The following is an analysis of one of the first tall mass timber projects in North America to benefit from years of in-service performance feedback and monitoring data.

Located in Vancouver, Canada, Brock Commons Tallwood House is an 18-story hybrid building that includes 17 stories of mass timber construction over a single-story above-grade concrete podium, and two full-height concrete stair cores. The floor system consists of 5-ply CLT panels supported on glulam columns, and the roof is made of prefabricated sections of steel beams and metal decking. As of this writing, the building has five

https://doi.org/10.52202/069179-0383

years of in-service life and has been monitored for vertical movement and moisture content since construction started in 2016.

For the design of a 53 m (174-ft)-tall hybrid building, it was critical to consider differential movement between the timber structure and concrete cores. A specific concern was the potential impact of vertical movement on the mechanical services running through the CLT floor panels adjacent to the concrete cores.

Cumulative differential movement between mass timber members due to fabrication tolerances was minimized by the relatively low probability of occurrence. Glulam columns are typically manufactured with a tolerance of +/- 1.6 mm (1/16-in.) along their height. The probability of having all the shortest members on one side of the panel span and longest on the other is low and was compensated by surveying column datums and using shims as required. Another way to mitigate this risk is to utilize proper truck loading and column identification number tags, such that longer columns are installed above shorter ones and vice-versa.

The following vertical movements for Brock Commons were assessed using structural analysis methods prior to construction and represent cumulative totals at the roof of the building.

- Column shrinkage: 11 mm (0.43-in.)
- Column elastic shortening (short term loading): 25 mm (1-in.)
- Column shortening (creep): 12 mm (0.47-in.)
- Concrete core shrinkage: 12 mm (0.47-in.)
- Concrete core elastic shortening (short term loading): 2 mm (0.08-in.)
- Concrete core shortening (creep): 3 mm (0.12-in.)
- Foundation differential settlement: No critical impact on this project
- Tolerances intra-material: Mitigated by truck sequencing, column marking
- Tolerances extra-material: Interface details between timber and concrete allowing for movement

The anticipated concrete core movement was mainly due to shrinkage, as elastic shortening was negligible. Construction sequencing allowed the design team to minimize this discrepancy because the concrete core was cast in full prior to the erection of timber elements; most of the shortening had already occurred and therefore did not impact the final differential movement between materials.

Based on discussions with the design and construction team, most of the shortening and joint settlement was mitigated by adding a series of 1.6 mm (1/16-in.)-thick steel shim plates at the column-to-column connections on three strategic levels (eight, 12, and 16). The top of the first level column was surveyed and adjusted with leveling nuts at the base to mitigate any differential between columns due to concrete tolerances.

The total shim package thickness varies based on assumed loads and a varying elastic modulus. Due to the general level of uncertainty surrounding these two parameters, only 50% of the calculated values were mitigated, while details were designed to accommodate the other 50% if they were to occur. It is important to maintain this level of flexibility at critical locations so as not to overcompensate for calculated differential movement that does not occur because certain assumptions weren't realized.

The design and construction team also defined a moisture management plan that limited exposure to weather and water accumulation. This plan relied on the following:

- Fast erection pace of one story per week
- Prefabricated enclosure panels installed as soon as each level was built
    - For tall buildings, wall enclosure is a more effective way to reduce exposure to weather than temporary roof enclosure.
- Erection of the timber structure during summer
- Use of sealant and tapes to limit water penetration in the timber
    - With non-edge-glued CLT, this was not sufficient to stop water transfer from the active deck to lower floors; as the CLT panels dried and shrank, some of the lamination lines opened, creating passages for water.
- Use of concrete topping to create an effective water barrier
    - Concrete topping was placed four levels below the active deck, acting as a temporary roof and preventing water transfer to the floors below.
- Fans strategically placed to avoid moisture accumulation

Recording of moisture content across the thickness of CLT panels began at the manufacturing plant, continued through transportation and installation, and is ongoing today. Data showed that panels were kept at a consistent and relatively low moisture content at the factory and during transportation (<19% MC) but that many panels were subject to a large increase on site, especially in the top lamination, exceeding in some cases the fiber saturation point at their surface. Rapid increase and decrease during and after a rain event demonstrated the drying ability of the CLT, such that within a few days the exposed layer was back to an MC below 16%. Data generated from the CLT moisture monitoring was also used to understand the MC of glulam columns.

Throughout construction, strategies were developed to limit water exposure and transfer to lower floors to ensure

that the MC of timber elements could decrease to acceptable ranges as each story was partially enclosed. Once that occurred, the average moisture level during construction was kept below 20%, decreasing to below 15% once the building was complete. After the first two years of use, the MC had settled to between 8% and 15%.

If a proper water management plan is established (and followed), higher moisture content readings during construction should not significantly affect the level of shimming or material interface connections. Real data from Brock Commons confirmed that the variation of moisture content from factory to the project's in-service condition is close to the ranges assumed in the initial column shrinkage calculations.

As part of the Tall Wood Building Demonstration Initiative, Brock Commons benefited from 338 sensors located throughout the structure to measure vertical compression of the timber columns, moisture content, temperature, and humidity. Implemented by SMT Research, instrumentation of the building was deemed important to provide a better understanding of the behavior of tall mass timber structures. This also allowed better tracking of potential issues during construction and a documented comparison of expected vs. actual differential movement.

The timber columns were instrumented to record data for vertical displacement at the first four stories, except for a few columns that were monitored through the roof level. The displacement on the outer columns was about half that of the inner columns, as expected due to the smaller loads. The most recent published shortening record was between 2 mm (5/64-in.) and 4 mm (5/32-in.) per column between levels two and seven, and 0.25 mm (0.01-in.) to 1 mm (0.04-in.) per column between level seven and the roof. Based on this, cumulative column shortening can be assumed to be 22 mm (0.87-in.) total at the roof.

In addition to vertical displacement sensors, the elastic modulus of the lam stock used to manufacture the glulam columns was collected. The average elastic modulus was 20% higher than the design value, which implies 20% less elastic shortening and creep. The values used for elastic modulus, live load, creep, joint settlement, and moisture variation can compel designers to overestimate the total shortening and lead to over-shimming. Engineering judgement and experience in mass timber buildings are important to balance theoretical study. The theoretical study for Brock Commons resulted in 48 mm (1.89-in.) of total shortening compared to 22 mm (0.87-in.) from site monitoring; therefore, the safeguard of shimming up to 50% of the calculated shortening was deemed appropriate for this design. Slight shortening is still expected to occur in the future due to creep.

9 CONCLUSION

The Brock Commons Tallwood House data confirms that it is critical to consider axial column shortening in tall mass timber buildings and that precautions should be taken to address estimated shortening due to the uncertainties that lie within assumptions. It is critical to understand where a designer should allow for flexibility and how to protect other components from structural movements. When properly accounted for, shortening should not negatively affect the construction, use, or long-term performance of the building. Negative impacts can be avoided through a combination of proper detailing and effective moisture management strategies that involve coordination and discussion among all members of the design and construction team.

In addition to regular, on-site observation and movement monitoring, third-party inspections to review movement-accommodating details as installed, and to check items such as shims, will help to ensure that performance matches design intent. To have successful vertical movement performance, proper detailing must lead to proper installation. Education may also be necessary for the building owner, contractor and subcontractors to understand potential issues and how to avoid them. Once fully understood, accommodating vertical movement simply becomes another design criteria.

SERVICEABILITY PERFORMANCE OF TIMBER DUAL FRAME-WALL STRUCTURAL SYSTEM UNDER WIND LOADING

Osama Abdelfattah Hegeir[1], Haris Stamatopoulos[2], Kjell Arne Malo[3]

ABSTRACT: Due to the moderate stiffness and low mass of timber multi-storey buildings, wind-induced accelerations and displacements usually govern the design. Moment-resisting timber frames (MRTFs) are structural systems that can provide open space and architectural flexibility. However, in regions with moderate to high wind velocities, MRTFs can be used for up to 8 storeys with small out-of-plane spacing between frames (C/C distance of the order of 2-3 m). In this paper, a dual frame-wall structural system is investigated. A parametric study using 2D linear elastic Finite Element Analysis (FEA) is performed to explore the feasibility of the system in regions with moderate wind velocities, considering serviceability requirements (lateral displacements and wind-induced accelerations). Floor vibrations are also taken into account. A 3D FEA model is used to verify the results of the 2D FEA model. Although the focus of the paper is devoted to serviceability requirements, some ultimate limit state considerations are discussed. The results highlight the possibility of using the dual system for multi-storey buildings, with up to 12 storeys and 5 m C/C distance in regions with basic wind velocities up to 26 m/sec.

KEYWORDS: Moment-resisting frames, serviceability, deflections, CLT, glulam, wind-induced accelerations, human-induced vibrations

1 INTRODUCTION

Timber has a very good strength/weight ratio due to its light weight compared to other building materials such as concrete and steel. Moreover, timber can be considered a more environment-friendly construction material than concrete and steel in terms of greenhouse gas emissions [1, 2]. Due to the lightweight nature and moderate stiffness of wood, timber structures are prone to serviceability problems such as excessive accelerations and displacements [3, 4]. Excessive accelerations can cause discomfort to the occupants, and excessive displacements can cause damage and therefore should be kept within acceptable limits.

There exist several structural systems that can provide lateral stiffness to a building. A common structural system used for tall timber buildings is diagonal bracing, such as Treet [4] and Mjøstårnet [5] in Norway. However, these buildings require huge bracing elements running along the height of the structure, which may compromise the architecture flexibility. Cross laminated timber (abbr. CLT) can also be used as a Lateral Load Resisting System (abbr. LLRS). An example of timber building with CLT walls is Stadthaus in London [6]. However, such structures are material-intensive, cellular, and can impose space limitations.

Open and flexible architectural design of buildings is a desirable property, which can be achieved by use of Moment-Resisting Timber Frames (abbr. MRTFs) as a LLRS. In MRTFs, the lateral stiffness relies largely on the stiffness of beam-to-column connections. A feasibility study of glulam MRTFs has been carried out by Vilguts et al. [3], showing that in high-wind regions, glulam MRTFs can hardly be used for more than 8 storeys. The study [3] assumes a prefabricated floor with a small 2.40 m out-of-plane spacing between adjacent frames (abbr. C/C). These limitations are due to wind-induced accelerations and lateral displacements [3].

To overcome the limitations on the number of storeys and achieve larger C/C distance, it is necessary to use larger columns and beams compared to standard glulam dimensions. CLT panels are currently produced with standard dimensions up to 3.5x16.0 m, and therefore can be used to achieve these larger dimensions.

In this paper, the feasibility of using dual frame-wall structural system to build up 12 storeys with C/C distance of 5 m considering a basic wind velocity of 26 m/sec is explored. The system consists of CLT walls, glulam columns and beams, and semi-rigid connections between beams and columns/walls. The feasibility of the system is evaluated, mainly, in terms of Serviceability Limit State (abbr. SLS). However, some Ultimate Limit State (abbr. ULS) considerations are also presented.

2 STRUCTURAL SYSTEM

In this section, the dual frame-wall structural system is explained. Both the LLRS and floor system are described in two different subsections.

2.1 LATERAL LOAD RESISTING SYSTEM

An example of the structural system is shown in Figure 1 (a). In this paper, the focus is given to the structural system in X direction (marked with dotted red box in Figure 1 (a)) where the dual system is used. It consists of continuous CLT walls, continuous glulam columns, and glulam beams. Semi-rigid connections using threaded rods are assumed between beams and walls/columns (see Figure 1 (b)). More details on the connections using threaded rods can be found in [7]. In Y direction, the building may be stabilized by use of diagonal bracing. The LLRS is discussed in more detail in section 4.

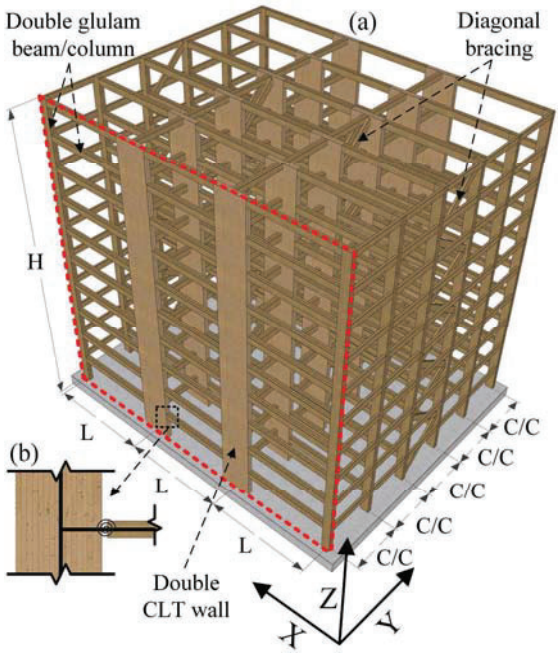

Figure 1: *(a) 3D view of the structural system, (b) semi-rigid moment connection*

2.2 FLOOR SYSTEM

In this paper, a ribbed slab floor system is assumed, see Figure 2. The system consists of CLT panels resting on simply supported secondary beams (glulam). The secondary beams are supported on the main LLRS working in X direction. The floor system is one way with load bearing parallel to Y axis. For better acoustic performance, double beams, columns, and walls are considered. Analysis of floors is discussed in section 3.

3 ANALYSIS OF FLOORS

Human-induced vibrations can be decisive in the design of timber floors [8, 9]. This section explores the serviceability performance of the floor system shown in Figure 2, which includes satisfying deflection limits and human-induced vibrations. However, the vibrations were found to be more critical than deflections. Therefore, the performance was only evaluated with respect to human-induced vibrations.

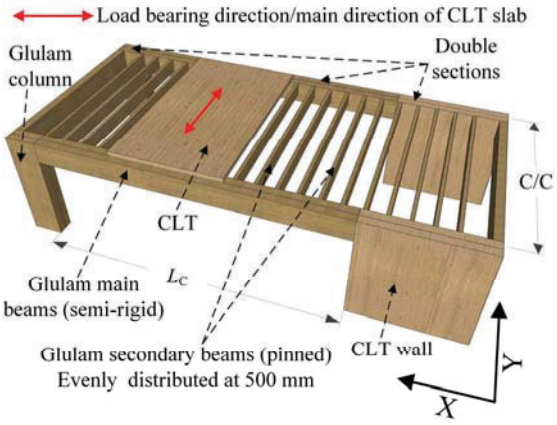

Figure 2: *Floor system*

Linear elastic Finite Element Analysis (abbr. FEA) was used to calculate the fundamental frequency and the deflection of the floor under unit load. The clear span L_C (confer Figure 2) and the stiffness of main beams' connections (confer Figure 2) were varied. The vibration performance of the floor was evaluated using the simplified Hu and Chui criterion [8].

3.1 MATERIALS

The glulam beams used in the floor is assumed of strength class GL30c as defined by EN 14080 [10]. The boards constituting the CLT panels are assumed of strength class C24 as defined by EN 338 [11]. In this paper, it was assumed that (2/3) of the boards are parallel to the main direction of CLT panels (confer Figure 2). The remaining (1/3) are orthogonal to the main direction. Table 1 summarizes mean stiffness properties for GL30c and C24, and the corresponding material axes are illustrated in Figure 3.

Table 1: *Mean stiffness properties for floor elements*

	GL30c	C24	Unit
E_1	13000	11000	N/mm^2
E_2	300	370	N/mm^2
E_3	300	370	N/mm^2
G_{12}	650	690	N/mm^2
G_{13}	650	690	N/mm^2
G_{23}	65	69	N/mm^2

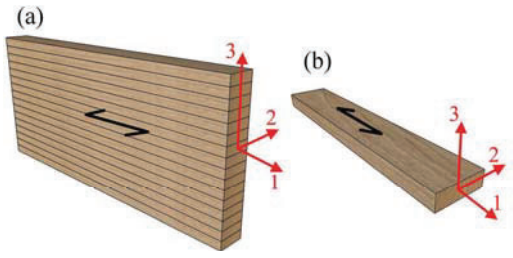

Figure 3: *Material axes for (a) glulam GL30c, (b) C24 boards*

https://doi.org/10.52202/069179-0384

3.2 FINITE ELEMENT MODELLING

CSI SAP2000 [12] was used for FEA. The software can be automated using Open Application Programming Interface (abbr. OAPI). The FEA model of the floor is shown in Figure 4. The main beams (glulam) are modelled using linear beam elements. The ends of the main beams are partially released with respect to bending moment to consider the semi-rigid connections. The secondary beams (glulam) are modelled using shell elements (shown in blue in Figure 4). The CLT slabs are modelled using layered shell elements (shown in red in Figure 4). The connections between the CLT slab and secondary beams, and the connections between the secondary beams and the main beams are modelled using link elements with only axial and shear stiffness (no rotational stiffness).

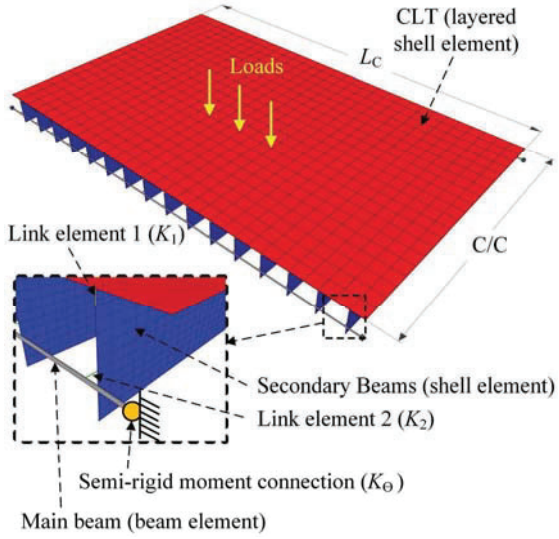

Figure 4: *FEA model of the floor*

3.3 ACCEPTANCE CRITERIA

Several design criteria exist for assessing floor vibrations caused by human activity (e.g. [8, 13]), each taking into account different factors and making different assumptions. In this paper, the simplified criterion proposed by Hu and Chui [8] is used:

$$\frac{(f_{n,1}/18.7)^{2.27}}{w_{1\ kN}} \geq 1.0 \qquad (1)$$

Where $f_{n,1}$ and $w_{1\ kN}$ are the fundamental frequency and the static deflection due to 1.0 kN.

The criterion [8] was developed based on testing of more than one hundred timber floors. Although this criterion [8] was developed in Canada, it is based on physical and subjective evaluations of floors with damping properties comparable to wooden floors found in Norway [14].

3.4 PARAMETRIC STUDY

A parametric study was performed to evaluate the performance of the floor. The parameters varied are summarized in Table 2. Two load scenarios are investigated, namely: heavy load, and light load, see Table 3. The heavy floors represent a case where additional mass is added to improve the performance of the building with respect to wind-induced accelerations (discussed in section 4).

The fundamental frequency $f_{n,1}$ used in evaluating human-induced vibration (see equation (1)) is calculated assuming only the dead load is applied to the CLT slab.

The connections between the CLT slab and the secondary beams, as well as the connections between the secondary beams and the main beams are assumed of equal translational stiffness K_1 and K_2 respectively, confer Figure 4 and Table 2. The main beams connection stiffness K_Θ is reasonably assumed based on the experimental work performed by Vilguts et al. [7] and the analytical work done by Stamatopoulos et al. [15]. Two sets of beams cross-sections and CLT layups are used depending on the load scenario, see Table 4. In total, 60 3D linear elastic analyses were performed.

Table 2: *Parameters used in the parametric study of the floors*

	Value(s)	Unit
Clear span L_C	7−9	m
C/C	5	m
K_Θ	0−15,000	kN·m/rad
K_1*	10	kN/mm
K_2	20	kN/mm
Damping ratio (ξ)	2	%

* Evenly distributed at 250 mm

Table 3: *Load scenarios*

	Heavy load	Light load	Unit
Dead load G_k*	2.0	1.0	kN/m^2
Live load Q_k	3.0**	2.0***	kN/m^2

* Including the own weight of beams and slabs
** Office buildings as defined by EN 1991-1-1 [16]
*** Residential buildings as defined by EN 1991-1-1 [16]

Table 4: *Beams cross-sections and CLT layups used in the parametric study of the floors*

	Load scenario	Cross-section/layup	Unit
Main beam	Heavy/light	$215 \cdot 585$	mm^2
Sec. beam	Heavy	$115 \cdot 450$	mm^2
CLT slab	Heavy	30/30/30	mm
Sec. beam	Light	$90 \cdot 450$	mm^2
CLT slab	Light	40/40/40	mm

Figure 5 shows the performance of the floor according to Hu and Chui [8] as function of the clear span L_C. As shown in Figure 5, for $K_\Theta = 15{,}000$ kN·m/rad, light floors with clear span up to 8.5 m and heavy floors with clear span up to 7.5 meet the acceptance limit. For $K_\Theta = 0$ (pinned), only light floors with clear span of 7.0 m meet the limit.

According to EN 1995-1-1 [17], special investigation is needed for residential timber floors with fundamental frequency less than 8 Hz. Modal analysis is used to calculate the fundamental frequency assuming only dead

load is applied to the CLT slab. The frequencies of light and heavy floors are shown in Figure 6. For floors with $K_\Theta = 15{,}000$, the frequencies of all light floors meet the acceptance limit (8 Hz), while only heavy floors with clear span ≤ 7.5 m meet the limit. For floors with $K_\Theta = 0$, only light floors with clear span ≤ 8.5 m meet the frequency limit.

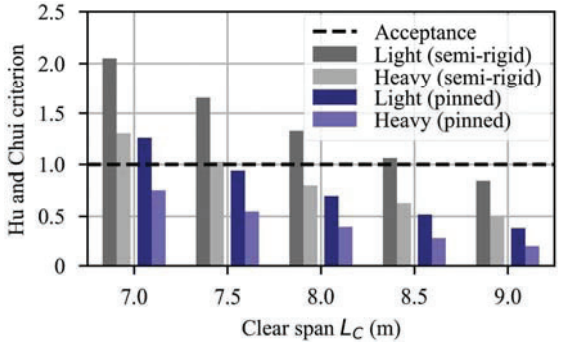

Figure 5: *Hu and Chui [8] criterion for human-induced vibrations (pinned: $\mathbf{K}_\Theta$=0, and semi-rigid: $\mathbf{K}_\Theta$=15,000 kN·m/rad)*

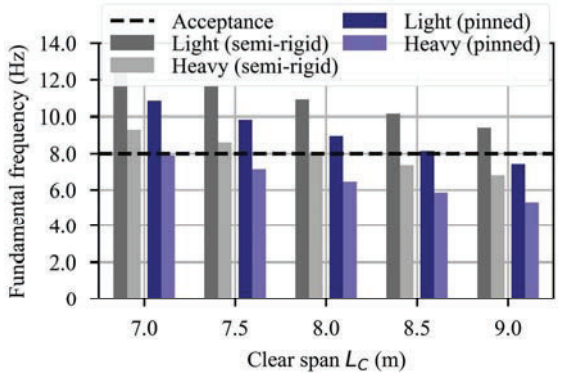

Figure 6: *Fundamental frequencies of floors (pinned: $\mathbf{K}_\Theta$=0, semi rigid: $\mathbf{K}_\Theta$=15,000 kN·m/rad, and only the dead load is considered)*

According to Hu and Chui criterion [8], and in compliance with EN 1995-1-1 [17] requirement of a minimum frequency of 8 Hz, some conclusions can be drawn from the parametric study (see Table 2):

- Light floors with clear span ≤ 8.5 m satisfy the requirements given that $K_\Theta \geq 15{,}000$ kN·m/rad.
- Heavy floors with clear span ≤ 7.5 m satisfy the requirements given that $K_\Theta \geq 15{,}000$ kN·m/rad.
- If pinned connections are used ($K_\Theta = 0$), only light floors with clear span ≤ 7 m meet the requirements.

The influence of main beam connection stiffness (K_Θ) on frequency and vibration performance is shown in Figure 7, where the rotational stiffness (K_Θ) is varied from 0 (pinned) to 15,000 kN·m/rad for a light floor with a clear span of 8 m. As depicted in Figure 7, an increase in K_Θ results in a higher floor frequency and improved vibration performance, owing to the increased floor stiffness.

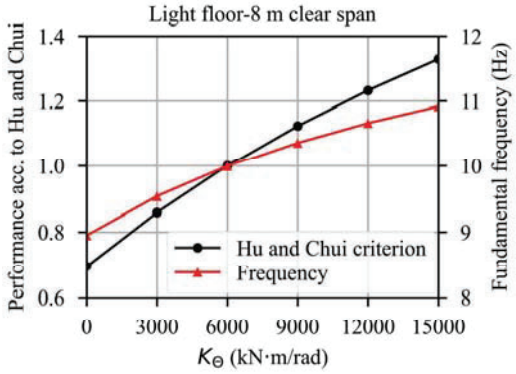

Figure 7: *Influence of main beams connections' stiffness on frequency and vibration performance as per Hu and Chui [8]*

4 ANALYSIS OF LATERAL LOAD RESISTING SYSTEM

Figure 1 shows a 3D structural system with X and Y directions perpendicular to each other. In this section, a small parametric study is performed to evaluate the feasibility of the dual frame-wall LLRS (in X direction) using 2D linear elastic FEA. Although the feasibility is evaluated primarily with respect to SLS, some ULS considerations are discussed. To validate the conclusions drawn from the 2D FEA, a 3D linear elastic FEA model was prepared, and the results were compared with those of the 2D FEA model.

Intuitively, higher connections' stiffness is required at lower storeys. The possibility of using lower connections' stiffness at the higher storeys is also explored.

