a structural design, cost, and durability perspective. The structural design of mass timber noise barrier to resist wind and earthquake loadings will be discussed. Cost comparisons between noise barriers constructed using pre-cast concrete panels and cross-laminated timber panels indicate that mass timber noise barrier is cost competitive. As part of this study, a prototype noise barrier was constructed for evaluating the constructability of the proposed design and for monitoring the moisture performance in an exposed weather environment.

KEYWORDS: Cross-Laminated Timber, Noise Barrier, Highway

1 INTRODUCTION

Highways are some of the biggest causes of noise pollution in the United States of America. To deal with the traffic noise coming from these highways, noise barriers have been erected across major highways. Several materials are used for sound barriers, including steel, wood, concrete, composites as well as insulating wool. These materials help to abate noise via reflecting, diffusing or absorbing sound waves. Concrete and steel are the most common materials for highway noise barriers. However, wood products are known to be more environmentally friendly than concrete or steel. Additionally, the use of wood products is also considered to be more aesthetically appealing to most motorists. Wood products also have the benefit of being lighter and thus easier to transport and erect compared to concrete and steel.

The design of a highway noise barrier is typically based on the structural design, sound efficiency, long-term durability, and material and construction cost associated with implementation [1]. A comparative study on the performance of wood highway sound barriers revealed that wood barriers (solid sawn or glue-laminated timber) which were properly installed, designed, and detailed could be designed to achieve similar acoustic performance to precast concrete panels [2]. Given that most mass timber elements are thicker than those measured in this study, it was assumed that a sufficient acoustic performance could be achieved by utilizing mass timber elements.

In this study, wood products, specifically Cross-Laminated Timber (CLT) and Mass plywood Panel (MPP) are considered as potential materials for noise barriers. A representative noise barrier design is presented and compared to typical concrete construction with respect to cost and carbon footprint. Additionally, a prototype sound barrier was constructed and instrumented for long-term moisture monitoring.

2 DESIGN OF MASS TIMBER NOISE BARRIER

Cross-laminated timber (CLT) is made from lumber boards that have been glued to each other forming layers. Structurally, mass timber exhibits high bending strength and has lower weight than a concrete or steel system. A CLT noise barrier was designed considering the wind load and seismic loads across the US following the design procedure of AASHTO (American Association of State Highway and Transportation Officials) [2] and FHWA (Federal Highway Administration) [3]. The panel span width was limited to 6m (20 ft) based on an attempt to maximize the efficiencies of current CLT fabrication facilities and to produce the easiest construction sequence. The analysis results showed that 3-ply CLT panels could withstand winds of up to 80.5 m/s (180 mph), however larger steel posts were required. Seismic analysis was

[1]Weichiang Pang, Professor, Clemson University, USA, wpang@clemson.edu

carried out and a smaller W10x33 steel post was shown to be sufficient for the very high seismic region with an S_s value of 2.25g. Table 1 shows the design criteria for the CLT noise barrier.

***Table 1**: Design Criteria of CLT highway noise barrier*

Design Criteria	*Value*
Design Wind Speed	80.5 m/s (180 mph)
Wind Pressures	2.9 kPa (60 psf)
Spectral Response Acceleration @ 0.2s (S_s)	2.25 g
Peak Ground Acceleration	0.9 g
Steel Post Design	W10 x 33
CLT Panel Design	3-ply V3: 105 mm (4.13 in)

Figure 1 shows the top and isometric views of the noise barrier with two 3-ply CLT panels of 6.1m x 2.4m (20-ft. x 8-ft.) stacked vertically along the long edge and W10x33 structural steel posts. The installation of the noise barrier begins with typically installed foundations concrete foundations. Structural steel posts are installed with four cast-in-place anchor bolts. Figure 2 shows the details of connections used to fasten the CLT panels to the steel posts. After the steel posts are bolted the foundation, shim angles and seating angles are fastened to the post using bolt connections, the CLT panel is then slid into the post from the top (Figure 3). In this example, a second panel is added on top of the first and jointed using a lap joint connection with wood screws.

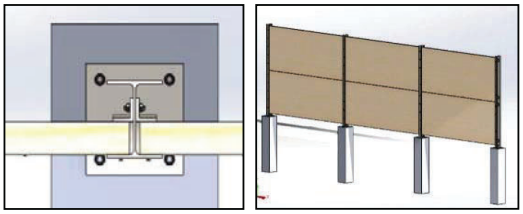

***Figure 1**: Top View of 3-D Model (left), Isometric View of 3-D Model (right)*

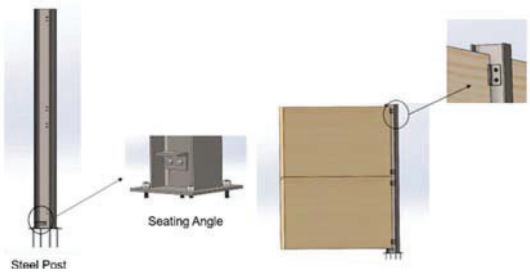

***Figure 2**: Seating Angle (left), Shim Angle (right)*

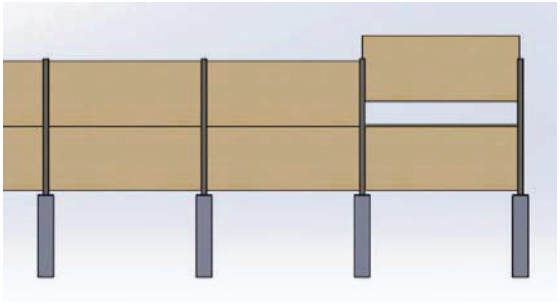

***Figure 3**: Installation of CLT Noise Barrier.*

Additional improvements in the structural design to further increase the structural efficiency, reduce the amount of non-wood components, reduce the number of concrete foundations, and reduce the time for construction of the highway noise barrier system using CLT.

3 COST COMPARISON AND ENVIRONEMNTAL IMPACTS

Factors such as the environmental impacts, costs, waste management, and aesthetics play a role in the selection of what construction materials will be used in a construction project. The use of wood and its different forms and products has substantially reduced environmental pollution and greenhouse gas emissions within the building sector [3]. A carbon emission study on a 6m x 4.9m x 10.4cm (20’ x 16’ x 4.125”) timber panel used as the primary structural component in a highway noise barrier and an equivalent size concrete panel was carried out during this research. It was found that 740 kg (1630 lbs) of CO2e is emitted during the construction process of the concrete panel whereas 2040 kg (4500 lbs) of CO2e will be stored if a CLT panel is used. Therefore, adoption of mass timber noise panels will result in a reduction of up to 2780 kg (6130 lbs) of CO2e for every 6m (20 ft) of noise barrier. These environmental calculations did not include the environmental impacts of the foundations, steel posts, or transportation of such elements.

***Table 2**: Cost Analysis Summary of 800m Case Study*

	CLT	Precast Concrete
Panel Dimensions	6 m x 2.4 m	3 m × 2.4 m
Distance From Project Site	400 km	160 km
Material Cost	\$185.67/m^2 including posts and treatment	\$123.79/m^2 including posts
Total Material Cost	\$ 644,554	\$ 485,760
Transportation & Installation cost	\$ 91.49/m^2	\$145.31/m^2
Total Project Cost	\$1,003,594	\$1,056,000

https://doi.org/10.52202/069179-0125

A cost study for a project in 2020 in Florida was conducted for a representative CLT noise barrier compared to a concrete noise barrier using construction cost data collected for typical concrete noise barriers. The cost study was performed on for an 800m (1/2 mile) length of noise barrier. The factors considered in the cost study include the material cost, transportation cost, and installation cost described in detail in Table 3.

***Table 3**: Detailed Cost Breakdown of Case Study*

	CLT		Precast	
	per m^2	total	per m^2	total
Material	$1.60	$728,640	$1.07	$485,760
Transport	$0.03	$13,563	$0.06	$25,575
Install	$0.76	$345,477	$1.20	$544,665
Total	$2.39	$1.00 mil	$2.32	$1.06 mil

Reductions in the transportation cost for the CLT noise barrier were due to the reduction in weight per panel resulting in 14 truckloads versus 66 truckloads for the precast panels. Additionally, reduction in the installation cost was due to the reduction in foundations and lifting equipment required for the CLT noise barrier. Additional cost was included for the treatment of the CLT panels, though the maintenance cost was not included as the extent of such costs was unknown at the time of the study.

It was determined for the 800m (½ mile) case study length, a cost reduction of around 5.2% was achieved. The saving mainly comes from transportation and installation costs as wood is about 1/5 of the weight of concrete.

4 MOCK-UP CONSTRUCTION AND MOISTURE MONITORING

A 2.4m x 2.4m (8 ft x 8 ft) prototype CLT noise barrier was built and installed at the Clemson University Built Environment Laboratory located in Pendleton, South Carolina. Two different Sansin coatings applied on the CLT panel to protect the panels from UV and moisture (Figure 4). Each coating was applied in two coats per the manufacturer recommendation with sanding of the surface between each coat. The total thickness of the coating after both layers were applied was 0.3 mm (11-12 mils).

***Figure 4:** Application of UV and moisture protection*

The prototype noise barrier was constructed in accordance with the design procedures mentioned (Figure 5). The panel was instrumented with temperature and moisture sensors to measure the moisture fluctuation in the panels. SMT Research sensors were used to instrument the prototype noise barrier and obtain moisture, temperature, and rainfall data. In total, 18 moisture sensors, 2 rain gauges and 2 temperature sensors were installed in the panel and data is being collected remotely. The sensors were installed at depths of 2.5 cm (1 in.), 5.1 cm (2 in.), and 7.6 cm (3 in.) at three locations on each of the two coatings. Figure 6 and Figure 7 represent the location and depths of the moisture sensors installed in the prototype panel.

***Figure 5:** Front view of prototype noise barrier (left), Rear view of prototype noise barrier (right).*

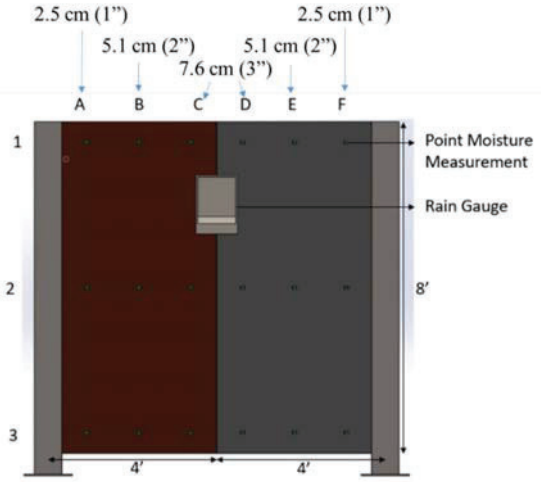

***Figure 6:** Schematic view of sensors installed in the prototype noise barrier.*

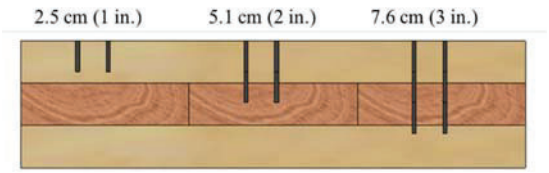

***Figure 7**: Depth of moisture sensors in prototype noise barrier*

https://doi.org/10.52202/069179-0125

The intent of the sensors was to determine the moisture content fluctuations in the CLT panel due to rainfall events. Information such as the peak moisture content after a rainfall event, the variation in moisture in each layer, and the rate at which the moisture content returned to pre-rainfall event levels were all of interest. The amount of rainfall in each rainfall event was captured by rain gauges located on either side of the prototype panel. These rainfall events are summarized in Figure 8. Gaps in the data between October 2022 and January 2023 exist due to battery outages in the sensors. In total 105 measurable rainfall events were recorded by the system over the time of the measurement.

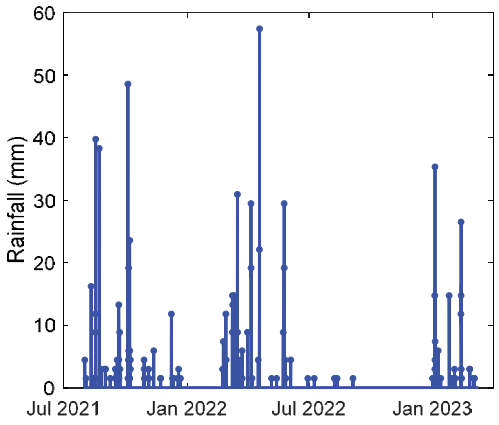

***Figure 8**: Rainfall events July 2021-Mar 2023*

The moisture content in the CLT panels were quantified in terms of the peak moisture content after the rainfall event. In data presented in Figure 9 shows the distribution of the peak moisture content after each event as an average of the three sensors placed at identical depths in each of the two coatings. After rainfall events, the moisture content increases to between 15% to approaching the fiber saturation point of wood. Though differences in the moisture content by layer were evident, no trend was found consistent between the two coatings. The average peak moisture content measured between 20% and 23.5%, which is just above the point at which the effects of increased can begin to occur, usually around 20% [5].

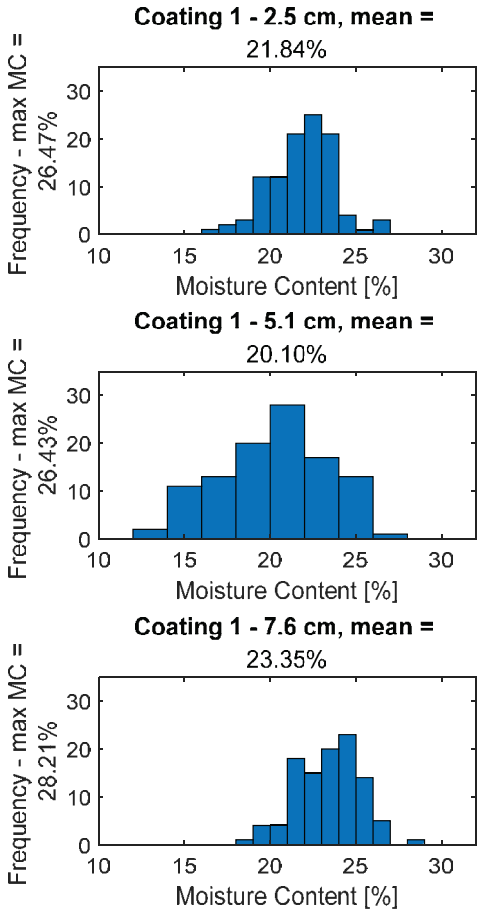

***Figure 9:** Distribution of peak moisture content readings after rainfall event for Coating 1*

https://doi.org/10.52202/069179-0125

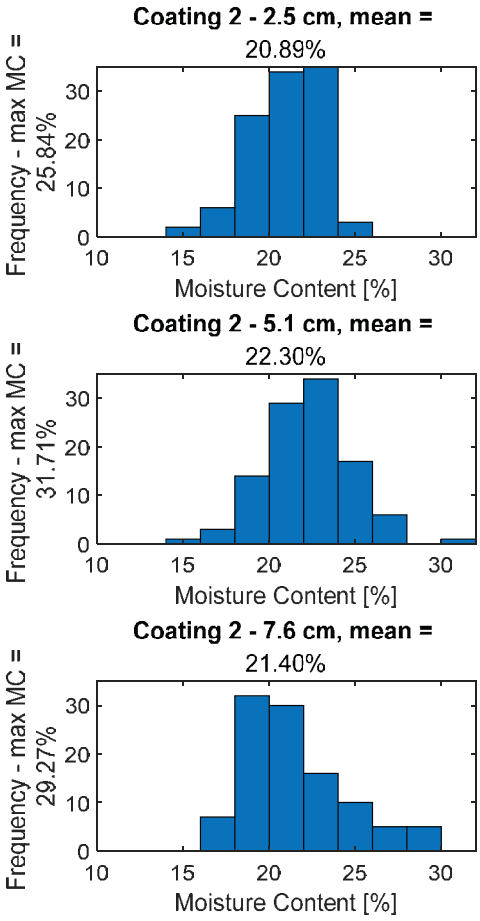

Figure 10: *Distribution of peak moisture content readings after rainfall event for Coating 2*

In addition to the peak average moisture content, the return of moisture content to pre-event levels was tracked by the sensors. As the moisture content exceeded the point at which decay to the wood fibers, it became important to track the amount of time to return to a moisture content below 20% and below 16%, the recommended moisture content for dry service conditions specified in the National Design Specification [6]. Figure 10 represents the average moisture content after a peak rainfall event and the subsequent 24 hours following the event. It shows that within the first two hours after the peak moisture content was measured, the moisture content in the wood drops below the 20% threshold. After approximately 5-7 hours, the moisture content returns to at or below 16% indicating that the wood fibers do not experience elevated moisture content for very long.

The qualitative degradation of the noise barrier over time was measured through periodic inspections of the panel. Discoloration of the noise barrier over the 20+ months of exposure was minimal, indicating the coatings were performing as intended. Delamination of a single piece of the outer layer of the CLT barrier at the top of the wall was observed, likely due to the repetitive moisture cycling (Figure 12). For future installations of the panel, it is recommended that a steel cap be placed on top of the noise barrier to prevent such delamination from occurring and to prevent moisture intake on the panel end-grain. An additional CLT noise barrier with no coating will be installed and monitored in the same way to compare the moisture and degradation performance.

Figure 12: *Delamination of top of CLT noise barrier*

5 SUMMARY AND CONCLUSIONS

Cross-laminated timber has the potential to serve as the primary structural material for highway noise barriers in an effort to reduce environmental impact and sequester carbon from the atmosphere. Based on the structural design and cost estimates presented, such a noise barrier is comparable to a similarly designed barrier made of precast concrete with substantial carbon advantages. A prototype noise barrier was installed and instrumented ot determine the long-term moisture performance and degradation of the panels. The data from the prototype noise barrier has been monitored since mid-August 2021 and will be continually monitored as part of a long-term study. For the initial monitoring period from August 2021 to November 2021, the moisture content in the CLT goes up to 28% during heavy rain and drops down to 10% within 24 hours under dry conditions. Using durable and high-quality breathable coating appears to be a viable solution that addresses the effect of moisture retention in CLT panels.

CORROSION INHIBITOR POTENCIAL WITH BOLDO BRASILEIRO COMPARED TO COMMERCIAL INHIBITOR OI WOOD CONNECTIONS

Letícia Costa[1], Ana Farias[2], Antonio da Silva[3], Francisco Lahr[4]

ABSTRACT: The corrosion caused in metallic elements in connection with wood is a relevant fact for scientific research, since this problem directly affects the strength and service life of structures. When metal alloys are subjected to wood, exposure to corrosion is noticeable, due to the presence of water and oxygen in the cellular structure of wood, as well as chemical reactions between its constituents. Although metals have definite and advantageous mechanical properties, they are still not sufficient to contain the oxidation content. It is observed that these connecting pieces embedded in wood present easy degradation, bringing high economic, environmental and technological costs in their maintenance or replacement. Through analysis, a comparison was made between the corrosion rates and protection efficiency of different corrosion inhibitors that are often marketed, replacing them with green inhibitors, also known as natural inhibitors, used to prevent the corrosion process in metals. In the tests, several specimens were tested, with and without the presence of the natural additive, thus being able to evaluate satisfactory results in which the extract plectranthus barbatus Andrews, also known as Brazilian boldo, formed a protective layer on the metals. In summary, it is notorious that these natural inhibitors do not harm the environment, as well as economic advantages when compared to the commercial inhibitor, which is harmful and toxic to the environment.

KEYWORDS: **Corrosion, natural inhibitors, plectranthus barbatus Andrews.**

1. INTRODUCTION

Wood is a precursor material, widely used in civil construction. It has several applicability because it is a massive and versatile element, used in structures, especially in roofs or finishes (MATIELLO and NESPOLO, 2015). According to Nagaoka (2014), wood has been a material that is not very resistant, but with a high market value, generally used in craft techniques. In countries in the northern hemisphere, it is also used as a structural material, due to its technological devices. Its geometry, areas and proportions allow the creation of different parts, and allows the realization of amendments and/or connections with metallic elements that make up the structure. On the other hand, it is observed in several conventional constructions the use of nails, pegs and screws, which are interconnection components for elements that have the same material or different materials. For large industries, a good example of this, which has the possibility of quick assembly and standardization in the connections, are the Gang Nail connectors, an element made of hot-dip galvanized steel. In general, steels are widely sold in several industrial sectors due to their other properties and resistance to the effects of corrosion and oxidation. In theory, they are alloys composed of iron and carbon, which respond positively to the way they are exposed to weather and stress, as a result of their composition, microstructure, morphology, electrical resistivity, heat treatments, among other factors. The metallic elements are fundamental pieces that strongly contribute to the wood-metal junction, making it a technological and comprehensive innovation. In the constructive system, the combination of these materials can cause a series of damages in the structures, due to a phenomenon called corrosion (NAPPI, Manuela Marques Lalane et al, 2012)ɜIt is known that despite the high resistance of metals, corrosion is a redox process that occurs in the

https://doi.org/10.52202/069179-0126

midst of natural agents, and thus compromises the performance and functionality of the material. Therefore, the present work aimed to study corrosion in marine environments, since seawater has a high concentration of sodium chloride (NaCl), magnesium chloride (MgCl2), magnesium sulfate (MgSo4), calcium sulfate (CaSo4), potassium chloride (KCL) and other dissolved and particulate gases. It is noteworthy that the atmospheric environment also influences the high percentage of relative humidity, solar radiation and tidal effects. According to De Melo, Grazielma Ferreira; et al (2021, p.68) are "factors that act as propellants and catalysts in the corrosion process". Therefore, the following research has investigative data sources for the plectranthus barbatus Andrews extract, also known as Brazilian Boldo, against corrosive media to inhibit the corrosion process in metals, acting as a protective layer. Among the metals, galvanized steel was studied, which served as studies for testing specimens together with the natural extract, serving as a main additive in the concentration that will be mentioned in topic 3 of the methodology. But before, it will be presented in topic 2, the materials that were made to obtain the specimens.

2. MATERIALS

2.1 PLECTRANTHUS BARBATUS ANDREWS

The Plectranthus barbatus Andrews also known as Brazilian Boldo, from the lamiaceae family, originating in Africa is widely used in Brazilian territory. Because it is a bushy, aromatic, perennial plant with erect branches, it can reach a height of up to 1.5 meters, has oval, hairy and thick leaves, its flowers have a bluish color and grow like spikes in rainy seasons. Plectranthus barbatus Andrews is an herb recognized in Brazil as a medicine for the treatment of liver diseases, infections, liver problems and food digestion. Due to the presence of flavonoids, tannins and alkaloids in their composition, these substances have antioxidant actions, making the natural extract an excellent inhibitor in combating corrosion, which justifies and makes it important to study this plant, since it has a good inhibition efficiency shown in previous researches.

2.2 GALVANIZED STEEL

Galvanized steel is a material that undergoes several processes, one of which is the galvanizing process where it is coated with a very thin layer of zinc, which provides resistance against corrosion. Steel itself is a material that is widely marketed and used in building structures. It is worth remembering that its initial material, which is iron or zinc, is not yet as resistant and ends up being corroded by rust, over time, bringing expenses and maintenance to companies.

2.3 HDF- HIGH DENSITY FIBERBOARD

HDF is its abbreviation for High Density Fiberboard or Industrialized Wood Panel. HDF is a material derived from wood, produced with fibers from selected Pine or Eucalyptus woods from reforestation, introduced by thermosetting resins by pressure and high temperature. In the quality certificate and in its technical reports, it offers great resistance, homogeneity and dimensional stability. of furniture, side and bottom of drawers. It offers excellent cutting and machining capacity, not to mention that it has a great cost benefit. However, when this wooden panel is subjected with pins, screws, or any type of metal exposed to room temperature, it is subject to oxidation, corrosion and other types of degradation, leading to the useful life of wooden structures.

3. METHODS

3.1 PRODUCTION OF EXTRACTS

In the production of extracts, it was first necessary to analyze the leaves of the Brazilian Boldo. They were removed from the herbarium at Ceuma University, and selected for the drying process. The research continued in the laboratory of the Federal Institute of Maranhão (IFMA), where a new plantation of Brazilian boldo was made with the same species of leaves that were cultivated at the Ceuma university. Then, the leaves were placed in an oven at a temperature of 100° degrees celsius for 24 hours to carry out a new drying, after this procedure, the leaves were sent to the materials laboratory, then they were removed from the oven and part of them were introduced on a precision balance to obtain its original mass. Therefore, the leaves were transferred to a mortar to carry out the maceration process, previously grinding the leaves for the preparation of tea in order to reduce the size of the particles and facilitate dissolution in an aqueous medium. Then, in a closed glass container, 500 grams of macerated leaves, as weighed by the volumetric balance, and 500 ml of H2O were added, subject to room temperature for a few hours. The following figures show the procedures for making the extracts.

https://doi.org/10.52202/069179-0126

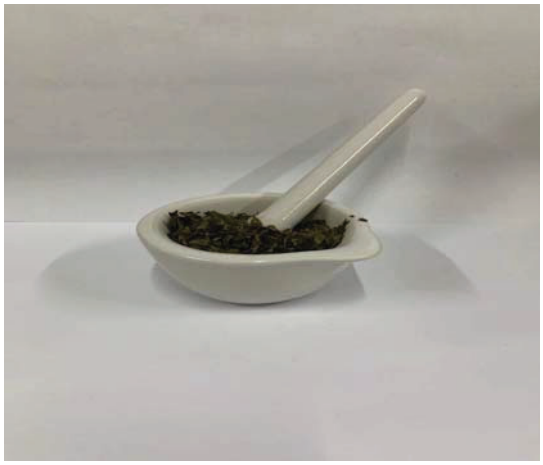

Figure 3. *Maceration process (Source: Author, 2023)*

Figure 4. *Brazilian Boldo Extract (Source: Author, 2023)*

3.2 MANUFACTURE OF TEST SPECIMENS

In this research, galvanized steel screws and pins were used fixed in 4 sheets of laminated flooring composed of HDF, wood fibers in its structure, specifically mentioned in the materials in topic 2. Before being submitted to their sheets, the materials were weighed to obtain their referred initial masses, then they were bathed each in their respective beakers. Each container having a mixture and concentration of different extracts. The first CP (Proof body) having only H2O, the second CP only with natural extract (additive) and H2O, the third CP with H2O and NaCl (sodium chloride) popularly known as table salt, and the fourth and last CP, was obtained from all mixtures previously formed (H2O + Nacl + natural extract). In the research, 4 divergent CPS were used, precisely to compare the efficiency of inhibition in each test requested. The figures below show the respective samples that were prepared to bathe the 4 HDF sheets which were tested in the gravimetric tests.

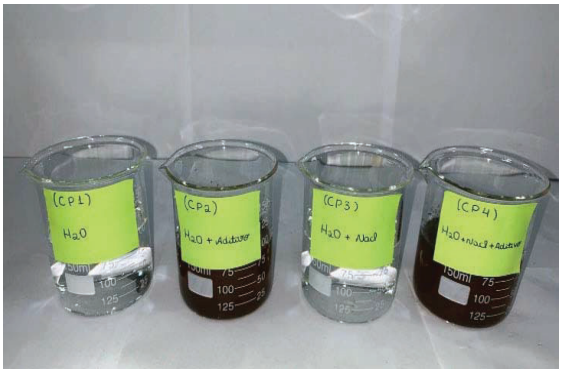

Figure 5. *Samples (Source: Author, 2023)*

.

Figure 6. *Representation of inserted pins and screws on the HDFsheet (Source**:** Author, 2023)*

3.3 MANUFACTURE OF SPECIMENS WITH COMMERCIAL INHIBITOR

As the research was intended to compare the natural inhibitor with the commercial inhibitor, it was necessary to carry out new tests by bathing other HDF sheets made using TF7 (industrial inhibitor), an excellent rust converter sold in Brazil to eliminate rust in surfaces, forming films that eliminate and prevent corrosion. Therefore, 3 beakers were prepared to carry out new tests and serve as a comparison for the other specimens. Figure 7 shows the CPs with TF7 and HCL (hydrochloric acid). In this test, 90 ml of TF7 and 10 ml of HCL were used in concentration.

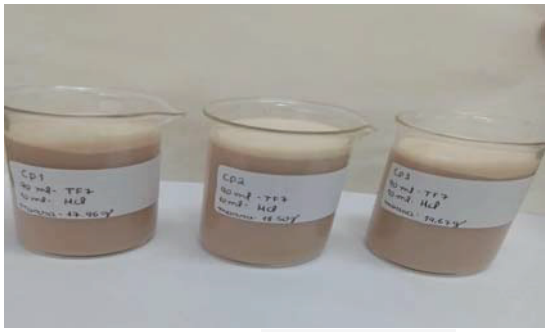

Figure 7. *CP1, CP2 e CP3 (Source: Author, 2023)*

3.4 CORROSION RATE AND INHIBITION EFFICIENCY CALCULATIONS

The fraction from the extraction of plectranthus barbatus Andrews, with the presence of H2O and Nacl acid, was evaluated as a potential corrosion inhibitor for galvanized steel, using gravimetric tests for mass loss. The intensity of corrosive processing was determined by calculating the corrosion rate (TC), which, according to ASTM G1-03 (2011), is represented by the following formula:

TC = (K.W) / A t p (equation 1)
Where:
K=Specific Constant (8.76 x 10^4)
W= mass loss (in grams)
A= area (in cm^2)
t= time (in hours)
p= specific mass (in $g.cm^{-3}$)

As a final result, the average corrosion rates were applied to the first 4 specimens of each test. The inhibition efficiency (EI) of the extract as a corrosion inhibitor was calculated from the corrosion rates (TC) by the following formula: (OLIVEIRA, T.M.de; CARDOSO, S.P., 2014).

EI = (T0 – T1) / T0 (equation 2)
Where:
T0= corrosion rate without the presence of the inhibitor;
T1= corrosion rate with the presence of the inhibitor.

4. DISCUSSION AND RESULTS

Mass loss tests were carried out according to the proposed methodology, in figure 8 shows the CP1, specimen that was submitted in a container containing only H2O. Note some corrosion spots on screws and pins. Figure 9 shows CP2, a specimen that was inserted into a container containing H2O along with the natural extract. A yellowish coloration is observed, due to some antioxidant substances contained in its composition, which implies and makes the research even more investigative. It is likely that this coloration presented in metals is a protective layer in the fight against corrosion.

Figure 8. *CP1 (H2O) (Source: Author, 2023)*

https://doi.org/10.52202/069179-0126

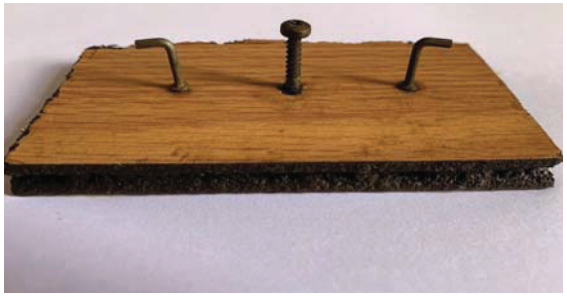

Figure 9. *CP2 (H2O+ Natural Extract (Source: Author, 2023)*

In view of this analysis, two more CPS were tested to obtain results. CP3, a specimen containing H2O + Nacl without the presence of the natural natural extract, was tested precisely to compare its corrosion rates. With this, it was possible to observe how much metals corrode, especially when they are close to saline areas. Finally, CP4 was performed, a specimen containing H2O + Nacl + natural extract (Brazilian boldo additive). In this CP, it presented a behavior equivalent to CP3, and also similar to CP2. It is observed that the compounds of this mixture act against and in favor of corrosion, a factor that provokes and induces researchers to look for results. Image 10 and 11 show the behavior of the CP tested at 14 days, which were soaked with their respective extracts.

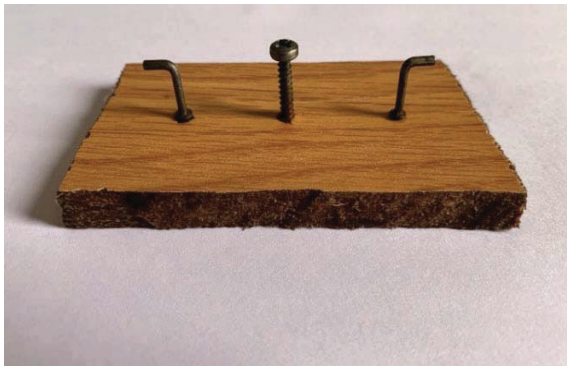

Figure 10. *CP3 (H2O + Nacl)(Source: Author, 2023)*

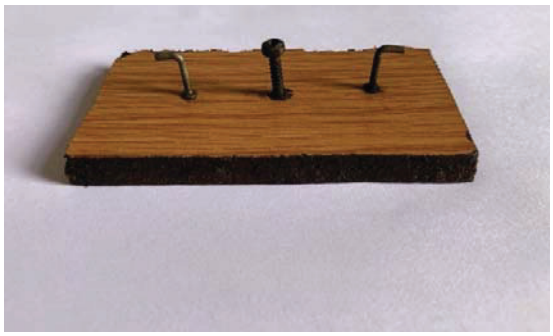

Figure 11. *CP4 (H2O + Natural Extract + Nacl) (Source: Author, 2023)*

Table 1 first shows the initial mass of the specimens referring to all the pins and screws that were embedded in the HDF sheets, before being inserted in their respective extracts.

Table 1. *Initial mass of pins and screws*

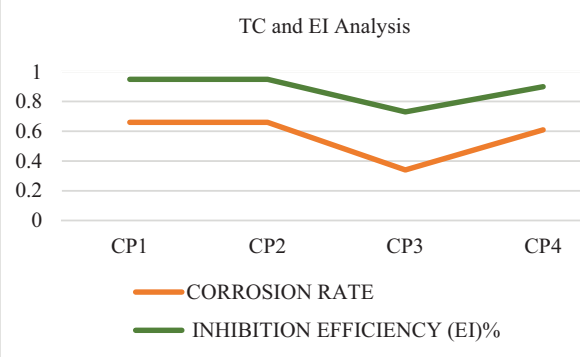
Graph 2. *Corrosion rate analysis and inhibition efficiency- Screw*



Source: Own authorship

According to the results provided by the research, there is a satisfactory reduction in the speed of the corrosive process of the CPS, this behavior is satisfactory, since there is use of the natural inhibitor in the concentrations. The data in the table and graph were calculated and compared with CP1, a neutral specimen with H2O only, which was tested without the presence of extract and Nacl in the composition. It is noteworthy that due to the delay in weight loss (w) of metals and the search for a commercial inhibitor for galvanized steel, it has not yet been possible to calculate the weight loss of pins and screws subjected to industrial anticorrosive. However, the specimens are still being tested and after 14 working days it will be possible to compare the efficiency rate with the Brazilian boldo, a natural inhibitor under study.

5. CONCLUSIONS

In the tests carried out, the loss of mass of the galvanized steel in the absence and presence of the inhibitor is verified. Even without the results of mass loss from the commercial inhibitor, it is clear that the Brazilian boldo extract presents a satisfactory inhibitory behavior for research. It can be seen in the specimens presented, a reduction in the speed in the corrosive process, leading to an efficiency of 90% and 95% of inhibition. Studies indicate that this efficiency can provide protection for both steel and wooden structures, which are subject to damage from corrosion. Given this analysis, we can conclude that Plectranthus barbatus Andrews extract becomes an excellent natural extract, as it meets the inhibition requirements. Because it uses a clean, renewable and sustainable technology, minimizing the deterioration of metals and benefiting in economic and environmental aspects when compared to other commercial inhibitors.

ACKNOWLEDGEMENT

First of all, I would like to thank God for allowing me to have health and determination not to lose heart during this work, to my parents and my sisters for all the support and help in my most difficult moments, to my teachers for all the advice and guidance and for all the patience with which they guided my learning. To the IFMA teaching institution, essential in my professional training process, for the dedication and for everything I have been learning over these years in the Civil Engineering course.

REVIEW AND COMPARISON OF DIFFERENT TIMBER BUILDING PRODUCTS' EMBODIED EMISSIONS USING FREE DATABASES.

Felipe Victorero[1,2,3] , Daniela Mendez[1,2], Felipe Bascuñan[1,2], Waldo Bustamante[3,4].

ABSTRACT: This paper aims to present a brief review of sources of information for studying the variability of embodied carbon emissions in structural wood products commonly used in construction. The review considered 13 primary sources, focused on EPDs and generic databases, and allowed the collection of data for the study of 140 products divided into Sawn lumber, Glulam, OSB, and Plywood. The information collected made it possible to identify factors such as the variability of density properties, wood species, the origin of the products, among others. In addition to analyzing the variations in the biogenic carbon of the different products studied. The results allow us to conclude that although the variability of wood products can be significant, like any product of natural origin, when they are studied within the framework of the analysis of the materials of a building, they can present a smaller fluctuation than other materials such as concrete. Moreover, this effect can be accentuated in wood products with greater density or have undergone processes that increase the mass of biogenic carbon per cubic meter in the final product.

KEYWORDS: CO2 Emissions, Embodied Carbon, Global Warming Potential, Biogenic carbon.

1 INTRODUCTION

The building sector is one of the main contributors to the global warming crisis, associated with anthropogenic GHG, with nearly 39% of the global CO2eq emissions. Moreover, when we disaggregate this percentage, we realize that almost 23% of the worldwide CO2eq emissions correspond to building materials production and transport, such as steel and cement, which represent nearly 11% of the global total [1]; while 9% of the emissions to the building's operation, and especially the energy required for space heating [2]. Even more, recent studies have raised evidence that in 2020 the anthropogenic mass became equivalent to the whole planet's biomass. More importantly, approximately 70% of this anthropogenic mass corresponds to concrete and aggregates, the most abundant manmade materials in the world and with the highest environmental impact on the planet's emissions [3].

As a result, the materials we use in our built environment are of utmost importance, since their production and effects on a building's life cycle have been responsible for a good part of the anthropogenic GHG emissions. This could also be extended to other environmental indicators such as energy use, waste production, and water pollution. Therefore, previous research has suggested that replacing steel and concrete with bio-based construction materials could help answer the current construction sector environmental problem. Likewise, studies such as the one led by the researcher Churquina [3] also present a scenario in which massive timber buildings and cities could not only reduce CO2eq emissions but also help to capture it from the environment. Turning cities into long-term carbon storages and promoting a more sustainable forest sector that could foment reforestation and afforestation processes worldwide, also helping to keep capturing carbon from the atmosphere and eventually even returning it underneath the Earth.

On the other hand, although there have been attempts to reduce the building sector's GHG emissions during the past decades, these have been insufficient and carried out primarily in developed countries. Moreover, developed countries' new and increasing attempts to reduce building sector emissions during the following decades might still be unsuccessful. This is because it is expected that the world population will increase by nearly 20% by 2050, although this will not be concentrated in developed countries but developing countries. In this matter, the need for new housing and infrastructure, in regions such as Asia, Africa, and Latin America, will be decisive if we want to decrease anthropogenic GHG emissions and limit global temperature rise under 2°C before the 2050 tipping point.

Developing countries, such as Chile, have made great efforts to commit to achieving carbon neutrality before 2050. Mostly relying upon increasing their renewable energies share, from the current 40% to an ambitious 70%

https://doi.org/10.52202/069179-0127

by 2050; but also by increasing their CO2 sequestration through new forest plantations, capturing almost 50% of the total country's emission. Moreover, this presents a scenario where buildings would benefit from a cleaner energy source, drastically reducing their operational emissions. Still, it also means that buildings' embodied emissions would become more relevant to achieve carbon neutrality emissions in the Chilean building sector. Also, creating an opportunity to get the advantage of the new forest plantation and the promotion of low embodied carbon timber buildings, which may kickstart a more sustainable development model.

2 GLOBAL WARMING POTENTIAL AND TIMBER PRODUCTS

CO2 is the most common anthropogenic GHG emission and a by-product of burning fossil fuels or biomass, being determined as the reference by which other GHG are compared in their effects on the Earth's radiative balance and global warming over a known period. Therefore, the global warming potential or GWP defines the amount of energy that the emissions of 1 ton of a determined GHG will absorb compared to 1 ton of CO2 over 100 years. In this matter, gases such as methane tend to have a GWP twenty times higher than CO2, while hydrochlorofluorocarbon gases can reach tens of thousands more GWP.

To compare the effects of different GHGs emissions with independent GWP, it is usual to multiply the GWP for a 100 years period by the total gas emission, this way obtaining a CO2 equivalent or CO2eq value. This equivalent emission allows comparing the radiative and global warming effect of different GHG, or even mixed emissions from the same or different production process. Moreover, diverse GHG emissions associated with a specific building product manufacturing can be grouped under a total global CO2eq value.

This CO2eq emission data, associated with GHG GWP factors, is usually used by designers and investors to select building products to reduce a project's overall CO2eq emissions in the early design stages. This is done mainly by comparing the buildings products' embodied equivalent CO2 emissions; when considering raw materials extraction, transport, and manufacturing prosses. Generally corresponding to a cradle-to-gate stage analysis of the life cycle or "Product stage" A1-A3 according to the EN 15978's "System Boundary."

For the designers to obtain the embodied emission information of building materials, they usually must ask manufacturers for the Environmental Product Declaration or EPD for their specific products. EPDs that consider technical standards, such as EN 15804, give detailed information on the product's environmental impact and declare the stages considered on the system boundary for evaluation. Another way to obtain the emission data is to check building products' emissions inventories databases or use specialized tools to estimate emissions through a specific material manufacturing process analysis. Although depending on the data source, emissions could drastically vary their results between products and manufacturers, depending on the process or methodology applied.

It is also important to state, especially for this review, that materials such as wood can also have biogenic carbon sequestration, considered in EPDs and databases that use more up-to-date standards, such as EN15804. This biogenic carbon corresponds to carbon captured from the CO2 in the atmosphere when the tree grows and becomes part of the final timber product structure. Therefore, depending on the process involved in timber product manufacturing and the methodology used to account for emissions, the balance between emissions and CO2 capture can be negative.

Nevertheless, obtaining the embodied emission data can be challenging, especially for timber building products. Data gathering for producing EPDs, or product inventories, is extremely time-consuming and too expensive for many companies. Moreover, free access databases are rare, limited, outdated, and usually constrained to some regions in developed countries. Thus, this is especially complicated in developing countries, where data is almost non-existent, and designers have few tools to select building materials according to their embodied CO2eq performance.

3 METHODOLOGY

This document seeks to review the most used and free access, building product's embodied emission catalogs, focusing on databases that gather EPDs and generic product inventories. Thus, comparing the GWP CO2eq emission variability of more common timber structural products with fewer production prosses, such as saw wood, and those more sophisticated such as plywood or CLT. Meanwhile, other private or paid access databases are not considered since; although they might be more comprehensive, updated, and have a friendlier user interface; they are less used by designers and project managers. A situation that is most frequent in developing countries where the requirements for this analysis are less usual, and paying for this information is not part of a project's budget.

For this purpose, the reviewed sources prioritize first more detailed data from EPDs Program Operators under the ISO 14025 standard; and second, generic environmental impact data from public catalogs and databases worldwide. Moreover, it is important to notice that the catalogs presented later are the ones that declared timber construction products at the moment of the review. In contrast, other discarded catalogs did not have timber products or any construction data, or it was impossible to access them or the information within their platforms. Also, the information needed to be accessed remotely and

in English to be useful for designers' decision-making worldwide. Yet, some specific countries' databases were language exclusive for global use purposes and, therefore, not considered.
Although data from the EPDS's Program Operators and catalogs might have differences that could make their study difficult, such as their Product Category Rules (PCR) conventions, an effort is made to homogenize de data for comparison. This is done by applying data selection criteria, simplifying their analysis, and converting functional units for comparison. Moreover, a minimum of ten different data sources is required to have representative data to analyze a specific structural timber product, such as glulam. This way, a product with little information that might distort the comparative analysis is not considered.

The criteria for selecting the data and subsequently compare results, from the mentioned sources, consider; i) selecting information from timber structural products commonly available in the market, non-structural timber products such as floors or sheathing are not considered; ii) that the EPD data considered the inclusion of EN 15804:2012+A1:2013, EN 15804:2012+A2:2019 or ISO 21930:2017 standards, which are specific for building products and give more comparable information; iii) that the LCA data consider at least product stage information, modules A1-A3 regarding extraction, material transport and manufacturing; that the global warming potential data available for the product stage, includes separate wood biogenic information; iv) that the wood spices, water content and/or density is declared, in order to identify if the product consists of softwood or hardwood; v) that the functional unit is in cubic meters or there is enough information to make a suitable conversion; vi) that the data is not older than five years, in accordance with international standard. If any previous criteria are not fulfilled, the product is not included in the study. Moreover, timber building products EPDs that could be part of multiple Program Operators or Catalogues are assigned to only one data source to avoid duplicated information.