4.1 MATERIALS

The LLRS in X direction consists of glulam beams, glulam columns, and CLT walls. The stiffness properties of glulam are the same as the floor (see Table 1).

A simplified modelling approach of CLT is to model CLT using equivalent stiffness properties assuming homogeneous cross-section with grain direction of all layers parallel to stress direction as proposed by [18]. This simplified modelling of CLT has shown good accuracy for CLT loaded in-plane [19]. Similar to the floors, 2/3 of the boards are assumed parallel to the main direction of CLT panels and the remaining 1/3 are orthogonal to the main direction. Equivalent stiffness properties of CLT walls are summarized in Table 5. The corresponding material axes are shown in Figure 8. Since linear elements were used to model the CLT walls (explained in 4.2 in this paper), only E_1 and G_{12} are relevant (confer Figure 8). E_1 affects the vertical axial stiffness and the bending stiffness of the CLT walls, and G_{12} affects their in-plane shear stiffness.

Table 5: *Equivalent stiffness properties of CLT walls*

	Equivalent stiffness	Unit
E_1	7457	$\mathrm{N/mm^2}$
G_{12}	518	$\mathrm{N/mm^2}$

https://doi.org/10.52202/069179-0384

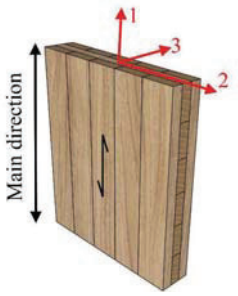

Figure 8: *Material axes for CLT walls*

4.2 FINITE ELEMENT MODELLING

Figure 9 shows the FEA model of the dual frame-wall system (X direction). CSI SAP2000 [12] was used to perform 2D linear elastic FEA. Glulam columns and beams were modelled using linear beam elements with the stiffness properties in Table 1. The CLT walls were also modelled using linear beam elements with the equivalent properties in Table 5. The linear beam elements representing the CLT walls were verified against the layered shell elements available in CSI SAP2000 [12] under in-plane loading. The verification was done on both stresses and displacements and the difference was less than 5%. Hence, linear beam elements were deemed to have sufficient accuracy for the purpose of this study.

All connections (beam-column/wall, wall-foundation, and column-foundation) were modelled using moment partial release available in CSI SAP2000 [12], and were considered semi-rigid with respect to moment and rigid with respect to translation.

Columns and walls have finite heights (in-plane dimension of the cross-section), therefore, when modelled using linear elements, beams' spans are increased. To account for this increase, end-length offset available in CSI SAP2000 [12] is used, see Figure 9. At each end of the beam, a length equal to half the column/wall height is assumed rigid for bending and shear deformations.

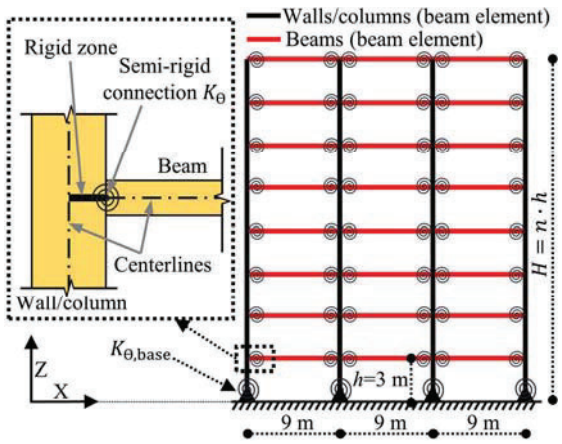

Figure 9: *2D FEA model of LLRS in X direction*

4.3 PARAMETRIC STUDY

In this parametric study, two variations of the LLRS in X direction shown in Figure 9 are considered, namely: exterior CLT walls, and interior CLT walls, see Figure 10. Both heavy and light loading scenarios are considered (see Table 3). The dead load in Table 3 includes the weight of the floor, while the own weight of LLRS is automatically calculated by CSI SAP2000 [12]. The parameters of the parametric study are summarized in Table 6 (total of 520 analyses).

The cross-sections of walls and columns, and the stiffness of their connections to the foundation were varied according to the number of storeys n, see Table 7. All beams, columns, and walls are double sections, confer Figure 2. The cross-sections and stiffness values in Table 6 and Table 7 are for single cross-section.

Table 6: *Parameters of the parametric study of the LLRS*

Parameter	Value(s)
Number of storeys (n)	4/6/8/10/12
Number of bays (n_b)	3
Gravity loads	Light/heavy
Variation	Interior/exterior CLT
C/C (Figure 1)	5 m
Basic wind velocity	26 m/sec
Beams	$215 \cdot 585$ mm^2
Beam-column/wall connection stiffness (K_Θ)	2,500-15,000 kN·m/rad

Table 7: *Cross-section of columns and walls and the stiffness of their connection to foundation (n: number of storeys)*

	n	Cross-sec. (mm^2)	$K_{\Theta,base}$ (kN·m/rad)
Glulam columns	12	$215 \cdot 720$	5,000
	10	$215 \cdot 630$	3,750
	8	$215 \cdot 540$	2,500
	6	$215 \cdot 450$	1,250
	4	$215 \cdot 450$	1,250
CLT walls	12	$215 \cdot 3500$	200,000
	10	$215 \cdot 3000$	150,000
	8	$215 \cdot 2500$	100,000
	6	$215 \cdot 2000$	60,000
	4	$215 \cdot 1500$	30,000

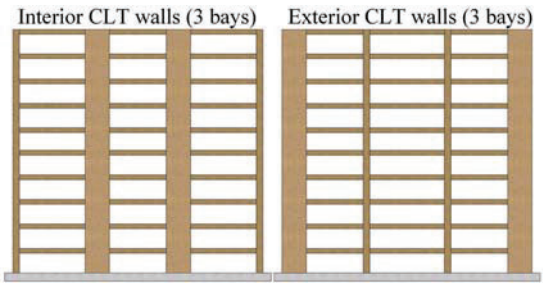

Figure 10: *Two variations of LLRS in X direction*

4.3.1 Serviceability performance

The serviceability performance of LLRS is evaluated in terms of wind-induced accelerations, top floor displacement (abbr. Disp.), and inter-storey drift (abbr. IDR). For the calculation of lateral displacements (Disp. and IDR) due to wind loading (W_k), the characteristic load

combination as defined in EN 1990 [20] with wind as a leading variable was used:

$$E_{\mathrm{d}} = G_{\mathrm{k}} + W_{\mathrm{k}} + \psi_0 \cdot Q_{\mathrm{k}} \quad (2)$$

The combination factor ψ_0 was set to 0.70 according to EN 1990 [20].

Some recommendations of deflections limits are provided by EN 1995-1-1 [17]. According to these recommendations, deflections in simple beams under characteristic load combination defined in EN 1990 [20] should be limited to $1/300 - 1/500$ of the span. No recommendations are given on structure level. As an approximation, the limits for simple beams are used for both lateral displacement at the top of the building (Δ) and relative displacement between two successive storeys (δ):

$$\Delta \leq {}^{H}/_{300}, \delta \leq {}^{h}/_{300} \quad (3)$$

Where h is the height of a storey and H is the total height of the building.

For the calculations of wind-induced accelerations, procedure 1 in Annex B of EN 1991-1-4 [21] was used. The procedure is based on gust factor approach. For the calculation of wind-induced accelerations according to EN 1991-1-4 [21], the mode shape, and the fundamental frequency are required. To obtain both the mode shape and the fundamental frequency, modal analysis using CSI SAP2000 [12] was performed. In the modal analysis, the mass is calculated using the quasi-permanent load combination defined in EN 1990 [20]:

$$E_d = G_k + 0.3 \cdot Q_k \quad (4)$$

Damping is an important input to the wind-induced acceleration calculation. Little research has been done on damping of timber structures, see e.g. [22]. In this paper, 2% damping ratio (ξ) was assumed based on [22]. Basic wind velocity of 26 m/sec and urban environment (IV) as defined by EN 1991-1-4 [21] were assumed for the calculation of wind loads and wind-induced accelerations. Relevant parameters used in the calculation of wind-induced accelerations are summarized in Table 8.

Table 8: *Relevant parameters for calculation of wind loads and wind-induced accelerations*

Parameter	Value
Directional factor C_{dir}	1.0
Seasonal factor C_{season}	1.00
Probability factor C_{prob}	0.73
Orography factor $C_{0(\mathrm{z})}$	1.00
Turbulence factor k_{I}	1.00
Terrain category	IV
Reference height Z_{t}	200
Reference length L_t	300
Structural damping ξ	2%
Width of the building ($C/C \cdot 5$)	25 m

In this paper, the wind-induced acceleration acceptance criterion of ISO 10137 [13] is used. The criterion covers the range from a fundamental frequency of 0.063 to 5 Hz for a maximum wind velocity with a return period of one year, for both residential and office buildings.

Figure 11 shows the wind-induced accelerations against ISO 10137 criterion [13] for all frames (see Table 6). Figure 12 shows the maximum and minimum lateral displacements and IDR for all frames (see Table 6), where maximum and minimum correspond to a set of frames with common parameters and K_Θ =2,500 kN·m/rad and 15,000 kN·m/rad respectively. Light and heavy frames have the same lateral displacements since gravity loads have no influence on lateral displacements.

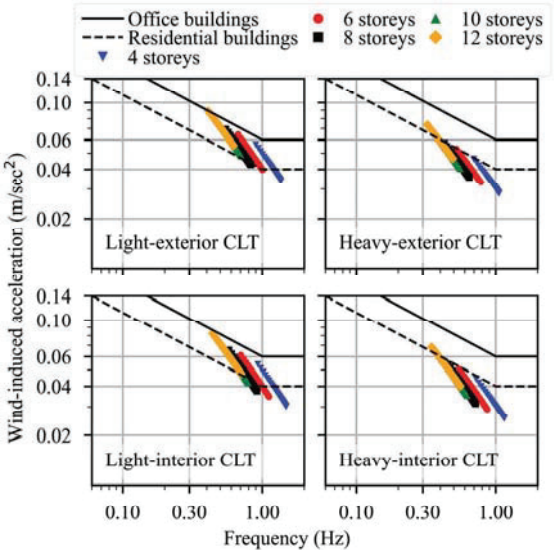

Figure 11: *Wind-induced accelerations against ISO 10137 [13] criterion*

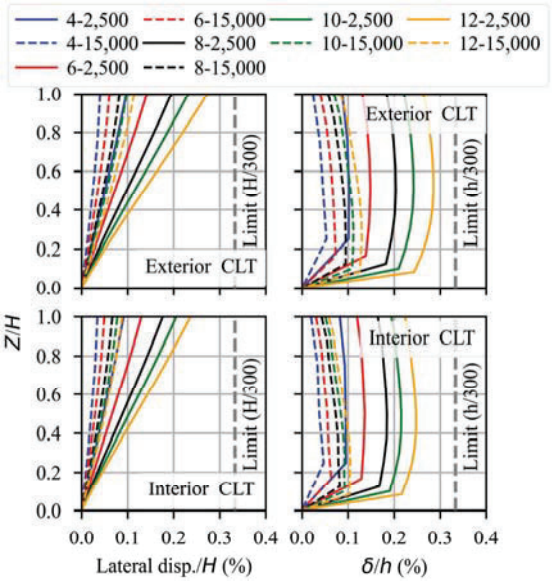

Figure 12: *Lateral displacements and inter-storey drift (Legend: number of storeys-K_Θ, and Z: height above ground)*

As shown in Figure 11 and 12, the variation with interior CLT walls is slightly outperforming the variation with exterior CLT walls. The variation with interior CLT walls has 5-10% lower wind-induced accelerations and 5-15%

https://doi.org/10.52202/069179-0384

lower lateral displacements. Frames with heavy loads have 20% lower wind-induced accelerations.
Observing Figure 11 and Figure 12, some conclusions can be made:

- All frames satisfy the requirements of top floor displacement and IDR by a good margin.
- Heavy frames up to 12 storeys meet the requirement of residential buildings provided that $K_\theta \geq 2 \cdot 5{,}500$ kN·m/rad (5,500 for single cross-section).
- Light frames up to 10 storeys meet the requirement of residential buildings provided that $K_\theta \geq 2 \cdot 11{,}500$ kN·m/rad (11,500 for single cross-section).
- Light frames of 12 storeys do not meet the requirement of residential buildings.
- Light and heavy frames up to 12 storeys meet the requirement of office buildings provided that $K_\theta \geq 2 \cdot 2{,}500$ kN·m/rad (2,500 for single cross-section).

4.3.2 Stiffness reduction in higher storeys

Connections with high stiffness are intuitively required at lower storeys, and connections with lower stiffness may be used in upper storeys. To verify such hypothesis, a 10-storey frame, with interior CLT walls and light gravity loads, is selected as a benchmark. All other parameters remain the same (see Tables 5-7).
A rotational stiffness (K_θ) of 5,000 kN·m/rad is assigned to all beam-to-column/wall connections, this is referred to as the reference case. High stiffness of (K_θ) 15,000 kN·m/rad is then assigned to all connections of one floor at each step starting from the bottom up (total of 10 steps). At the final step, all connections have a stiffness (K_θ) of 15,000 kN·m/rad. The case of all connections being rotationally rigid is also shown. In total, 12 analyses were performed. Figure 13 shows the top floor displacement, maximum IDR, and wind-induced acceleration, all normalized to the reference case (K_θ = 5,000 kN·m/rad). In Figure 13, a value of 0 at the horizontal axis represents all connections with stiffness of 5,000 kN·m/rad (reference case), while a value of 10 represents all connections with a stiffness of 15,000 kN·m/rad.

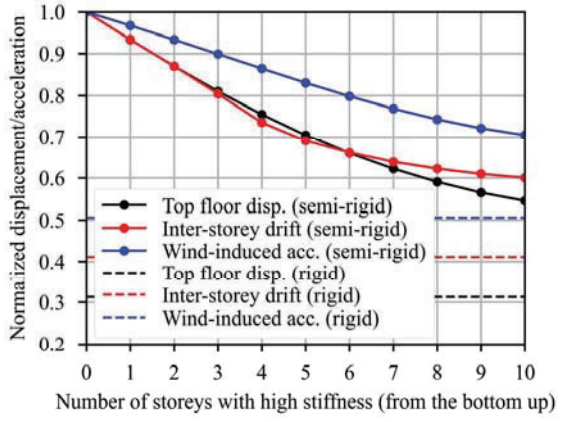

Figure 13: *Top floor displacement, maximum IDR, and wind-induced acceleration with variable K_θ (higher at lower storeys) normalized to the reference case (K_θ = 5,000 kN·m/rad).*

As shown in Figure 13, IDR shows the fastest convergence, followed by top floor displacement and wind-induced acceleration. Using high stiffness (K_θ =15,000 kN·m/rad) for the bottom 5-6 storeys results in 70-90% of the reduction in lateral displacements (top floor displacement and IDR) compared to the case with all connections of high stiffness (10 at the horizontal axis of Figure 13). Using high stiffness for the bottom 5-6 storeys results in 60-70% of the reduction in wind-induced acceleration compared to the case with all connections of high stiffness.

4.3.3 Ultimate limit state considerations

The results of the parametric study (520 analyses) are used to perform design checks for beams, columns, and CLT walls. For the calculation of forces used in the design, the fundamental ULS combination defined in EN 1990 [20] with wind as leading variable action was used:

$$E_d = \gamma_G \cdot G_k + \gamma_Q \cdot W_k + \gamma_Q \cdot \psi_0 \cdot Q_k \quad (5)$$

Where $\gamma_G = 1.20$, $\gamma_Q = 1.50$, $\psi_0 = 0.70$.
The structural design was performed in accordance with EN 1995-1-1 [17]. Since no CLT design checks are included in EN 1995-1-1 [17], the design checks of CLT walls were performed according to [23]. The buckling length was evaluated using linearized buckling analysis. The utilization ratios for beams, columns, and CLT walls are shown in Figure 14 for a total of 520 analyses. As shown in Figure 14, all utilization ratios of beams, columns, and walls are well below unity.

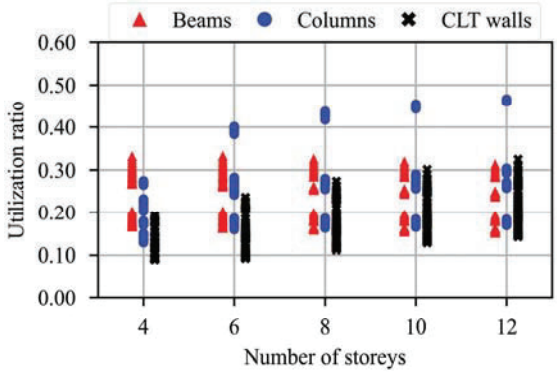

Figure 14: *Utilization ratio for beams, columns, and CLT walls*

Another important consideration is the beam-column/wall connection capacity. For each analysis case (out of the 520), bending moments are calculated at all connections in the frame, the maximum absolute value is then selected, the results are shown in Figure 15.
As shown in Figure 15, all moments are below 70 kN·m. An experimental work performed on moment resisting connections based on threaded rods [24] reported capacity up to 130 kN·m with glulam beams and columns of dimensions ($140 \cdot 450$ mm^2). Based on the calculated bending moments (see Figure 15), and the results in [24], the connections in the dual frame-wall system seem feasible. However, the reported testes in [24] were performed on glulam beam-column connections. Moreover, the limited number of experiments performed

on such connections does not allow the estimation of characteristic capacity. Therefore, further experimental work on moment resisting connections using threaded rods and CLT is needed.

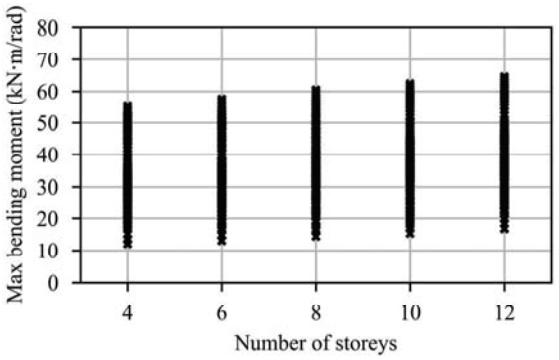

Figure 15: *Maximum absolute bending moment at all beam-to-column/wall connections*

4.4 3D STRUCTURE

To verify the results of the 2D FEA analysis performed in the parametric study, the dual frame-wall system is analysed in 3D. A 3D FEA model of an 8-storey building is analysed using CSI SAP2000 [12].

In X direction, the building is stabilized using the dual frame-wall system with interior CLT walls (confer Figure 1 and Figure 9). The beam-to-column/wall connection stiffness (K_θ) is set to $2 \cdot 12{,}500$ kN·m/rad (double cross-section), see Figure 9.

In Y direction, the building is stabilized using diagonal bracing (confer Figure 1 and Figure 16). The diagonals are modelled using link elements with axial stiffness only. The axial stiffness of each link element representing a diagonal is assumed to be 100 kN/mm (see Figure 16). This value takes into account the axial stiffness of both the diagonal member and the connections at each end of the member. The secondary beams (parallel to Y direction) are modelled using pinned beam elements. Similar to the FEA model of the floor, the CLT slab is modelled using layered shell elements.

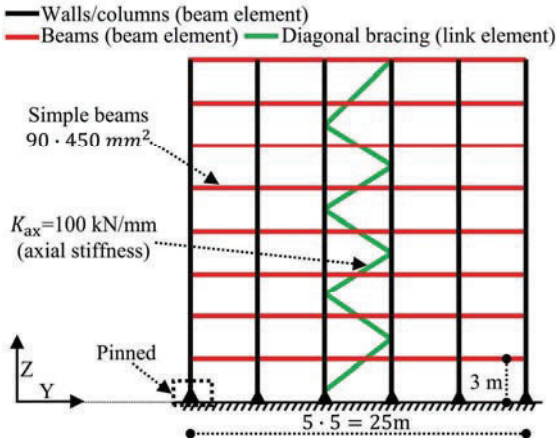

Figure 16: *2D FEA model of LLRS in Y direction*

Figure 17 shows the FEA model of the 3D structure (combining the structural systems in both X and Y). Light loads are applied to the CLT slab (Table 3). Wind loads, load combinations, parameters used for wind-induced accelerations, and cross-sections are the same as the parametric study (section 4.3, Tables 6-8).

Modal analysis of the 3D FEA model showed that the first 2 mode shapes are translational (no torsional modes). Wind-induced acceleration is calculated in X and Y directions. Figure 18 shows the accelerations against the ISO10137 [13] criterion based on 2D and 3D analyses. Wind-induced acceleration in X and Y directions meet the requirement for residential buildings.

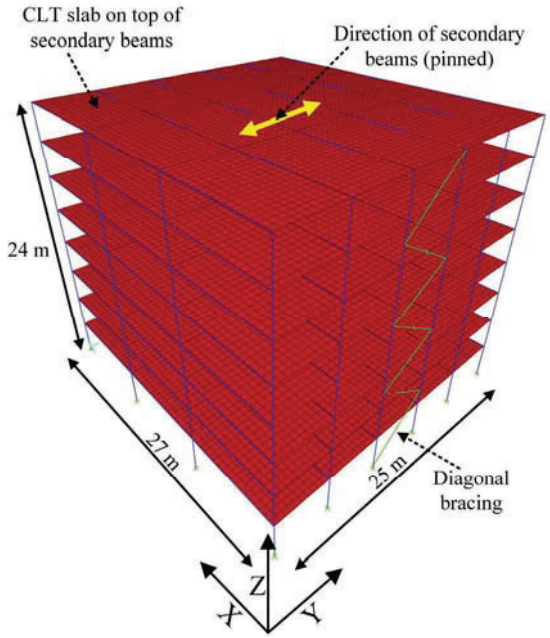

Figure 17: *3D FEA model*

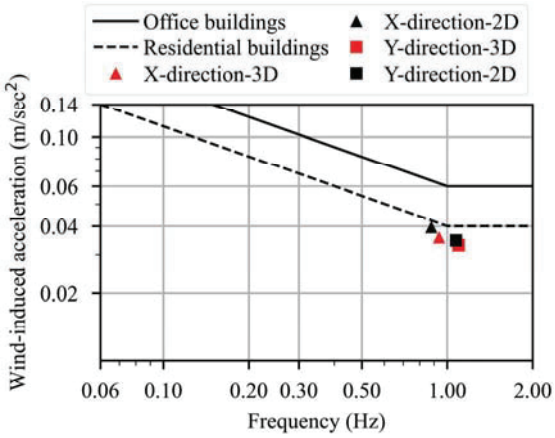

Figure 18: *Wind induced accelerations in X and Y directions of the 3D and the 2D FEA models against ISO 10137 [13] criterion*

The fundamental frequency, top floor displacement, inter-storey drift, and wind-induced accelerations of the 3D

https://doi.org/10.52202/069179-0384

model are summarized in Table 9 (both in X and Y direction). The results of the 2D counterpart model in X direction (results from section 4.3 in this paper) and Y direction are also summarized in Table 9 for comparison. The results of both 3D model and the 2D counterparts show that 2D analysis provides reasonable accuracy with the 3D model being slightly stiffer.

Table 9: *Frequency, lateral displacements, and wind-induced accelerations for the 3D FEA model and the 2D counterpart*

Direction	Property	2D	3D
X	Frequency (Hz)	0.88	0.94
	Top floor disp. (mm)	17.67	14.98
	IDR (mm)	2.61	2.18
	Acceleration (m/sec^2)	0.040	0.036
Y	Frequency (Hz)	1.07	1.10
	Top floor disp. (mm)	13.14	11.81
	IDR (mm)	2.39	2.29
	Acceleration (m/sec^2)	0.035	0.033

5 CONCLUSIONS

In this paper, a dual frame-wall structural system used as a lateral load resisting system in multi-storey timber buildings is studied. Parametric study using 2D linear elastic FEA was performed to evaluate the feasibility of the lateral load resisting system. The vibration performance of floors with respect to human-induced vibration is also discussed using linear elastic FEA. Although the main focus of the paper is on serviceability limit state, some ultimate limit state considerations are presented. To validate the results obtained from the 2D FEA model, a 3D FEA model was also prepared, and the results of both models were compared. The following conclusions are drawn (assuming wind speed of 26 m/sec and urban environment):

- Wind-induced acceleration is more critical than lateral displacements.
- Ultimate limit state is less critical than serviceability limit state. The utilization ratios of all structural elements are well below unity.
- Construction of multi-storey buildings up to 10 storeys with an out-of-plane spacing of 5 m and light flooring system is feasible if the stiffness of the beam-to-column connections is $\geq 2 \cdot 11{,}500$ kN·m/rad ($11{,}500$ for single cross-section).
- Construction of multi-storey buildings up to 12 storeys with an out-of-plane spacing of 5 m and heavy flooring system is feasible if the stiffness of the beam-to-column connections is $\geq 2 \cdot 5{,}500$ kN·m/rad ($5{,}500$ for single cross-section).
- The use of stiff connections can be optimized in such a way that stiffer connections are used in the lower storeys.
- Stiff beam-to-column connections improve the performance of the lateral load resisting system. Moreover, they also improve the performance of the floors with respect to human-induced vibration.
- The use of simplified 2D FEA modelling approach seems to give reasonable accuracy compared to 3D FEA modelling.