In addition, to uniform data, functional units expressed in kilograms or square meters, when available, are transformed to cubic meters using equivalent density data and product thickness. Moreover, for timber products that declare their biogenic carbon in kilograms, in accordance with EN 16449:2014 and the atomic weight of carbon and CO2, a factor of 3.67 is used to transform it to CO2eq. Even more, for specific timber product cases, where the total Global Warming Potential excluding the biogenic carbon is not given, this is estimated by resting the informed biogenic CO2eq from the total GWP.

At last, to identify the impact of using different GWP data in a specific case, a Chilean timber frame representative 6-story dwelling building is also studied. Therefore, allowing the understanding of using different timber products' embodied emissions data versus a traditional concrete structure. Moreover, considering the overall effect of the structural material quantities analysis in a complete building evaluation.

4 RESULTS & DISCUSSION

4.1 Timber structural database.

A total of 34 EPDs Program Operators, catalogs, and databases are reviewed, remaining only 13. Most of the sources reviewed considered a specific section for construction material data and filters that allows identifying particular materials such as wood products or capabilities as structural performance. Also, most sources consider digital EPDs documents in PDF format, and only a few have additional data in other forms, such as spreadsheets or HTML data.

Table 1: *Data source*

Data source	Type of data	Source origin	N° products
Environdec	EPDs	Europe	40
EPD Hub	EPDs	Europe	3
ASTM	EPDs	America	10
SPOT UL	EPDs	America	5
EPD Irland	EPDs	Europe	8
EDP Denmark	EPDs	Europe	8
EPD Norway	EPDs	Europe	1
INIES	EPDs	Europe	26
INIES	Generic	Europe	3
IBU EPD	EPDs	Europe	4
ECO Platform [a]	EPDs	Europe	2
ICE 2019	Generic	Europe	7
Quartz	Generic	America	5
ÖKOBAUDAT	Generic	Europe	18

[a] *Although ECO Platform is one of the most significant sources of EPDs information, the data comes from other Program Operators and therefore are assigned to the original source. The remaining data correspond to EPDs that were not accessible through their Program Operators.*

The final list of EPDs Program Operators and catalogue data bases, that can be seen with more detail in table 1, consist of the EPD Environdec System [4], owned by EPD International AB, and part of the Global EPD program for publication of ISO 14025 and EN 15804 compliant EPDs; the EPD Hub [5], based in Europe and in compliant with ISO 14025; the ASTM EPD program [6], managed by the ASTM International, North American organization devoted to standards development; SPOT UL [7], program operated by UL Solutions; EPD Ireland [8], consisting of a program managed by the Irish Green Building Council; EPD Denmark [9], focused in the construction sector and with del EN 15804 European standard; EPD Norway [10], established by the Norwegian Confederation of Business and Industry; INIES EPDs data [11], French national organization which gathers materials and construction system environmental data; IBU.dat [12], which is a data base created by the Institut Bauen und Umwelt oriented to the

https://doi.org/10.52202/069179-0127

European region (IBU EPD); and ECO Platform [13], International association of private and public EPD's Program Operators. Meanwhile, regarding generic data for timber construction products, the sources compromise of the University of Bath ICE 2019 database [14], which collects data from reports and EPDs; Quartz project [15], which gathers information from EPDs, the Pharos project, and GaBi database; the ÖKOBAUDAT platform [16], from the German Federal Ministry for Housing, Urban Development and Building; and the INIES's generic data [11], built from French EPDs representative data.

Regarding the revised structural timber products, more than 30 products were discarded from the study, primarily due to lack of information, having old data, being innovative products with low market share, and/or not meeting other methodological requirements for this study. Also, some product types, such as Laminated Veneer Lumber (LVL), Nailed Laminated Timber (NLT), Dowel Laminated Timber, Laminated Stand lumber (LSL), and I-joist beams, did not meet the minimum number of product data to be included.

Consequently, the remaining list consists of 140 entries, with information not older than 2018, representing five different structural timber products. Thus, they separate into 40 sawn wood products, finger-joints are not included in this group because of the lack of representative data; 35 glued laminated timber (Glulam), this combining different elements such as columns and beans; 26 Cross Laminated Timber (CLT) products, considering panels of various sizes; 26 Plywood boards, with different representative thickness and manufacturing process; and, 18 Oriented Strained Board (OSB), with different origins and layers.

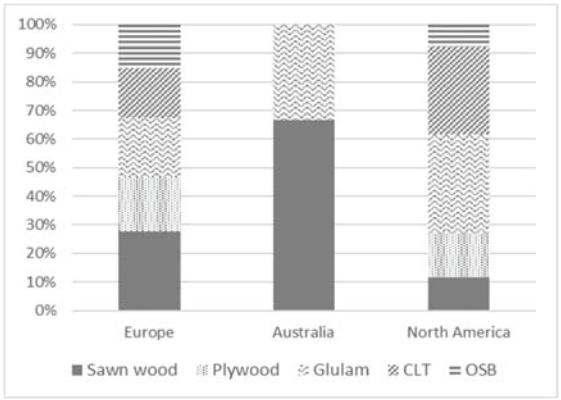

Figure 1: *Timber product share by region of origin. South America is not considered since it only has two EPDs***.**

4.2 Timber products properties.

It is well known that wood, as a natural product, presents different properties depending on various factors such as the species, growing considerations, carbon capture, water content, among many others. This has meant that many researchers have concluded that determining the global warming potential of wood products is particularly difficult. However, the properties of structural wood products are more similar to each other when compared to other non-structural products such as flooring, cladding, furniture, tools, decoration, etc. This is mostly due to the types of wood used for building structural purposes, which commonly consist of softwoods with similar properties. Moreover, engineering wood products used in building structures often have production standards that set similar physical properties to control their humidity and strength.

Therefore, from the data collected from EPD information and generic data, it is possible to identify that most of the timber structural products evaluated in this study consist of dried softwoods with an average density between 471kg/m^3 and 623kg/m^3, depending on the product type. Although some wood, such as Cypress, can have a density of more than 800kg/m^3.

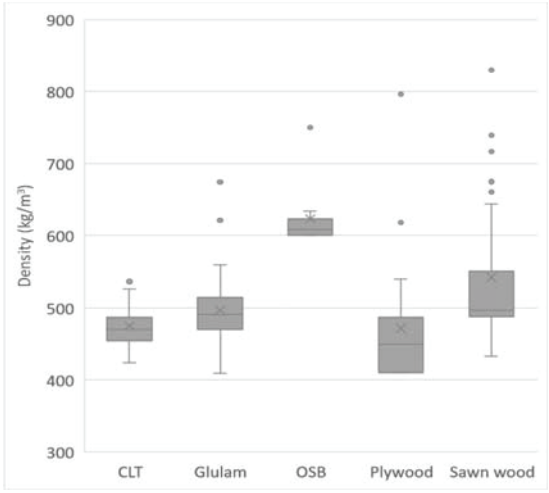

Figure 2: *Timber products and their density range.*

Moreover, the most common species within this study are different softwoods such as Spruce, Pine, and Douglas-Fir. Other hardwoods such as Poplar, Beech, or Oak are also present in products like plywood or sawn wood; nevertheless, they only represent less than 13% of the whole sample.

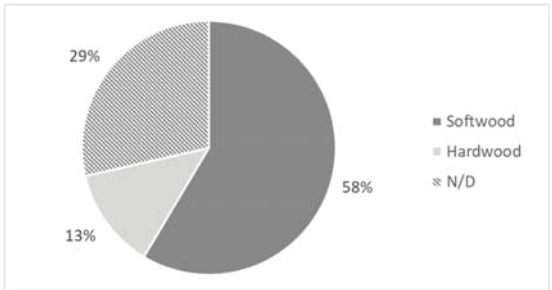

Figure 3: *Wood classification by softwood or hardwood, according to EPDs' data.*

4.3 Global Warming Potential and biogenic carbon

The wood products' Global Warming Potential results show that when biogenic carbon sequestration is considered in the product stage, the total GWP is negative in all the cases. Despite the variability in results within each timber product and the important difference that arise between product types. By comparison, products that require more manufacturing processes, have a higher adhesive or additives to wood mass relation, and present a more significant range of wood species, such as Plywood and OSB, tend to have considerable variability in their GWP results. While on the other hand, timber products with a lower manufacturing process, reduced adhesive to wood mass rates, and more consistent wood species use, such as the sawn wood, CLT, and glulam, present more consequent GWP results. Nevertheless, products with a more complex manufacturing process, such as OSB, still present lower GWP values than sawn wood.

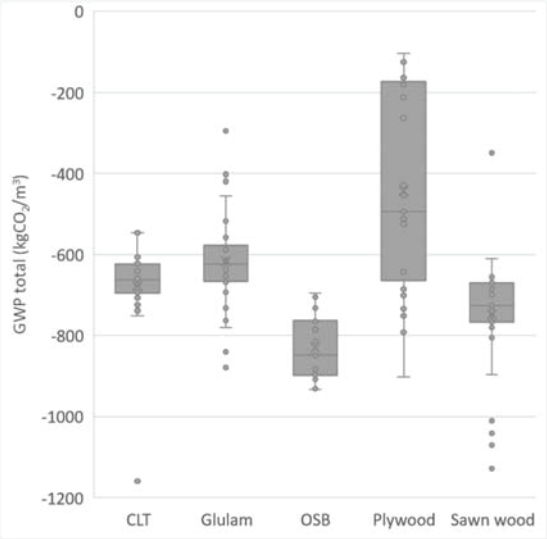

Figure 4: *GWP total by timber product, for product stage (cradle to gate), considering carbon biogenic captured in the wood mass.*

Regarding the manufacturing process, it is essential to notice that less complex manufacturing products will present lower GWP results when biogenic carbon is not considered. Explaining why, in this scenario, the sawn wood has a lower impact than the OSB and Plywood. Therefore, the final dry wood density of the product, regardless of the original wood product density before the manufacturing process, is a crucial factor to consider when studying the GWP of wood base products.

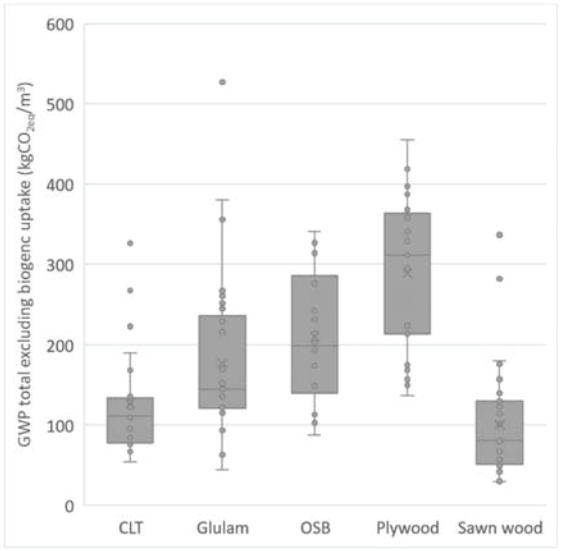

Figure 5: *GWP total by timber product, for product stage (cradle to gate), excluding biogenic carbon uptake by the wood mass.*

However, density and moisture content are crucial to determine the carbon captured in wood products, as presented in EN 16449 standard. Therefore, since structural timber products must be dry, the wood mass density would be the main factor in determining a product's biogenic carbon content. In this sense, the denser the wood used in a product, the more biogenic carbon and CO2eq are sequestered. For example, a cubic meter of dried saw Pine wood with a density of 450kg/m3 and 12% moisture content would have approximately 200.8kg of carbon or a biogenic GWP of -737.3 kgCO2eq. In comparison, a cubic meter of dried sawn Beech wood with a density of 740kg/m3 and a 12% moisture content would have 330.3kg of carbon and a biogenic GWP of -1,212.4 kgCO2eq.

Depending on the product manufacturing process, the amount of dry wood may vary. Therefore, timber products that compress wood might have a higher density than the original piece of wood used for its manufacturing and, therefore, more biogenic carbon by the cubic meter of product. On the other hand, the mass of an engineering timber product could be conformed of wood and other products such as adhesives or preservatives, reducing the amount of biogenic carbon by volume of product. For example, the density of an OSB board could be higher than the pine wood used for its production, but it is also important to take into account the adhesive density in the product to determine the total biogenic carbon. Nevertheless, and weighing their production process, an OSB board made from Pine could have a lower GWP than a Sawn wood piece of the same Pine when biogenic carbon is considered by volume in the product stage.

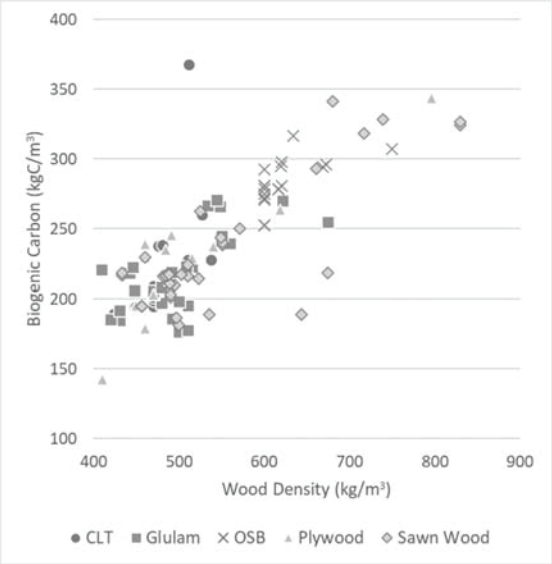

Figure 6: *Timber products' density and biogenic carbon content.*

4.3.1 Chilean case

As it is stated at the beginning of this document, the Chilean renewable energy growth scenario for the next decades is a particularly interesting case to evaluate buildings' embodied carbon versus operational emissions. Consequently, Chilean buildings that rely completely on electricity for their operation might become, in the future, almost net-zero without any important upgrades. And therefore, new building GWP emissions would mainly depend on the embodied emissions of materials.

On the other hand, Chilean structural timber is produced almost entirely in sustainable certified forests, making it possible to presume that carbon sequestration is taking place in the life cycle of a wood product. Moreover, Chilean structural timber consists exclusively of Radiata Pine, a softwood similar to the one found in the northern hemisphere market, allowing the promotion of knowledge transfer with other countries.

Nonetheless, Chile lacks information regarding the environmental impact of building materials, and the use of international EPDs or generic data is the only option in many cases. Most of the time, presenting uncertainty about the adequacy of the data and doubts about the obtained results, especially for wood-based products that also need to consider carbon sequestration as a critical factor. Moreover, the only two structural wood base products EPDs registered in South America by this study are Plywood boards from Chile, made from softwood Pine and with GWP results raging from -525kgCO2eq and -454 kgCO2eq.

Figure 7 presents the GWP totals of three 6-story buildings' structure materials, one with a timber frame construction system, a second with a mass timber structure in CLT, and a third with a traditional reinforced concrete configuration. It is essential to notice that this data does not consider a whole life cycle assessment, and it is only intended to compare the GWP of three structural building products to verify if wood-based products have higher variability in a project. For this purpose, non-wood product-stage carbon emissions are obtained from the international Institution of Structural Engineers [17] and used in the analysis along with the building's structure mass quantification.

Table 2: *Material GWP product stage (cradle to gate) in kgCO2eq/m³*

Material [a]	Avg. GWP	Min. GWP	Max. GWP	Var. GWP
Concrete C32/40 [b]	420	333.6	504	170.4
Steel plate [c]	12,403	4,451	19.233	14,782
Steel bar [d]	15,386	3,100	31,164	28,064
CLT	-678.6	-750.8	-546.7	204.1
Glulam	-617.2	-780.0	-456.8	323.2
OSB	-829.7	-933.3	-694.9	238.4
Plywood	-443.5	-901.7	-103.7	798.0
Sawn wood	-748.9	-897.2	-611.0	286.2

[a] Concrete and steel data obtained from the Institution of Structural Engineers.
[b] density of concrete 2400kg/m³
[c] Steel plate min and max GWP correspond to UK data, while average value to global data. Density 7850kg/m³
[d] Density of Steel bar 7850kg/m³

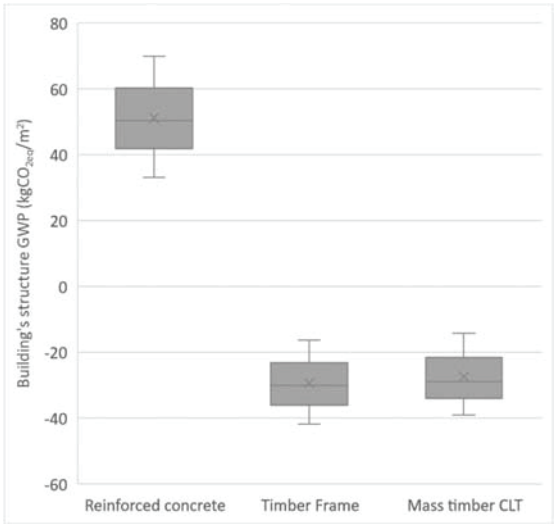

Figure 6: *Timber products' density and biogenic carbon content.*

The buildings' structural material analysis shows first, as expected, that the overall CO2eq emissions of the timber structures are lower than the reinforced concrete

alternative. It also presents that timber building structural materials' total emissions are negative, despite considering steel connectors and concrete foundations in their carbon balance. But what might be more interesting is that the variability of the CO2eq emissions is lower in the timber cases than in the concrete. This condition is explained by the higher mass of concrete in the buildings, compared to timber, and its greater importance contrasted to the structural products' GWP variability.

In the same way, although the volume of wood is higher in the mass timber case, the greater density of wood in OSB boards compensates for the embodied biogenic carbon. This makes the two structural timber systems have almost the same emissions performance for this 6-story building case. This raises the question of which timber structure is most suitable for reducing materials' carbon emissions when building mid-height structures. Tambien entre maderas mayor densidad.

5 CONCLUSIONS

First, it is relevant to remember that this is a brief study of the most popular free-access carbon emissions database for timber structural materials. Therefore it was never intended to address all the information available. Also important, it only focuses on the product stage emissions, not taking into account other important stages in a whole life cycle analysis, such as maintenance or renovations during the life span of the building product or disposal of the material at the end of life. Nevertheless, the previously mentioned stages will depend drastically on design and operation considerations and the scenarios defined for waste management. For example, burning wood products at the end of life would release biogenic carbon, although if it is reused, recycled, or buried in landfills, it might prolong the capture or even become permanent.

The study shows that most data comes from European sources, presumably because of more developed regulations and standards, along with a more informed population and industry. A condition is also reflected in the products data covering, having a similar number of EPDs available for common products such as sawn wood and more innovative products like CLT. Moreover, regions such as North America and Australia have fewer data and, in some cases, concentrate on a couple of timber structural products. Nonetheless, other developing areas have little or no data available at all, like South America, where only two timber structural products' EPDs were identified.

On the other hand, the known variability in wood's Global Warming Potential properties might be less in timber structural products than in non-structural elements. This might be explained by a more standardized manufacturing process and the preference for a small number of softwood species. Therefore spices such as Pine and Spruce are the most mentioned in the EPDs reviewed. Also, the higher density of the wood or timber products, the more significant the reduction in the total GWP associated with the biogenic carbon uptake.

Consequently, considering biogenic carbon and its mass in structural wood products used in a building shows that, although wood may have a higher GWP variability, this is offset by the lower mass required by other materials such as concrete. Thus, a concrete building may have a higher variability in its overall performance, despite concrete having more limited GWP data variability. Therefore, timber structural average GWP data, like the one presented by this study, might have less variability than other traditional material data, such as concrete, when a whole structure building is considered.

Finally, when comparing timber-frame and CLT structures, it is interesting that although their mass volume may vary, the greater density of products such as OSB boards make them have almost the same CO2eq emission for a 6-story building. Because even though the CLT and the OSB can be made of the same tree, the density of the second would have more biogenic carbon per cubic meter due to the manufacturing process and the increase in density. Nonetheless, there are several other factors to consider when studying timber products' environmental impact, apart from GWP, which could have significant implications in a whole life cycle assessment of a product and building. Therefore it is expected that more complete and detailed studies in this matter will follow the present work.

LIFE CYCLE ASSESSMENT ON DIFFERNET TIMBER BRIDGE TYPES: DECK BRIDGE, BLOCK GIRDER BRIDGE, TROUGH BRIDGE, PYLON BRIDGE

Özlem Özdemir[1], Annette Hafner[2]

ABSTRACT: Germany's national climate targets set the ambitious goal of achieving net zero emissions by 2045, which is in line with the Paris Agreement. The construction sector is a key player in reducing greenhouse gas emissions. In Germany, the focus has always been on the building sector, while little attention has been paid to civil infrastructures. At the international level, civil infrastructures are increasingly assessed and analysed for their environmental impact using life cycle assessment (LCA), although here, too, the use category of foot and bicycle bridges has hardly been studied. In the context of local mobility, foot and bicycle bridges (FBB) play an important role in the regional and local transportation network. Since in Germany timber bridges are used for FBB this paper presents, a standardized approach for life cycle assessment of bicycle bridges. A total of four different types of timber bridges are distinguished: deck, block girder, trough and pylon. The LCAs were performed following the applicable standards. The results show that the impact is influenced by different bridge components, although provides a basis that allows a first impression of the LCA results.

KEYWORDS: life cycle assessment, timber bridges, environmental footprint, carbon storage

1 INTRODUCTION

In line with the Paris agreement of 2015 [1] and in view of sustainable development goals, Europe has defined ambitious climate protection targets to be achieved by 2050. With 95 percent probability, human action has the greatest impact on climate change. [2] The use of resources is directly related to environmental impacts such as global warming and greenhouse gas emissions. Neverless, demand for natural resources will increase due the growth of the world population and increasing urbanization, as well as the needs of built city infrastructure. [3,4]

In the context of local mobility, foot and bicycle bridges (FBB) play an important role in the regional and local transportation network. The municipal budget situation is often a decisive criterion for awarding contracts. The construction of infrastructure demands nearly 40 % of all raw material consumption.

Bridge structures under municipal responsibility are assumed to be in similar condition to bridge structures under federal or state responsibility, increased replacement can be expected. It is therefore important to create basic data and to develop a uniform application system and to demonstrate the applicability and advantages to decision-makers.

The European Commission promotes the use of organic building materials such as wood from sustainable forestry to minimise the footprint of constructions through resource efficiency and circularity combined with transform parts of the construction sector into a carbon sink [5].

The primary energy non-renewable (PENRT) input in the life cycle represents the use of primary raw materials, the global warming potential (GWP) shows the impact on the global environment.

2 LITERATURE

The literature shows the beginnings and the developments of LCA in the field of bridges.

The beginning of LCA conducting on bridges were made by Horvath and Hendrickson [6], Widman [7] and Lünser [8] in 1998 wherein they compared different bridges on the environmental impact through the choice of material. Further LCA studies were conducted to analyse the impact of the of new materials compared to conventional materials [9]. Comparing of similar bridge components and materials with different maintenance scenarios were carried out by Penadés-Plà et al. [10]. Itoh et al. investigated for example whether the overall environmental impact of a bridge with increased maintenance is lower [11]. There have also been studies that examined the environmental impact of different bridge forms in different material categories by considering the construction and maintenance phases in terms of energy consumption and CO2 emissions [12].

https://doi.org/10.52202/069179-0128

In a further study, an approach is being developed in which the risk of natural events, such as earthquakes, is to be taken into account in the life cycle assessment of a bridge [13].
Although LCA has been applied in the research context of bridges since 1998 and a wide range of impacts have been studied taking into account varying aspects, it has not yet found its way into practice and is still rarely used in decision making. This is mainly due to the application method, which has not yet been harmonized.
To identify the significant differences in the methodological approach a literature survey were conducted. The main differences were identified, for example, in the:
- functional unit
- system boundaries
- functional equivalence
- period of consideration
- considered product systems

The functional unit (FU) is the basis for comparing LCA results. The survey has shown that the FUs are consistent within the studies but differ between studies, as follows:
- m² superstructure.
- m² roadway
- absolute or percentage comparison
- m superstructure.
The differences in the FUs complicates the comparison of different studies, regardless of functional equivalence and system boundaries.

system boundaries
The determination of the spatial and temporal system boundaries makes it possible to limit the system to be considered, in this case the bridge structure, so that concrete results can be obtained.
The spatial system boundaries include different observation areas in the studies carried out. For example, in some studies, the system boundaries are set such that the entire structure falls within the observation space. In other studies, however, the system boundaries are based only on the superstructure, or/and the effects of potential traffic disruptions due to rehabilitation measures are included.
The temporal system boundary allows the system to be divided into specific phases over the life cycle phases in order to identify specific hotspots. Thus, the historical development of the databases shows that more and more detailed life cycle phases could be included in the investigations.

functional equivalence
The definition of functional equivalence according DIN EN 15643-5 is, in which the function is described by the functional equivalence. The functional equivalence describes the quantified functional requirement and/ or technical requirements of an engineering structure or of a assembled component, and serves as a basis for comparisons. [14]

Most studies compared two alternative variants designed for the same conditions and for the same location.

period of consideration
The period under consideration can vary depending on the category of use, the main material or the objective of the study. Within the survey the period of consideration varies between 50 and 200 years. For the use categories, the time periods considered were defined as follows:
- Foot- and Bicycle bridge 50 years
- Railroad bridge: 100 to 120 years
- Highway bridges: 50 to 200 years

considered product systems
Bridge structures are examined in varying detail in the studies within the areas of consideration. Component groups are defined as the umbrella term for the grouping of components that serve similar purposes. The levels of detail differ from study to study. For example, bridge structures are only considered subdivided into the component groups substructure and superstructure (cf. [15]) or more detailed levels of detail are formed (cf. [8,16–18]).

The literature survey has also shown that most LCA studies were conducted for road bridges. And most of the conductions were not always in line with the standards.
Different studies has approved that the materials use in the construction has a variable of environmental impacts (e. g.: [6–10,19]).

3 METHODOLOGY

3.1 LIFE CYCLE ASSESSMENT

Life cycle assessment (LCA) is a methodical approach to assessing the environmental impacts associated with all phases of a construction's life, i.e., from raw material extraction through material processing and use to the end of use stage. The generally applicable standards are specified by the principles and framework in ISO 14040 [20] and the requirements and guidance in ISO 14044 [21]. Applied LCA for the construction sector is specified by EN 15804 [22], in which the framework is related to the building product level, and by EN 15978 [23], in which the framework conditions for assessing the environmental performance of buildings is defined.
The modular structure of the entire life cycle is in accordance to EN 15643: 2021 [24], which includes the production and construction phase (module A), the use phase (module B) and the end-of-life phase (module C).

3.2 LCA FOR FOOT AND BICYCLE BRIDGES

The framework for the conduction of LCA is explained step by step for the calculated bridges. The step of categorisation by main materials use will be skipped within this study.

3.2.1 Use category

In the first step the considered use category is defined. Within this study the considered use category is FBB and

FB and is defined analogously to the recommendations of the *Forschungsgesellschaft für Straßen und Verkehrswesen e. V.*, in which the geometric framework is defined. Accordingly, it is determined that a FB should have a minimum walkway width of 1.80m and a FBB a minimum path width of 2.5m. Figure 1 illustrates the distinction.

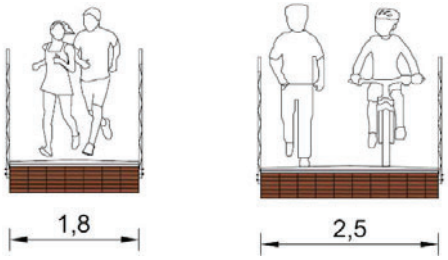

Figure 1: *Minimum path widths accordingly EFA und ERA, a) FB, b) FBB*

3.2.2 Bridge types

The different types of timber bridges which were considered as for foot and bicycle bridges (FBB) are as follows.

Deck bridge (DH): The main girder of the timber deck bridge consists of at least two solid girders and spans the entire bridge cross-section. The deck is attached to the longitudinal girders. The deck can be either waterproof or water-bearing. Depending on the decking, the structural timber protection is designed. [25]

Figure 1: *Example of a deck bridge*

Block girder bridge (BH): A further development of the traditional deck bridge is the timber block girder bridge. The timber block girder is composed of a solid block glued with timber and spans the entire cross-section of the bridge. The entire block cross-section can be used as a roadway, with the roadway itself serving as additional weather protection. Structural timber protection is established by the shape of the cross-section, the overhangs, and adequate air circulation. [25]

Figure 2: *Example of a Block girder bridge*

Through bridge (TH): The main structure of a wooden trough bridge is formed by two main girders and is located between the roadway and the railing at the railing level and is secured against tipping by a stiffening steel to prevent overturning. Structural wood protection is provided by the top cover and lateral cladding of the main girders. main girders. [25]

Figure 3: *Example of a Through bridge*

Pylon bridge (PH): The main component of the load-bearing system of cable-stayed or suspension bridges are pylons. The pylons are used to transfer loads from the superstructure to the substructure via stay cables or via hangers. The superstructure is formed by a bracing girder so that the loads from the deck are distributed to the cables or suspension cables. The stiffening of the superstructure eliminates the need for supporting structures. The types of construction described above are suitable as superstructure. [26]

Figure 4: *Example of a Through bridge*

https://doi.org/10.52202/069179-0128

3.2.3 Period of consideration
Within this study the considered period is 50 years.

3.2.4 Bridge size
The study includes a total of 10 bridges of different size and bridge type. The sizes of the considered bridges are listed in Table 1 and vary between 63 to 288 m².

Table 1: *Bridges and road areas*

Bridge	Road Area [m²]
DH4	69
BH1	288
BH2	68
PH1	114
PH3	146
PH4	125
PH5	141
TH1	85
TH3	63
TH4	169

3.2.5 Considered product systems
Despite the different types of construction, bridges are basically of comparable design and can be divided into main components and subcomponents. In bridge construction, a distinction is made between superstructure, substructure and equipment as main assemblies. Whereby a component group includes components that serve similar purposes.
In the context of this study, the superstructure is considered, which integrates the component group of equipment.

3.2.6 Functional equivalence
As the aim of this study is not to compare but to generate results to create a database the functional equivalence as it is defined is not given. Al considered bridges belong to the use category of foot and bicycle bridge.

3.2.7 Database and calculation program
Since 2013, the dataset Oekobau.dat comply with the standard DIN EN 15804 and includes information on the environmental impact of construction, transportation, energy disposal processes and building materials, enabling life cycle assessment over the entire life cycle.
The results base on Oekobau.dat Version 2020-I.
The calculations were conducted with the R_ENI-LCA Tool. The Tool is explained details in Özdemir [27].

4 RESULTS
The LCA-Results for the indicators GWP and PENRT are shown in Figure 5 and Figure 6.

The Database for the indicator GWP and timber bridges are between 3 and 7 [kg CO2 eq./m²*a]. Whereby the minimum GWP value was calculated for the bridge TH1 and the maximum Value for the bridge PH1.

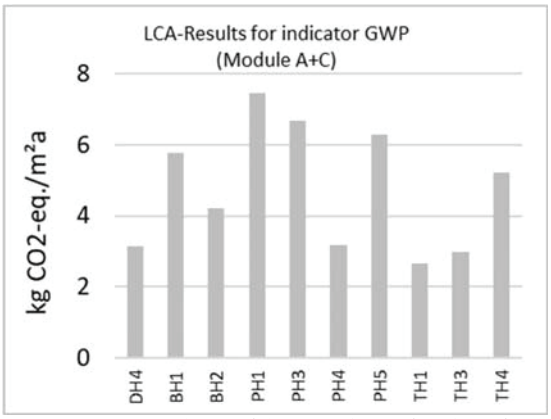

Figure 5: *LCA Results (Module A+C) for Bridges for indicator GWP [27]*

The Database for the indicator PENRT and timber bridges are between 32 and 92 [MJ/m²*a]. Whereby the minimum PENRT value was calculated for the bridge TH1 and the maximum Value for the bridge TH4.

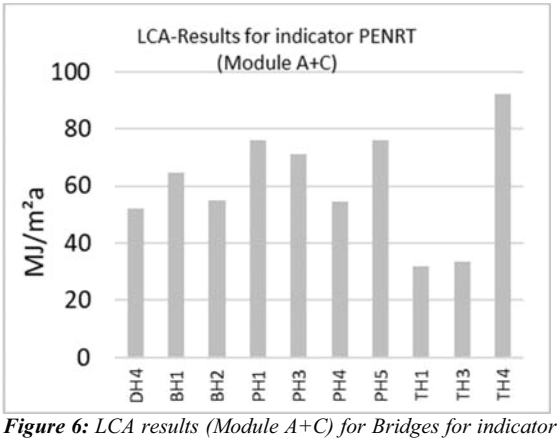

Figure 6: *LCA results (Module A+C) for Bridges for indicator PENRT [27]*

5 CONCLUSIONS
This study considers in detail the environmental impacts of municipal bridge structures, timber FBB, over the entire life cycle. The area of the use category GRB does not play a role in previous research on LCA. The present work forms the basis for further research projects.
An LCA bridge database can assist decision makers in decision making and facilitate the classification of LCA results. In the context of local mobility, foot and bicycle bridges (FBB) play an important role in the regional and local transportation network and focusing on timber bridges here could be an interesting focus for additional climate protection.

STRUCTURAL AND LIFE CYCLE ANALYSES FOR A TIMBER-CONCRETE HYBRID BUILDING

Xiaoyue Zhang [1], Wanru Huang [2], Mehdi Khajehpour [3], Mehrdad Asgari [4], Thomas Tannert [5],

ABSTRACT: The concerns related to the impact of construction materials are increasing globally. Timber-based hybrid buildings combine the structural benefits of multiple materials, reduce the carbon footprint, shorten construction times, and potentially improve seismic and building physics performances. In this paper, a ten-story timber-concrete hybrid building, designed for a location in the Guizhou Province, China, is compared to a pure concrete building. The structural analysis showed that the self-weight of the hybrid structure was reduced by 30% compared with the concrete structure, and the base shear forces in X- and Y-directions decreased by 43% and 29%, respectively. The life-cycle analysis showed that hybrid building had lower impacts than the concrete building in six categories: global warming potential, acidification potential, human health particulate, eutrophication potential, ozone depletion potential, and photochemical ozone formation potential. Specifically, in terms of global warming potential, the hybrid building had nearly 65% lower emissions, and the wood components have the additional advantage to store carbon over their lifetime. These results promote the development and application of high-rise timber-based hybrid buildings in China.

KEYWORDS: Tall Timber, Hybrid Building, Structural Design, Life Cycle Analysis

1 INTRODUCTION

1.1 BACKGROUND

Timber-concrete hybrid buildings combine the benefits of both materials, specifically the environmental benefits of timber and the fact that concrete is non-combustible. The most common type of tall wood hybrid structures is combining a cast-in-place concrete core that resists the lateral loads, with the timber structure carrying the gravity load [1]. Many feasibility studies have confirmed the significant potential of timber-concrete and timber-steel hybrid systems in terms of structural performance, sustainability, and construction speed [2-5].

Several timber-hybrid buildings have been successfully constructed. The 8-storey LifeCycle Tower ONE has concrete foundations and a concrete core, with glulam columns and hybrid slabs that span up to 9 meters [6]. The world's tallest hybrid wood-based building, the 18-story "Brock Commons" in Vancouver, Canada, features a cast-in-place concrete ground floor and two elevator cores with CLT floors and Glulam columns [7]. The 17 stories of mass-timber superstructure carry all gravity loads, while two concrete cores act as LLRS.

These successful examples illustrate the potential of timber-concrete hybrid buildings in offering a combination of structural and environmental benefits.

1.2 LIFE CYCLE ASSESSMENT

To evaluate the environmental impact of buildings, Life Cycle Assessment (LCA) has been developed to provide an in-depth assessment of the life cycle performances of entire buildings, construction materials, and components, from the "cradle" to the "grave" [8]. Designers use LCA to assess the impact of a building's energy and materials on the environment, systematically integrating the complete life cycle of products to develop sustainable building solutions [9]. LCA allows estimating the environmental impact over the entire lifespan of residential, commercial, and industrial buildings, from resource extraction to land filling and beyond [10].

Numerous previous studies have compared wood to other building materials such as reinforced concrete. For instance, Robertson et al. [11] demonstrated that the environmental impact from the cradle-to-construction site of traditional cast-in-place concrete is higher than that of wood products (hybrid CLT and glulam).

Basaglia et al. [12] compared the LCA of three materials (GLT, CLT, and concrete) and showed that the embodied energy of CLT is almost 2.5 times higher than that of concrete. Lu et al. [13] sowed that emissions of engineered wood in the environmental categories of greenhouse gas, acidification, human toxicity, and fission depletion are all low compared to concrete and steel for multi-storey residential buildings. Jayalath et al. [14] assessed the environmental impact of high-rise residential buildings in CLT and showed that the carbon dioxide emissions were reduced by up to 34% compared with reinforced concrete residential buildings. However, there is limited research on LCA for timber-concrete hybrid systems.

1.3 OBJECTIVE

The objective of this research was to promote the development of timber-based hybrid high-rise construction systems in China. To meet this objective, the structural and environmental performance a 10-storey case-study glulam timber frame with concrete core structure is compared to that of a pure concrete building.

1.4 BUILDING DESCRIPTION

A hybrid system composed of wood frames and concrete shear walls for a 10-storey hotel, located in Jianhe County, Guizhou province of China, was designed. The storey height was 3.9 m, for a total building height of 46.4 m to the top of the roof, with a typical story floor area of 924 m^2 (23.1 × 40 m) for a total 10,000 m^2 building area.

The hybrid building, shown in Figure 1a, consisted of a concrete core, concrete base, and a glulam frame system. The first concrete floor is the parking lot, and the upper nine stories consist of mass-timber superstructure, carrying all gravity loads. The concrete core acts as the wind and seismic lateral load-resisting system [15]. The structure was designed in accordance with the structural design codes and technical standards of China. For some connection and component design, i.e., the timber-concrete composite (TCC) beams, Eurocode 5 [16] was used as a reference.

The pure concrete building, illustrated in Figure 1b, also consisted of a concrete core and a concrete base used as the parking lot, but instead of using wood frames for the gravity system, it had a reinforced concrete gravity framing. The design was based on Chinese building code GB50010-2010[17].

2 METHODS

2.1 STRUCTURAL DESIGN

The gravity loads included dead load, live load, and snow load. The total dead load for typical floor (including 100 mm concrete topping, partition load and miscellaneous) was 380 kg/m^2. For the roof, the total dead load was 280 kg/m^2. The live load was 250 kg/m^2, and the roof snow load was 500 kg/m^2, based on the location. All values are typical for Chinese hotels and were obtained from GB 50009-2012 [18]. According to GB50011-2010 [19], the lateral systems were designed for seismic intensity 7 with a basic ground acceleration of 0.1 g for a site class II.

The hybrid model adopted Glulam frames to transfer the gravity loads to the foundation. Grade TC_T21 was used for both girders and columns [15,18]. Based on the vertical loads, the typical column size was 580 × 580 mm. The Glulam girders as the main framing beams span between 9 and 11 m in north-south direction with secondary glulam beams placed on top in east-west direction, see Figure 2. The depth of girders was 580 mm to satisfy the structural clearance requirements. The 290 × 290 mm cross section was selected for the glulam beam girders and 240 × 400 mm cross section was selected for secondary glulam beams, all based on the Chinese timber building design codes GB 50009-2012 [18], GB5005-2017 [20], GB 50206-2012 [21], and GB T 50329 2002 [22].

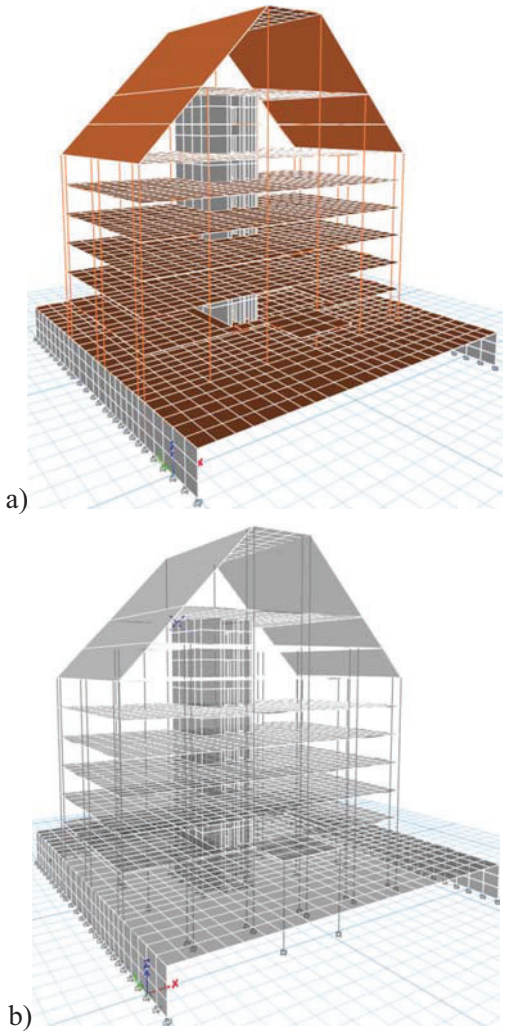

Figure 1: *3D ETABS models: a) hybrid building; b) concrete building*

Figure 2: *Typical floor plan for both buildings*

2.2 STRUCTURAL ANALYSIS

Both buildings were modelled in ETABS [23]. In the hybrid model, the wood frames were used to transfer the gravity loads. The columns were pinned to avoid imposing any lateral stiffness on the lateral load-resisting system. P-Delta effects, which are created from the lateral deflections, were also considered.

The concrete building design was based on GB 50010-2010 [17]. There, concrete slabs and columns transfer the gravity loads, and the slab/beams and columns were connected through a fixed connection. Normal density concrete with a strength grade of C30 was used.

For both models, the main structure (top 9 stories) stands on the underground floor with perimeter retaining walls. The loads coming from the soil pressure were also taken into account and imposed on the retaining walls. The column bases were modelled as pinned to the ground to neglect the stiffness of the base column connections, which is negligible compared to the stiffness of the shear walls. The foundations were composed of strip footing under the columns and perimeter retaining walls, with a slab (pad) footing under the core shear wall.

Regarding the lateral load resisting system, ductile-reinforced concrete shear walls were assigned to both models. In the hybrid model, the walls were put in the middle of the plan as a “core” system to accommodate architectural elements. Concrete slabs on the metal deck, which seats on the wood frames, were modelled to carry the gravity loads, and to act as the diaphragm to transfer the seismic shear to the core shear walls. For the concrete model, the shear walls were optimized along with the reinforced concrete moment frames to transfer the seismic loads.

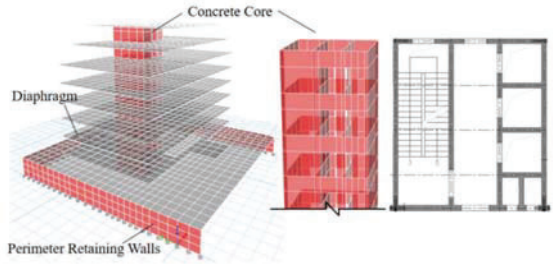

Figure 3: *Lateral Load Resisting System for both models*

2.3 LIFE CYCLE ASSESSMENT

The Athena Impact Estimator for Building (IE4B) [24], an open-source software, was used to assess the environmental impact of both buildings. It can be applied to any type of new construction, renovations, and additions projects in North America.

Athena IE4B contains life cycle inventory (LCI) called the Athena database, or TRACI [25]. LCI is the data collection portion of the LCA [26]. These methods focus on the following impact categories: ozone depletion climate change, acidification, eutrophication, smog formation, and non-renewable energy consumption [27]. The material inputs for LCA came from the building's design blueprints and were included in the Data collection report. 60 years was selected as the service life for a commercial structure. The cradle-to-grave LCA data found within the various LCI databases conform to ISO 14040 standards [28].