INVESTIGATION OF LONG-TERM MODAL PROPERTIES OF A TALL GLUE-LAMINATED TIMBER FRAME BUILDING UNDER ENVIRONMENTAL VARIATIONS

Saule Tulebekova[1], Kjell Arne Malo[2], Anders Rønnquist[3], Petter Nåvik[4]

ABSTRACT: Evaluation of long-term modal properties, such as natural frequencies and damping ratios, is important for tall timber buildings, which can be prone to environmental variations. However, in long-term operational modal analysis, the estimation of modal properties, especially damping ratios can be subject to significant uncertainty due to requirement of stationarity of the input data. Therefore, a combined variational mode analysis and data-driven stochastic subspace identification method was used for modal identification to reduce the potential errors related to the input data. The method was employed to investigate the long-term modal properties of an 18-story glulam frame building using ambient vibration data of 18 months. The observed natural frequencies exhibit seasonal behaviour with an average variation of ±0.02 Hz. Damping ratios do not show a seasonal relationship as opposed to the natural frequencies. The identified natural frequencies tend to have an inverse relationship with the mean temperature, while a positive correlation between the natural frequencies and the relative humidity is observed.

KEYWORDS: dynamic identification, ambient vibrations, tall timber building, VMD, SSI, modal properties.

1 INTRODUCTION

Tall timber buildings are relatively new in the construction industry, and as a result, there is still much research being conducted to understand their dynamic response under different loads, including service loads [1]. In general, tall timber buildings tend to have a lower natural frequency compared to traditional steel and concrete buildings due to inherently low stiffness and mass properties. This means that they are more susceptible to vibrations caused by external forces such as wind or human activities, and this can affect their performance and occupant comfort [2]. Excessive vibrations during strong winds might lead to discomfort for building occupants, particularly on the higher floors, if the design is incorrect.

Modal identification is a process used to determine the natural frequencies, damping ratios, and mode shapes of a structure. It is an important step in evaluating the dynamic response of a structure, as it provides information about the behaviour of the structure under different loading conditions.

Different techniques and methods can be used for modal identification of structures. For example, the operational modal analysis (OMA) method, which relies on ambient vibrations induced by natural events, can be used to identify the dynamic properties of the structure under real-life operating conditions. Other techniques such as impact testing or shaking table tests can also be used to identify the dynamic properties, but they require significant planning and labour and can be quite costly. In comparison to other techniques, OMA is a cost-effective and relatively easy method, which is suitable for long-term measurements.

Data-driven stochastic subspace identification (SSI-DATA) is an OMA technique used to extract dynamic models from ambient vibration data. SSI techniques involve constructing a mathematical model of the structure using the measured response data. This model can then be used to estimate the properties of the structural system. One of the limitations of ambient vibration techniques for modal identification, such as SSI, is the assumption of stationarity. This assumption requires that the ambient vibration signals remain constant over time, which is not always the case in practice. Non-stationarity can occur due to changes in the ambient conditions, such as wind or temperature, or due to changes in the dynamic behaviour of the structure itself. To overcome this issue, the variational mode decomposition (VMD) can be used, which decomposes the initial signal into a set of oscillatory components containing the modes of the structure.

The modal identification of timber buildings presents some additional challenges that are unique to this type of construction. For example, timber structures are more susceptible to environmental factors such as temperature

and humidity, which can cause changes in their material properties over time. In addition, timber buildings tend to have a more complex and variable behaviour compared to traditional steel and concrete structures, which can make their modal identification more challenging.

Several studies investigating the effects of environmental variations on the dynamic properties of timber buildings are available [3,4]. However, no previous studies on the relation between the environmental factors and the dynamic response of tall glulam frame building were conducted.

Considering these challenges, this paper investigates the modal properties of a tall glue-laminated timber (glulam) frame building under long-term ambient and operational variations using combined VMD/SSI technique. The effect of the variational environmental conditions on the identified dynamic properties is investigated using the meteorological data from the nearby weather station.

2 FIELD MEASUREMENTS SETUP

2.1 BUILDING DESCRIPTION

Mjøstårnet is an 18-storey tall glulam (glue-laminated timber) frame building located in Brumunddal, Norway (Fig.1). As of March 2023, Mjøstårnet is considered the tallest residential timber building in the world [5]. The load-bearing system of the building consists entirely of structural timber elements. The building height is 88.8 meters and the structural system consists of glulam trusses connected with slotted-in steel plates [6]. Cross-laminated timber (CLT) is used in the elevator and staircase shafts and the floors are made of prefabricated timber decks (floors 1-10) and concrete decks (floors 11-18). The concrete decks are added purely as additional mass due to occupational serviceability requirements. The pergola truss is mounted at the top of the building for architectural appearance.

(a) Building location (b) The Mjøstårnet building view

Fig.1. The Mjøstårnet building

2.2 EXPERIMENTAL SETUP

A long-term ambient vibration monitoring system was installed inside the building (Figs.2-4). The hardware in the system consists of three Kistler K-Beam® accelerometers, model 8395A2D0 [7], one CompactRIO controller by National Instruments, and connecting wires and cables. The accelerometers have sensitivity of 2000 mV/g and the sampling rate for data was 400 Hz. The building has been in full operational condition, therefore, the placement options for the long-term monitoring setup were quite limited. After the discussion with the building manager, the setup was installed in the emergency staircase shaft. This staircase could only be accessed in emergency cases only, therefore, it was not obstructing the normal operations of the building. Prior to the current accelerometer setup, the accelerometers were installed at the roof of the building. Therefore, to ensure that the captured modes from the current setup were representative of the global structural behaviour, the identified modes were compared against their counterparts from the setup on the roof. More details regarding the comparison of the two setups can be found in [8].

3 METHODOLOGY

The combined VMD and SSI-DATA methodology is outlined in the Fig.5. First, the initial ambient vibration data is decomposed into a set of modal components using the VMD technique. These identified modal components are then evaluated using the spectral analysis and the modes containing the structural behaviour are selected for further analysis. Then, the SSI-DATA technique is applied separately on each structural mode and the corresponding natural frequencies and damping ratios are identified. The following sections present the methodology in more detail.

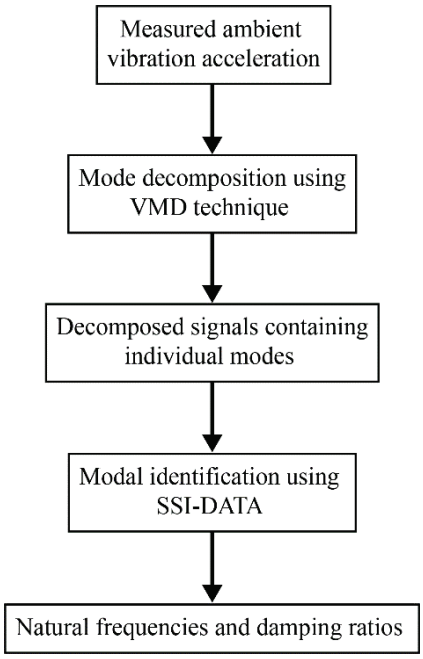

Fig.5. Combined VMD/SSI-DATA methodology.

3.1 VARIATIONAL MODE DECOMPOSITION (VMD)

VMD is a signal decomposition method that aims to decompose a complex signal into a set of intrinsic mode functions (IMFs) or oscillatory components [9]. Each IMF represents a distinct oscillation mode in the signal, which is characterized by a particular frequency and amplitude modulation. The VMD algorithm is based on an optimization problem that seeks to minimize the total power of the signal subject to a set of constraints. The constraints ensure that the extracted IMFs are spatially and temporally localized and are well-separated in the frequency domain. A more detailed description of the technique can be found in [9]. The VMD algorithm can be briefly described as follows:

- Obtain frequency spectrum of each mode by applying the Hilbert transform.
- Shift the frequency spectrum of the mode to the estimated centre frequency using the exponential tune.
- Solve the following minimisation problem to estimate the bandwidth of each mode using the Gaussian smoothness of the demodulated signal:

$$\min_{\{u_k\},\{\omega_k\}} = \left\{ \sum_k \left\| \partial_t \left[\left(\delta(t) + \frac{j}{\pi t} \right) * u_k(t) \right] e^{-j\omega_k t} \right\|_2^2 \right\}$$

$$s.t. \quad x(t) = \sum_{k=1}^{K} u_k(t)$$

where $u_k(t)$ are the decomposed modes, ω_k are the corresponding central frequencies, $\|.\|_2$ is the L2 norm, ∂_t is the derivative with respect to time, $\delta(t)$ is the Dirac delta function, $x(t)$ is the original signal.

After application of the VMD the initial signal is decomposed into a set of modes compacted around the central frequency. The signals containing structural modes are then selected for further analysis.

3.2 STOCHASTIC SUBSPACE IDENTIFICATION (SSI)

Once the signals containing structural modes were identified, thee data-driven stochastic subspace identification (SSI-DATA) technique is applied on each signal separately. The procedure for the SSI-DATA method is explained in detail in [10-12], and a brief description of the method is presented here. In SSI-DATA, the dynamic system is assumed to be described by the discrete state-space model:

$$\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k + \mathbf{w}_k \qquad (1)$$

$$\mathbf{y}_k = \mathbf{C}\mathbf{x}_k + \mathbf{v}_k \qquad (2)$$

where x is a state space vector, which holds the current state of the system at time instant t, y is a measured output at a specified sampling rate, w and v are system noise and measurement noise, respectively, A is a state matrix, and C is an output matrix.

The state-space model of order i is used to identify the eigenvalue μ_i, from which the corresponding pole λ_i can

be obtained at a sampling period t_s. Then, the frequency and damping values, ω_i and ξ_i, can be calculated for each pole. The expressions for the calculation process of the values mentioned above are as follows:

$$\lambda_i = \ln(\mu_i)/t_s \quad (3)$$

$$\omega_i = Im(|\lambda_i|) \quad (4)$$

$$\xi_i = -Re(\lambda_i)/|\lambda_i| \quad (5)$$

Stabilization diagram is then plotted with the stability criteria for natural frequency and damping ratio of 1% and 5% respectively, and the vertically aligned poles on the stabilization diagram indicate a stable frequency.

4 RESULTS

4.1 MODAL DECOMPOSITION

The acceleration time series were processed separately in the x- and y-direction (see Fig.3 for coordinate reference). Acceleration time series were resampled to 8 Hz sampling rate and the band-pass filter between 0.2 Hz - 1.0 Hz was applied to remove the noise and response outside the range of interest. In total three fundamental frequencies were identified: mode 1 at 0.5 Hz (first bending in the x-direction), mode 2 at 0.54 Hz (first bending in the y-direction), and mode 3 at 0.84 Hz (torsion). Fig.6(top) shows the original acceleration time series containing noisy data in the x-direction with the corresponding Fourier spectrum, where the peaks at 0.5 Hz (mode 1, bending) and 0.84 Hz (mode 3, torsion) can be seen.

Below the original data series are the two decomposed signals, which are called the intrinsic mode functions (IMFs) using VMD method, which show only one peak at their respective frequencies, indicating that the signals containing fundamental modes have been successfully separated. Similarly, Fig.7 shows the original acceleration time series containing noisy data in the y-direction (top) and its decomposed IMFs containing the fundamental modes along with the Fourier spectra indicating the fundamental frequencies in y-direction: mode 2 (bending) and mode 3 (torsion). These intrinsic mode functions containing the modes of interest were further processed using the SSI-DATA technique to identify the natural frequencies, damping ratios and mode shapes. Each mode-containing signal was processed separately. The methodology was applied continuously over the entire monitoring period (Jan.2021-Jun.2022) on 1-hr data segments to investigate the variation of the identified modal properties with time.

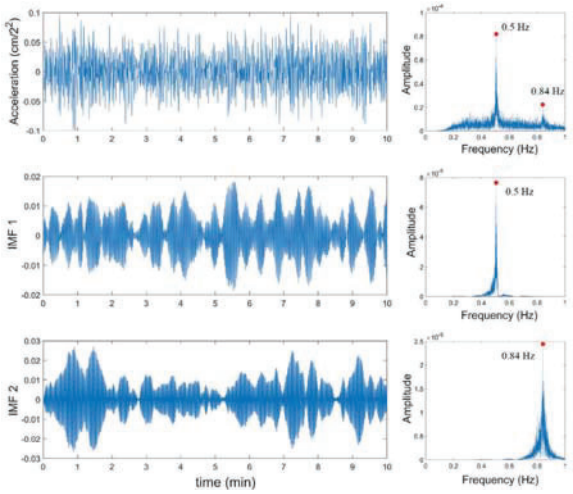

Fig.6. Input signal in x-direction (top) and its decomposed intrinsic mode functions (IMFs) with the corresponding Fourier spectra.

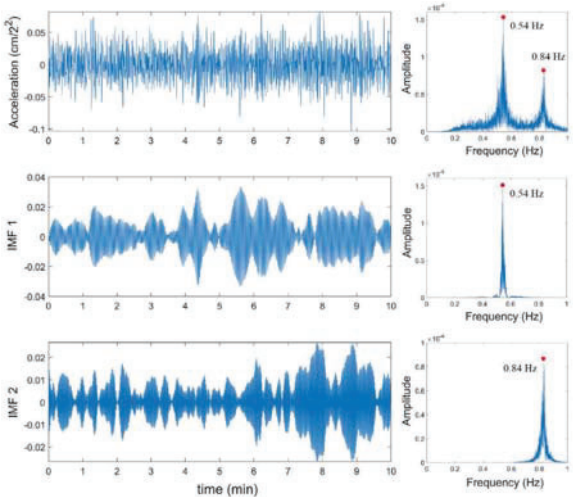

Fig.7. Input signal in y-direction (top) and its decomposed intrinsic mode functions (IMFs) with the corresponding Fourier spectra.

4.2 LONG-TERM MODAL PROPERTIES

The long-term monitoring records of the total of 18 months (Jan.2021-Jun.2022) were processed using the combined VMD/SSI-DATA methodology. Fig.8 shows the variation of the identified natural frequencies with time and the corresponding statistical distributions using 1-hour increments of the acceleration response for the first three modes of vibration. The torsional mode is plotted in both x- and y-direction. From observation, a seasonal pattern of natural frequencies can be observed. The highest values for natural frequencies are observed in the late winter (January-March), while the lowest values are observed in the late summer (July-September). The total natural frequency variation is ±0.015 Hz for mode 1, ±0.02 Hz for mode 2, ±0.03 Hz for mode 3. A larger scatter of identified values can be observed for mode 3 in

https://doi.org/10.52202/069179-0385

the x-direction compared to the y-direction which might be due to the accelerometer placement: location of accelerometers close to the centreline might not allow for a proper identification of the torsional mode in the x-direction.

Fig.9 shows the variation of the identified damping ratios with time and the corresponding statistical distribution using 1-hour increments of the acceleration response for the first 3 modes. Similarly, a larger scatter is observed for mode 3 in the x-direction compared to the y-direction. Unlike natural frequencies, no seasonal variation of damping ratios can be observed. The mean values for the identified damping ratios seem to be quite stable at values around 1% except for mode 3 in the x-direction, where a larger variation is observed.

From Figs.8 and 9, it can be seen that the natural frequencies and damping ratios can be identified quite stably indicating the effectiveness of the combined VMD/SSI-DATA technique for extraction of long-term modal properties from ambient vibration data.

4.3 EFFECT OF ENVIRONMENTAL CONDITIONS

The meteorological data from the closest weather station was used to investigate the effect of the environmental conditions on the identified dynamic properties. The location of the weather station is approximately 10 km away from the building and the weather statistics for the monitoring period was obtained from the Norwegian Climate Service Centre [13]. The following environmental properties were selected for further analysis: mean air temperature (°C) and mean relative humidity (%).

The building in this study is located in a region with humid continental climate with cold and dry winters and comfortably warm summers. The warmest month of the year is July with mean daily temperature of 17°C and the coldest month of the year is December with daily mean temperature of -4.5°C.

Fig.10 shows the mean daily natural frequencies for the first 3 modes plotted together with the mean daily air temperature. The smoothed variations using 1-month averaging window are plotted to represent the trend of the parameters with time. From observation, for all natural frequencies the variation occurs in a similar seasonal manner. The highest frequencies are observed in the late winter and the lowest frequencies are observed in the late summer, with an exception of the first frequency, where the additional peak can be observed in the early summer period. For modes 2 and 3 (x- and y-direction) an inverse relationship is observed between the natural frequencies and the air temperature. The inverse relationship might be caused by the delay between the variational changes and the structural response. For mode 1, the inverse seasonal relationship can be observed in the winter, however, in summer the frequencies seem to have an increasing trend with increase of temperature.

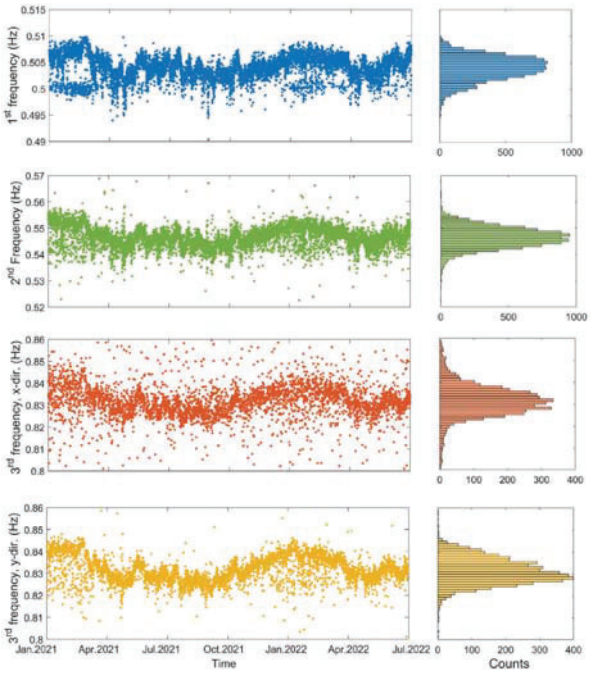

Fig.8. Variation of identified frequencies from 1-hour data segments over time (left) and the corresponding statistical distributions (right) for the first 3 modes of vibration.

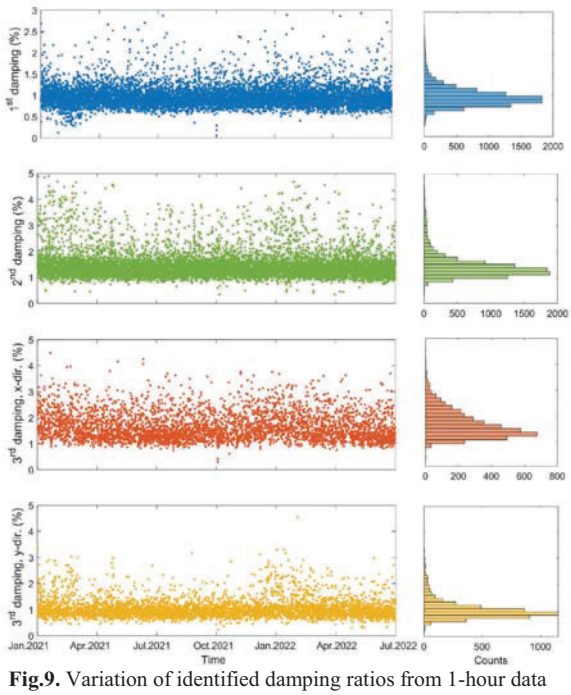

Fig.9. Variation of identified damping ratios from 1-hour data segments over time (left) and the corresponding statistical distributions (right) for the first 3 modes of vibration.

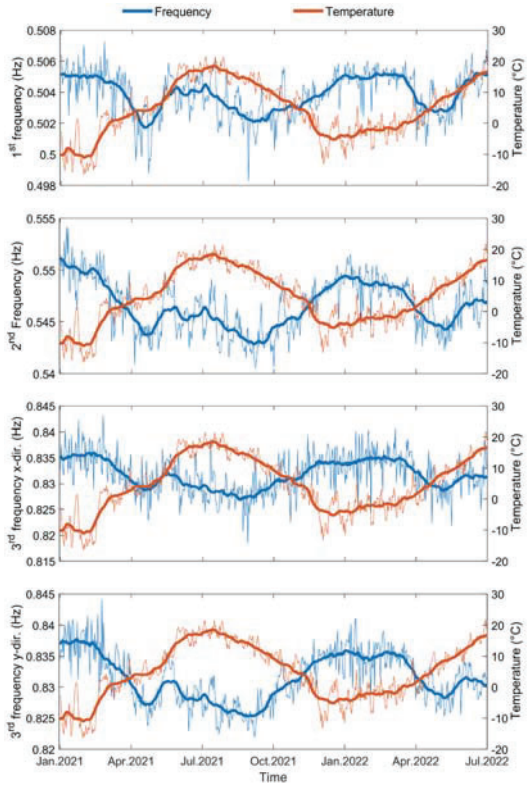

Fig.10. Variation of identified frequencies (1-day mean) and temperature.

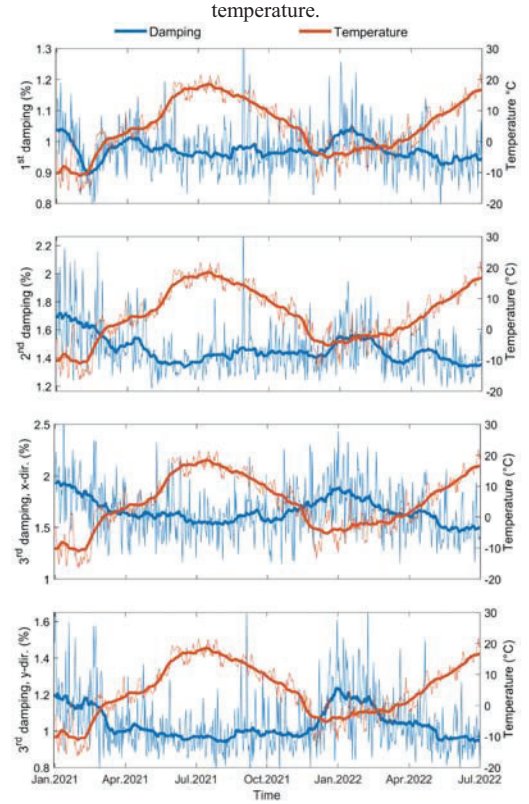

Fig.11. Variation of identified damping ratios (1-day mean) and temperature.

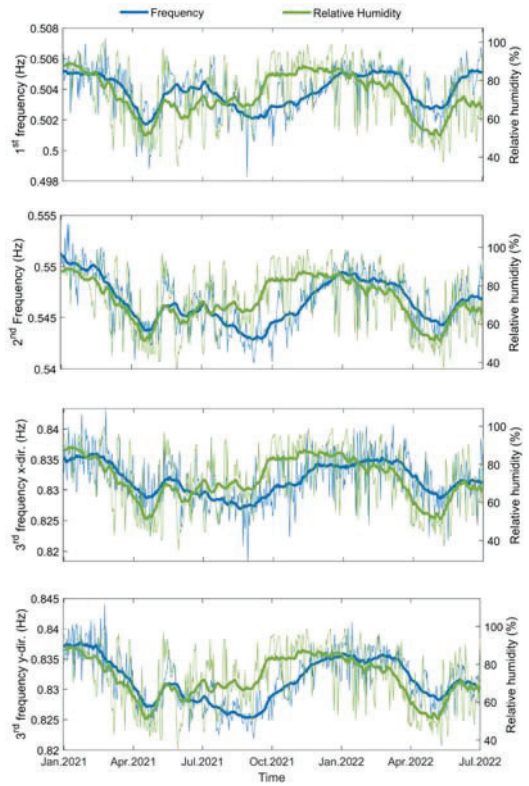

Fig.12. Variation of identified frequencies (1-day mean) and relative humidity.

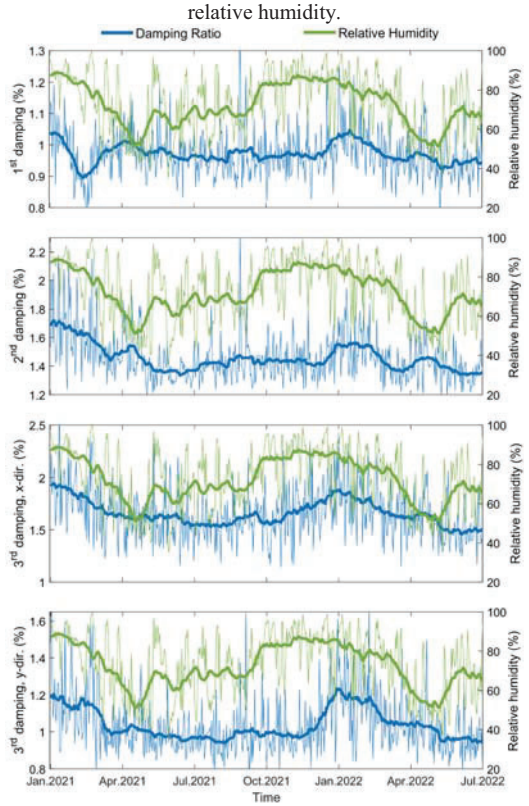

Fig.12. Variation of identified frequencies (1-day mean) and relative humidity.

https://doi.org/10.52202/069179-0385

The variation of mean daily damping ratios is plotted together with the mean daily air temperature as shown in Fig.11. The 1-month smoothed plots are plotted on top of the variations to indicate the trend of parameters with time. No clear relationship is observed between the damping ratios and the seasonal temperature for all three modes of vibration. However, it can be observed that damping ratios are higher in the January-February period compared to the other months for all modes.

Fig.12 shows the variation of the mean daily natural frequencies plotted together with the mean daily relative humidity. The thick smoothed plots (1- month averaging) indicate the trend of the parameters with time. All of the natural frequencies exhibit a positive trend with the relative humidity: with increase of mean relative humidity the natural frequencies increase as well. However, a small delay is observed, indicating that it takes time for the structural properties to respond to the change in relative humidity.