To conduct LCA and compare the environmental impact of the hybrid and pure concrete buildings, six impact categories of the TRACI protocol were used. The calculation process is divided into three main parts: (i) estimate of quantities of materials and processes in the building; (ii) estimate of environmental impacts for each material and process; (iii) estimate of the total environmental impact of the building. The scope of this LCA was a cradle-to-grave assessment of the material effect of structure, envelope, and operating energy and water use during 60 years modelled by IE4B [24].

3 RESULTS

3.1 BASE SHEAR COMPARISON

The base shear forces were obtained from the ETABS models based on the seismic provisions of the Chinese code. As shown in Figure 4, the seismic base shear forces for hybrid model (timber-concrete hybrid structure) and concrete model (pure concrete structure) in the X direction are 3,449 kN and 4,716 kN respectively, which is 43% different. The values in the Y direction are 3,084 kN and 3,983 kN, almost 29% different. The lower base shear of the hybrid model shows the efficiency of replacing the concrete framing.

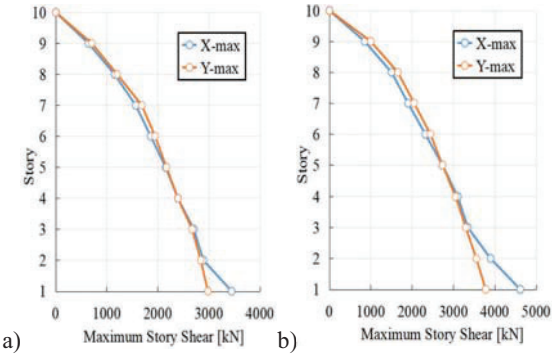

Figure 4: *Storey shear: a) hybrid building; b) concrete building*

https://doi.org/10.52202/069179-0129

3.2 INTER-STORY DRIFT

The current Chinese Code for Seismic Design of Building (GB50011-2010) [19] limits the elastic and elastic-plastic inter-story drift to 1/800 and 1/100, respectively, to limit the damages to the lateral load resisting systems and the non-structural components and sensitive elements of a structure. Figure 5 shows the "elastic" story drifts of hybrid and pure concrete structures, respectively, under the response spectrum in the X direction.

For the real "inelastic" story drifts, these values must be multiplied by the corresponding ductility coefficient of the structure. Since the intention of this article is simply to compare these two systems, we will only consider the elastic story drift ratios. The drift of storey 2 in the hybrid structure is nearly half of that in the pure concrete structure (0.030% versus 0.056%), which were below the drift limit of 1/800. The reason for this large difference is that the weight of the super-structure is much higher in the pure concrete structure.

On the other side, the stiffness of the storey 2 lateral load-resisting system in both buildings is almost the same, since both buildings' shear wall thicknesses are the same. The reason is that, in Chinese concrete code, the shear wall thickness is usually governed by the "minimum" wall thickness based on the level of "ductility" and the height and width of the walls, in other words the geometry. Therefore, both buildings required the same wall thickness. The second main observation is that, for the higher stories, the drift ratios for the pure concrete structure are higher than the hybrid structure, however, this difference is lower, around 25% to 50%.

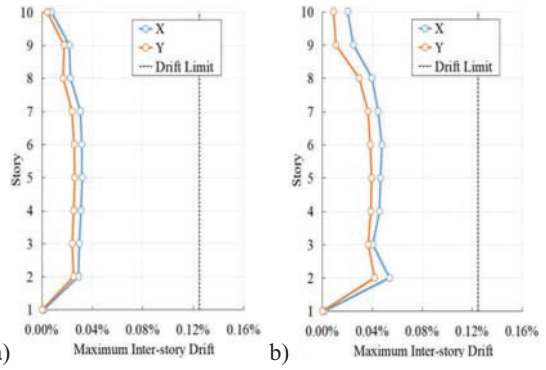

Figure 5: *Maximum story drift in X direction: a) hybrid building; b) concrete building*

3.3 BUILDING MATERIAL INVENTORY

The 10-storey concrete building set the baseline for the Bill of Material (BOM). The BOM of the buildings exported from ETABS includes foundations, columns, beams, floors, and walls. The pure concrete structure consists of a shear wall, concrete slabs, concrete columns and beams, and all the rebars related. On the other hand, the hybrid structure includes a foundation, concrete shear walls, concrete topping of the slab, and glulam beams and columns.

After inputting the BOM of the two buildings, the total mass value of materials used in each building component was computed. As shown in Table 1, replacing concrete frames with wood frames has reduced material consumption. The amount of concrete used in timber-concrete hybrid structure is 5632000 kg, versus 9189000 kg used in the pure concrete structure, which is 40% less. Additionally, the foundation in the hybrid building is only 700 mm thick under the core wall, versus 900 mm thick core wall slab footing under the concrete footing. This will require less excavation and a faster construction procedure. Lower concrete consumption along with the lower base shear has also resulted in less steel reinforcement needed for the composite structure. The hybrid structure only used 39% steel reinforcement of the amount used in the pure concrete structure. This reduction in concrete and steel consumption will have a great impact not only financially, but also in terms of CO_2 emission and environmental effects.

Table 1: *Bill of Material for hybrid and pure concrete building*

Hybrid model			
Materials	Concrete (m^3)	Glulam (m^3)	Steel (kg)
Columns, beams	0	304	0
Floors	1041	1251	26000
Foundation	599	0	16000
Roof	0	0	0
Wall	791	0	35000
Total Volume (m^3)	2431	1555	-
Total Mass (kg)	5632000	727000	77000
Pure concrete model			
Materials	Concrete (m^3)	Glulam (m^3)	Steel (kg)
Columns, beams	210	0	42000
Floors	1933	0	100000
Foundation	889	0	19000
Roof	0	0	0
Wall	791	0	39000
Total Volume (m^3)	3823	0	-
Total Mass (kg)	9189000	0	200000

3.4 LIFE CYCLE ANALYSES

Table 2 shows the comparison of the overall impacts of the two buildings. The hybrid building performs better in all analyzed impact categories. The critical part of these results is the difference in Global Warming Potential (GWP) where the hybrid building has 65% lower value. The tropospheric ozone formation potential (Smog or POCP) value of forest operations is affected by the emissions of a chainsaw, but the wooden material still performs better than concrete with 18.4 kg O_3 eq /m^2 less. Stratospheric Ozone Depletion (ODP) and Acidification Potential of the hybrid building are 9% and 15%, respectively.

Table 2: *Cradle to Grave LCA comparison for two functionally equivalent buildings*

Summary measure	Hybrid building	Concrete building
Global warming potential (kg CO_2 eq)	1.79E+06	6.26E+05
Stratospheric ozone depletion (kg CFC-11 eq)	1.58E-02	1.44E-02
Acidification potential (kg SO_2 eq)	8.76E+03	7.42E+03
Eutrophication (kg N eq)	8.02E+02	7.01E+02
Tropospheri ozone formation (kg O_3 eq)	1.84E+05	1.48E+05
Depletion of non-renewable energy resources (MJ)	1.66E+07	1.25E+07

Figure 6 displays the percentage contributions of the building components to six environmental impact categories using LCA results. For the concrete building, the foundation which was the second most concrete and the floor and roof which was primarily concrete by volume contributed approximately 50% of the building material. Similarly, the timber-concrete hybrid building was separated into the same components, except that the mass-timber superstructure, responsible for carrying all gravity loads, rested on a concrete core that acted as both the wind and seismic lateral load-resisting systems.

The environmental impact indicators for both buildings were primarily attributed to the floors and roof, with roughly 50% impact in all categories, except for Global Warming Potential (GWP), which had a lower emission rate of 15% in the hybrid building due to the use of mass timber. As a result, the GWP was reduced by 35% in the timber-concrete building. In the pure concrete structure, the foundation was responsible for the second-highest emission portion, with 23% in Ozone Depletion Potential (ODP), 22% in Acidification Potential (AP), Human Health (HH) potential, Eutrophication Potential, and 21% in Smog Potential. However, the foundation's contribution decreased to approximately 17% in the timber-concrete hybrid building, while it remained the second-highest emitter in GWP with 42%. Shear walls had similar emissions in both buildings, with approximately 21% in the concrete structure and around 22%, except for GWP with 57%, in the hybrid building. The columns and beams had the lowest contribution to environmental impact, with approximately 7% in the pure concrete building and around 6% in the hybrid building. However, this decreased to -14% in GWP due to the glulam material used.

Overall, the use of timber in the hybrid building results in a lower environmental impact across all indicators, especially in terms of GWP. The environmental emissions of the hybrid building are improved by incorporating TCC floors, replacing the traditional cast-in-place concrete floors. As a result, the GWP of a 10-story timber-concrete hybrid building is estimated to be reduced by approximately 35%.

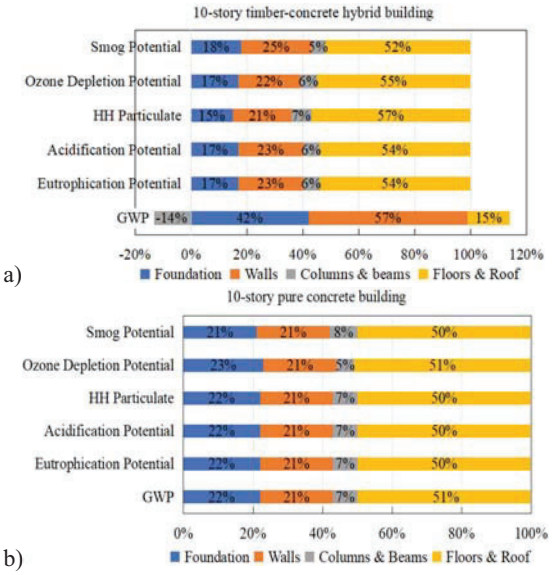

Figure 6: *Percentage of contribution to environmental impact category: a) hybrid building; b) concrete building*

Figure 7 presents the emissions of concrete and mass timber buildings separated by life-cycle stage for the categories of GWP, acidification potential, human health particulate, eutrophication potential, ozone depletion potential, smog potential, and total primary energy. The A1-A3 stage contributed 88% and 87% of the total GWP emissions for concrete and mass timber buildings, respectively. The construction (A4 and A5) and end-of-life (C) stages contributed more to the total emissions of the hybrid buildings than the concrete building. In addition to GWP, ozone depletion potential, and human health particulate, eutrophication potential has a significant environmental impact on both buildings, with total eutrophication potential emissions of 829 and 712 kgN eq for pure concrete and timber-concrete hybrid buildings, respectively, of which 80% and 84% are attributed to the production stage (A1-A3).

The beyond-life considerations are difficult to predict decades into the future. For mass timber buildings, the GWP impact category can be highly influenced by the beyond-building life stage (D) and how carbon emissions are accounted for. Figure 8 studies the beyond-building life emissions (stage D), including the biogenic carbon of the mass timber buildings. The results show that the amount of sequestered carbon for the hybrid building, stage A-D, is significantly lower than the total amount of embodied carbon for stages A-C. It should be noted that this study does not include the contributions of non-structural interior building components, such as partition walls, carpeting, windows, etc. Therefore, the timber-concrete hybrid building has a significantly lower environmental impact than the concrete structure, mainly due to the much smaller amount of sequestered carbon related to the timber-concrete hybrid building.

4 CONCLUSIONS

The structural and environmental performance of two ten-storey buildings with different frames was compared: one with a wood frame and the other with a concrete frame. The following main conclusions were drawn:

1) Using wood in the hybrid building led to a significant reduction in weight of about 30%. Additionally, the hybrid building had superior seismic performance, which reduced foundation requirements, resulting in time and cost savings. The maximum inter-storey drift in the hybrid structure was almost half that of the all-concrete structure, which was below the drift limit of 1/800.

The LCA results indicated that the hybrid building had favourable values for all categories considered, such as global warming potential, stratospheric ozone depletion, acidification potential, eutrophication, smog potential, human health particulate, non-renewable energy consumption, fossil fuel consumption, and total primary energy consumption. The hybrid building emitted nearly 65% less CO_2, and the wooden components acted as carbon storage for its entire lifetime.

Based on the structural and environmental performance of the hybrid building, this study can serve as a useful guide for the design of timber-based hybrid high-rises in China. The results demonstrate the benefits of using wood in construction, including reduced weight and improved seismic performance, which can save on foundation requirements, time, and cost. Moreover, the significant reduction in CO2 emissions and the carbon storage potential of wooden components in hybrid structures can contribute to mitigating the effects of climate change.

EVALUATION OF THE RECYCLABILITY OF WOODEN BEAM STRUCTURES

Zsofia Varga.[1], Antonia Birkholz[2], Anna Wagner[3] Stefan Winter,[4]

ABSTRACT: The aim of this paper is to present a methodology for increasing the material recyclability of wooden beam structures. The methodology was developed as part of a research project in which the deconstructability of wooden beam structures of agricultural halls was investigated. The load bearing structure of six agricultural halls was documented and the connection points of their main structure were evaluated with regard to their recyclability. In the following, it will be investigated to what extent the choice of fasteners is relevant with regard to the recyclability of the timber. For further development the methodology could be applied to other beam structures such as roof trusses or a combination of plates and beam structures such as wood panel construction.

KEYWORDS: recycling, reuse, wood, material recycling, material utilization, deconstruction

1 INTRODUCTION

The increasing scarcity of resources and augmenting material costs are leading to a rethinking in the construction industry.
The aim of the German Resource Efficiency Program (ProgGressIII), which serves to implement the German sustainability strategy, is to identify ways of using resources sparingly and thus reducing the burden on the environment. One measure is to promote the use of renewable raw materials such as timber from sustainable forestry as a construction product. [1]
Timber as a construction material serves as a carbon store and should be kept in the material cycle for as long as possible, which is why reusing timber is in line with the German resource efficiency program. To keep the timber in the material cycle for as long as possible is necessary to not only extend one material life cycle for as long as possible, but also to use the wooden resource in cascades which means to reuse, recycle or utilize material substitution. Due to photosynthesis, timber stores CO_2 during the growth of the tree, which is why it is called a carbon reservoir. After the timber has been used to generate energy, the CO_2 is released back into the atmosphere. Therefore, the goal should be to keep timber in the material cycle for as long as possible in the form of cascade utilization. This means that the timber should be downcycled in another form. For example, a beam can be processed into a wooden slat and then into a chipboard.[2]

The research project is about developing a concept for design for reuse and recycling of the hall supporting structures made of timber. This should enable reuse, re-utilisation and thus a cascade use of timber. The aim is the renewal and extension of conceptual methods for the investigation of life cycle processes of bar supporting structures made of timber.
Reuse means that the timber beam can be used again in the same way as a beam in a new supporting structure. [3]
Recovery means that the beam can be used materially for the same application (equivalent material recovery) [4] or be downcycled, e.g. in the form of a chipboard, final material recovered or final energetical recovered as firewood [5].
According to [6] the reuse of timber components depends mainly on their installation situation and on the type of fastener used to join the components. In the case of detachable connections, disassembly is mostly possible in a non-destructive manner [6]. The choice of fasteners should be considered at the very beginning of the design of timber structures. The fasteners should be easy to find, accessible, and detachable with standard tools. Also, as few nail and adhesive connections as necessary should be used to promote non-destructive disassembly. [6]
In principle, as few and similar fasteners as possible should be used. In this way, faster dismantling is possible. In addition, there is less damage to the assembled components. By using similar, uniform fasteners, there is no need to change tools, which would otherwise slow down the dismantling process. The dismantling effort is

reduced and disassembly is faster, which reduces costs. To ensure rapid deconstruction, the fasteners should be easily identifiable and accessible even after the planned service life. [3] It is important to detach the fasteners after service life, because sometimes the building is be used longer then its planned service life.

The ongoing research project „*Entwicklung zukunftsweisender Konzepte zum landwirtschaftlichen Bauen mit Holz - von der Planung bis zum Rückbau (ZukunftLaWiBau)*“ is intended to give farmers the opportunity to take timber from their own forest and use it as building material for their agricultural halls. At the end of their life cycle, it should be possible to dismantle the halls as efficiently as possible, while leaving as much running meter of undisturbed timber as possible. Thus, farmers should be given the opportunity to use their timber for other purposes.

In the following, a methodology developed to evaluate and to increase the material recyclability of wooden hall structures is presented.

2 BACKGROUND AND METHOD

To apply the method, six agricultural halls made of timber with span widths equal to the modular construction hall shown in Figure 1 Figure 6[7], were inspected. The beam structures of the halls consist of solid timber wood, glued laminated timber and steel fasteners. The foundations are made of reinforced concrete. An as-built survey helped to identify and to record the dimensions as well as the type of detail points of the main supporting structures.

Further, the inspection and documentation of the detail points helped to find out in which way and by using which fasteners the detail points have been assembled. Based on the results of the as-built survey, the **equivalent material recovery** of the timber structures could be determined. The detail points were assessed in terms of their **deconstructability**. To do so, a ranking of the fasteners of each detail point was carried out, and the results were included in a detail catalogue. Based on this, a methodology could be developed to increase the recyclability of timber structures.

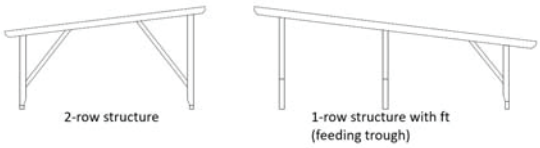

Figure 1: *Profile modular construction hall, Modulbausystem Grub-Weihenstephan according to [7]*

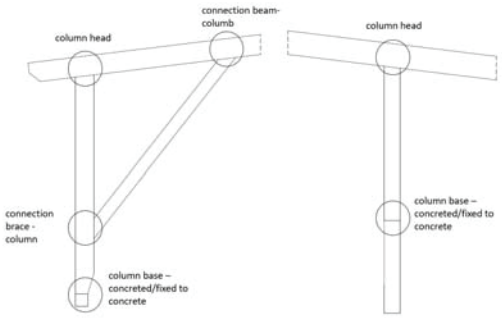

Figure 2: *Considered detail points of main structure*

2.1 EQUIVALENT MATERIAL RECOVERY OF THE TIMBER

By equivalent material recovery amount of recyclable material within one wooden beam is meant after the areas affected by fasteners would have to be cut out by a saw in the worst case. It is being assumed that the saw cut is made with the maximum necessary edge distance to the fastener. The edge distances were determined according to DIN EN 1995-1-1/NA:2013-08, p.45 ff.; DIN EN 1995-1, p.78ff [8]

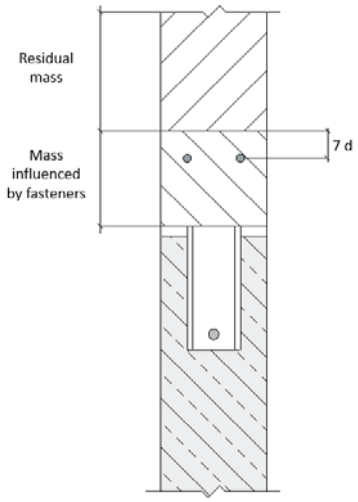

Figure 3: *detail column base, connection wood-concrete*

2.2 DECONSTRUCTABILITY

In addition to the equivalent material recovery, the evaluation of the fastener regarding fast deconstruction was carried out in terms of removability, accessibility and recognizability, because these aspects ensure fast deconstruction according to [5].

https://doi.org/10.52202/069179-0130

Table 1: *definition and evaluation of removability according to DIN 8593-0 [9]*

	removability sign	evaluation
without damage	+	(3)
with (sufficiently) low damage	0	(2)
with damage	-	(1)

For the evaluation of the removability, the recycling tool of the research project *Ressourcennutzung Gebäude* [10] was used and modified. (Table 1)
A subdivision was made according to the accessibility of the detail points and the fasteners.

Table 2: *definition and evaluation of the accessibility of the detail points according to VDI 2243[5]*

		accessibility sign
directly accessible	no optimization necessary	+
indirectly accessible	improve possible disassembly depth	0
not accessible	check modification for axial accessibility	-

The evaluation of the accessibility of the detail points was neglected, because in a hall structure all detail points are accessible with a ladder. (Table 2)
The accessibility of the fasteners was evaluated according to VDI 2243. [5] The shortcut F stands for fastener

Table 3: *definition and evaluation of the accessibility of the fasteners according to VDI 2243[5]*

		sign	fastener	accessibility of the fastener element
directly accessible	no optimization necessary	F +		
Indirectly accessible	improve possible disassembly depth check modification for axial accessibility	F 0	slotted-in steel plate	when fish plate removable
not accessible		F -	hidden slotted-in steel plate, split ring	completely hidden by the element

The third evaluation was made according to the recognizability of the connecting means. The definition of recognizability of the connecting means of the bar supporting structures is based on VDI 2243 [5].

Table 4: *definition and evaluation of the recognizability of the fasteners according to VDI 2243[5]*

		sign	Recognizability of the fastener
definitely visible	No optimization necessary	R +	fastener carpenter joints
Not visible, but with indication	Provide labeling	R 0	slotted-in steel plate
Not visible, no indication	Provide notice and labeling	R -	split ring

The recognizability of the fasteners was evaluated according to VDI 2243 [5]. The shortcut (R) stands for recognizability. The *slotted-in steel plate* was defined as not visible, but with indication (R0), since it was hidden by the timber structure on the outside as an internal fastener, but the bar dowels give an indication of it from the outside. *Split ring* was considered to be a non-findable fastener (R-). The fastener is *not directly visible*, only after removing the timber structure. There is also no indication

of the fastener. All other fasteners, as well as *carpenter joints* were defined as definitely visible (R+), because the type of the fastener is definitely visible.

3 EVALUATION METHOD

3.1 EVALUATION OF EQUIVALENT MATERIAL RECOVERY

To evaluate the part of a wooden beam structures, which could be equivalent material recovered, it was necessary to determine how much additional timber, potentially damaged, had to be removed by a saw in the area influenced by the fasteners.
For example, if the fasteners cannot be removed due to aging, such as rust, or there are other reasons, the fasteners can be cut out with a saw. In this way, a wooden beam is obtained which can be equivalent material recovered. The remaining material around the fastener can be further processed and be recycled. Sawing out the fasteners is possible in this case of the bar structure, since it is not a flat component consisting of several layers.

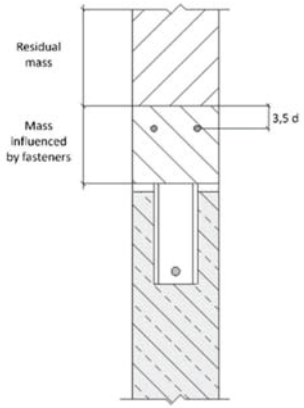

Figure 4: *detail column base, connection wood-concrete*

3.2 DECONSTRUCTABILITY, EVALUATION OF THE FASTENERS

The evaluation method should be shown as an example on Figure 5.

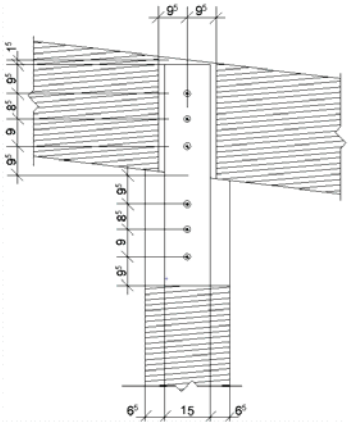

Figure 5: *Detail column head-beam: bracket + fully threaded screw*

First, the individual joints of the components and fasteners were evaluated among themselves. For this purpose, the individual components and fasteners that come into contact with each other were compared in a table. Based on the documented detail point, the removability of the layers was evaluated with numbers (Figure 5) (+ (3); 0 (2); - (1)) and divided by the maximum possible scoring combination ((3) for each joint). Thus, the percentage evaluation of the removability of the detail point was obtained. (Figure 6)

Table 5: *definition and evaluation of the removability of fastener according to [11]*

	removability of the fastener
	sign
without damage removable	+
removable with sufficiently low damage	0
with damage removable	-

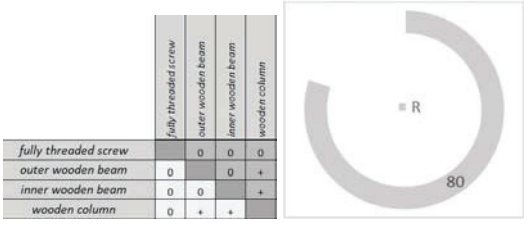

Figure 6: *removability of the layers, Graphical evaluation of removability*

4 EVALUATION OF THE AGRICULTURAL HALLS

As both detail points, the column head and the connection beam column, are constructed in the same way with the same fasteners (Figure 2), the removability of the column head is the same.
Therefore, the faster deconstruction of the detail points

1. column base
2. connection beam-columb
3. column head

is discussed below. Since all detail points of the 2-row structure are represented in the 1-row structure, only the 1-row structure is considered in the following. (Figure 1)

4.1 EQUIVALENT MATERIAL RECOVERY OF THE TIMBER

In order to determine the equivalent material recovery of the timber, the amount and the type of fasteners were calculated and dimensioned for the load case of the worst load case. A sensitivity analysis was carried out to find out to what extent the choice of fasteners plays a role for the equivalent material recovery of the timber or if deconstruction of the fasteners plays a neglectable role.

For this purpose, the main structure was divided into different areas. Their beginning and end were delimited by the detail points (DP). The sections were named according to their location; *apex column* (*AC*), *center column (CC)*, *eaves column (EC)*, *eaves brace (EB)*, *apex brace (AB)*). The beam (B) was divided into five sections (B1-B5). (Figure 7)

The aim was to find out to what extent the choice of fasteners has an influence on the length of the timber components after the removal of the areas affected by the fasteners. For this purpose, the distances between the fasteners were determined for the respective structural members according to the standard. [8]
The minimum edge distances for the worst case to remove the fasteners were calculated.

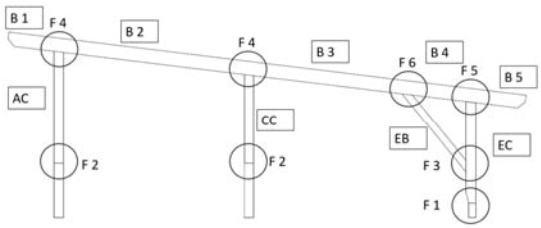

Figure 7: *1-row feeding trough (ft) structure: overview elements and detail points*

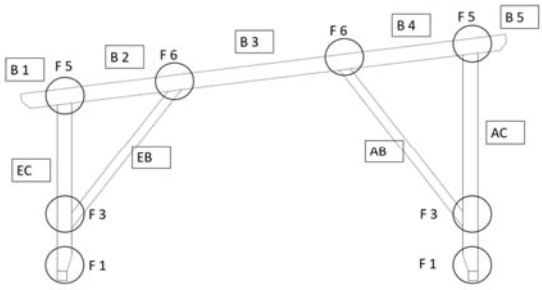

Figure 8: 2-row structure: elements and detail points

The shortcuts for the fasteners are listed in Table 6 and Table 7:

Table 6:*acronyms for different fasteners*

fastener	acronym
slotted-in steel plate	SP
split ring	SR
staggered joint	SJ
pin	P
fully threaded screw	FS
ear	E
U-steel profil	U
Steel profil	S
steel dowel pin	DP
staggered joint	SJ

Table 7: *Overview of possible combinations within one detail point (F)*

F1	F2	F3	F4	F5	F6
SP	SR + P +S	SJ+P	SP +DP	SR + P +E	E+FS
U+ SR	SP	SP +DP	SR + P	SR + P	SR +P+E
S+SP+DP	U+SR		SR +P+E		
	E+FS	SR + P			

In (Figure 9-Figure 11) the remaining lengths after cutting out the areas of the connection points for the different variants are compared to the initial length. It was found out, that there was no fastener which was responsible for cutting the less wood out. When comparing the different variants, only one recommendation can be made for the choice of the connection means of column base (F1 and F2) (Figure 9 and Figure 10) and the connection eaves column bottom (F3) (Figure 11). For this detail points following fasteners should be taken, so that the smallest area is cut off from the supports around the fasteners: F1:S+SP+SD/ SP, F2:SP and F3:SJ +P. By choosing these fasteners, the maximal length of the beams could be achieved.
The highlighted dark beams indicate the maximum and minimum, respectively, after cutting out the fasteners.

https://doi.org/10.52202/069179-0130

The empty frame indicates the original length of the beam. The shortcut F stands for the fasteners in the respective detail points. Figure 7

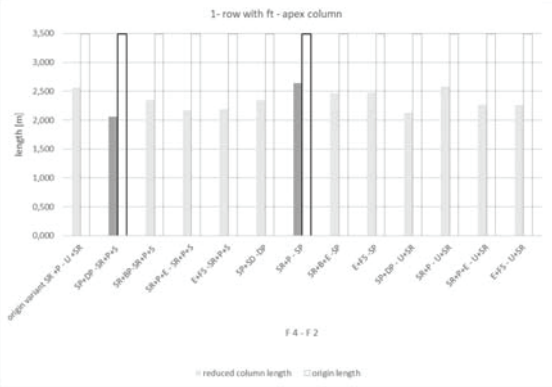

Figure 9:*1-row ft structure - apex column*

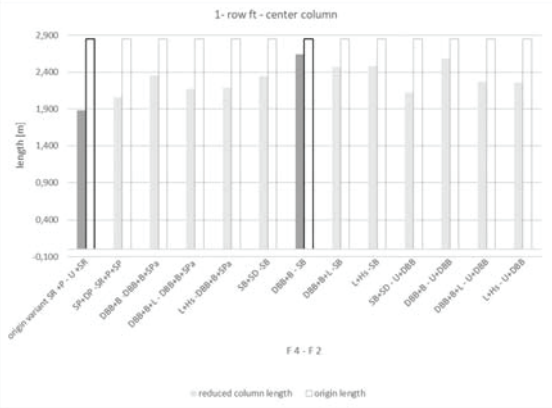

Figure 10:*1-row ft structure - center column*

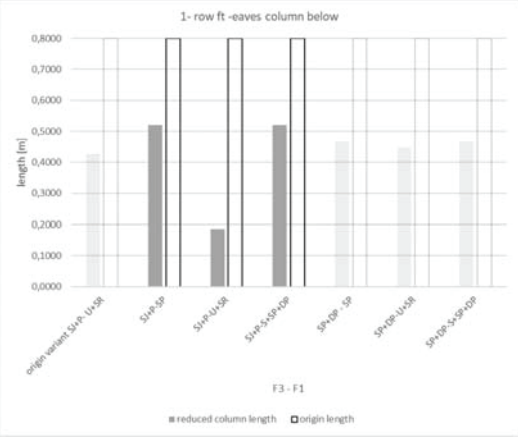

Figure 11: *1-row ft structure – eaves column bottom*

In all three cases, the variant with staggered joint and dowel pins has led to more residual length of the column, regardless of whether or not the staggered joint was concreted into the column base or the one attached to the concrete column. (Figure 11 and Figure 12)

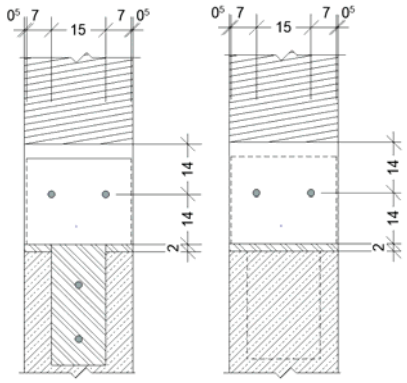

Figure 12: *slotted-in steel plate und dowel pins fixed on concrete column(le.) slotted-in steel plate und dowel pins, Steel profile set in concrete in support (ri.), F2*

For the fastener F, pin *eaves diagonal-eaves column*, the staggered joint and pin performed best in terms of the amount to be cut off and is preferable to the fixation slotted-in steel plate and dowel pins .(Figure 13)

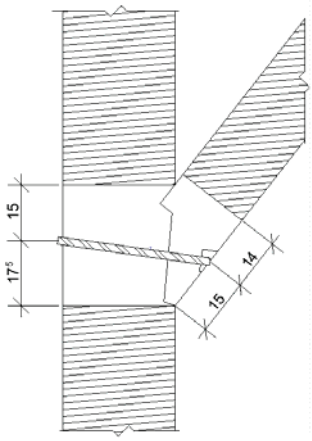

Figure 13: *staggered joint and pin, F3*

The evaluations of the detail point are shown in Figure 14-Figure 16

https://doi.org/10.52202/069179-0130

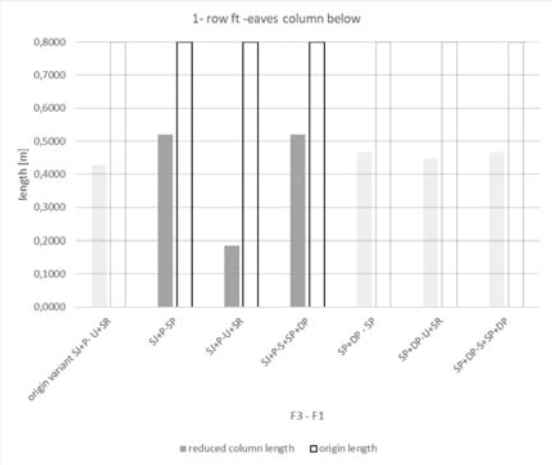

Figure 14: *1-row FT structure – eaves column, bottom*

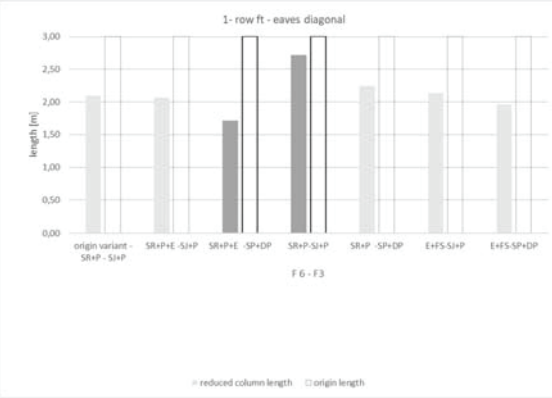

Figure 15: *1-row FT structure – eaves diagonal*

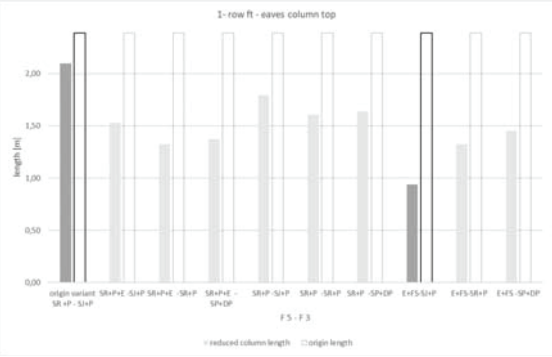

Figure 16: *1-row ft structure – eaves column top*

For the fasteners connecting the columns/diagonals to the beams, always different fasteners performed best or worst, depending on the combination.
The choice of fastener does not seem to have a significant influence on reusability.

4.2 FAST DECONSTRUCTABILITY

Since all fasteners are accessible with a ladder and, in the case of agricultural sheds, the structural components are generally not cladded, an evaluation with regard to recognizability and accessibility is neglected. The classification of fasteners according to their accessibility and recognizability was already conducted in chapter 3.1 and could easily be applied to all considered connections. Only the removability of the fasteners will be considered in more detail.
Of the variants identified, the fasteners for the best possible removability of the detail points are presented:

4.2.1 Column base

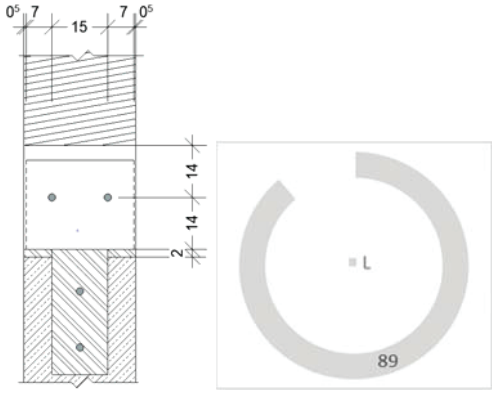

Figure 17: *slotted-in steel plate laterally fixed to concrete (left), removability [%] (right)*

The highest removability of 89% was achieved for the detail column base by the fastener alternatives *slotted-in steel plate laterally fixed to concrete.* (Figure 17)

4.2.2 connection brace – column

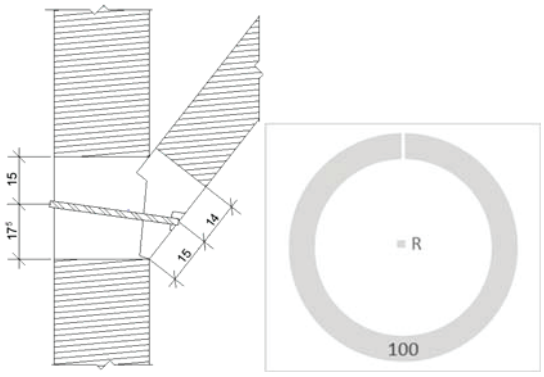

Figure 18: *staggered joint and pin (left), removability [%] (right)*

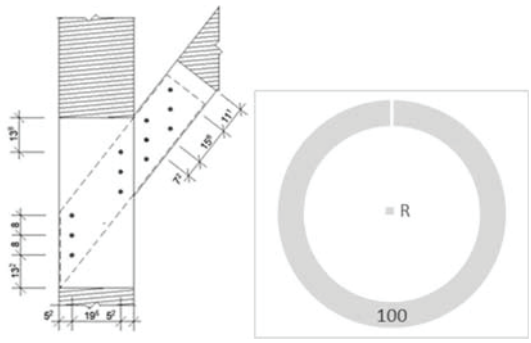

Figure 19: *slotted-in steel plate und dowel pins (left), removability [%] (right)*

The highest removability with 100% was achieved for the connection brace-column fastener alternatives *staggered joint and pin* and *slotted-in steel plate and bar dowels.(*Figure 18-Figure 19)

4.2.3 Connection column head

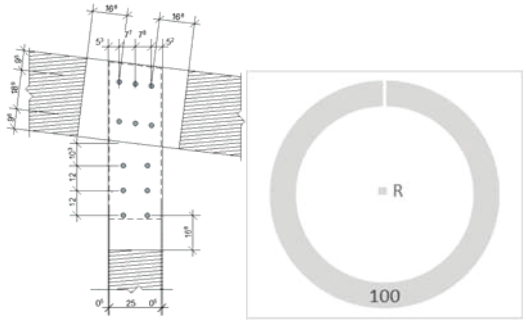

Figure 20: *slotted-in steel plate and dowel pins (left), removability [%] (right)*

The highest removability of 100% for the detail column head fastener alternatives had *slotted-in steel plate and dowel pins.* (Figure 20)

5 CONCLUSIONS

In the worst case, the areas of the construction affected by the fasteners can be removed by means of a saw, which is why the focus was on the rapid recoverability of the hall and thus, in a narrower sense, the detail points. [11]
A recommendation regarding the equivalent material recovery of the wood can only be given for the detail points *brace -column connection*. For the remaining detail points, no fastener can be identified that could significantly account for an increased number of running meter (lfm) of equivalent material recovered timber.
With regard to the fast deconstructability of the fasteners, the variant *slotted-in steel plate und dowel pins fixed on concrete column* can be recommended for the column base, for the connection brace-column: staggered joint and pin and slotted-in steel plate und dowel pins and for the detail point connection column head the fasteners *slotted-in steel plate* and *dowel pins* can be recommended. The only match between the two criteria of equivalent material recovery of the timber and fast deconstructability is in the detail item *staggered joint and pin.*
The general equivalent material recovery of the timber could not be clearly attributed to a fastener.
In order to determine the equivalent material recovery of wooden beam structures, it should not first be determined as fast deconstructability and equivalent material recovery of the timber as assumed at the beginning. Rather, the focus should be on the removability of the fasteners, since the fastener selection does not significantly affect the beam length remaining after deconstruction.
Accordingly, the methodology for determining the recyclability of timber agricultural beam structures can be further developed and transferred to other beam structures or a combination of beam and sheet structures made of timber. For example, the deconstruction potential of roof structures or elements of wood panel construction could be determined. The focus should also be on further development with regard to the evaluation of the removability of the fasteners.

ACKNOWLEDGEMENT

Thanks go to the LfL [7] for providing the plans and to the farmers who allowed us to examine their agricultural halls. The project is funded by Fachagentur Nachwachsende Rohstoffe e.V, FNR FKZ 2220HV 036B.

SUSTAINABLE ASSESSMENT: A CONTRIBUTION TO IMPROVE THE RELIABILITY OF NDT ON OLD CHESTNUT PURLINS

Vittoria Borghese[1], Silvia Santini[2], Lorena Sguerri[3]

ABSTRACT: The aim of this study is to give an additional contribution to the improvement of a sustainable diagnostic practice to be used for the assessment of ancient wooden structures, in order to limit the damage of the existing ones through destructive tests, and to have a reliable prediction of old element properties, with their historical value, reducing demolition and substitution with consumption of new materials. To achieve this purpose, correlation laws and methodologies that can be used to facilitate the performance of non-destructive testing (NDT) in situ, will be highlighted. Seventeen chestnut purlins, dated between the 19th century and the 20th century and coming from the roof of the Cloister of Michelangelo at the Baths of Diocletian in Rome, are tested. As the first part of a wider experimentation, the aim is to identify the best practice for three relevant unknowns that characterize a wooden structural element: the geometry, through the survey and the BIM modelling; the density by means of the penetrometric tests (Resistograph and Woodpecker); the elastic module through direct and indirect ultra-sonic tests.

KEYWORDS: Assessment, chestnut, NDT

1 INTRODUCTION

The proposed research aims to combine the best diagnostic practices with the most recent dictates of sustainability, giving itself as a meeting point between the assessment commonly understood and the application of the best methodologies to preserve the environment.
Usually, a critical point is represented by the scheduled maintenance operations in order to protect the historical heritage and ensure greater sustainability of the restoration. The aim is to highlight sustainability in historic buildings through methodologies and correlations useful to facilitate the performance of non-destructive testing (NDT) *in situ* on existing timber structures without altering the characteristics of the analysed element and to limit the consumption of new materials or the damage of existing ones through destructive tests.
Moreover, several Countries have a wooden historical-artistic heritage plagued by aging and bad reworkings, all factors that aggravate its conservation. For this reason, it is important to provide a sustainable and reliable methodology for the assessment of this heritage developing procedures for the historical timber structures.
As the first phase of wider experimentation that includes destructive tests too, this study aims to develop the best practices for the estimation of three important unknowns that characterize a wooden structural element: the geometry, through the visual survey and the photogrammetry; the density by means of the penetrometric tests, such as the Resistograph and the Woodpecker [1]; the elastic module through direct and indirect ultra-sonic tests [2], thanks to the relationship that connects the static modulus with the dynamic one calculated by density and the stress wave speed parallel to the grain. However, at the moment, only the correlation between the direct and indirect measures was investigated To achieve this purpose, chestnut (*Castanea Sativa Mill.*) roof purlins were used, all dated between the 19th century and 20th century and coming from the Cloister of Michelangelo at the Baths of Diocletian in Rome (Figure 1).

Figure 1: *Reference sections and position of the penetrometric tests*

In conclusion, the aim of this study is to give an additional contribution, with new data and analysis, in order to improve a sustainable methodology, that can be used on-

site, able to estimate these three fundamental characteristics of an ancient wooden structural element.

2 CASE STUDY

To carry out the proposed research, seventeen purlins coming from Michelangelo's Cloister of the Baths of Diocletian in Rome were examined.

2.1 CLOISTER OF MICHELANGELO

The Cloister of Michelangelo is part of the complex of the Diocletian's Baths in Rome, located near the Termini station [3].
The famous Baths of Diocletian were immediately considered witnesses of Roman greatness, built in 302 A. C. and they were the largest in Roman times by extension [4].
Each side of the internal Cloister consists of the ground floor of 25 spans of vaults and Tuscan columns in travertine. The structure ends with a roof inclined to a wooden pitch.
Since the 80s of the last century, the building of the Cloister has undergone many interventions of structural consolidation, due to the critical conditions of the supporting structure. The few diagnostic operations carried out in the last 40 years have led to low knowledge of the load-bearing capacity and countless consolidation interventions throughout the structure.