Mean daily damping ratios are co-plotted together with the mean daily relative humidity in Fig.12. From observation no evident effect of the relative humidity on the damping ratios is observed.

For a closer investigation of the effect of environmental conditions on the natural frequencies, 1-month variations of the parameters were co-plotted as shown in Fig.13 for July 2021. Each dot on the figure represents a 1-hour mean value of the parameter. From observation, the relationship between the natural frequency and temperature is not fully clear. A positive relationship between the natural frequency and the relative humidity is observed: increase in the relative humidity results in the gradual increase of the natural frequency with a delay. A similar positive trend between the 1st natural frequency and the relative humidity in Fig.13 was observed for the other two frequencies as well.

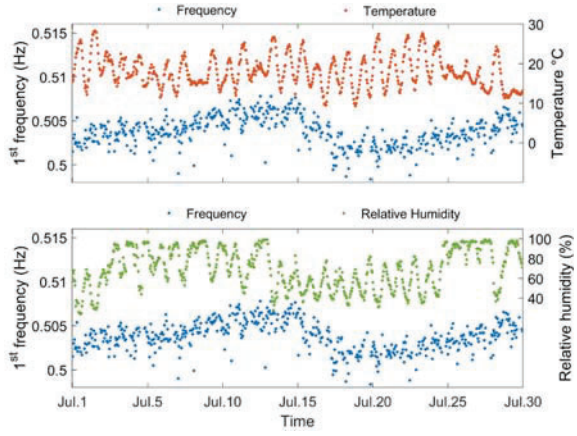

Fig.13. 1-month period (July 2021) variation of identified frequencies co-plotted with mean temperature and mean relative humidity (each dot represents 1-hr segment).

5 CONCLUSIONS

This paper investigated identification of the long-term modal properties under variable environmental conditions of an 18-story glulam frame building in Norway. The combined VMD/SSI-DATA scheme was applied to the measured ambient vibration response. First, the original signal was decomposed with VMD technique into intrinsic mode functions containing the modes; then, the SSI-DATA technique was applied separately on each mode-containing signal to obtain natural frequencies and damping ratios. The identified modal properties were quite stable indicating that the combined methodology can be effectively used for dynamic properties extraction from the ambient vibration data of the tall glulam frame building. The identified natural frequencies for most modes exhibit a similar seasonal behaviour, where highest values for natural frequency are observed in the late winter and the lowest values are observed in the late summer. The identified damping ratios for all modes did not exhibit seasonal variations and have quite stable mean values. From co-plotting the identified frequencies and mean air temperatures, the inverse relationship can be observed for most modes. From co-plotting the natural frequencies and mean relative humidity, a clear positive trend is observed, where the increase in the relative humidity is followed by the increase of the natural frequency for all modes. A delay in response might be caused by the time required for the structural properties of timber to be affected by the environmental conditions. Thus, both temperature and relative humidity impact the natural frequencies: high delay (around 6 months) is observed for temperature variations and a low delay (1-2 months) is observed for the relative humidity.

It is important to note, that in this study analysis of the effect of environmental conditions on the natural frequencies and damping ratios has certain limitations. A longer period of observation is needed to establish a clearer relationship between the seasonal variations and the natural frequencies. Additionally, an on-site weather station measuring both the indoor and outdoor environmental conditions should be installed for a more accurate investigation of the effect of environmental conditions on the dynamic properties of the building.

ACKNOWLEDGEMENT

The research in this paper has been conducted as part of the Dynamic Response of Tall Timber Buildings under Service Load project (DynaTTB). Norwegian Research Council was responsible for providing funding in Norway, grant no.297513.

INVESTIGATIONS ON SUITABLE LATERAL STIFFENING SYSTEMS FOR TALL TIMBER BUILDINGS

Charles Binck[1], Andrea Frangi[2]

ABSTRACT: As the height of timber buildings continues to increase, the importance of their lateral stiffness concept is growing. At present, the predominant structural system of timber buildings is a timber-concrete hybrid where the lateral stiffness of the building is provided by a reinforced concrete core. However, it is unknown which lateral stiffness concepts for tall timber building are feasible without the use of reinforced concrete. In this paper, five different lateral stiffening systems for tall timber buildings were investigated, with a focus on building heights between 50 and 230 meters. For this purpose, over 12 million building configurations were analysed with different lateral stiffening systems, and a design optimization was performed based on the dynamic response of the buildings subjected to wind loading. The study revealed that the development of semi-rigid connections for moment-resisting timber frames should target a stiffness ratio between 1% and 10% towards a fully rigid joint, to guaranty efficient connection solutions. For such connection stiffnesses, building heights of up to 190m may fulfil the serviceability criteria for cross-sections smaller than 40 x 120 cm.

KEYWORDS: Tall timber buildings, Lateral stiffening systems, Semi-rigid connections, Moment-resisting timber frames, Tube-in-tube systems, Serviceability criteria, Equivalent building stiffness, Height investigations.

1 INTRODUCTION

In the 20th century, buildings in steel and reinforced concrete saw rapid technological and engineering advancements. This enabled the construction of ground-breaking new tall buildings [1]. At present, a similar advancement for tall timber buildings is underway with ever-increasing building heights [2–4]. Two of the world's tallest timber buildings were built in Europe, namely the "HoHo" in Vienna at 84.0m and the "Mjøstårnet" in Brumunddal at 85.4m [5,6]. Since 2022, the tallest timber building is the "Ascent" in Milwaukee at 86.6m [4,7]. However, "Ascent" is constructed on a multi-storey reinforced concrete base [7,8].

As the buildings become taller, wind-induced serviceability vibrations and deflections become the governing design criteria. Here, the importance of the lateral stiffening system grows with increasing building heights. Currently, the predominant structural system is a timber-concrete hybrid where the lateral stiffness of the building is provided by a relatively stiff reinforced concrete core [4,8–10]. However, the use of reinforced concrete is a strong contributor to greenhouse gas emissions [11,12]. Consequently, there is a growing incentive to explore alternative solutions. Besides the promotion of renewable materials, other strong advantages of timber solutions are the lightness of the structures, the potential for a dry construction site and a shorter construction time.

While taller and taller timber buildings are being constructed, the development of feasible alternative lateral stiffness concepts comprising timber components has been stagnant. However, timber has the strength and stiffness to provide feasible solutions. Because of the unparalleled strength-to-weight ratio and similar stiffness-to-weight ratio of timber compared to other conventional building materials, competitive solutions can be provided for both the vertical and lateral load transfer. In Norway, both "Treet" in Bergen and "Mjøstårnet" in Brumunddal, demonstrate options for the lateral stiffening with bracing in the façade [6,13]. However, it is uncertain if other lateral stiffness concepts are feasible for tall timber buildings and which building heights could be achieved with these solutions.

For this purpose, the objective of this paper is to provide a comprehensive analysis of five different lateral stiffening systems, to explore their limits, and to present feasible solutions for building heights up to 190 meters. The systems are examined through more than 12 million simulations of unique building configurations subjected to service-level wind loading. The building configurations comprise different global and local geometries, material properties, mass, structural damping properties, joint stiffnesses, and serviceability criteria. In an analogy to the pioneering work of Fazlur Kahn on the premium for heights for steel and reinforced concrete buildings [14], this paper provides a guideline for current height limits of the lateral stiffening systems for tall timber buildings. The presented investigations of the different systems should be seen as a classification with feasible heights within the range of the chosen parameters and are not intended as boundaries outside this array.

2 THEORETICAL FRAMEWORK

2.1 STRUCTURAL TYPOLOGIES

Investigations were conducted on a braced inner core (Type I), an external frame tube in the façade (Type II), bracing systems in the façade (Type III and IV) and a tube-in-tube system with an external frame and an internal braced tube (Type V).

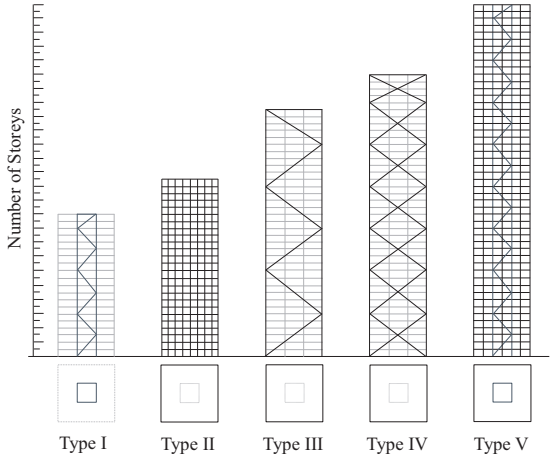

Figure 1: *Overview of the investigated structural typologies based on the work of Fazlur Kahn* [14]

A description of the tube-in-tube concept is given in Binck et al. [15] where the system is illustrated in depth. By introducing moment-resisting connections, the timber parts, which are usually constructed as vertical load-bearing beam-column systems, may contribute substantially to the lateral stiffness. This would enable the beam-column structures to contribute with both vertical and lateral load-transfer.

2.2 PERFORMANCE CRITERIA

To assess the feasibility of the buildings, the serviceability criterion in ISO 10137 [16] based on occupant comfort is used. It is derived from measurements of buildings in vibration use. The serviceability criterion is for peak accelerations of offices or residential uses and is a function of the building's first natural frequency. In this paper, the stricter requirements for residential uses are used.

EN 1994-1-4 [17] provides in Annex B a framework to determine those accelerations and equivalent wind loads based on the gust factor approach for building heights up to 300 m height. In this paper, the basic wind velocity $v_{b,0}$ is 25 m/s. Accelerations are computed with subsequent computations based on a 1-year return period with a probability factor $c_{prob} = 0.73$.

In contrast to the accelerations, the peak deflections are calculated for a corresponding return period of 100 years by the static equivalent loads taking only the first mode into consideration. The higher return period is chosen here for a design criterion where damage on non-structural elements shall be avoided. In literature, there is no consensus or consistency for the criterion to avoid damage to non-structural elements [18,19]. However, current recommendations are in a range between $1/300$ to $1/1000$ of the building height for peak deflections and the inter-storey drifts [18,19]. Here, the performance criteria for peak deflections are set to a maximal global deflection of:

$$u_{peak} \leq \frac{H}{500} \tag{1}$$

for the building and a maximal inter-storey drift of:

$$\delta u_{peak} \leq \frac{h_s}{500}, \tag{2}$$

where H and h_s are the building height and the storey height respectively. The parameters used for the wind actions are summarised in Table 1.

Table 1: *Overview of the parameters for the wind actions according to EN 1991-1-4 (2010).*

Description		a_{peak}	u_{peak} & δu_{peak}

2.3 METHOD

2.3.1 Finite Element Modelling

The structural analysis and simulations were conducted by adopting and expanding the finite element framework for assessing wind-induced vibrations for planar frames, first developed by Cao & Stamatopoulos [20–22]. In the framework, the trusses and beams use Euler-Bernoulli beam theory, and the columns use Timoshenko beam theory with a shear correction factor of 5/6. The beam-column connections are idealized as linear-elastic rotational springs with a stiffness K_θ, the axial flexibility in the joints of the trusses is neglected, and the column-column joints are assumed to be rigid. More details can be found in Binck et al. [15] and Cao & Stamatopoulos [20–22].

https://doi.org/10.52202/069179-0386

2.3.2 Connection Stiffness

For a rigid beam-column joint, the equivalent rotational joint stiffness $K_{\theta,eq}$ can be derived by static condensation and expressed as:

$$K_{\theta,eq} = \frac{145EI_c}{6h} + \frac{239EI_b}{6l} + \frac{110EI_b^2 \cdot h}{6EI_c \cdot l^2} + 4\frac{EI_c^2 \cdot l}{EI_b \cdot h^2}, \quad (3)$$

where h is the column height, l is the bay length and EI_c is the column stiffness and EI_b is the beam stiffness, clarified in Figure 2. Hence, for a semi-rigid connection, the beam-column connection stiffness K_θ is defined as a fraction α_θ of the equivalent beam-column joint stiffness $K_{\theta,eq}$:

$$K_\theta = \alpha_\theta \cdot K_{\theta,eq}, \quad (4)$$

Where α_θ is the stiffness ratio and varies in the parameter study between 0.1 % and 100%. The connection stiffness K_θ can be illustrated as a reduced cross-section of the beam-column joint, as clarified in Binck et al. [15].

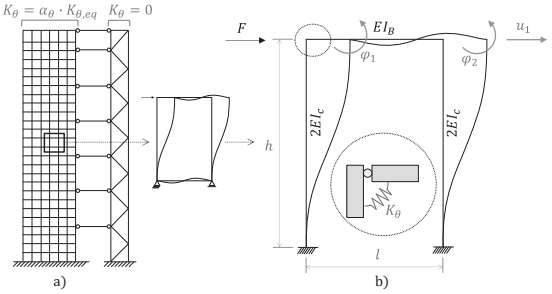

Figure 2: *Structural system (a) and the statically equivalent model for determining the rotational stiffness (b).*

2.3.3 Equivalent Cantilever Stiffness

From a static perspective, a tall building can be illustrated as a vertical, encastered beam. By using this beam, the stiffness of the multi-degree-of-freedom system can be expressed in terms of a simple Timoshenko cantilever beam. This enables an easier expression and comparison of the different structural typologies in relation to the stiffness if an equivalent bending stiffness EI_{eq} and shear stiffness GA_{eq} can be determined. To find EI_{eq}, and GA_{eq}, the deformations can be decomposed as a superposition of the pure bending displacement u_{EI}, and pure shear displacement u_{GA}. Subsequently, the fraction of bending γ_{EI} and shear γ_{GA} contributions can be computed by linear regression.

With this approach, the analytical expression of the predicted displacement $u_{j,pred}$ can be written as:

$$u_{j,pred} = \gamma_{EI} \cdot u_j + \gamma_{GA} \cdot u_j. \quad (5)$$

By solving for γ_{EI} and γ_{GA}, the fraction of bending displacement and shear displacement on the equivalent Timoshenko beam are determined and through the inverse procedure, the equivalent bending stiffness EI_{eq} and shear stiffness GA_{eq} can be derived.

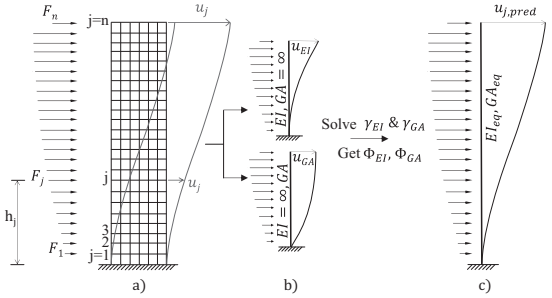

Figure 3: *Model sketch of the mathematical procedure to determine the equivalent beam stiffnesses.*

An appropriate method to determine these stiffnesses for the equivalent cantilever beam, loaded by non-uniformly distributed loads, is the use of the curvature. The building displacements at storey height h_j can be calculated as:

$$u_j = u_{j-1} + \delta u_j, \quad (6)$$

where $u_{j-1}$is the displacement from the storey below and δu_j is the current storey drift, shown in Figure 4. This storey drift δu_j is computed by curvature on the equivalent Timoshenko beam.

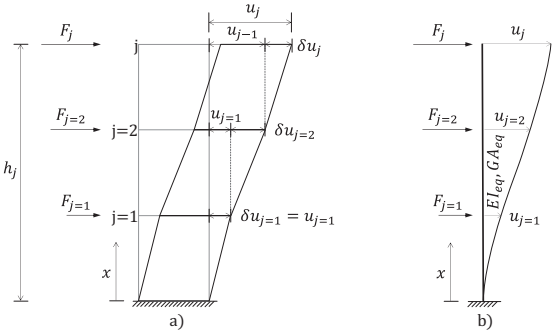

Figure 4: *Calculation method of the deflections for the equivalent cantilever beam.*

For a homogeneous beam with a constant cross-section, the differential equation of a Timoshenko beam is given by:

$$EI_{eq}\frac{\delta^2\phi_y}{\delta x^2} - k_s GA_{eq}\left(\frac{\delta u_z}{\delta x} + \phi_y\right) = 0, \quad (7)$$

where k_s is the Timoshenko shear coefficient, φ_y is the curvature from pure bending, $\gamma_{xz} = -\varphi_y + \phi_y$ is the curvature from pure shear, and ϕ_y is the resulting angle of rotation from both, illustrated in Figure 5.

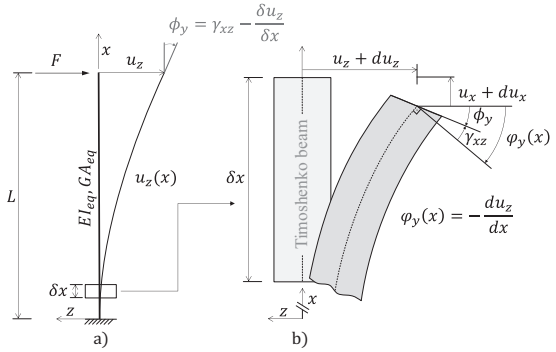

Figure 5: *Applied Timoshenko beam theory.*

Internal forces in a beam are related to the strain, i.e., to the displacement u and the rotation φ_y. For a linear elastic Timoshenko beam, the relations to the bending moment $M_y(x)$ and the shear force Q_z are:

$$M_y(x) = -EI_{eq}\,\frac{\delta\phi_y}{\delta x}, \tag{8}$$

$$Q_z = k_s GA_{eq}\left(\frac{\delta u_z}{\delta x} + \phi_y\right). \tag{9}$$

For the cantilever beam, shown in Figure 5 a), where x gives the positive direction from the clamped end to the free end, the bending moment $M_y(x)$ can be computed from the free-body diagram, as:

$$M_y(x) = F \cdot L - F \cdot x, \tag{10}$$

where F is a point load at position L. Substituting Equation (9) into (7) gives:

$$EI_{eq}\frac{\delta\phi_y}{\delta x} = -F \cdot L + F \cdot x. \tag{11}$$

By integration, the bending curvature is written by:

$$\phi_y(x) = -\frac{1}{EI_{eq}}\left(F \cdot L \cdot x - \frac{1}{2}F \cdot x^2\right) + c_1, \tag{12}$$

where c_1 is a constant. Thus, substituting equation (12) into Equation (9), the total curvature of the Timoshenko beam can be expressed as:

$$\frac{\delta u_z}{\delta x} = \frac{Q_z}{k_s GA_{eq}} + \frac{1}{EI_y}\left(F \cdot L \cdot x - \frac{1}{2}F \cdot x^2\right) + c_1, \tag{13}$$

where the first part of the equation defines the curvature form pure shear and the second part defines the curvature from pure bending.

Equivalent bending stiffness

With Equation (12), the equivalent bending stiffness of a multi-storey building under nonuniform distributed loads can be written as:

$$EI_{eq} = \frac{1}{\frac{\delta u_{j,EI}}{\delta x}} \cdot \left[F_j \cdot \left(h_j \cdot x - \frac{1}{2}x^2\right) + c_{j,EI}\right], \tag{14}$$

where $c_{j,EI}$ is a constant resulting from the curvature at level j as a consequence of the actions below:

$$c_{j,EI} = F_{j-1} \cdot \left(h_{j-1} \cdot x - \frac{1}{2}x^2\right) + c_{j-1}. \tag{15}$$

Equations (14) and (15) show, that the bending curvature at storey j refers to the curvatures and loads from the entire building and indicate the advantage of computer aided calculations. Finally, the inter-storey drift δu_j is written by:

$$\delta u_j = \frac{\delta u_j}{\delta x} \cdot h_j - \frac{\delta u_j}{\delta x} \cdot h_{j-1}. \tag{16}$$

Shear stiffness

In analogy to the bending stiffness, the shear stiffness is derived by Equation (13) to:

$$GA_{eq} = \frac{Q_z \cdot x}{\delta u_{j,GA}}, \tag{17}$$

where Q_z is the shear force and thus the sum of the non-uniformly distributed loads above the height x:

$$Q_z = \sum_{i=j}^{n} F_i. \tag{18}$$

Equivalent cantilever stiffness

With the bending stiffness and shear stiffness, the equivalent beam stiffness can be computed by:

$$K_{B,eq} = \left(\frac{1}{K_{EI,eq}} + \frac{1}{K_{GA,eq}}\right)^{-1}, \tag{19}$$

where:

$$K_{EI,eq} = \frac{3EI_{eq}}{H^3}\ , \quad K_{GA,eq} = \frac{GA_{eq}}{H}. \tag{20}$$

3 PARAMETER STUDY

The parameters are chosen to cover the most realistic variations of the building geometry. Because of the high number of possible configurations, over 12 million simulations are analysed. The varying parameters are the number of stories n_s, number of bays n_b, bay length l_b, column cross-sections $b_c \times h_c$, beam cross sections $b_b \times h_c$, bracing cross-sections $b_{br} \times h_{br}$, rotational stiffness ratio of the beam-column joints α_θ, glued laminated timber strength grades between GL28h and GL75, characteristic storey loads p_s, the internal core ratio β, which is the ratio between the external tube B and the internal tube L_{br}, logarithmic decrement of the structural damping δ_s and the return period R for the basic wind speed. The mass of the building is assumed to be uniformly distributed along the height of the buildings. Figure 6 shows the parameters graphically.

https://doi.org/10.52202/069179-0386

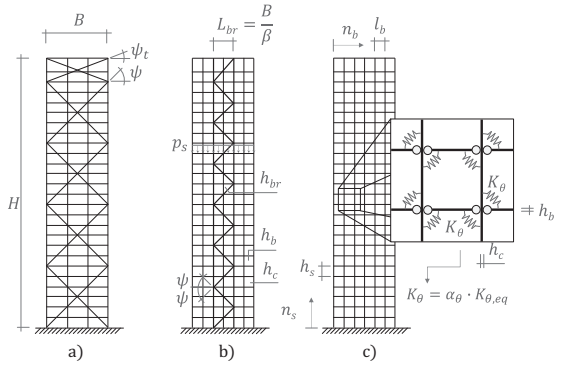

Figure 6: *Illustration of the parameters.*

The constant parameters are the storey height h_s which is fixed at 3.5 m. The bracing angle ψ is variable and determined by the building width and internal core width. However, ψ is approximately 45° and is optimised to find the closest storey, to connect centred to the beam-column-joint. ψ_t is the resulting bracing angle of the top bracing. Table 2 summarises the parameters for the structural investigations. The investigations on the Type II and on the Type V are constant member widths $b_{c,b,br}$, of 0.4m. Here, only the member heights $h_{c,b,br}$ are paramterised and vary between 0.4m and 1.2m. For the braced systems in Type I, III, and IV, the brace cross-sections are square.

Table 2: *Overview of the parameters for the structural investigations*

4 RESULTS AND DISCUSSION

4.1 EQUIVALENT CANTILEVER STIFFNESS

The equivalent stiffness approach in Section 2.3.3, enables the comparison of the different structural systems in terms of the global building stiffness. Independent from the lateral stiffening, the equivalent cantilever beam can quantify the building stiffness. For all the simulations, the coefficient of determination R^2 from the deflections of the finite element results and the predicted deflections of the equivalent cantilever beam is between 0.975 and 1.0. The approach is promising and enables the structural typologies to be assessed in terms of their serviceability.

Based on the results, the varying systems can be analysed towards their bending and shear stiffnesses. Figure 7 shows the scatter of the equivalent bending stiffness EI_{eq} in relation to the equivalent shear stiffness GA_{eq}, where both, horizontal and vertical axis are shown on the base-10 logarithmic scale. In the figure, a set of the results is shown which fulfil the serviceability criteria from Section 2.2 and reveals a slenderness of $H/B > 3.0$. In addition, the plotted results are computed for member grades in GL28h. For the frames and tube-in-tube systems, Figure 7 only presents results for rotational connection stiffness with $\alpha_\theta \leq 1.0$ % and internal core dimensions with $\beta_{br} = 3.0$, i.e. $L_{br} = 1/3 \cdot B$ for Type I and Type V.

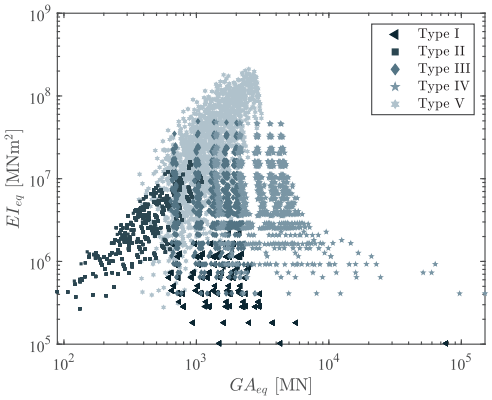

Figure 7: *Behaviour between the equivalent bending stiffness EI_{eq} and shear stiffness GA_{eq}.*

The relation between EI_{eq} and GA_{eq} reveals the strengths and weaknesses of the different systems. Knowing that the frames are more shear compliant than bracings, Figure 7 proves that the tube-in-tube systems as combined configurations achieve bending stiffnesses in the order of braced systems in the façade.

Figure 8 highlights the study resulted building stiffnesses from above in a swarm chart. The figure can be used as a qualitative assessment, to assess the different systems on their global stiffnesses according to the frequency of the results. For all types, the results are visualised in Figure 8 with their distribution of the achieved stiffnesses.