2.2 PREVIOUS WORKS

This research is the prosecution of two previous works carried out on the first part of the sample that originally counted 40 purlins. The first work addresses the issue of sustainability for interventions on ancient wooden structures, proposing a methodology of analysis of NDT, aimed at limiting the decommissioning and replacement of roofing, suggesting non-invasive methods of analysis to understand the bearing capacity of the primary elements [5].
The second work focuses on the assessment of the sustainability of the interventions carried out over the decades on the Cloister of Michelangelo. The aim is to demonstrate how the development of NDT can be more sustainable than the complete replacement but also compared with local structural reinforcement interventions carried out without careful analysis. Classic rehabilitation interventions are also compared and a multi-criteria Decision Analysis (MCDA) based method is provided to assess sustainability and establish a ranking of intervention alternatives [6].

3 GEOMETRY

3.1 SAMPLE PROPERTIES

The elements analyzed are in chestnut wood and date back a period included between 1865 and 1911 and had the function of purlins in the roof of the Cloister.
The purlins examined are seventeen. Eight of them are confined with an old metallic continuous spiral (from F6 to F15) while the others are free (from SF6 to SF21). All the specimens were submitted to the NDT. Section dimensions and length vary from one to the other and the average values are given in Table 1.

3.2 VISUAL INSPECTION

Wood is a living material defined, which has continuous exchanges with the external environment, heterogeneous and anisotropic (also defined as orthotropic). It is a complex material to analyze and it presents defects that are part of its nature and that are partially eliminated in innovative engineered timber elements, but that are present in historic ones. Wood defects produce a material discontinuity that causes a change in physical and mechanical characteristics, resulting in the formation of critical zones that affect the overall strength.
In Italy, there is a specific standard, the UNI 11119:2004, that provides criteria for the visual strength grading of the ancient timber elements when they are still in place [7].
The Standard requires a visual survey of the geometry (maximum dimensions and presence of wanes) and the defects (knots, knot clusters, mechanical cracks, splits, ring shakes and slope of the grain). It is returned, by tree species, a classification in three different categories of strength with the relative modulus of elasticity in bending (MoE) and allowable tension and compression stress values. Regarding the purlins, 7 samples were classified in class II with a corresponding MoE value of 9000 N/mm^2 and the remaining 10 in class I with a MoE of 10000 N/mm^2.
The visual grading was made excluding the section wanes, since the geometrical limitations provided by the standard are considered too penalizing for historical timber elements.

Table 1: *Purlin dimensions and strength-classes given by the visual grading*

Purlin	Strength Class	Width (cm)	Hight (cm)	Lenght (cm)
F06	II	16,0	18,0	262
F07	II	14,0	13,0	265
F08	II	18,0	16,0	264
F09	I	14,0	15,0	263
F11	II	12,0	10,5	301
F12	I	13,0	12,0	255
F13	I	13,0	14,5	299
F15	I	11,5	15,5	297
SF06	I	15,0	13,0	263
SF07	I	15,5	19,0	263
SF09	II	16,0	15,0	260
SF10	I	15,5	15,5	306
SF12	II	12,5	12,5	271
SF13	II	17,5	17,0	263
SF14	I	16,0	16,0	240
SF15	I	13,0	18,0	263
SF21	I	18,5	13,0	306

3.3 VOLUME ESTIMATION

In order to estimate the correlation laws between the NDT and the chestnut density, it is required to determine the density of the 17 purlins. For this purpose, it is necessary

to derive the actual volume and weight, the latter measured by a dynamometer, of the specimens. For the volume the task is more complex, being the beams very irregular in every direction. Two measurement methods were applied. The first one detects a detailed geometry in several sections approximating the variations in shape along the purlin. The sections were recreated in the HBIM environment, linking them and obtaining the volume (Figure 2a). The second one employs the photogrammetric technique creating a PointCloud dataset of points, giving a very accurate geometry elaborated with a Matlab code and also with the identification of cracks [8] (Figure 2b).

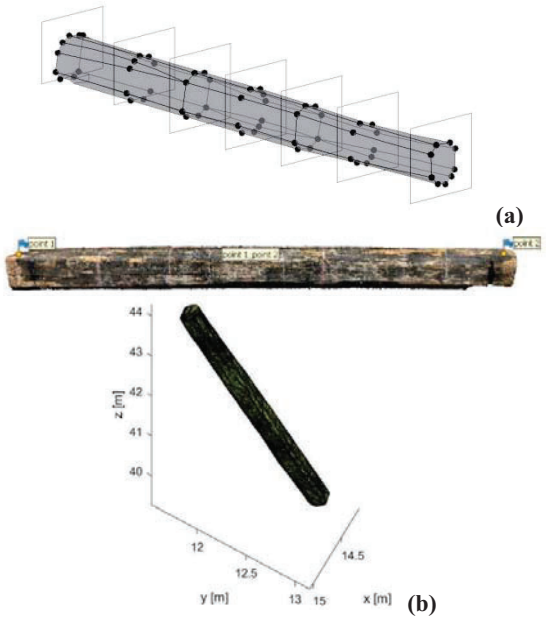

***Figure 2: (a)** BIM element created by sections; **(b)** Photogrammetry Point Cloud and MatLab elaboration*

In Table 2 the volumes and the resulting densities obtained by the two methods (V_{BIM}, V_{PHG}, ρ_{BIM}, ρ_{PHG}) are reported and compared. However, the photogrammetric method was applied to the purlins without confinement only, since the presence of the metal band causes an important alteration of the computed volume. The change in density associated with the change in the volume estimation is expressed as a percentage variation and may have significant values included between 3% and 21%.
In the following, the density obtained by sections and then computed for the whole sample will be considered as the actual density ρ on which to estimate the correlation laws.

4 DENSITY

4.1 PENETROMETRIC METHODS

The penetrometric methods include all those tests performed with devices that involve penetrating the wood with a needle. The needle can be short or long. In the first case the superficial layer is involved only, while in the second case the entire section can be crossed. In any case, these types of tests cause little damage to the material and then they can be counted among the non-destructive methods (NDT). For the actual experimentation the Woodpecker and the Resistograph were employed both alone and by combining the results.

***Table 2:** Volume, density and percentage variation results for the third and fourth methods.*

Purlins	V_{BIM} (m^3)	ρ_{BIM} (Kg/mc)	V_{PHG} (m^3)	ρ_{PHG} (Kg/mc)	$\frac{\rho_{BIM}}{\rho_{PHG}}$ (%)
F06	0,068	524	-	-	-
F07	0,055	545	-	-	-
F08	0,069	560	-	-	-
F09	0,059	588	-	-	-
F11	0,053	618	-	-	-
F12	0,042	602	-	-	-
F13	0,055	547	-	-	-
F15	0,061	595	-	-	-
SF6	0,057	676	0.055	658	3%
SF7	0,073	569	0.081	512	11%
SF9	0,061	597	0.067	546	9%
SF10	0,050	595	0.052	578	3%
SF12	0,054	518	0.061	461	12%
SF13	0,068	639	0.072	608	5%
SF14	0,059	631	0.067	563	12%
SF15	0,065	610	0.078	505	21%
SF21	0,082	630	0.088	583	8%

Considering the medium purlin length and the intention to perform bending tests in the future, three reference sections have been chosen in order to execute the penetrometric tests: the central one and the two sections delimiting the middle third as illustrated in Figure 3.

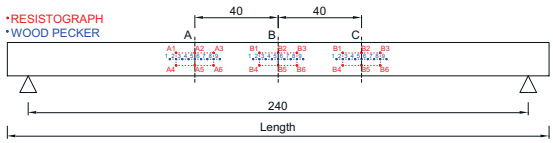

***Figure 3:** Reference sections and position of the penetrometric tests*

4.1.1 Woodpecker

The Woodpecker (WP), produced by the Italian company DRC, is a modified Schmidt hammer. On the percussion, the rod was added a removable needle in hardened steel with a conical tip, a diameter of 2,5 mm and a total length of 50 mm. The test is to insert the needle into the wood with a given number of shots. Then, the penetration depth (*PD*) is obtained by measuring the exposed part of the needle.
The penetration depth is related to the superficial density of the wooden element and the manufacturer gives some correlation laws *PD*-ρ concerning different wood species,

https://doi.org/10.52202/069179-0131

including chestnut. These relationships were estimated on the basis of experimental research conducted on a limited number of new timber specimens with dimensions 80x80x1300 mm [9]
In order to use these results, the manufacturer recommends to drive the needle with 5 consecutive shots and to execute at least 9 insertions in the same area following a grid with 25÷30 mm interaxis. Obviously, the test must be performed by choosing a possible defect-free area along the wooden surface.
Few studies have been performed on the reliability of the WP up to now. Lliana et al. 2018 [10] utilized twelve Norway spruce joist specimens, extracted from a dismantled 19th century building, in order to compare four different test methodologies suitable for *in-situ* density estimation: the needle penetration resistance (NPR) including both the Woodpecker and the Pylodin, the screw withdrawal resistance (SWR), the core drilling (CD) and the drilling chips extraction (DCE). Concerning the WP, the authors evaluated the test results driving the needle with one, three and five shots. The last option, which is the one recommended by the manufacturer, gave the best correlation with density with a coefficient of determination of 0,33. This value is higher than the one obtained with the Pylodin, but lower than those related to the other three test methodologies.
Similarly, Osuna-Sequera et al. 2019 [11] compared the NPR, SWR and DCE methods in order to optimize the number of measurements to be performed along extended wooden elements where the density variation, due to the growth of the original tree, becomes important from one end to the other. Then, they demonstrate that the penetration depth measured with the WP is considerably influenced by the position of the test area reaching differences up to 5 mm between the bottom of the original tree and a section 10 meters high. Anyway, performing ten measurements along the element they obtain R^2=0,55. In this case, the coefficient of determination is higher than the one obtained with the Pylodin and with the SWR method too.
Regarding chestnut, Faggiano et al. [12] used the WP upon 24 wooden elements extracted from a dismantled roof of an ancient building in Naples. In this case, the authors made the tests following the producer's recommendations. In detail, they performed 10 tests, including 9 measurements each, along with all the specimens.
According to the description they gave, the surface conditions of the 24 elements seem to be very similar to the actual ones with an extended decay due to the attacks of xylophagous insects in addition to the presence of defects as knots, cracks and holes. The correlation that they found between the penetration depth and the density was quite low with R^2 = 0,30 and the regression line was:

$$\rho = -11{,}40 \times PD + 777{,}69 \quad (1)$$

where *PD* is included in the range 13÷19 mm, while the manufacturer's correlation law, calibrated on new chestnut samples, covers a depth range between 9 and 14 mm.
Besides, it seems to be obvious that the superficial decay makes the cortical layer of an old wooden element softer, permitting the needle of the WP to penetrate deeper. This is a very crucial factor since it is not easy to quantify the amount of this decay and the way it is distributed along the surface, being inhomogeneous.
In order to investigate, with more data, the relationship between the penetration depth and the density of old chestnut structural elements, 6 tests, with 9 measurements each, were performed along the 17 purlins. The test grids were located next to the three central reference sections and on two opposite sides of the specimen (Figure 3). The spacing of the grid was about 30 mm and the area with the best superficial condition, without knots and at least 25 mm far from any crack or hole was chosen.

4.1.2 Resistograph

The Resistograph was developed from the second half of 80s by a german researcher: Frank Rinn. The device is characterized by a thin needle that can be 400 mm long and penetrates, like the tip of a drill, inside the wood. Then, the drilling resistance is measured, registered and displayed by a graph that highlights density variations due to the annual growth circles of the trunk and to the presence of eventual defects as cracks or decay with a sharp drop in resistance, or knots with peaks of resistance. Moreover, the relationship between the drill resistance and the density of the wood was demonstrated in 1996 by comparison with some X-ray tests [13].
Given the results of the test, the Resistograph is very suitable to detect possible states of decay hidden inside a wooden element and then not identifiable by a visual survey. However, given also the relationship with the material density, several attempts to correlate the outcome of the test directly with the density and even with the mechanical properties of the wood, as the elastic and the rupture modulus, were done. In fact, if *DR* (%) is the drilling resistance, expressed as a percentage of the amplitude, and *h* (mm) is the progressive drilling depth up to *H*, a medium rate (DR_m) may be calculated by the integral of the graph (Figure 4):

$$DR_m = \frac{\int_0^H DR \cdot dh}{H} \quad (2)$$

The outcomes of these correlation attempts are very discordant [13]. On the other hand, the result of the test depends on several factors including, first of all, the tree species and then the moisture content, the drilling direction in relation to the growth circles, the model of the Resistograph, the drilling speed and many more.
Some experimental works aimed to find the correlation laws between the drilling resistance and the physical and mechanical properties of wood were made about chestnut too. With regard to density, processing the data obtained by Faggiano et al. [12] who tested 24 ancient chestnut beams by means of a Resistograph IML RESI F400, a correlation with R^2 = 0,43 was obtained, while the authors themselves, with the same device, found a correlation with R^2 = 0,32, performing the test along 9 purlins of the late nineteenth century [5].

For the actual experimentation, a Resistograph IML RESI PD400 was employed. This tool can provide not only the drill rate (*DR*) but also the feed rate (*FR*). The outcomes are two different graphs where *DR* and *FR* are both expressed in percentage of the amplitude. In either case, it is possible to detect an eventual decay within the wooden element and to calculate a medium rate, however, the drill rate is generally affected by the friction that develops between the needle and the wood during the test. This friction is affected by several factors as the tree species, the density, the moisture content and the penetration depth. In any case, a very simple linear model, with friction depending only on the drilling depth, can be assumed. In this way, the drill graph can be easily corrected just by subtracting the increasing friction along the path [14] (Figure 4).

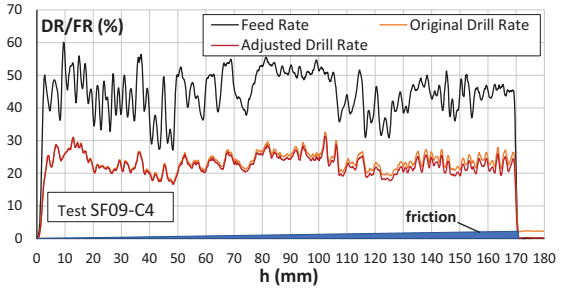

Figure 4: *Resistograph - Comparison between the original drill rate graph, the adjusted one and the federate graph*

The comparison between the correlations found for the feed rate and the drill rate with the mechanical and physical properties of four tree species developed by Sharapov et al. [15] suggests that *DR* is more reliable than FR. In detail, about the relationship *DR*-ρ, coefficient of determinations generally higher than 0,76 were found.
In a similar way, the tests performed along the 17 purlins were processed considering both the drill rate and the feed rate (Figure 4). For each element, 6 tests around the three reference sections, were executed, for a total of 18 tests (Figure 3). The rotational speed was set at 3000 rpm, while the feed speed at 100 cm/min.
When processing, both FR_m and DR_m were calculated, the latter having subtracted the friction component. In both cases the medium resistance was computed excluding all the inhomogeneous parts of the graphs as peaks or drops due to the presence of knots, cracks or decay.

4.1.3 Combined method

The superficial decay that generally affects the ancient timber structural elements and its randomness compromise the reliability of the Woodpecker, since this kind of test involves just a thin layer of material close to the surface. On the other hand, the Resistograph involves all section thickness, but any correlation laws with density are strictly connected with the model of the instrument and with the drilling speed. In order to overcome these limits, it is proposed to combine the two methods as already suggested by the authors [5], although in place of the Woodpecker, the Pylodin was used.

If the WP producer law is considered reliable enough for any value of the penetration depth, the resulting density (ρ_{WP}) can be related with the medium resistance computed along the initial or the final section of the Resistograph graph for a length equal to PD_m ($R_{m,PD}$). Then, the following ratio can be calculated;

$$C = \frac{\rho_{WP}}{R_{m,PD}} \tag{3}$$

Assuming that this ratio remains constant along the entire section thickness, the wood density can be estimated multiplying the coefficient C by the medium resistance computed on the remaining part of the graph:

$$\rho_{comb} = C \cdot R_{m,(H-PD)} \tag{4}$$

Obviously, both tests must be executed close to each other so that their combination makes sense. In fact, regarding the 17 purlins, the two tests were performed at the three reference sections (Figure 3). Then, the WP was executed both on the inlet and outlet side of the Resistograph so that both the initial and final parts of the feed rate and drill rate graphs were considered.

4.2 RESULTS

Regarding the WP, the mean penetration depth of one purlin is calculated as the average value of the six tests outcomes, while the single test result is evaluated as the mean value of 9 measures. In Table 3, the mean penetration depths (PD_m) and the related coefficients of variation (*CV*) are reported for each purlin, together with the maximum and minimum values (PD_{min} and PD_{max}) registered by the six tests.

Table 3: *Wood Pecker tests results*

Purlin	PD_m (mm)	*CV* (%)	PD_{min} (mm)	PD_{max} (mm)
F06	18,83	10,9	17,02	22,89
F07	18,02	1,8	17,50	18,38
F08	17,63	4,9	16,30	18,52
F09	16,52	2,0	15,94	16,84
F11	17,89	9,4	16,39	20,71
F12	16,88	3,4	16,46	17,97
F13	19,07	3,7	17,94	19,66
F15	17,96	7,4	16,66	20,49
SF06	18,04	7,8	15,60	19,40
SF07	16,94	6,5	15,61	18,44
SF09	16,29	5,6	15,46	17,64
SF10	16,54	3,6	17,58	16,83
SF12	20,18	6,2	17,92	21,64
SF13	16,95	10,2	15,67	19,31
SF14	17,10	5,9	16,37	18,88
SF15	17,04	7,3	15,74	19,21
SF21	16,19	5,9	15,52	18,06

It can be observed, that the mean penetration depths are included between 16,2 mm and 20,2 mm, while the results of the single tests have a wider range from 15,5 mm to 23

https://doi.org/10.52202/069179-0131

mm. The coefficients of variation, as well as the minimum and maximum depths, highlight that the experimental data are quite scattered along the same purlin, probably due to the inhomogeneity of the surface decay. In addition, the conditions of the cortical layer make completely inadequate the producer's law as illustrated in Figure 5.
On the other hand, Figure 6 shows the regression line built on the actual data (ρ and PD_m) with the related 95% confidence and prediction intervals. The purlin SF06 was excluded from the analysis, since the related data seems to be an outlier (Figure 5). The coefficient of determination is $R^2 = 0,55$.
The actual regression line is compared with the one obtained by Faggiano et al. [12] (Eq. (1)). The two lines have a quite different slopes, however they are strictly connected considering that the second one falls almost completely within the confidence limits of the first one. Anyway, the general randomness of the superficial decay and the lack of knowledge about the sample that Faggiano et al. used, does not encourage data to be merged to achieve a single law.

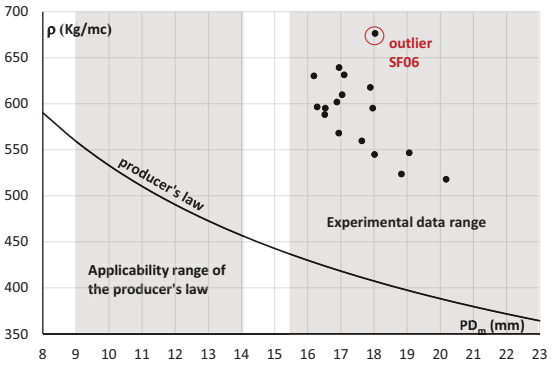

Figure 5: *WP - Comparison between the experimental data and the producer's law*

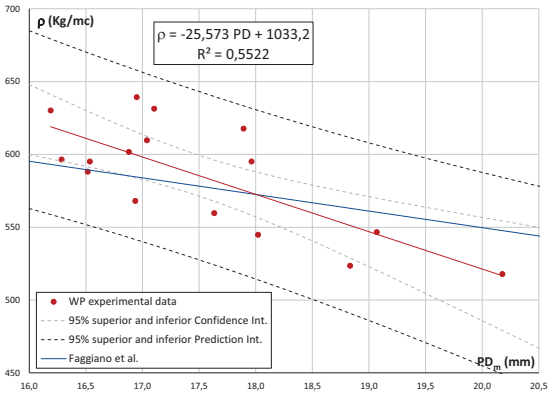

Figure 6: *WP - Correlation between the penetration depth and the actual density*

Better results are obtained by means of the Resistograph, probably because this method involves the entire section, rather than just the cortical layer, and therefore the superficial decay is irrelevant.

In Table 4 the medium feed rate (FR_m) and the medium drill rate (DR_m) are reported together with the respective coefficient of variation (CV_{FR} and CV_{DR}).