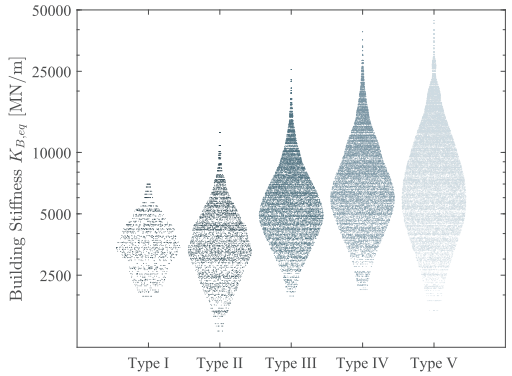

Figure 8: *Equivalent building stiffnesses of the different systems for a set of simulations.*

4.2 ROTATIONAL CONNECTION STIFFNESS

Figure 9 shows the relation of the equivalent rotational joint stiffness $K_{\theta,eq}$ and the bay length l_b, the storey height h_s and varying beam dimensions.

It is apparent from Figure 9 that the storey height h_s becomes less significant with increasing bay lengths l_b. Its impact is smaller in comparison to the bay lengths l_b, the cross-sections of the members $b_b \times h_b$, $b_c \times h_c$, and the young's modulus E. However, the storey height h_s is not negligible, particularly for small bay lengths. For beams which are weaker than the columns, the impact of the bay length l_b diminish and the influence of the storey height h_s is approximately constant for increasing bay lengths. This can be seen in Figure 9.

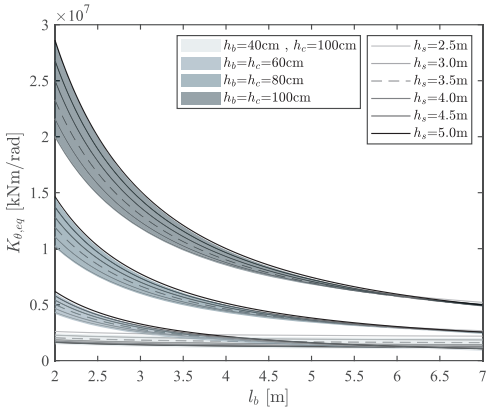

Figure 9: *Relation of the equivalent rotational joint stiffness $K_{\theta,eq}$, bay length l_b, storey height h_s and member cross-sections.*

Since the beam-column connection stiffness K_θ is only a fraction α_θ of the equivalent rotational joint stiffness $K_{\theta,eq}$, as expressed in Equation (4), it is appropriate to identify the impact of the joint stiffness in relation to the building stiffness.

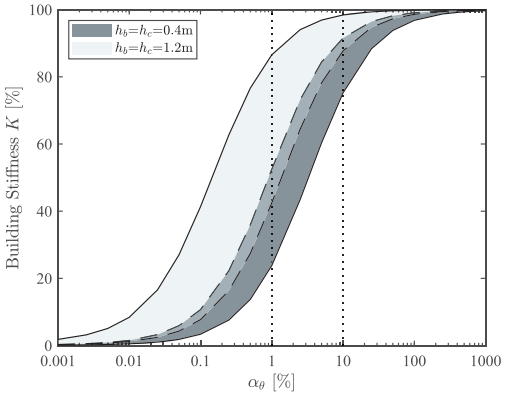

Figure 10: *Impact of the connection stiffness on the global building stiffness. α_θ is plotted on the logarithmic scale to clarify the increase of the building stiffness in the smaller range.*

Figure 10 presents the behaviour of the building stiffness K in relation to the connection stiffness ratio α_θ for a wide range of parameters. The building stiffness K on the vertical axis is here illustrated as the fraction of the equivalent beam stiffness $K_{B,eq}$ towards a fully rigid moment resistant frame to normalise the results. Hence, the building stiffness is expressed in percent:

$$K = \frac{K_{B,eq}(\alpha_{\theta,i})}{K_{B,eq}(\alpha_\theta = 100\%)} \tag{21}$$

The hatched areas in the figure contain all possible combination for the varying parameter configurations,

https://doi.org/10.52202/069179-0386

where configurations with the smallest member cross-sections h_b=h_c=40cm and larges cross-sections h_b=h_c=120cm are subdivided.

Figure 10 reveals, that the beam-column connection stiffness K_θ has a large impact on the building stiffness when the stiffness ratio α_θ is within the range of 0.01% to about 10%. For stiffness ratios α_θ of more than 10%, the impact is smaller because of the exceedingly high values of K_θ and the large number of beam-column joints. A stiffness ratio α_θ of 5% in the beam-column joints results in a global lateral stiffness K between 60% and 98% when compared with an equivalent building with rigid beam-column joints. Whereas slender beams need higher connection stiffnesses than stiffer or larger beams, to achieve maximal building stiffnesses.

So, for instances, achieves a building with a framed tube (Type II) in GL28h with n_b=6 bays, bay lengths l_b=3.6m, n_s=25 storeys, storey height h_s=3.5m, beam and columns cross-sections of $b_b \times h_b$=40×100cm and $b_c \times h_c$=40×60cm a global lateral building stiffness of K=79% for a connection stiffness ratio of α_θ=1.0%. Whereas the same building with a relatively equal stiffness ratio α_θ=1.0%, but with reversed member dimensions, i.e., beam cross-sections $b_b \times h_b$=40×60cm and columns $b_c \times h_c$=40×100cm, only achieves a global building stiffness of K=32%. Figure 11 shows, that only a small α_θ is needed to provide stiff connections as peak accelerations and deflections are only slightly affected after a certain achieved rotational stiffness. For the illustrated 25 multi-storey frame, the gain with connection stiffness ratios α_θ above 1% is marginal.

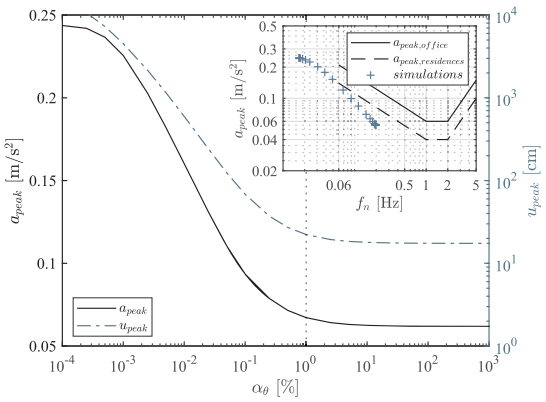

Figure 11: *Behaviour of the peak accelerations and peak displacements related to the rotational connection stiffness for an illustrative external frame (Type II) in GL28h with 25 storeys, 6×3.6m bays, storey height 3.5 m, δ_s=0.1, beam cross-sections 40×100cm and column cross-sections 40×60cm.*

Apart from slender beams, an increase of the stiffness ratio α_θ above 10% is in general not worthwhile. Consequently, the development of semi-rigid beam-column joints should target a stiffness ratio α_θ between 1% and 10% to guarantee efficient solutions. Such stiffness ratios result in stiffnesses, which are high and currently challenging in timber to achieve. However, they are not impossible. Considering the mentioned building above for instances, where beam and column cross-sections are $b_b \times h_b$=40×100cm and $b_c \times h_c$=40×60cm, bay length l_b is 3.6m, storey height h_s is 3.5m, and the elastic modulus E is 12'600N/mm², then, a stiffness ratio α_θ=1% results in a rotational stiffness K_θ of 242'150kNm/rad. Through experimental and analytical considerations Stamatopoulos et al. [26] showed that their current system based on threaded rods results in rotational stiffness ratios α_θ in the order of 2.3%, when the connections would be applied in the mentioned building. Their investigations proved a connection stiffness K_θ in the order of 7618kNm/rad for two threaded rods in plane with members in GL30c and cross-sections of b_b/h_b=14/45cm and b_c/h_c=14/45cm respectively. From an engineering point of view, these results indicate that multi-storey frame structures could enable a new era of tall timber buildings, when combined with an internal core, as will be shown in the following.

4.3 SERVICEABILITY STUDY

The wide-ranging parameter study enables the sensitivity analysis on the significance of the different parameters. The impact and weight of the varying parameters are described in depth in Binck et. al. [15]. Towards the serviceability limit state, the most important parameters of the different systems are the rotational connection stiffness K_θ while stiffness ratios α_θ are under 10%, the member dimensions $b_{b,c,br}$ and $h_{b,c,br}$, the timber grades and the number of bays n_b which have a higher importance than the bay length l_b and storey height h_s. In contrast to the peak displacements, the mass, its distribution, and the damping properties have a pronounced importance on the peak accelerations.

To assess the height limitations of the different stiffening systems, the structures are subjected to the performance criteria, presented in section 2.2. Depending on the varying parameters, the height limit is defined for the tallest structures, which still fulfil all three, the peak acceleration criterion a_{peak}, the peak displacement criterion u_{peak}, and the maximum inter-storey drift δu_{peak} criteria.

For the structural types II, IV and V, Figure 12 shows the structural height limitations with the dashed grey line. The limits are expressed in terms of the maximum storey number and the common parameters. If the peak displacement criteria are the decisive criteria, the height limit is plotted trough the grey circled markers. The grey markers indicate the ultimate storey number for the satisfaction of the displacement criteria. If the acceleration criterion is the decisive criterion, the decision line pass through the black, squared markers. For the latter, the requirements for residential uses according ISO 10137 [16] are assessed.

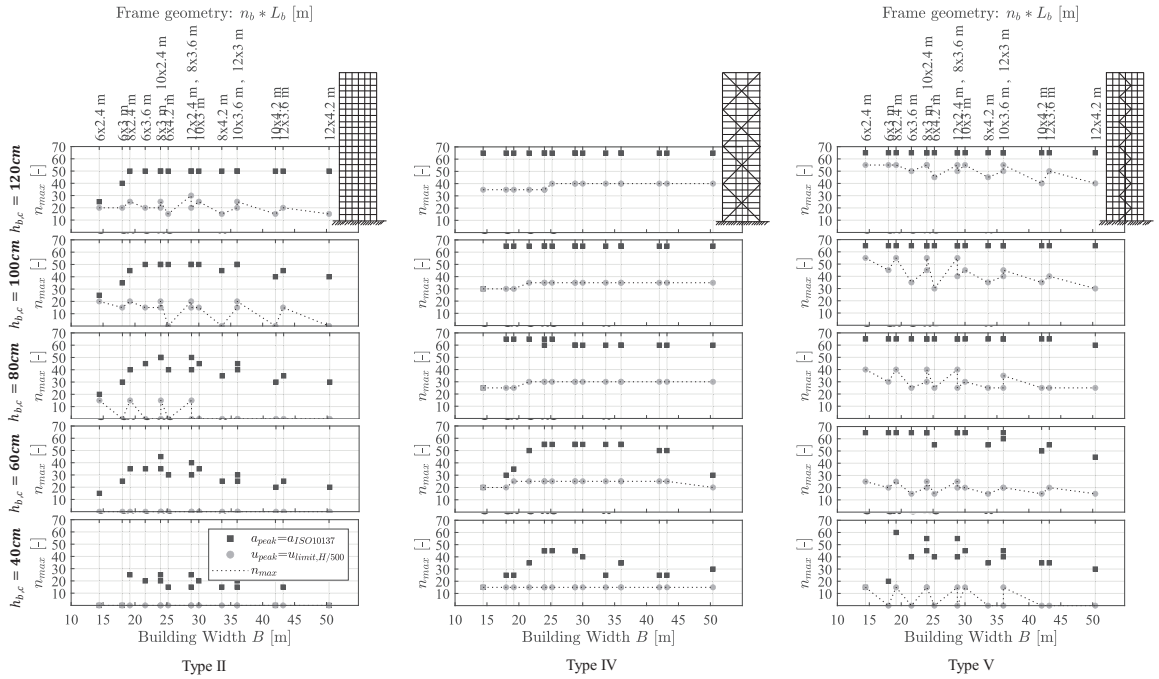

Figure 12: *Height investigations of Types II, IV and V which fulfil the serviceability criteria, expressed in terms of the storey number n_{max}. The common parameters for the shown results are the glued laminated timber strength grades in GL28h for all members, constant characteristic storey loads of p_s=7.5kN/m², storey height h_s=3.5m, structural logarithmic damping decrements of δs=0.1, rotational connections stiffnesses of α_θ=1.0% for the semi-rigid connections and beam and bracing cross-sections of 1) $b_{b,br} \times h_{b,br}$=40×40cm, 2) $b_{b,br} \times h_{b,br}$=40×60cm, 3)) $b_{b,br} \times h_{b,br}$=40×80cm, 4)) $b_{b,br} \times h_{b,br}$=40×100cm, 5)) $b_{b,br} \times h_{b,br}$=40×120cm in the different figures. Type II and V have same column cross-sections. For type IV, the column cross-sections are squared, thus 1) $b_{b,br} \times h_{b,br}$= 40×40cm, 2) $b_{b,br} \times h_{b,br}$=60×60cm, 3) $b_{b,br} \times h_{b,br}$=80×80cm, 4) $b_{b,br} \times h_{b,br}$=100×100cm, 5) $b_{b,br} \times h_{b,br}$=120×120cm.*

Figure 12 reveals the relevance of the displacement criteria for various parameters. In general, three main reasons indicate the relevance of the displacement criteria: first, the small young's modulus E of GL28h leads to relatively weak structures, compared to other materials. This is also a reason for why the height limits for increasing building widths are constant. Regarding the increasing wind contact surface which larger buildings provide, the strains in the extensive large members mount up to large deformations. Only a simultaneous increase of the member cross-sections enables deflection reductions in that case. The second reason is the relatively high storey load for the comparatively weak structures, which is here set to p_s=7.5kN/m² as a characteristic load and corresponds to a building density of about 214 kg/m³ including all dead loads and quasi permanent live loads. For lightweight buildings with storey loads of 5.0 kN/m² for instances, the acceleration criterion becomes frequently the governing criterion. Finally, the third reason is the calculation for the higher return period of 100 years for the displacements.

4.4 HEIGHT INVESTIGATIONS

Based on Figure 12, the determination of the height limits for the structural timber systems is carried out for all parameter configurations. Analogously, Figure 13 summarises the achievable heights for all investigations with varying parameters listed in Table 1 and Table 2. Here the results are valid for the fixed parameters with a constant storey height h_s=3.5m, a logarithmic damping decrement of the structure δ_s=0.1 and constant characteristic storey loads of p_s=7.5kN/m². In Figure 13, the current height limits for GL28h are presented:

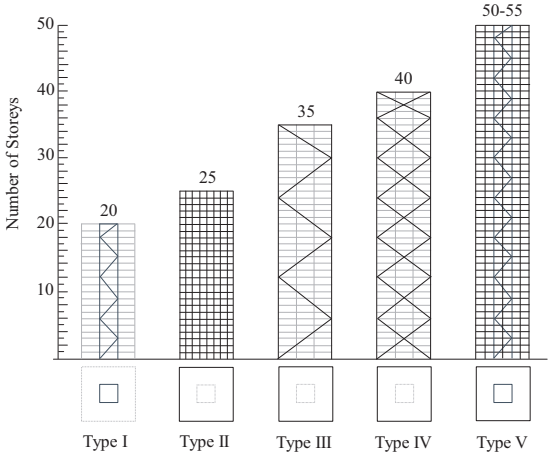

Figure 13: *Height investigations for structural timber systems subjected to wind loading.*

https://doi.org/10.52202/069179-0386

From a serviceability point of view, the results indicate that the braced systems in the façade (Type III and IV) and the tube-in-tube systems (Type V) presents feasible solutions for building heights H>100m. Considering the requirements of $u_{peak} \leq H/500$, $\delta u_{peak} \leq h_s/500$ and the acceleration criterion in ISO 10137 [16] as comfort criteria, the structures perform well up to 140m for Type IV and 175m-190m for Type V with storey heights h_s=3.5m. However, this should be seen more as a guideline than as a stringent boundary. Regarding the serviceability, investigations on higher structures are feasible when larger cross-section will be guaranteed to provide the required stiffnesses.

The advantage of Type V as a tube-in-tube system would be the use of the existing structure from the vertical load transfer while applying simultaneously to the horizontal load transfer, without adding further members in the façade layer. However, high demands are made on the moment-resisting connections as they have to act as key elements to provide the required stiffnesses. At present, these connections are still challenging because of the anisotropic material properties, and their development has just begun. Moment-resisting connections are no common solutions in timber structures but could enable a new field for tall timber buildings.

5 CONCLUSIONS

At present, the predominant structural system for tall timber buildings is a hybrid solution, where a reinforced concrete core provides the lateral stiffness. To assess alternative solutions in timber, five different systems were analysed in this paper to assess the performance of lateral stiffening systems in timber. The main goal was to explore the feasible heights of timber solutions for the presented systems.

Based on a parameter study, the classification of efficient height limits was induced on the lateral stiffness capabilities for wind induced vibrations. The structural typologies have been compared with respect to their stiffness and analysed for peak accelerations and displacement limitations. The height indications have not been analysed and classified according to the ultimate limit state.

With an efficient and well-designed lateral stiffening system, holistic timber buildings can satisfy the acceleration requirements for residential uses according to ISO 10137 and the peak displacement criteria of $u_{peak} \leq H/500$ and $\delta u_{peak} \leq h_s/500$ for a 100 year return period. There is a great potential for timber solutions that will allow buildings to reach heights up to 190m. This potential is dependent by a wide range of parameters and is presented for a certain parameter range in this paper. The key takeaway from the analysed structures should be, that the wind induced deformations are in most cases the decisive requirement while assessing the displacement criteria to $u_{peak} \leq H/500$ at the head deflections and $\delta u_{peak} \leq h_s/500$ for the inter-storey drift.

The comparison can be seen as a fundamental research for height investigations for a new era of timber buildings in terms of different structural systems. This will enable a more global perspective of quantifying the lateral stiffness for tall timber buildings to enforce its structural design. However, a more in-depth study is needed to include the structural analysis on the ultimate limit state in order to provide a holistic assessment on the ultimate height limitations and to identify the “premium for heights”.

PERFORMANCE VERIFICATION AND TRIAL DESIGN FOR HIGH-RISE TIMBER FRAME BUILDINGS WITH BUCKLING-RESTRAINED BRACE PART 2: ANALYSIS OF THE TRIAL DESIGN BUILDING

Ryota Minami[1], Toshio Maegawa[2], Taisuke Nagashima[3], Kazuki Tachibana,[4] Hiroki Nakashima,[5] Nobuhiko Akiyama,[6] Yoshihiro Yamazaki,[7] and Takahiro Tsuchimoto[8]

ABSTRACT: Demand has recently emerged for large-scale structures made of timber. In earthquake-prone areas, such structures must feature adequate bearing capacity against major earthquakes. Part 1 of our research in this area entailed studies of methods to strengthen the bearing capacity of timber structures against the forces generated by major earthquakes. The work described in this paper confirms the seismic performance of a 10-story timber building designed by these methods. Analysis confirmed that the suggested methods strengthen the bearing capacity of large timber buildings against the forces generated by major earthquakes.

KEYWORDS: High-rise timber frame building, trial design, nonlinear dynamic analysis, buckling-restrained brace

1 INTRODUCTION

In earthquake-prone areas, structures made of timber tend to suffer significant damage when subjected to earthquake forces. For this reason, in Japan, virtually all medium- and large-scale structures are made of reinforced concrete or steel. However, various recent trends, including environmental issues, have generated demand for medium- and large-scale structures made of timber.

Medium- and large-scale buildings made of steel often incorporate buckling-restrained braces (BRBs) to boost bearing capacity against earthquake forces [1]. BRBs provide significant energy absorption capacity. BRBs incorporated into medium- and large-scale timber frame buildings should shoulder a significant share of the earthquake energy generated and improve building energy absorption capacity. This study assumes a 10-story timber frame building incorporating BRBs in Japan and proposes methods for achieving these design goals. The study also confirms the validity of these methods.

Building a 10-story timber frame building incorporating BRBs also requires sufficiently strong connections between beams or columns and the BRBs. This is due to the considerable strength and stiffness of the BRBs compared to timber constructions. It also requires column base connections with sufficient strength due to the large pull-out forces that can occur at the column base connections of buildings incorporating many braces or shear walls. In Part 1, we proposed multi knife plate steel dowel connections between beams or columns and BRBs (Figure 1) and glued-in rod (GIR) connections for the column base. To confirm the performance of these connections, we performed vertical loading tests of multi knife plate steel dowel connections, cyclic loading tests of timber frames with BRBs, and cyclic loading tests of column base connections with GIR.

This paper describes the trial of a seismic design for a 10-story timber frame building incorporating BRBs and using the connections proposed in Part 1. Our results confirmed their effectiveness, even for a 10-story timber frame building incorporating BRBs. The results reported here confirm the validity of incorporating BRBs in high-rise timber frame buildings.

2 TRIAL DESIGN BUILDING

2.1 TRIAL DESIGN BUILDING PLANS

Figures 2 and 3 show the plan view and frame diagram of the trial design building. In this paper, only the upper structure is considered. The building is assumed to be used for residential. BRBs are installed in the core (along the X direction) and between the rooms (along the Y direction). Columns and beams are made of glued laminated timber (GLT).

2.2 CONNECTIONS

Figures 4 and 5 show the beam-column connections at which the BRBs are attached. Figure 1 shows the connection between beams and BRBs. In these connections, beams, columns, and BRBs are connected via multi knife plate steel dowel connections. Figure 6 shows other beam-column connections; here, beams and column are connected with bolts and steel dowels due to the perpendicular orientation relative to the connections shown in Figures 4 and 5. In the connections shown in Figures 4 and 5, the steel plate holes of the beams into which the steel dowels are inserted are long. The steel dowels configured parallel to the direction of the grain are not subject to forces perpendicular to the direction of the grain; the steel dowels configured perpendicular to the direction of the grain are not subject to forces parallel to the direction of the grain.

2.3 COLUMN BASE CONNECTIONS

Figures 7 and 8 show the column base connections of the trial design building. Timber column and steel shoes are connected with the GIR connections proposed in Part 1. In this connection, reinforcement bars D29 are inserted and a plasticized section (φ22) is provided to ensure the uniform distribution of forces for the reinforcement bars. Steel shoes and foundations are connected with anchor bolts. In the trial design building, the column base connections in X1, X2, X5, X6, X9, and X10 are Type A (Figure 7). The others are Type B (Figure 8).

2.4 FLOOR SLABS AND CEILINGS

Figure 9 shows the floor slab and ceiling for an apartment in the trial design building. The dead loads are 2,270 N/m^2 (floors 2 to 6) and 1,880 N/m^2 (floors 7 to 10). Figure 10 shows the floor slab and ceiling for the rooftop. Figure 11 shows the floor slab and ceiling for the corridor. The dead load for the rooftop is 1,120 N/m^2; the dead loads for the corridor are 1,930 N/m^2 (floors 2 to 6) and 1,540 N/m^2 (floors 7 to 10).

The design value assumed for the floor slabs and beams live loads on these floor slabs is 1,800 N/m^2. The design value assumed for the frame members is 1,300 N/m^2; and the design seismic load assumed is 600 N/m^2 [2].

3 ANALYSIS METHOD

3.1 SEISMIC DESIGN METHOD [3]

The building discussed in this paper is designed to satisfy the structural requirements specified by the Response and Limit Capacity Method, a Japanese code. This code requires verification of dead, live, snow, wind, and seismic loads. This paper considers only seismic loads. Seismic load verification requires drift pushover analysis, a method of nonlinear static analysis that involves increasing lateral loads in increments as shown in Figure 12 and checking the following criteria:

(a) Damage limit

This criterion is used to verify that damage caused by rare large-scale earthquake motions remains within the allowable range. In this paper, the damage limit is defined as the state in which the stress attributable to the lateral seismic load exceeds the temporary allowable stress (2/3 of material strength for timber members and yield strength for steel members) or at which the maximum interstory drift angle exceeds 1/200 rad. The lateral seismic shear force at the damage limit calculated by drift pushover analysis should exceed the lateral seismic shear force given by the following equation:

$$P_{di} = S_d B_{di} Z G_s m_i \quad (1)$$

(b) Safety limit

This criterion is used to verify that the building will not collapse when subjected to extremely rare large-scale earthquake motions. In this paper, the safety limit is defined as the state in which the maximum interstory drift angle exceeds 1/60 rad. The stress attributable to the lateral seismic loads at the safety limit should not exceed the material strength. The lateral seismic shear force at the building safety limit given by drift pushover analysis should exceed the lateral seismic shear force given by the following equation:

$$P_{si} = F\, S_s B_{si} Z G_s m_i \quad (2)$$

where S_d is the acceleration response at the damage limit on engineering bedrock; B_{di} is the acceleration distribution factor at the damage limit (first mode participation vector); Z is the seismic hazard zoning factor,; G_s is the surface soil amplification factor; m_i is weight of the *i*-th story; F is the acceleration reduction factor due to damping at the safety limit; S_s is the acceleration response at the safety limit on engineering bedrock; and B_{si} is the acceleration distribution factor at the safety limit (first mode participation vector).

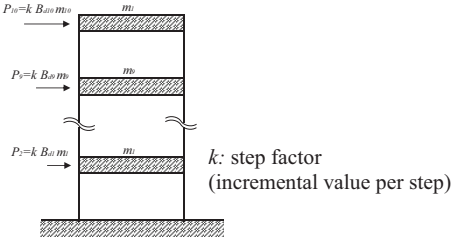

Figure 12: *Distribution of lateral force*

https://doi.org/10.52202/069179-0387

S_d and S_s are as in Figure 13.

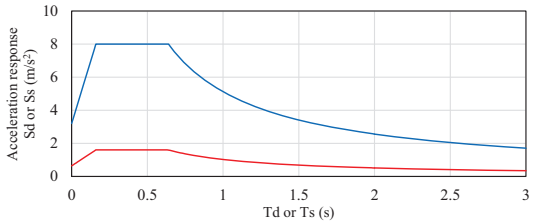

Figure 13: *Acceleration spectrum* $\boldsymbol{S_d}$ *and* $\boldsymbol{S_s}$

G_s is given by the following equation:

$$G_s = \begin{cases} 1.5 \quad for\ T < 0.64 \\ 1.5T/0.64 \quad for\ 0.64 \le T < 0.864 \\ 2.025 \quad for\ 0.864 \le T \end{cases} \qquad (3)$$

where $T = T_d$ when calculating P_{di} and $T = T_s$ when calculating P_{si}.

F is given by the following equation:

$$F = 1.5/(1 + 10\zeta) \qquad (4)$$

T_d and T_s are the response period at the damage limit and safety limit obtained by evaluating story stiffness and mass from the drift pushover analysis results and replacing the building with a 1DOF model, as shown in Figure 14. ζ is the damping ratio of the building given by the following equation:

$$\zeta = (\Delta s \cdot Q_d)/(\Delta d \cdot Q_s) \qquad (5)$$

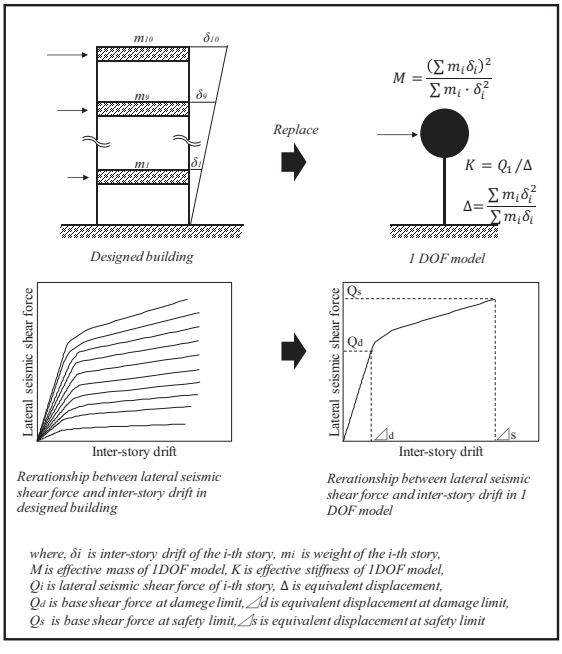

Figure 14: *Method to replace the building with 1DOF*

In addition to verification by the Response and Limit Capacity Method, the building performance upon the input of extremely rare large-scale earthquake motions is confirmed via time history analysis, accounting for P-Δ effects. Figure 15 shows the input earthquake ground motions. These are extremely rare large-scale earthquake motions as defined under Japanese Building Standard Law, which simulates earthquakes using random phase spectra (AW1-L2), the phase spectra specified in HACHINOHE 1968 NS (AW2-L2) and JMA KOBE NS (AW3-L2). The acceleration spectra for the engineering bedrock are shown in Figure 13 (S_s).

The analyses assume a rigid floor assumption and were performed using midas iGen V.920R1x.

3.2 NUMERICAL ANALYSIS MODEL

Figures 16 to 19 show numerical analysis models of the connections shown in Figure 1 and Figures 4 to 8.

In Figures 16 and 17, multi knife plate steel dowel connections are modelled by shear springs (parallel to the direction of the grain and perpendicular to the direction of the grain) and by rotational springs. The stiffness and yield strength values are calculated by the method proposed in Part 1. Knife plate steel dowel connections with long holes are not subject to bending moments and modelled with pin connections. For beam-column connections at which no BRB is attached, the knife plate steel dowel connection in the column is assumed to be rigid due to the negligible influence on building performance during an earthquake.

The connection in Figure 18 is modelled with pin connections since connections incorporating bolts and steel dowels have low stiffness.

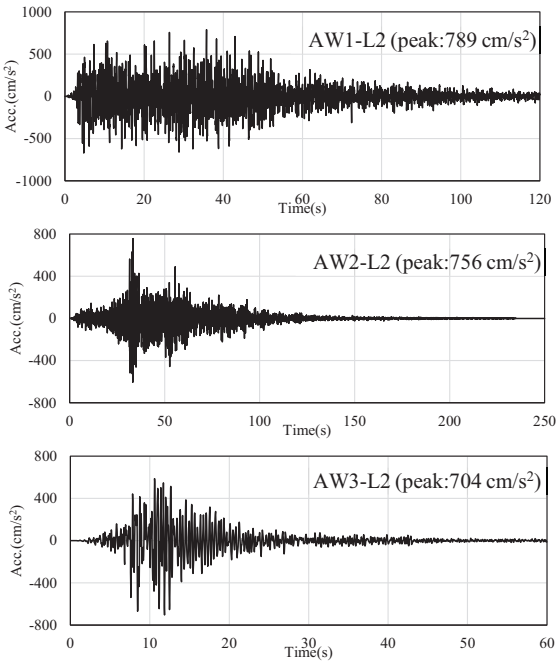

Figure 15: *Accelerations of input earthquakes*

https://doi.org/10.52202/069179-0387

In Figure 19, connections with GIR are modelled by a multi-spring model. (The values for stiffness and yield strength of the spring are given in Part 1.) Connections with anchor bolts are modelled with a multi-spring model. The values for spring stiffness are given by the following equations:

$$k_b = n_b A_b E_b / L \quad (6)$$

$$k_c = B_s \, s \, E_c / L \quad (7)$$

where k_b is the stiffness of the anchor bolt spring; k_c is the stiffness of the base concrete bearing spring; n_b is the number of anchor bolts; A_b is the cross section area of the anchor bolts; E_b is the elastic modulus of the anchor bolts; L is the length of the anchor bolts; B_s is the width of the steel shoe; s is the distance between the springs (= 50 mm); and E_c is the elastic modulus of the base concrete.

4.2 RESULTS OF PUSHOVER ANALYSIS

Figures 20 to 23 show the relationship between the interstory drift angle and lateral seismic shear force calculated by drift pushover analysis. In Figures 20 and 21, the damage limit state is the step at which the stress attributable to the lateral load exceeds the temporary allowable stress for the first time. In Figures 22 and 23, the safety limit state is the step at which the maximum interstory drift angle exceeds 1/60 rad for the first time.

From Figures 20 and 21, assuming the cross section shown in Tables 1 and 2, the lateral seismic shear capacity at the damage limit of the trial design building exceeds the lateral seismic shear force in Equation (1); the maximum interstory drift angle does not exceed 1/200 rad. In both the X- and Y- directions, the BRBs are the first structural members to exceed the temporary allowable stress value. From Figures 22 and 23, assuming the cross section shown in Tables 1 and 2, the lateral seismic shear capacity at the safety limit of the trial design building exceeds the lateral seismic shear force given by Equation (2). It was confirmed that the stress attributable to the lateral seismic load in the timber members does not exceed the material strength. Damping ratio ζ in Equation (5) is 15.1% in the analysis for the X-direction and 14.3% in the analysis for the Y-direction. Since the BRBs yielded, significantly high damping was observed. This is consistent with the design philosophy of this building, which is to improve the energy absorption capacity of the building by adopting BRBs.

Figure 24 shows the maximum value of the grain stress at the multi knife plate steel dowel connection between the beam and the BRBs (Figure 1) in this building at the safety limit calculated by pushover analysis for the X-direction. Figure 25 shows the maximum value of the grain stress at the multi knife plate steel dowel connection between the column and the BRBs (Figure 5) in this building at the safety limit calculated by pushover analysis for the Y-direction. They show the stress at multi knife plate steel dowel connections at which the BRBs are arranged in a K-shape does not exceed the temporary allowable stress at the safety limit. In the multi knife plate steel dowel connections used in this building, the greatest stress arises in connections at which the BRBs are arranged in a K-shape. This shows that the connections between the timber structures and the BRBs proposed in Part 1 remain reliable even in a 10-story timber frame building incorporating BRBs.

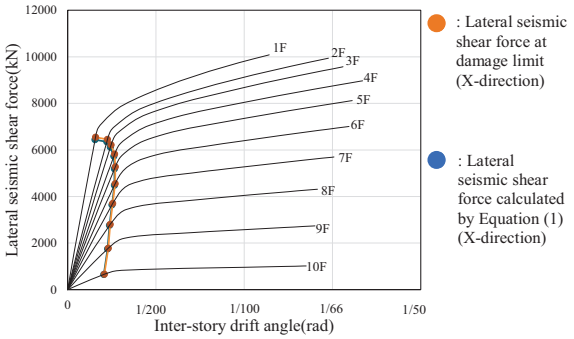

Figure 20: *Relationship between lateral seismic shear force and inter-story drift angle at damage limit in X direction analysis*

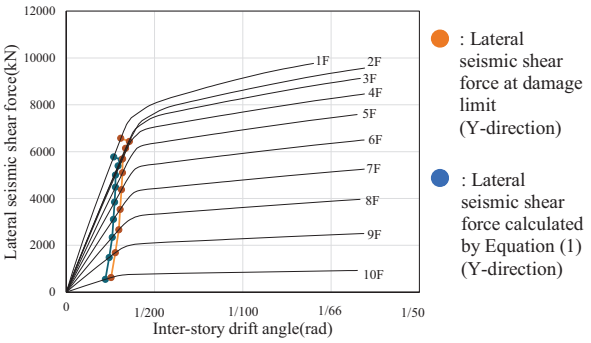

Figure 21: *Relationship between lateral seismic shear force and interstory drift angle at damage limit in Y direction analysis*

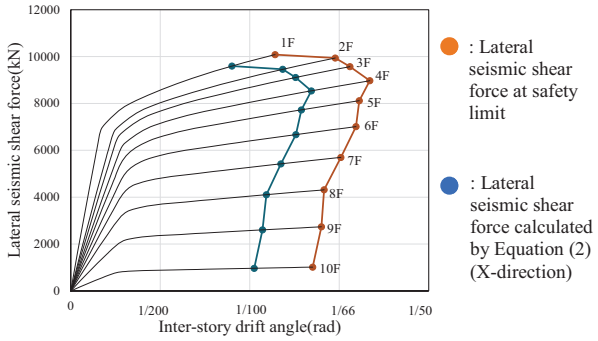

Figure 22: *Relationship between lateral seismic shear force and interstory drift angle at safety limit in X direction analysis*

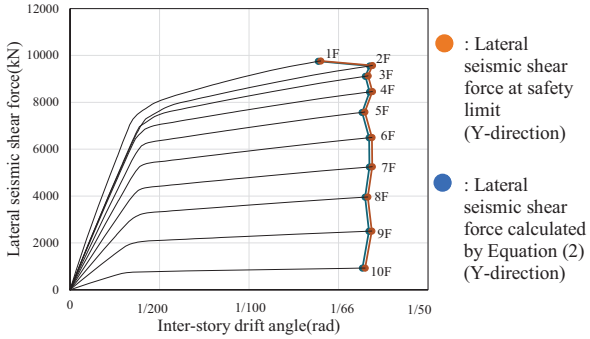

Figure 23: *Relationship between lateral seismic shear force and interstory drift angle at safety limit in Y direction analysis*

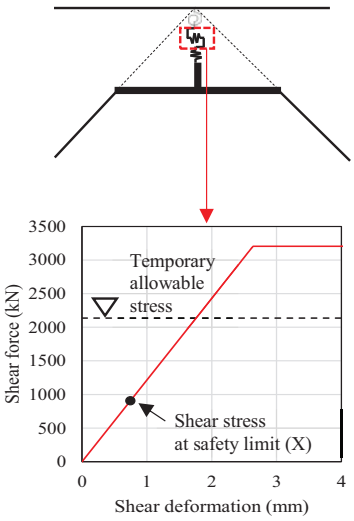

Figure 24: *Maximum grain direction stress at the multi knife plate steel dowel connection between beam and BRBs*

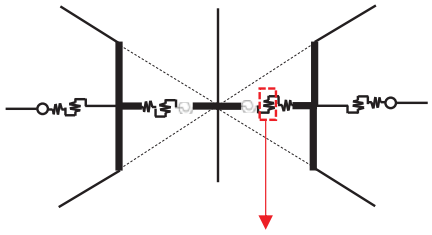

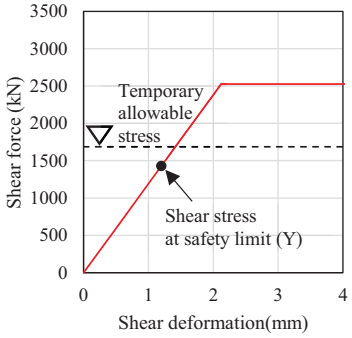

Figure 25: *Maximum grain direction stress at the multi knife plate steel dowel connection between column and BRBs*

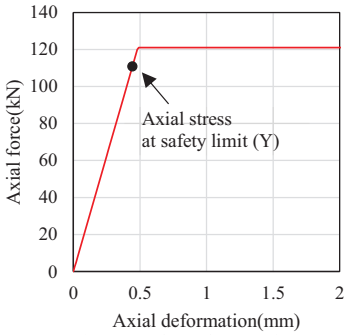

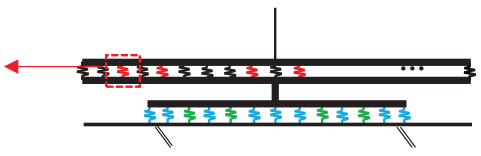

Figure 26: *Maximum axial stress of reinforcing bar in GIR connections*

https://doi.org/10.52202/069179-0387

Figure 26 shows the maximum axial stress for the reinforcing bar in GIR connections (Figures 7 and 8) attributable to the lateral seismic force at the safety limit (in both the X and Y directions). Figure 25 shows that the stress on the reinforcement bar does not exceed the yield strength for the plasticized section at the safety limit. Figure 27 shows M-N interaction curves for GIR and anchor bolt connections (Figures 7 and 8). It indicates that the anchor bolt connections yield before the GIR connection at the column base connection of this building. This means that the GIR connection proposed in Part 1 remains reliable even for a 10-story timber frame building incorporating BRBs in which anchor bolt connections are designed to yield before GIR connections.

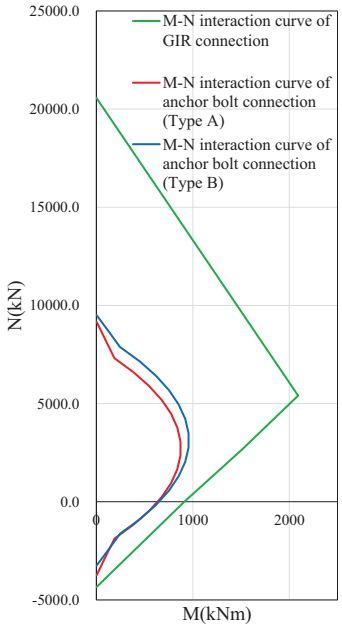

Figure 27: *M-N-interaction curves of GIR connection and anchor bolt connection*

4.3 RESULTS OF TIME HISTORY ANALYSIS

Figure 28 shows the maximum interstory drift angle of the trial design building obtained via time history analysis. Figure 28 shows that the maximum interstory drift angle of the trial design building given by time history analysis does not exceed 1/60 rad, which is assumed to be the interstory drift angle at the safety limit in the drift pushover analysis. It was also confirmed that the stress attributable to the lateral seismic load in the timber member does not exceed the material strength via time history analysis.

Figures 29 and 30 show the maximum value of the grain stress at the multi knife plate steel dowel connection between the beam and the BRBs (Figure 1) and the maximum value of the grain stress at the multi knife plate steel dowel connection between the column and the BRBs (Figure 5). Figure 31 shows the maximum axial stress on the reinforcing bar in the GIR connections, as in the previous section. Figures 29 to 31 show the results of the time history analysis, confirming the effectiveness of the connections proposed in Part 1.

5 CONCLUSIONS

This paper discusses aspects of trial seismic design for a 10-story timber frame building incorporating BRBs and using the connections proposed in Part 1.

Static analysis based on the Response and Limit Capacity Method and time history analysis confirmed that these BRBs will absorb considerable energy in the event of an earthquake and improve the bearing capacity of high-rise timber frame buildings. Our efforts also confirmed that the stress arising in multi knife plate steel dowel connections between BRBs and beams or columns and in GIR connections of column base connections proposed in Part 1 remains within the experimentally confirmed bearing capacity, thereby confirming the validity of the connections proposed in Part 1.

POINT-SUPPORT REINFORCEMENT FOR A HIGHLY EFFICIENT TIMBER HOLLOW CORE SLAB SYSTEM

Cristóbal Tapia[1], Hans Jakob Wagner[2], Simon Treml[3], Achim Menges[4], Simon Aicher[5]

ABSTRACT: The paper presents a new point-supported slab building system concept developed at the Cluster of Excellence on Integrative Computational Design and Construction for Architecture (IntCDC) at the University of Stuttgart. The system uses a hollow-core system with two thin CLT plates acting as flanges and a set of distributed shear web elements in-between. The introduction of point supports induces large shear forces concentrated in the narrow region surrounding the column. This area is reinforced by an LVL core placed in-between CLT flanges, at the column-head position, with discrete web elements connected laterally to introduce the shear forces. Two alternative solutions for this connection are presented, differing mainly in the chosen strategy to bond both components: side bonding of web beams into the LVL core, or only gluing the frontal sloped face of the web beams. An experimental campaign was set, where a total of three specimens of each alternative where manufactured and tested. The results showed a clear superiority of the side-bonded web beams, reaching capacities between four to five times larger than the alternative without side bonding. The paper discusses the relationship of the system with robotic manufacturing processes and presents experimental and corresponding finite element results.

1 INTRODUCTION

The last decade has seen a steady increase of multi-storey timber projects [2, 9, 14, 16] enabled by the continuous development of new technologies, including novel connections and structural elements (see e.g. [10, 22]). This trend will foreseeable continue during the next years, as it allows for an efficient use of the already scarce construction area in cities, while offering incentives to reduce CO_2 emissions and improve construction conditions (less noise and shorter build times). Thus, timber is becoming a viable alternative to the presently dominant reinforced concrete (RC) building systems. This is at least true for multi-storey building typologies that afford rigid grids and single span structural systems [16]. However, to achieve similar capabilities as with reinforced concrete or steel buildings in terms of architectural flexibility and long-term (re)-usability, timber-based construction systems must be further developed to increase the possibilities and design freedom of the (re-) distribution and (re-) partitioning of inner spaces. This typically requires relatively long spans, a limited amount of columns that can be freely positioned to optimize flexible use-options and a flat bottom side of the slab to simplify the reinstallation of spatial divisions (inner walls).

Applied to timber structures, such a flexible point-supported slab structure presents several challenges. For example, this concept presupposes a biaxial mechanical behavior of the plate elements, which for the case of timber requires special considerations on the level of edge connections, as plate dimensions are limited by production and transport constraints. Then, since the whole floor plan acts as a monolithic, biaxial plate, large and rather concentrated negative moments form in the immediate proximity and directly above each column, which adds to the high shear stresses in the same region.

These problems constituted important research topics in the last years, where the focus has been placed mainly on the use of cross-laminated timber (CLT) plates. These efforts have lead to the development of several connection concepts for point-supported CLT plates [10, 11, 18, 22], as well as stiff edge connections for CLT plates [3, 17]. Both of these concepts are essential to achieve a slab system with biaxial mechanical behavior, large spans and a flexible arrangement of columns.

However, in terms of material efficiency, the use of CLT

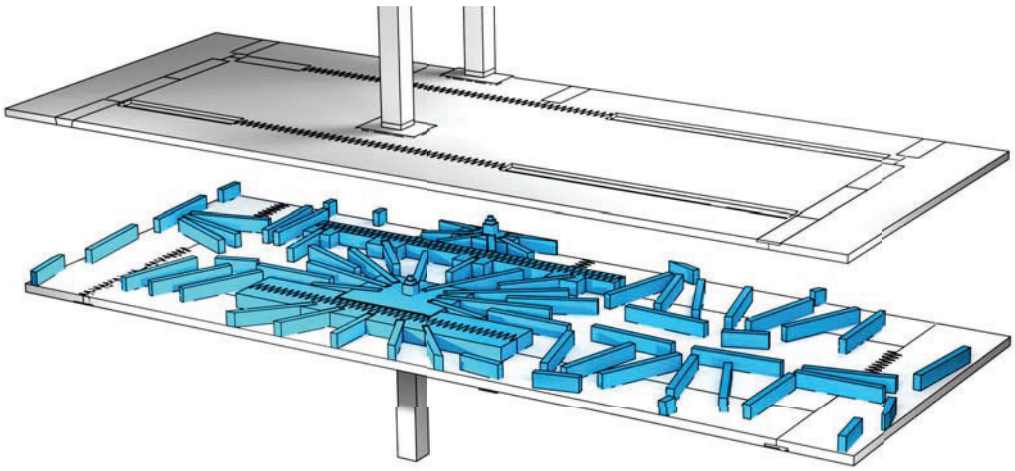

Figure 1: *Illustration of the development of a new hollow-core slab building system based on CLT outer plates with discrete distributed GLT web elements*

for large spans can be regarded as rather wasteful compared to different, more optimized systems. For example, the slab elements used in the building "Mjøstårnet", Norway, were conceived as ribbed elements, thus making a more efficient use of the material [2]. The general concept of ribbed slab elements is appealing in many ways, however, the current implementations—mostly devised as unidirectional elements—restrict the layout of columns to rather strict rectangular grids. Hence, the design space is severely limited [16]. Concepts also exist for computationally designed reinforcing beam networks of timber slabs for flexible column positions [4]. Several questions regarding its structural performance and fire-resistance are not yet answered and in the immediate future this approach seems not economically viable for large-scale building structures.

At the Cluster of Excellence on Integrated Computational Design and Construction for Architecture (IntCDC) of the University of Stuttgart a new slab building system concept is currently being investigated that aims to overcome design limitations of conventional systems in an economically viable manner. This timber building system is conceptualized as a point supported flat slab for large and multi-directional spans without the use of steel and concrete details. An early iteration of the system was presented in [8, 13]. The general concept consists of a hollow-core system with two rather thin CLT plates acting as flanges and a set of discrete, optimally distributed shear web elements in-between. Such a system is naturally very efficient for long spans, however, the introduction of point supports presents demanding challenges, as large shear forces concentrate in one narrow region. Due to the hollow nature of the slab, not enough material is present to resist the highly concentrated shear forces, thus requiring a special solution to reinforce the plate in the region of the supports.

This contribution presents the current development state of a hybrid hard- and softwood solution for the reinforcement of the highly stressed region above the point-supports of a hollow-core slab system. Important aspects of the interrelationship of the system with robotic manufacturing processes are discussed, and first experimental and corresponding finite element results are presented. Finally, the possibilities and limitations for practical applications of the system will be discussed.

2 DESCRIPTION OF THE SYSTEM

2.1 GENERAL

The slab system is composed of two CLT plates acting as biaxial *flanges* and a set of relatively short GLT elements glued between both CLT plates, which take the role of web elements (see Fig. 1). The exact position and orientation of these web elements varies throughout the extension of the floor and is determined by an agent-based model that considers the field of shear forces computed by a finite element (FE) model of the analyzed building [12]. In essence, the web elements are oriented following the shear force trajectories, thus aiming at an efficient utilization of the material. The described build-up of the slab system enables a biaxial behavior with very similar bending stiffness in both principal axes. Depending on the floor plan of the building, the column positions and applied set of loads, regions of high or low *density* of these web elements arise.

2.2 ROBOTIC MANUFACTURING CONCEPT

This differentiated distribution of shear webs within the hollow slab is further enabled by a robotic assembly process of the hollow slab elements. The exact position data of the webs from the computational design methods mentioned above can be directly streamed to a robotic fabrication platform, that assembles the web elements in their exact position. This process was tested for a small scale project presented in [15]. As the robotic platform is digitally controlled the complexity of assembling webs in unique patterns is the same as assembling the webs in standardized positions. Hence the co-design of the slab with optimized web layouts together with digital manufacturing processes allows for optimization potentials in the slab that would be not feasible without the integration of digital design and

https://doi.org/10.52202/069179-0388

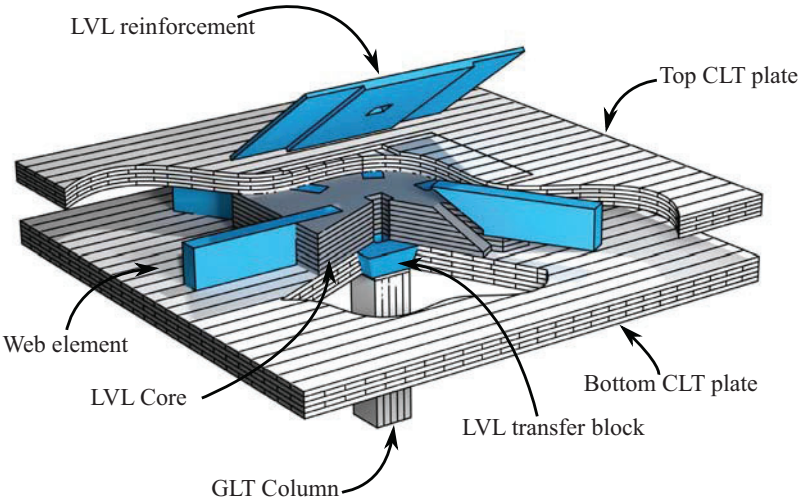

Figure 2: *Concept point-supported hollow-core plate system*

robotic fabrication. The robotic fabrication process nevertheless also has reciprocal requirements to be considered in the internal structural details of the slab. This is especially relevant regarding the structural connection of webs to upper and lower flange and their connection to reinforcement elements inside the hollow slab. The fabrication concept envisions that the robot first selectively applies adhesive on the bottom plate in all areas where webs will be placed. Subsequently webs are placed on the adhesives and pressed with partially-threaded screws. After curing of the bond line between bottom plate and web beams and removal of screws, the plate arrives again at the robotic fabrication setup. Adhesive is applied on top of the webs and the top plate is placed and pressed again using screws. Through this process a structural bond of the inner elements with upper and lower plate can be established completely independent of hydraulic, mechanical or vacuum cramping equipment.