Table 4: *Resistograph tests results*

Purlin	FR_m (%)	CV_{FR} (%)	DR_m (%)	CV_{DR} (%)
F06	32,1	5,3	18,8	10,9
F07	38,8	14,2	18,0	13,4
F08	39,3	4,3	18,7	5,6
F09	44,9	8,3	20,4	8,7
F11	47,2	5,3	22,0	10,9
F12	44,7	10,0	20,9	10,8
F13	39,2	11,8	17,3	8,9
F15	41,5	7,3	19,3	7,1
SF06	53,4	6,1	25,9	8,4
SF07	38,9	7,7	18,0	5,5
SF09	42,6	6,5	20,8	10,9
SF10	38,8	6,8	17,9	5,9
SF12	30,7	11,2	14,6	8,7
SF13	46,2	4,3	21,9	6,6
SF14	47,5	9,5	22,8	11,2
SF15	46,3	4,0	22,2	5,7
SF21	46,8	8,1	22,0	9,6

In both cases, the correlations between FR_m and DR_m and the actual density of the purlins are strong. However, the regression line FR_m - ρ is slightly more reliable than the other one with a coefficient of determination $R^2 = 0,89$ versus $R^2 = 0,82$. In Figures 7 a/b the regression lines with the related 95% confidence and prediction intervals are reported. Then, the chestnut density may be estimated through the following relationships:

$$\rho = 7{,}011 \cdot FR_m + 294{,}26 \mp 37 \left(\frac{Kg}{mc}\right) \quad (5)$$

$$\rho = 14{,}71 \cdot DR_m + 295{,}15 \mp 47 \left(\frac{Kg}{mc}\right) \quad (6)$$

Finally, it is necessary to point out that these correlation laws may be considered a reference just if the tests are performed with the Resistograph IML RESI PD400 with the same rotational and feed velocities set.
Regarding the combined method, for each section, the average values of all densities estimated by combining the penetration depth with the inlet and outlet sections of both the feed rate ($\rho_{comb,FR}$) and drill rate ($\rho_{comb,DR}$) graphs were computed. During processing, those combined densities that were lower than the ones estimated with the Wood Pecker only were excluded, as well as those ones higher than 700 Kg/mc. In Table 5 the combined densities estimated with both the graphs and the relative coefficients of variation are reported. These last highlight an important dispersion of the data.

https://doi.org/10.52202/069179-0131

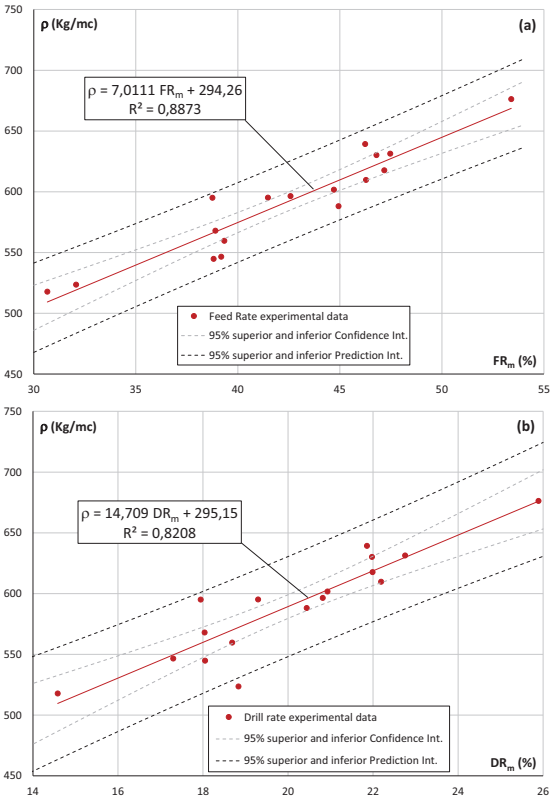

Figure 7: *Resistograph - Correlation between the Feed Rate (a) and the Drill Rate (b) and the actual density*

Table 5: *Combined method results*

Purlin	$\rho_{comb,FR}$ (Kg/mc)	CV_{FR} (%)	$\rho_{comb,DR}$ (Kg/mc)	CV_{DR} (%)
F06	491	9,5	468	8,1
F07	476	11,7	491	14,5
F08	469	11,6	493	10,7
F09	503	11,1	507	11,3
F11	491	12,5	505	13,4
F12	499	12,4	509	11,9
F13	490	13,0	485	14,2
F15	480	9,5	509	15,8
SF06	520	16,5	520	14,1
SF07	500	10,0	493	12,3
SF09	475	12,8	513	16,0
SF10	486	11,2	502	9,8
SF12	430	7,6	430	6,7
SF13	575	13,8	558	14,4
SF14	491	10,9	498	13,6
SF15	509	12,3	538	15,8
SF21	502	14,7	476	10,4

As can be seen from Table 5, the estimated densities are very conservative, anyway, the correlation between the actual densities and the ones evaluated through the drill rate graph has some interesting aspects. Considering the whole sample, the regression line is quite parallel to the equality one ($\rho_{comb,DR} = \rho$) with $R^2 = 0,48$ (Figure 8). Anyway, the data concerning the specimens SF06 and SF21 can be considered outlier and then they can be excluded from the correlation. In this case, the coefficient of determination increases up to 0,69, while the regression line slightly lowers keeping the slope almost the same. Considering the 95% prediction intervals, it can be assumed that:

$$\rho = 1{,}0838 \cdot \rho_{comb,DR} + 40{,}4 \mp 57 \left(\frac{Kg}{mc}\right) \tag{7}$$

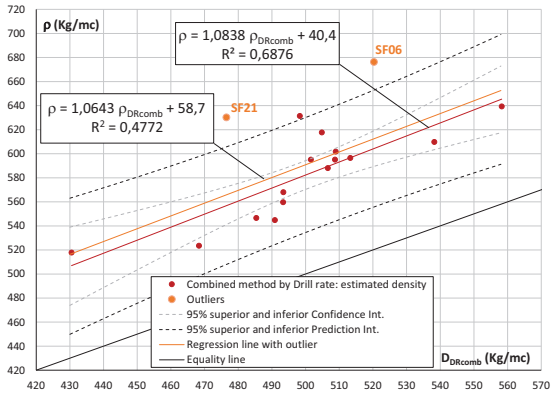

Figure 8: *Combined method - Correlation between the estimated densities evaluated through the Drill Rate graph and the actual densities*

5 MODULUS OF ELASTICITY

5.1 ULTRASONIC PULSE VELOCITY

The elastic properties of wood may be estimated through the so-called dynamic methods including the ultrasonic pulse velocity measurement (V). This velocity is strictly connected with the density of wood (ρ), with its dynamic modulus of elasticity (E_{dyn}) and with the Poisson modulus (ν). Since the latter is often ignored, the relationship between the remaining quantities becomes very simple:

$$V = \sqrt{\frac{E_{dyn}}{\rho}} \tag{8}$$

However, the correct application of the method and the subsequent interpretation of the data is not as simple.
First of all, wood is an orthotropic and inhomogeneous material with very different structural characteristics depending on the species. Then, the stress wave speed is influenced by the direction, the internal "architecture" of the material, the presence of any defect as knots, cracks or decay, as well as by the moisture content and even by the equipment employed for the test. Therefore, also among the same species, the ultrasonic pulse velocity measurement can vary greatly depending on the test conditions, compromising the reliability of the dynamic modulus estimation.
Second, the existing relationship between the dynamic modulus of elasticity and the static one is still discussed.

https://doi.org/10.52202/069179-0131

With regard to chestnut, some studies have been conducted on old structural elements with different results. Faggiano et al. [12] found a strong correlation between E_{dyn} and the bending modulus (E_b) with $R^2 = 0,76$ as well as Santini et al. [5] although in this case, the correlation involved the compression modulus ($E_{C,0}$). On the other hand, Koca et al. [16] found a weak correlation between E_{dyn} and E_b with $R^2 = 0,32$.

In any case, the stress wave speed is generally measured parallel to the grain (V_L). In fact, along this direction, it reaches the highest value and it is less influenced by local defects and by the arrangement of the growth circles of the wood since there is an important difference between the velocity along the radial or the tangential direction ($V_R \approx 1/2V_L$ and $V_T \approx 1/3V_L$) [17]. Then, a practical problem is added. During *in-situ* surveys, the ends of the investigated wooden elements are often not accessible making it impossible to measure the longitudinal pulse velocity by direct way.

In this case, a solution may be given by the indirect measure (V_{ind}), placing the two transducers along the same face of the element with an appropriate distance between them. Some studies highlighted that in this way it is possible to obtain a good approximation of the longitudinal velocity. Oh [18] finds out, by some tests performed on spruce lumber specimens, that the ratio V_{ind}/V_L increases with the distance (d) asymptotically tending to 0,87 for $d = 20$ cm. However, Machado et al. [19] demonstrate that when some superficial defects occur it is important to further increase the distance in order to involve deeper wood layers in the propagation path. In this case, they obtained a ratio V_{ind}/V_L greater than 0,90 with $d = 40$ cm.

These studies are all performed on small clear wood specimens without defects or with planned defects. On the contrary, the ultrasonic tests executed on the 17 purlins are aimed to estimate the ratio V_{ind}/V_L when the indirect method is applied directly on site and to evaluate the best methodology to perform it. The equipment employed is an ultrasonic system CMS HLF-P SG02_0128 series with 55 kHz piezoelectric transducers equipped with tips.

The direct longitudinal velocity was calculated for each purlin as the average value of five tests performed between the ends: one in the middle of the section and the others close to the four edges (Figure 9).

The indirect measures were executed along the four sides of each element and the transducers were placed at both a distance of 40 cm ($V_{ind,40}$) and 60 cm ($V_{ind,60}$) as illustrated in Figure 9. The chosen paths were apparently free from macroscopic defects as knots and holes or important decay and they were not cut by significant fractures.

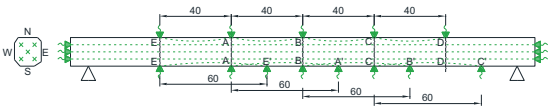

Figure 9: *Direct and indirect measures of the ultrasonic pulse velocity*

5.2 RESULTS

Following the tests, with regard to the choice of the distance between the transducers, it was observed that:

- the ratio V_{ind}/V_L remains approximately the same despite the variation of the distance ($V_{ind,40}/V_L$=0,85 - $V_{ind,60}/V_L$=0,86);
- it is more difficult to find a path with a length of 60 cm free of defects than one of 40 cm;
- the attenuation of the signal over 60 cm makes sometimes too difficult to read the time of flight of the stress wave.

For all these reasons the authors chose to deepen and analyse only the method that provide the shortest distance. The results of the direct (V_L) and indirect tests ($V_{ind,40}$) are given in Table 6. The indirect velocity is the medium value computed on 12÷15 different paths (N) for each purlin. In fact, despite a careful choice of the wave trajectory, the indirect velocities along the same element may be quite scattered with a coefficient of variation (CV) that can rise up to 10,63% (specimen F09). On the other hand, a relatively high number of measurements allows to maintain stable enough the ratio $V_{ind,40}/V_L$ with a CV less than 2%.

Table 6: *Direct and indirect ultrasonic tests results*

Purlin	V_L (m/s)	N	$V_{ind,40}$ (m/s)	CV (%)	$V_{ind,40}/V_L$
F06	5181	13	4521	5,55	0,873
F07	5264	12	4460	7,75	0,847
F08	5548	12	4653	5,69	0,839
F09	5392	12	4603	10,63	0,854
F11	5345	12	4597	4,67	0,860
F12	4948	12	4199	9,01	0,849
F13	5113	12	4530	7,80	0,886
F15	5358	12	4427	9,91	0,826
SF06	4944	12	4290	4,67	0,868
SF07	5316	12	4398	6,18	0,827
SF09	5248	12	4400	8,27	0,838
SF10	5397	12	4620	8,88	0,856
SF12	4944	12	4291	8,50	0,868
SF13	5638	15	4737	4,46	0,840
SF14	5645	13	4744	4,82	0,840
SF15	5379	14	4547	9,04	0,845
SF21	5260	12	4597	6,06	0,874
	Medium value of the ratio $V_{ind,40}/V_L$				0,852
	CV of the ratio $V_{ind,40}/V_L$ (%)				1,94

Figure 10 shows the correlation between the direct and the indirect readings. The coefficient of determination (R^2) is good and particularly it may be observed that there is quite no difference between the best fit regression line and the one forced to pass through the origin. Then, the latter may be considered reliable enough and, according to the related 95% prediction intervals, the longitudinal velocity can be estimated through the following relationship:

$$V_L = 1,174 \cdot V_{ind,40} \mp 229 \left(\frac{m}{s}\right) \quad (9)$$

where the slope is given by the ratio $V_L/V_{ind,40}$, which is 1/0,852.

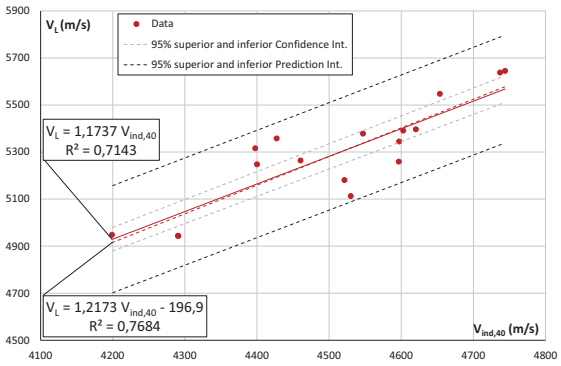

Figure 10: *Correlation between direct and indirect velocities*

6 SUSTAINABILITY CONSIDERATIONS

When addressing the issue of sustainability it is necessary to do so with full knowledge of the facts. In this research, authors talked about sustainability as material saving, but in reality, the considerations to be made are several.

In the first instance to conduct the experimental diagnostic operations on the samples were made of operations that have caused consumption and emissions that the proposed methodology offers to avoid. So the transport from the Diocletian Baths to the laboratory and the replacement of the elements are exactly the phases that, opting for non-destructive diagnostic operations, the research aims to avoid in the future.

On the basis of these considerations, it is necessary to think about actual consumption from a multi-parametric point of view, as carried out in previous research, as mentioned before. In this sense, NDT were analysed from an environmental, social, economic and structural point of view. There is no doubt, however, about savings in terms of assessment, transport, economics in the face of replacement works, and the social and cultural value of preserving not only the historical heritage but also the technology and materials.

This analysis compared various interventional alternatives, modelled using Heritage-Building Information Modelling (HBIM) technology, assessed using the multi-criteria decision analysis Analytic Hierarchy Process (AHP), and quantified sustainability using the multi-criteria Modelo Integrado de Valor para Evaluacin Sostenible (MIVES) methodology. To do this, the study offers a methodology to assess various interventions, including NDT diagnosis: i. replacement with the insertion of braces; ii. non-destructive testing and steel jacketing with shaped retaining profiles welded in situ; iii. non-destructive test and support beams bolted with braces; iv. NDT and simple braces addition.

Wood is a material that can be understood as a witness for such research and insights since it is often underestimated its strength in structural terms and the consequent economic and environmental savings resulting from its assessment.

Moreover, in the absence of many ancient wooden roof structures, it is also relevant for a cultural and architectural tradition that must be preserved and that must also be available to posterity.

7 CONCLUSIONS

The research aims to suggest a methodology that can provide a wide assessment examination for historic timber structures also taking into account sustainability, emphasizing the correlation that diagnostic tests can have with the environmental impact.

Non-destructive tests, given the low invasiveness, can be a set of scheduled maintenance operations that allow having a complete and constant overview of structural behavior over the years. Considering also the few analyses that are carried out on historic wooden buildings and the randomness of the results present due to the heterogeneity of the material, a procedural method is proposed in the research through combinations of different test results in order to obtain a complete assessment of the structure, without it being damaged or replaced.

The aim is to derive the estimates of the three unknowns concerning the wooden elements: geometry, density and elastic modulus.

The first, especially with regard to volume, is difficult to estimate on the construction site. The proposed analysis of several relevant techniques compared, allows having a general overview and a correlation between the data obtained. From the simple measurement of only the main dimensions to the photogrammetric survey, the authors have seen the influence that the estimated volume change can have on the density of the material.

The visual investigation deepens these analyses by providing a mechanical classification based on the defects observable from the outside.

The non-destructive tests provide estimation values of the physical and mechanical properties of the material, so the other two unknowns (density and elastic modulus) must be obtained through correlations that can make the results obtained reliably.

The correlations obtained from the proposed combined procedure, which are useful to derive the density estimate by comparing surface and depth results, have the limit of being able to be used only with the instrumentation used and with the same settings as those used in this research. In addition, the conservative state of the surface layer was also a key factor. Poor maintenance and deterioration of the wood surface layer is an important variable to consider especially with regard to surface testing.

For the modulus of elasticity through ultrasonic tests, instead, a comparison between estimated speeds based on the distance of the probes has been proposed, to understand which is more suitable for the use in situ.

The set of data and results obtained is useful in order to propose a useful methodology on site to carry out non-invasive diagnostic tests that can limit the consumption of material and maintain the historical value of ancient structures and technologies.

It is therefore intended to provide a method that can prevent the cultural, historical and architectural heritage

https://doi.org/10.52202/069179-0131

too many invasive changes and alterations that prevent their preservation, through timely diagnostic operations.

COMPARATIVE LIFE CYCLE ASSESSMENT OF TIMBER-CONCRETE-COMPOSITE WALLS WITH CONCRETE AND CLT-WALL ELEMENTS

Anna Wagner[1], Klara Winter[2], Anna Nestmann[3], Stephan Ott[4], Stefan Winter[5], Oliver Fischer[6]

ABSTRACT: In this study, Life Cycle Assessment of a new hybrid timber-concrete wall element was conducted. Furthermore, the results for the hybrid wall element were compared with the LCA results of a functional equivalent reinforced concrete wall element and a cross-laminated timber wall element. The thickness of the cross-section of the wall element (1 m² wall area) varied dependent on the applied load which was equal for every construction method. Modules A1-3, B4 as well as C1-4 and module D were considered. The results were analysed in terms of Global Warming Potential. The evaluation of the results indicated that, from an environmental impact point of view, the concrete-wall element is the least-reasonable option. The CLT wall element is the most suitable for small loads. However, with increasing load, a tipping point was reached. From this point on, the hybrid wall element showed lower environmental burden than the CLT wall element. This is because the thickness of the CLT used for the hybrid wall element and hence, its volume significantly increased compared with the volume of the hybrid wall element. Dependent on the applied load level, the difference in thickness among the cross-sections of the three construction methods can vary significantly.

KEYWORDS: comparative Life Cycle Assessment, hybrid construction element, timber-concrete wall

1 INTRODUCTION

In a completed research project, new hybrid timber-concrete wall elements were investigated by *Oberndorfer et al.* [1]. The wall elements consist of core lamellas in Ultra High Performance Concrete (UHPC) and exterior cross-laminated wooden lamellas. This composition should lead to a reduced use of concrete and at the same time, to a minimized component thickness compared to a Cross Laminated Timber (CLT) wall element. The reason for this is, that the combination of these two materials and their different properties enables an optimised utilisation for load-bearing purposes compared to CLT wall elements. [1]

The investigations of *Oberndorfer et al.* [1] focused on the force-fit adhesion of wooden lamellas to UHPC lamellas, showing promising results for a one-part polyurethane adhesive applied on a sanded UHPC lamella. In a follow-up research project, these hybrid CLT wall elements are now further investigated to evaluate their feasibility in practice. Thus, amongst other aspects such as hygrothermal behaviour and fire resistance, the environmental impacts of the wall elements are investigated.

To study the environmental performance of such wall elements, this article analyses the environmental impacts over their life cycle, in comparison with CLT and reinforced concrete (RC) wall elements dependent on the applied load.

By conducting a comparative assessment approach, the following research-questions should be answered:

- What are the environmental impacts of such hybrid CLT walls?
- What influence does the End-of-Life stage have on the results?
- Do these hybrid CLT walls have advantages over the environmental impact of common construction methods, such as reinforced concrete or CLT?

To enable prefabrication and the transport to the construction site, the focus is on wall elements. In this study, the term “wall” refers to wall elements.

2 BACKGROUND

2.1 Hybrid CLT walls

2.1.1 Composition of hybrid CLT walls

The investigated hybrid CLT wall resembles a common CLT wall. However, the core wooden lamella of the wall is replaced by an UHPC lamella (see Figure 1). This UHPC lamella can either be included continuously or, in the event of local load peaks, in an alternating way (see Figure 1).

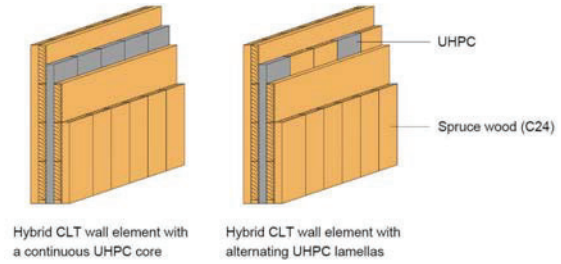

Figure 1: *Exemplary composition of Hybrid CLT walls*

The advantage of UHPC is that it shows much higher compressive strength than commonly used concrete, leading to thinner elements in comparison to concrete elements [2]. A one-component polyurethane adhesive is used to bond the lamellas (not bonded on the narrow sides). For an optimised application of timber and concrete, the UHPC lamella mainly bears the compressive force, whereas the outer wooden lamellas bear both compressive and tensile forces resulting from bending.

2.1.2 Production of hybrid CLT walls

In this study, the production process described in *Oberndorfer et al.* [1] is considered (see Figure 2). The production of hybrid CLT walls within the scope of the research project was partly manually conducted. For future practical applications, it is intended to produce the hybrid CLT walls on an assembly line that is comparable to the assembly line of CLT. The UHPC lamellas can be manufactured precisely because they are dimensionally stable in the setting process and are then precisely ground to size. Therefore, the processing steps can be automated. The extent to which the energy input for automated production influences environmental impact will have to be further investigated in the future.

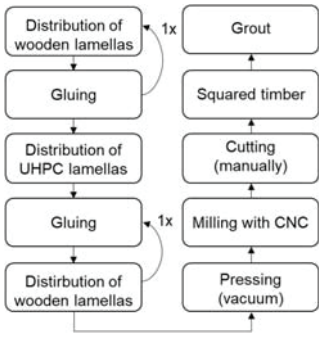

Figure 2: *Production process of hybrid CLT wall according to [1]*

The production process is similar to that of CLT walls. To produce the hybrid CLT walls, the wooden lamellas are slightly longer than the UHPC lamellas. Hence, after pressing, the wooden lamellas are milled with a CNC mill and manually cut without damaging the blades. After this process, a squared timber is inserted on the narrow sides. A small gap between the wooden and the UHPC lamellas results, which is filled with grout. [1]

2.2 LCA of hybrid construction components and of UHPC

2.2.1 LCA of hybrid construction components

To investigate the environmental performance of complex construction components and to compare different construction methods, Life Cycle Assessment (LCA) can be applied [3].

In different studies [4,5], LCA of hybrid timber-concrete components was conducted. In these studies, only the production stage was investigated based on already existing product-datasets. However, for a holistic consideration, all life cycle stages should be considered [3], because, especially for hybrid structures, the End-of-Life stage influences the environmental impact results of the full life cycle [6].

According to the European waste directive [7] and in terms of resource conservation and avoiding emissions, reuse or high-level material recycling should be favoured, instead of final material recovery, energy recovery or disposal. In 2020, around 57 % of construction waste in Germany was used as recycling material for street and earth work, 16 % was used to produce asphalt and concrete, while the resting percentage was disposed or landfilled [8]. Moreover, approximately 80 % of waste wood in Germany is incinerated [9]. This shows that, for both concrete and construction wood, high-level recycling or even reuse as required by the European waste directive [7] is not yet broadly established in practice.

To enable the reuse or high-level recycling of construction products, separability into homogenous and identifiable materials must be given [10,11]. Hence, for hybrid timber-concrete construction components, it is necessary to ensure the separability of timber and concrete at End-of-Life to enable the recycling of the different materials [6]. Solutions such as deconstructable connectors for Timber-Concrete-Composite floors may ease separation [12]. Further, the adjustment of legislations is necessary to allow the use of secondary materials in new products [11].

2.2.2 LCA of UHPC