2.3 STRUCUTRAL CHALLENGES AROUND COLUMN SUPPORTS

Intuitively, regions of higher positive moments towards the center of the spanned fields are subject to lower shear forces, thus reducing the density of web elements. On the other side of the spectrum, in the regions surrounding a column the sectional shear forces rapidly increase, requiring a higher amount of material (more webs). Furthermore, the same region will be subjected to highly concentrated negative moments, imposing high biaxial tensile stresses in the plane of the top CLT plate. This is further worsened by the typical presence of a hole, necessary for the transfer of vertical column loads originating in the upper floors of a multi-storey building (see e.g. [10, 14]).

In order to safely handle these unfavorable stresses, a special reinforcement concept is needed. Such concept must consider both, the shear forces and the tensile stresses in the top plate. A possible solution for this is shown in the following.

2.4 COLUMN-HEAD CONCEPT

The proposed solution is composed of three elements, which are illustrated in Fig. 2. Starting from top to bottom the following components are present: (i) an LVL plate on the upper side of the top CLT plate to take care of the reinforcement against high tensile stresses due to negative moments; (ii) a solid LVL block with cavities for the attachment of incoming web elements to help resisting the high shear forces; and (iii) a smaller LVL block inserted in the bottom CLT plate, directly above the column head, to reinforce against failure due to high shear and compressive stresses. These three components are glued to the CLT plates to ensure an efficient load and stress transmission.

The plate for the reinforcement of tensile stresses is the same as presented in [18] for a reinforcement concept for CLT plates, and is therefore not discussed in detail in this paper. The main topic of this paper is the LVL block for the reinforcement of shear forces, where different aspects related to the manufacturing and structural efficiency are covered.

The relatively high shear strength of the spruce LVL block—compared to typical softwood CLT—allows to resists the high shear forces in the region surrounding the column. These forces are mainly coming from the web elements, which raises the question regarding the connection between webs and LVL block.

For the ease of robotic fabrication it would be preferred if a lateral connection between shear web and LVL reinforcement can be avoided. However, for heavily loaded columns this would increase the necessary dimension of the LVL block, as enough surface is required to transfer the shear stresses. In this paper, two alternatives are investigated, resulting from the manufacturing constraints discussed above.

https://doi.org/10.52202/069179-0388

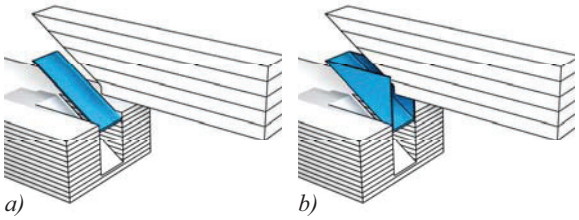

Figure 3: *Alternatives investigated for the application of the adhesive in the connection between GLT web and LVL core elements; (a) Alternative A; (b) Alternative B*

2.5 ALTERNATIVES FOR CONNECTION BETWEEN LVL CORE AND WEB ELEMENTS

2.5.1 Alternative A

The alternative A considers the milling of a wedge-shaped cavity with angle α in the LVL block with a width $w_b > w_w$, where $w_w = 100\,\text{mm}$ is the width of the web element (see Fig. 3a). The end of the web is cut with the same angle α as present in the LVL block. Relatively high tolerances in the horizontal plane need to be considered when large wooden elements are fully robotically assembled. This stems from several factors such as inconsistent dimensional accuracy of GLT beams, manufacturing tolerances of cavity and positioning accuracy of the robotic placement. Between the lateral faces of the GLT and LVL elements a gap with thickness $t_A = 10\,\text{mm}$ is left. This enables a robust robotic placement of the webs into the cavities.

The inclined surface of the web needs to be bonded with the inclined surface of the LVL block. The adhesive that can be applied by the robotic fabrication platform is partially gap-filling up to bond line thicknesses of 1.5 mm. This demands a highly accurate positioning of the web in direction of the longitudinal axis of the web. For this requirement a *locator feature* (see Fig. 4) was included in the web and LVL block geometry, which enables the robot to press the web laterally against the LVL block to ensure precise positioning. Subsequently, the adhesive interfaces between web-bottom plate and web-LVL block are pressed via screws. Further small pockets were included in the design of the LVL cavity and web geometry, to avoid that cured adhesives overruns restrict neither the correct positioning of the web nor that of the top plate.

2.5.2 Alternative B

Alternative B considers a three-sided embedment of the web beam end in the LVL block (see Fig. 3b). This is done by filling the lateral cavities between the LVL block and web beam with a gap-filling, two-component epoxy adhesive, enabling the transfer of shear stresses through these surfaces. From a mechanical perspective, this should be more efficient than alternative A, as more surface is available for the transfer of stresses, and on the side of the web element the surfaces are aligned with the main axis of the GLT element. Compared to alternative A, the gap must be smaller, to avoid using too much adhesive, leading to possible extreme exothermic reactions. Therefore, the gap is set to $t_B = 3\,\text{mm}$. For the fabrication of Alternative B the placement of the web can be achieved within the typical tolerances. Nevertheless, the filling of the gap with the two-component adhesive is a rather laborious task for an automated process. This is mainly because the gap between web and LVL needs to be sealed before glue application, then the glue needs to be filled without impacting the quality of the top web and LVL surface. Finally, the robotic fabrication platform considered for the fabrication of the hollow slab components is not equipped with a two-component epoxy application system. Hence, the fabrication concept for Alternative B considers the robotic placing the web beam into the LVL block, but bonding is performed exclusively to the bottom CLT plate. While the adhesive interfaces between inner elements and bottom plate are stored for curing, the gap between LVL block and web is manually filled with the two-component epoxy adhesive.

3 EXPERIMENTAL CONFIGURATIONS AND MANUFACTURING

3.1 STUDIED CONFIGURATIONS

The shear capacity of the connection was experimentally investigated for both alternatives A and B. The angle α was varied such that the side ratio $r_\alpha = \arctan(\alpha) = 1{:}1$, 1:1.5 and 1:2. The experimental set-up is illustrated in Fig. 5. Here, the LVL core is clamped by pressing a steel plate on the top of the LVL core to a steel I-beam on the bottom by tightening one full-threaded rod at each side. Below the LVL core a set of steel plates were arranged, such that only the area directly below the embedded web beam was allowed to rotate freely (see Fig. 5). The load was applied on a steel plate placed on the top face of the GLT web, at a distance of 20 mm from the edge of the LVL core. The total length of the loading plate varied for each configuration, being $\ell_s = 100\,\text{mm}$ for $r_\alpha = 1{:}1$ and $\ell_s = 220\,\text{mm}$ for $r_\alpha = 1{:}1.5$ and 1:2, respectively.

Self-tapping screws were inserted directly under the loading plate to reinforce this region and to better distribute the shear stresses within the cross-section.

The specimens were tested at the Division of Timber Constructions of the Materials Testing Institute, University of Stuttgart, with a servo-hydraulic universal testing machine with a maximum load capacity of 1.6 MN. The load was applied in displacement-controlled manner with a stroke rate of 0.1 mm/min.

3.2 PROTOTYPE MANUFACTURING

The LVL core was manufactured by bonding six layers of unidirectional spruce LVL plates, where each plate was oriented orthogonally with respect to the adjacent plates. The top-most plate is oriented in the direction parallel to the GLT's main axis. On each LVL block two inclined cavities were milled at the opposite sides, parallel to the main axis of the experimental set-up. This enabled to test connection alternative A on one side and alternative B on the opposite side independently. The cavities in the LVL block were milled with a Kuka Industrial Robot at Züblin Timber GmbH, Aichach, Germany.

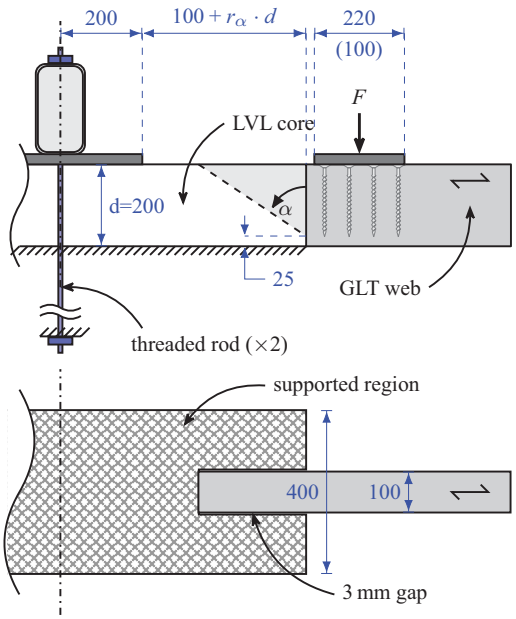

Figure 5: *Experimental set-up used for the study of both alternatives A and B*

Figure 6: *Realized experimental setup*

3.3 BONDING OF SPECIMENS

The bonding of alternative A was performed by applying an aminoplastic melamine-urea-formaldehyde (MUF) adhesive directly on the inclined surfaces of both, the GLT and LVL elements, and then evenly spreading the adhesive with a spatula. Hereinafter, the GLT beam was placed in its intended position, followed by the insertion of two to four partially threaded screws (depending on the geometry) to produce the required pressure. One or two screws were placed vertically, while the others were inserted in a direction perpendicular to the inclined surface. A dummy softwood plate, later removed, was placed below the LVL block in order to provide anchoring material for the threaded screw part.

The procedure followed to bond alternative B consisted on securing the GLT element in its position by means of screws and then sealing the vertical gaps between LVL and GLT by means of a special adhesive tape. Thereafter, the two-component epoxy adhesive was injected through predrilled holes until the gap was completely adhesive-filled.

All specimens were left to cure for at least two days before proceeding with the tests.

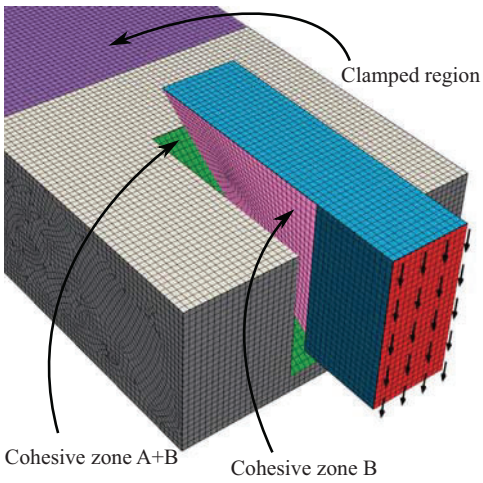

Figure 7: *Geometry, discretization of the implemented finite element model, together with the application of loads and definition of cohesive regions*

4 FINITE ELEMENT MODEL

A 3D finite element (FE) model was implemented with the Python API of the software Abaqus [1]. The model uses linear brick and wedge continuum elements of type C3D8 and C3D6, together with the elastic mechanical properties shown in Table 1. The length of the web beam was defined such that its outer end coincides with the center of the load application point. This reduces the amount of elements in the model and enables the load application in a more evenly distributed manner (see below).

An illustration of the discretization of the model is presented in Fig. 7, where the mesh size is about 20 mm. The bonded interfaces in both alternatives, A and B, were modelled with a cohesive behavior with stiffness parameters $k_n = k_t = 1000\,\mathrm{N/mm^3}$. The cohesive regions used for each alternative are shown in Fig. 7. The clamping condition was simulated by restraining the vertical displacement on a surface at the bottom face, according to Fig. 5, and at the top, while the load application was done by introducing a distributed vertical load on the outer vertical face of the GLT element (see Fig. 7).

The results were saved in the ASCII format (*.fil) and later post-processed with the Python library Pybaqus [19]. The scripts used for this paper are available in [20].

5 EXPERIMENTAL AND NUMERICAL RESULTS

5.1 FEM RESULTS

5.1.1 Shear stresses on the bonded surfaces

The FE model was used to inspect the distribution of shear stresses on the bonded surfaces. Figures 8a and 8b show the shear stresses obtained for r_α = 1:1.5 for alternatives A and B, respectively. It can be seen that the stresses on alternative B (side bonding) are more evenly distributed and reach lower maximum values than for the case of alternative A. Specifically, the stresses on alternative A reach values about two times higher (see Fig. 9). In general, this is an expected result, which is owed to the larger bond surface of alternative B.

Table 1: *Elastic material stiffness properties used for the FEM simulations*

Material	E_0 * [MPa]	E_{90} [MPa]	ν_{12} [–]	ν_{23} [–]	G [MPa]	G_r [MPa]
CLT[1)]	11 000	370	0.2	0.02	690	50
LVL[2)]	12 800	2000	0.2	0.02	430	43

[1)] acc. to values in [6] for softwood boards strength class C24 as indicated in [7]

[2)] acc. to values in [5, 21] (except ν_{ij})

* E_0: MOE parallel to fiber; E_{90}: MOE perpendicular to fiber; G: shear modulus; G_r: rolling shear modulus; $\nu_{12} = \nu_{13}$: Poisson coefficient between the fiber direction and the other two orthogonal directions; ν_{23} Poisson coefficient between both directions perpendicular to the fiber direction.

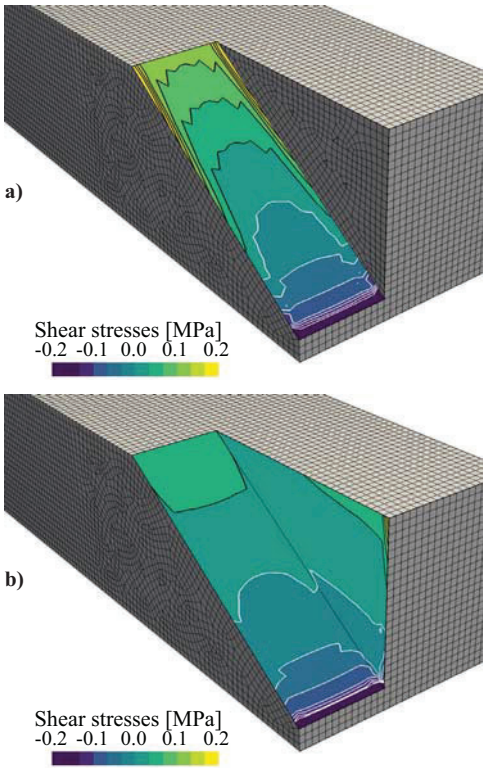

Figure 8: *Shear stresses on the bondfaces for a ratio r_α = 1:1.5; (a) Alternative A; (b) Alternative B*

5.2 EXPERIMENTAL RESULTS

5.2.1 General behavior

The general behavior of the tested specimens can be described with the help of Fig. 10a–c, where the load-displacement curves corresponding to the averaged measurements of front and back LVDT's are presented. These LVDT's measure the relative vertical displacement between GLT and LVL elements (see Fig. 6). The load-displacement responses of the specimens of type A presented mostly a perfectly linear behavior until the maximum load was

https://doi.org/10.52202/069179-0388

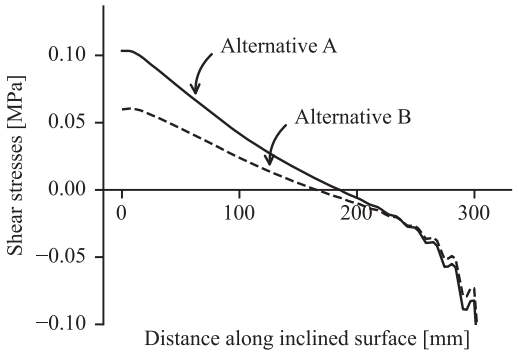

Figure 9: *Shear stresses along the longer dimension of the inclined bonded surface for both alternatives with r_α = 1:1.5 (applied load of* 1 kN*)*

Table 2: *Maximum capacities reached by each specimen*

r_α	Alternative A [kN]	Alternative B [kN]
1:1	20.0	106.1
1:1.5	31.4	122.5
1:2	31.2	119.6

reached, followed by a very brittle failure. The exception was Specimen A-1, which presented a clear stiffness reduction at about 10 kN, thereafter exhibiting a rather nonlinear behavior. The global failure was characterized by the complete de-bonding of the GLT from the LVL element (see Figs. 11a–c).

The behavior of specimens of type B presented a clear nonlinear behavior beyond about 40 % to 50 % of ultimate capacity, then showing a progressively decreasing stiffness for higher loads. The type of post-peak behavior varied for each specimen, where Specimen B-1 (r_α = 1:1) presented the most brittle behavior and Specimen B-3 (r_α = 1:2) showed an almost perfectly plastic behavior. Specimen B-2 (r_α = 1:1.5) lays in-between specimens B-1 and B-3 regarding the post-peak behavior.

Regarding the maximum capacities, Specimens B-2 and B-3 present a similar level ($F \approx 120$ kN), while Specimen B-1 showed a lower value of F = 106 kN. The maximum loads achieved by each specimen are summarized in Table 2. In general, the specimens of type B reached maximum capacities about four to five times larger than specimens of type A. This is an expected results, as the specimens of type B (bonded on the side-faces) not only have a larger bond surface, but also present a more favorable bonding regarding the orientation of the fibers (in type A the fibers are mostly bonded on the end-grain).

5.3 COMPARISON WITH FE RESULTS

The dashed lines in Fig. 10b represent the load-displacement results obtained by the FE model. While a good agreement can be observed for alternative A, the calculated stiffness for alternative B is clearly underestimating the experimental results. This discrepancy might

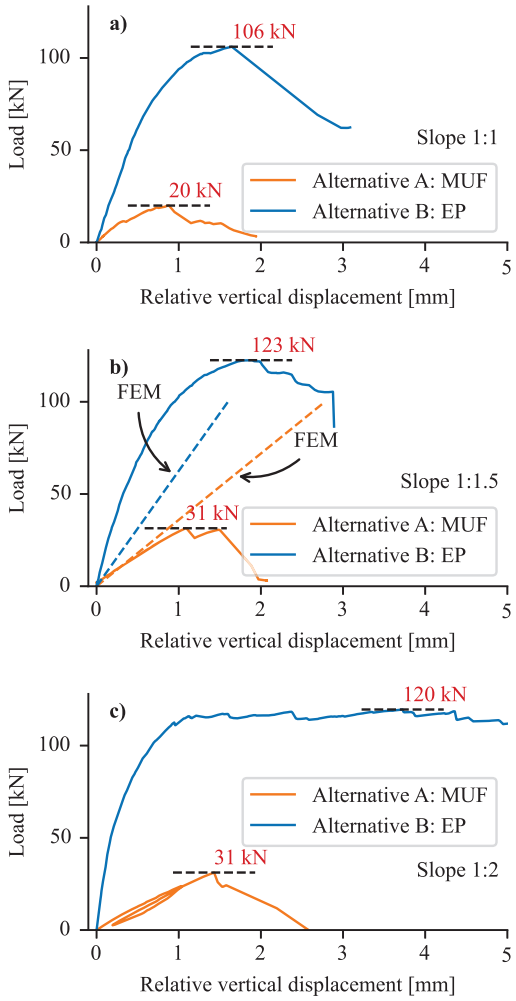

Figure 10: *Load-displacement curves and maximum capacities with data from LVDT's measuring the relative vertical displacement between GLT and LVL for the different investigated alternatives A and B; (a) slope r_α = 1:1; (b) slope r_α = 1:1.5; (c) slope r_α = 1:2*

be explained by the simplification of the load application in the model with respect to the actual load application, as shown in Fig. 5. The numerical corroboration of this effect was left out of this paper due to time constraints.

5.4 ACHIEVED QUALITY OF THE BONDFACES

The bondfaces of the three specimens corresponding to alternative A can be seen in Fig. 11a–c. All surfaces were fully detached immediately after reaching maximum load, as can be suspected from the rather brittle behavior observed. Based on the amount of fiber breakage present, it can be stated that the quality of the bonding was rather poor, as large regions with blunt failures can be seen. This means that the relatively low maximum capacities obtained by the specimens of type A are strongly influenced by the difficulty associated to this kind of bonding.

6 DISCUSSION

6.1 SUITABILITY FOR THE LARGE DEMONSTRATOR BUILDING

Although the connection of type B achieves clearly a better performance than alternative A, the suitability of both alternatives should be assessed based on the requirements for the connection in a real case-study. In this paper, the "Large-Scale Construction Robotics Laboratory" (LCRL)—a building set to apply the different research outputs from the IntCDC Cluster—is used as an example by considering the maximum design loads at the position of the column supports. According to the current state of the design of this building, the column has to resist a maximum design shear force of 753 kN. Considering a total of eight such web elements embedded in a radial pattern around the LVL core element, it is clear that the experimental capacities from alternative A do not reach the needed requirements for the connection. Therefore, alternative B should be preferred in this case.

6.2 GEOMETRY ADJUSTMENTS

Having done the experiments and considering the clearly better results obtained for alternative B, a logical next step is to simplify the connection by removing the inclined bondface altogether. Then, the web would have a typical prismatic shape and would be embedded into the LVL core by means of the same procedure used for alternative B. Experiments to assess this idea are underway and their results will be used to plan a full sized prototype of the slab system.

7 CONCLUSIONS AND OUTLOOK

This paper presented the current state of the slab system developed within the IntCDC Cluster at the University of Stuttgart. In particular, the connection of the shear web elements to the LVL core was investigated by analyzing different geometries and bonding strategies. Based on the experimental and numerical results, as well as on the experience gained from manufacturing the tested specimens, the following conclusions can be stated:

1. The bonding of the lateral faces (alternative B) delivered between four and five times larger maximum capacities in the connection.
2. Based on preliminary design loads for a planned demonstrator building, the rather low capacities exhibited by alternative A do not meet the requirements for the intended use case, thus alternative B should be preferred.
3. The rather low capacities achieved by alternative A, are due to an inferior bonding quality, as could be corroborated in a post-mortem analysis of the specimens.
4. The visualization of the shear stress distribution on the bond faces by means of FE simulations revealed rather uniformly distributed stresses for alternative B, providing additional evidence for the better suitability of side bonded faces for this application.
5. Based on the experimental results, the geometry of the connection will be simplified, removing the inclined surface to increase the lateral bonding surface.

ACKNOWLEDGEMENTS

The presented ongoing research is partially supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – EXC 2120/1 – 390831618. Likewise, the authors would like to thank Thomas Mantzel, Simon Schmid and the team at Züblin Timber (Aichach) for their support.

R&D PROJECT FOR TECHNOLOGIES ABOUT MID- AND HIGH-RISE TIMBER CONSTRUCTION IN JAPAN

Takahito Tsuchimoto[1], Nobuhiko Akiyama[2], and Yoshihiro Yamazaki[3]

ABSTRACT: The share of the timber construction per building area in the low-rise building was increased, but that in the mid- and high-rise building has never grown so much. Then, we conducted the R&D project for the technologies about mid- and high-rise timber construction in Japan. As a results, the performance evaluation method under the load duration of the wood-based composite components and the design method of the semi-rigid glulam frame jointed by drift pins with inserted steel plate were developed. The good results or the effective technical datum for the future implementation of the mid- and high-rise timber construction.

KEYWORDS: Duration of load, CLT panel construction, Design method for ultimate capacity of glulam frame

1 INTRODUCTION

The Act for Wood Use Promotion in Public Buildings was established at 2010 and revised as The Act for Wood Use Promotion to Contribute Realization of Carbon-Free Society at 2021. After 2010, the share of the timber construction per building area in the low-rise building was increased, but that in the mid- and high-rise building has never grown so much. Then, we conducted the R&D project for the technologies about mid- and high-rise timber construction in Japan. The summary of the following 4 themes which the project has focused on are reported in this paper;

1) The performance evaluation method of the wood-based composite components based on the element.
2) The ultimate capacity design of glulam semi-rigid frame and the possibility of the GLT mass timber.
3) The various performance evaluations of the mid-rise wood frame construction using the full-sized 6-story 2x4 testing building.
4) The studies on the simple structural design method for the CLT panel construction and the various performance evaluations using the full-sized test house.

2 PERFORMANCE EVALUATION OF WOOD-BASED COM-POSITE COMPONENT BASED ON ELEMENT

2.1 BACKGROUNDS

The performance evaluation methods for the I-joist which are provided as the designated building materials in Building Standard Law of Japan (hereinafter, "BSL") are specified in the Ministry of Construction Notification No. 1446 of 2000 as the methods based on only tests or that of estimating from the quality of the elements. However, the estimation methods were not clarified and rarely used for the accreditation of Minister of Land, Infrastructure, Transport and Tourism.

It is known that the performance under short-term load can be estimated from the performance of the elements employing the classical strength of materials method. But, it is unknown that those against long-term load can be estimated by the element.

2.2 COEFFICIENT OF DURATION OF LOAD

Therefore, as the one of the typical I-joist, that with 235 mm depth consist of the flange of LVL and the web of OSB were subjected to evaluate the coefficient of duration of load. The flange of 53 x 36 mm LVL, the web of 9.5 mm thick OSB and I-joist were subjected to the creep failure tests, as shown in Photo 1. As a result, the adjustment coefficient with respect to load duration of OSB, LVL and I-joist were 0.62-0.69, 0.73 and 0.72, respectively. The details of test conditions and results would be reported by Dr. R. Takanashi[1]. It was clarified that the adjustment coefficient with respect to load duration might be determined by those of elements whose failure occurred under the static load.

Photo 1: *Tests to evaluate the duration of load for (a) the flange of LVL, (b) the web of OSB and (c) I-joist.*

3. THE ULTIMATE CAPACITY DESIGN OF GLULAM SEMI-RIGID FRAME

3.1 BACKGROUNDS

In the high seismic country Japan, BSL requires that all buildings have to prevent to deform beyond the damage

[1] Takahiro Tsuchimoto, Building Research Institute (BRI), Japan, tutti@kenken.go.jp
[2] Nobuhiko Akiyama, National Institute for Land and Infrastructure Management (NILIM), Ministry of Land, Infrastructure, Transport and Tourism (MLIT), Japan, akiyama-n92rg@mlit.go.jp
[3] Yoshihiro Yamazaki, Building Research Institute (BRI), Japan, y_ymzk@kenken.go.jp

https://doi.org/10.52202/069179-0389

limit under the rarely occurred strong earthquake and that all building have to prevent to collapse under the extremely rarely occurred strong earthquake. In order to design the prevention of collapse, the designer needed to evaluate the ultimate capacity of structure.

3.2 SPECIMENS

Therefore, as one of the typical glulam semi-rigid frames, the estimation formula[2] of the drift pin joint with inserted steel plate was developed and verified in comparison with moment resisting joint tests on them. The specimens had variations in the diameter of pins, arrangements in rectangular or circle and the double or triple layouts, as shown Figure 1.

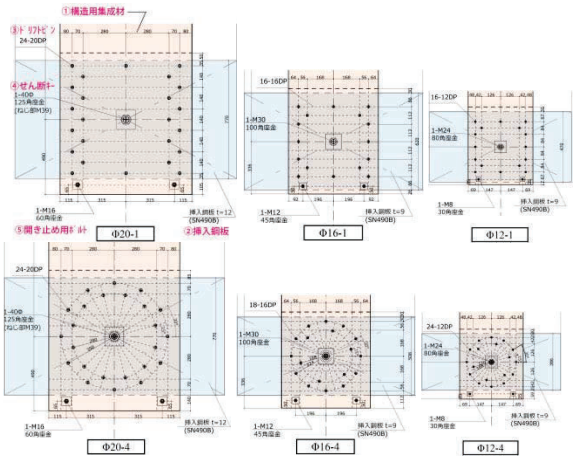

Figure 1: *Specimens of moment resisting joint of drift pins arranged in rectangular with inserted steel plate.*

3.3 TESTS AND RESULTS

The moment tests were conducted to them, as shown Figure 2. The positive and negative alternating load was applied to the top of specimen using an actuator and gradually increased to the failure of specimens. Several examples of the moment-rotational angle relations and typical fracture modes obtained by the tests were shown in Figure 3.

.

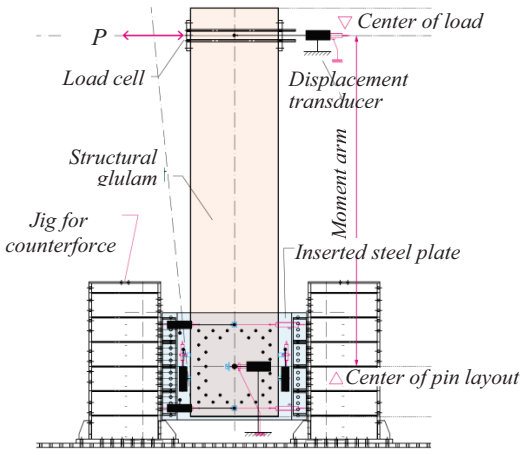

Figure 2: *Schematic diagram of the moment test for joint.*

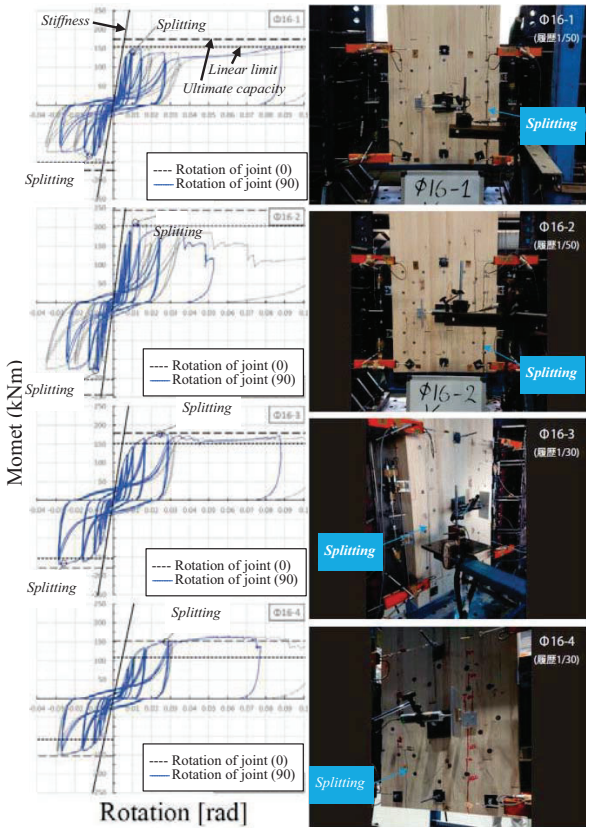

Figure 3: *Examples of* moment-rotational angle relations *and typical fracture modes of the moment test for joint.*

The plasticity factor μ was calculated from moment-rotational angle relations and compared with the depth of beam, as shown in Figure 4. Regarding the plasticity rate, the laminated timber thickness was 6.79 to 8.71 for 750 mm and 4.08 for 500 mm for the double circle, and the laminated timber thickness for the triple circle was 6.78 for 900 mm and 4.61 for 750 mm. Regarding the effect of the number of arrayed circles, the specimens with triple circle array tended to decrease the load earlier than those with double circles, resulting in a lower plasticity factor μ.

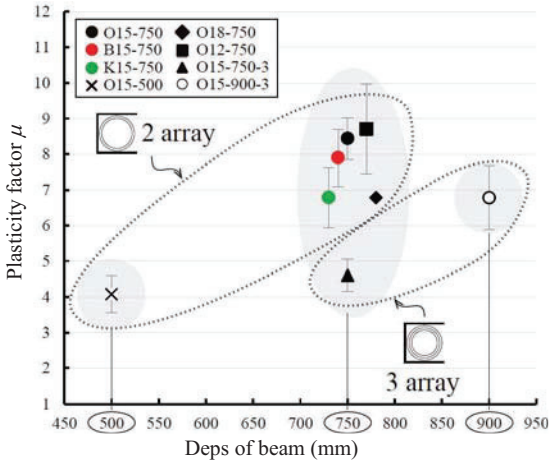

Figure 4: *Relationships between beam depth and plasticity factor μ.*

https://doi.org/10.52202/069179-0389

Then, the stiffness, the yield moment and ultimate moment calculated by the developed estimation formula [2] were compared with those obtained by the tests, as shown in Figure 5, 6 and 7, respectively.

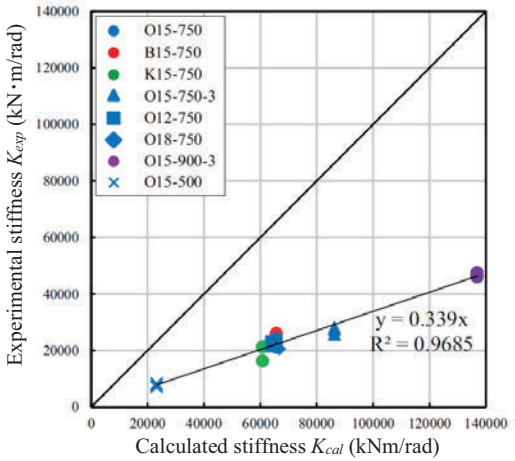

Figure 5: *Relationships between calculated and experimental stiffness.*

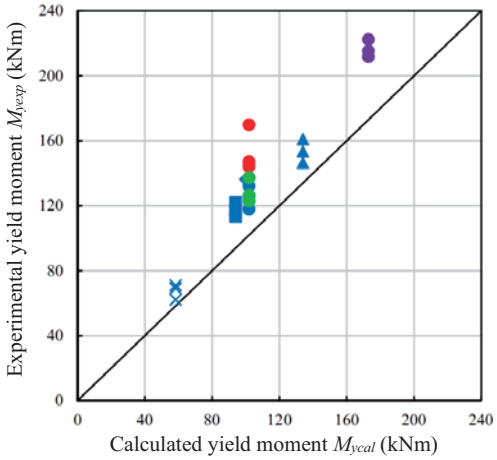

Figure 6: *Relationships between calculated and experimental stiffness.*

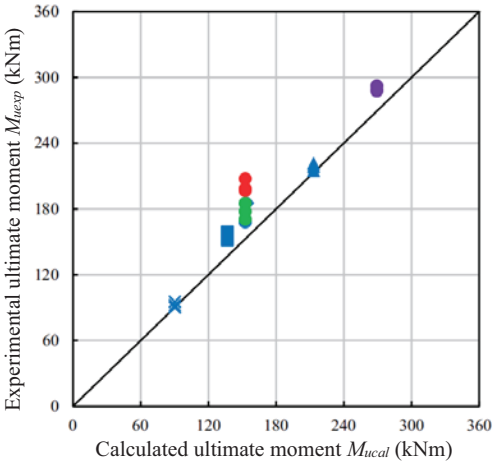

Figure 7: *Relationships between calculated and experimental stiffness.*

Regarding the possibility of estimating the rigidity, the ratio of the experimental value to the estimated value calculated assuming that there is no slip of the steel plate pin diameter + 1 mm tip hole is about 1/3. It was confirmed that the reduction rate indicated in the manuals was insufficient.

Regarding the estimation of yield strength, although Douglas fir was slightly higher, it generally showed high adaptability. It was suggested that a more rational evaluation method can be adopted than the method of setting the short-term allowable strength to 2/3 of the yield strength at which one of the connectors yields, which is written in conventional guidelines and manuals.

In addition, based on them, the evaluation method of the ultimate capacity for the semi-rigid glulam frame jointed by the drift pins with inserted steel plate were derived, and the validity was verified by the full-sized 2-story glulam frame as shown in Photo 2. Details are omitted due to space limitations.

Photo 2: *Tested full-sized 2-story glulam frame jointed by the drift pins with inserted steel plate.*

4 EVALUATION OF DUCTILITY FACTORS FOR TIMBER CONSTRUCTIONS

4.1 BACKGROUNDS

In high seismic country Japan, the ultimate capacity of building over a certain scale must be design under the extremely rarely occurred earthquake. In other words, it need be verified that the applied load or stress on the members, horizontal elements and joints under the base shear of 1.0 is not over the ultimate capacities of them. However, the applied load or stress can be decreased depending on the abilities of deformation. The factor indicating how much they can be decreased is called as Ds and provided in the Notification No.1791 of Ministry of Construction, 1980.

Although the Notification provides Ds according to the specifications of the frame and the L/D of joint, there is little technical knowledge on the relationships between the ductility of the joint or the frame and the Ds of the story. Therefore, these relationships were analysed numerically in this project.

Moreover, the Notification has never shown the Ds of the structure combined by parts with different ductility factor. Therefore, the Ds of the timber constructions combined by parts with different ductility factor were studied analytically in this paper.

https://doi.org/10.52202/069179-0389

4.2 NUMERICAL ANALYSES ON RELATIONS BETWEEN DUCTILITY OF JOINT AND GLULAM STRUCTURES

4.2.1 Analysis models

Three- and five-story semi-rigid frame, the brace and arch structure model in which elastic members are connected by rotation/axial springs were subjected to be analysed. Based on previous experimental data, three cases of high, medium and low capacity were set for the rotation / axial spring, as shown in Figure 8 as an example of a three-layer semi-rigid frame.

4.2.2 Analysis method

For the above-mentioned analysis models, (1) the pushover analyses were carried out, and the ductility factor of the structure, μs1 was obtained by applying the perfect elastoplastic model to the load-story drift curves with. (2) Nonlinear seismic response analyses were carried out, and the ductility factor of the structure, μs2 was obtained by the load-story drift curves. (3) The pushover analyses were applied to the contracted equivalent 1-DOF model of the analysis model, and the ductility factor of the structure, μs3 was obtained by the load-representative story drift curves.

4.2.3 Results and discussion

The relationships between the ductility factors of joint, μj set in the analysis models and those of structure, μs1, μs2, μs3 obtained by the analyses were shown in Figure 9(a), (b) and (c), respectively.

The semi-rigid frame, brace and arch structure model constructed by the joint with the 3-level capacity were subjected to the pushover analysis and others. As results of com-parison of the ductility factor of each structure calculated by the analyses with those of joint, the followings were obtained.

- The ductility factors of structure were usually lower than those of joints.
- The results of analyses on the contracted 1-DOF model were different from other 2 method of analyses.
- If the results of analyses on 3D model and the seismic response analyses were correct, the μ of arch would be lowest, the μ of semi-rigid frame would be relatively high, and the μ of brace would be various.
- Most of μs1 and μs2 were over the 0.5 x μ_j and below the 0.8 x μ_j, so the decreasing factor of seismic load under extremely rarely occurred earthquake may be able to be determined as the value of $(1.5 \times \mu_j - 1)^{-0.5}$ or more.

Notes: The legend of each plot is shown at the right end of (c), and its meaning is as follows. 1st letter shows the structure type of R: semi-rigid frame, B: brace and A: arch structure. 2nd figure shows the story of 3, 5 and 1. 3rd letter shows the joint capacity of H: high, M: medium, and L: low.

https://doi.org/10.52202/069179-0389

4.3 DUCTILITY FACTORS OF TIMBER CONSTRUCTIONS COMBINED BY PARTS WITH DIFFERENT DUCTILITY FACTORS

4.3.1 Analytical model and parametric study

From the past papers, the load-deformation relationships of the semi-rigid glulam frames, the shear walls, the brace systems and arch structure were picked up and modelled, as shown Figure 8. The vertical axis of it was normalised by the allowable capacity, Q_a. The semi rigid glulam frame was assumed as 3 variations with high, medium and low capacity. The shear wall was distinguished between the plywood and gyp-sum board. The brace system was distinguished between the glulam jointed by the drift pins with steel plate and jointed by the bolts. The arch structure was distinguished be-tween the curved glulam without joints and with some joints and straight glulam joint-ed by the drift pins. The ultimate capacity obtained by the bilinear model of the load-deformation relationships was defined as Q_u. The D_s of alone structure is no other than Q_a/Q_u. The D_s of medium glulam frame, SW with plywood and gypsum board and brace jointed by DP and bolts were 0.37, 0.609, 0.707, 0.505 and 0.244, respectively.

The combinations with variable load-deformation relationships, as mentioned above, were applied to the structural model which the summation of allowable capacity, Q_a is 1.0. The mixture ratio of the different load-deformation relationships was defined as β. The summation of the ultimate capacity of the different structure, Q_u was varied from 0.2 to 0.75. The time history response analysis were con ducted to the structural model till the ultimate state.

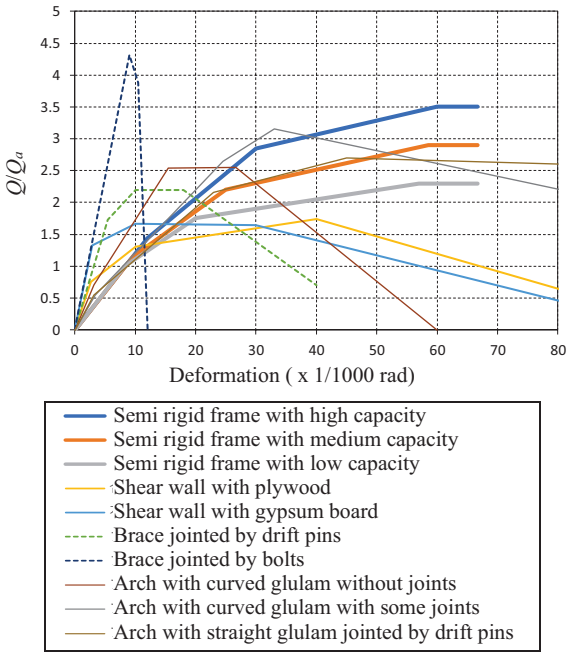

Figure 8: *The picked up and modelled load-deformation relationships.*

4.3.2 Result of parametric study

As a result of the parametric study, the response load-deformation relationships were obtained. When the maximum response deformation agreed with the ultimate deformation, the base shear was calculated by the results and defines as Cu. The Cu is no other than the ductility factor, Ds of combination structure after all. Some samples of Ds were shown in Table 1.

Table 1: *Examples of ductility factor Ds obtained by the analysis*

Glulam frame with medium capacity combined with		Shear wall with plywood	Shear wall with gypsum board	Brace jointed by drift pins	Brace jointed by bolts
Combination ratio β	0	0.34	0.34	0.34	0.34
	0.1	0.34	0.34	0.34	0.29

4.3.3 Conclusion

The ductility factor of timber constructions combined by parts with different ductility factor need to adopt the higher one. However, the case of combination with shear wall had a possibility to decrease the ductility factor still more.

5 6-STORY 2X4 TEST BUILDING

5.1 BACKGROUNDS AND OBJECTIVES

In Japan, there were few construction examples of the mid- and high-rise wood frame construction. High-capacity shear walls and fire-resistant structures have been developed for the mid- and high-rise buildings, however, they have never been constructed actually using them together. In addition, it was necessary to evaluate the performance of each part because the mid- and high-rise buildings were subject to heavy rain and winds, and flat roofs, which had not been implemented for low-rise buildings, were also constructed.

5.2 WORKABILITY

The test building was built in BRI (Photo 3) was completed in 2016 and employed the large amount of gypsum boards in order to satisfy the fire requirement by BSL. The construction of the frame wall construction is to lift and install the frame panels produced in the factory with the crane. The number of man-hours for each process was measured from the number of working days and the number of workers. It took a total of 100 working days and 666 manpower to construct the construction. The number of days and man-hours for each procedure were shown in Table 2. The workability of 0.14 man/m^2 is

https://doi.org/10.52202/069179-0389

about the same as the construction efficiency of a low-rise light frame construction house, but for a medium-rise building, 0.07 man/m^2 is required for marking to ensure construction accuracy. As a result, accuracy of 1 to 1.5/1000 was confirmed both horizontally and vertically after the completion of the framework construction.

This 6-story test building has two-hour fire resistance specifications (triple thick reinforced gypsum boards) on the 1st and 2nd floors, and one-hour fire resistance specifications (double one) on the 3rd to 6th floors. It took 252 man-days to install the large amount of gypsum boards, and they accounted 1/3 of total man-hours, as shown in Figure 10.

5.3 SINKAGE

The sinkage due to further drying of dimension lumbers or the creep behaviour under the dead and live load is one of the important problems on mid-rise 2x4 construction. It was measured by the displacement transducer set at the end of the wire which was hang from each story to the base, as shown Figure 11.

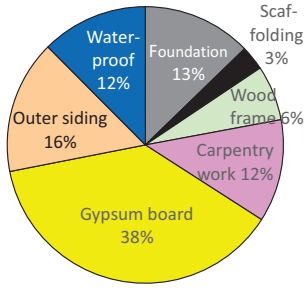

Figure 10: *Distribution of working time of each process.*

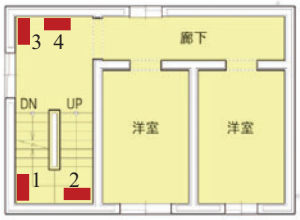
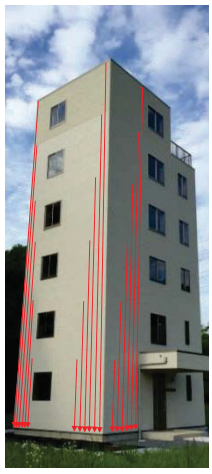
Among the measurement results of the sinkage, the measured value of No. 4 is shown as a typical example in Figure 11. It was gradually increased within 1 mm per story, but settled down over 1 year after.

(a) Displacement transducer



(b) The position of sensors (1-4)



(c) Image of wires

Figure 11: *Measuring methods of sinkage.*

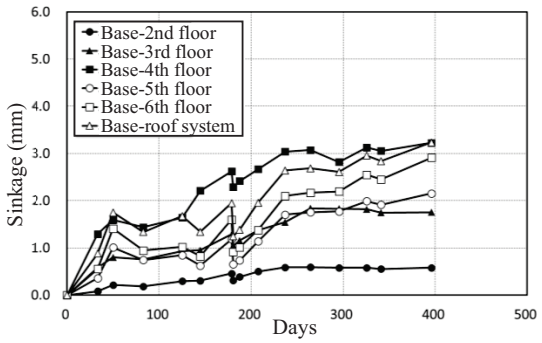


Figure 12: *Sinkage of 6-story 2x4 construction.*

5.4 VERIFICATION OF WATERPROOFING OF FLAT ROOF

The flat roofs are often used for the roofs of mid-rise wooden buildings. Moisture, such as rainwater, acts before waterproofing construction and may be confined by waterproofing layer. Contained moisture conditions that are maintained for long time are likely to cause biodegradation of the structural members.

https://doi.org/10.52202/069179-0389

Therefore, a grid-like ventilation groove was provided in the insulation material to be installed on the roof base material, and this groove was used to discharge moisture from the roof base material to the outside from the deaerator, as shown Figure 13. The water was intentionally sprinkled on the flat roof before waterproof, as mentioned above. The humidity sensors were installed near the grooves of the insulation at every 1 m from the deaerator to measure the humidity continuously. On the other hand, the flat roof balcony without deaerator was subjected to measure the humidity near the grooves of the insulation as a control.

The relative and absolute humidity under the waterproof layer of the flat roofs and the roof balconies decreased regardless of the presence or absence of the deaerator. The humidity of the flat roof with the deaerator reduced faster than the roof balcony without the deaerator. It was clarified that the deaerator installed at the flat roof contributed to the improvement of the moisture emission rate.

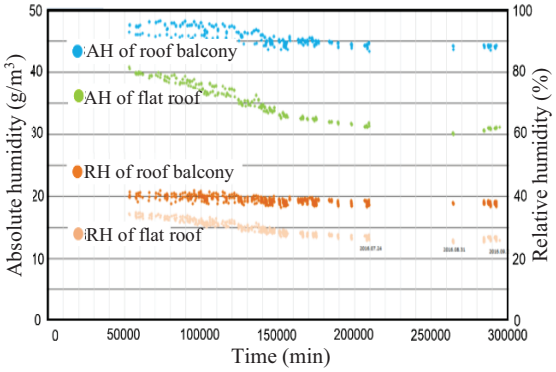

Figure 14: *Time history change of absolute and relative humidity at the flat roof with deaerator and the roof balcony without it.*

5.5 CONCLUSIONS OF 6-STORY 2X4 TEST BUILDING

Through the constructing the 6-story 2x4 test building and the trials to evaluate the various performance, results are summarized as follows:

- The workability of 6-story 2x4 construction is about the same as the construction efficiency of a low-rise light frame construction house.
- The man-hour to install the many gypsum boards accounted 1/3 of the total.
- The sinkage was gradually increased within 1 mm per story, but settled down over 1 year after.
- The deaerator installed at the flat roof contributed to the improvement of the moisture emission rate.

In addition to those, the good results or the effective technical data for the future studies were obtained by the measuring of the seismic response under strong ground motion[3], the water-proof performance of window sash in higher story, the floor impact sound insulation[4] and others.

6 CLT TEST HOUSE

The 2-story CLT test house, as shown in Photo 4, was built in BRI for the experimental construction and the various performance evaluation of the CLT panel construction which had little experienced in Japan. The good results or the effective technical data for the future studies were obtained by the measuring of the dimension stability and the mechano-sorptive deformation of CLT panel, the air tightness, the desorption behaviour of the humid shut in the waterproof layer, the floor impact sound insulation and others.

Photo 4*. 2-story CLT test house in BRI.*

7 CONCLUSIONS

As mentioned above, we have conducted the R&D project for technologies about mid- and high-rise timber construction in Japan in order to grow up the share of the timber construction in the mid- and high-rise building. The results are summarised as follows:

- Through the creep fracture tests on the I-joists and their elements, the adjustment coefficient with respect to load duration of the I-joist might be determined by those of elements whose failure occurred under the static load.
- The developed estimation formula of the yield and ultimate capacities of the moment resisting joint using the drift pin with inserted steel plate was verified by the moment tests on them.
- As the results of the numerical analyses on the relations between ductility factors of joint and glulam structures, it was clarified that the ductility factors of the semi-rigid frame was lower than those of their joints generally, the results of pushover analysis with 1-DOF model were different from those with 3D

https://doi.org/10.52202/069179-0389

model and seismic analysis and the results of the nonlinear seismic response analyses, and others.

- As the results of the ductility factors of the timber constructions combined by parts with different ductility factors, it was clarified that such construction needed to adopt the higher one. However, the case of combination with shear wall had a possibility to decrease the ductility factor still more.
- Through the constructing of 6-story 2x4 test building and the measuring of various performance of it, the results are summarised in section 5.5.

ACKNOWLEDGEMENT

A part of this research was funded by the Public/Private R&D Investment Strategic Expansion Program of Cabinet Office. The studies on 2x4 and CLT testing building were conducted as one of the collaborative research with Japan 2x4 Home Builders Association and Japan CLT Association, respectively. We would like to thank the people concerned.

A PROPOSAL FOR THE MECHANICAL CLASSIFICATION OF BEAM-TO-COLUMN JOINTS FOR TIMBER STRUCTURES

Giacomo Iovane, Celeste Noviello, Federico M. Mazzolani, Raffaele Landolfo, Beatrice Faggiano

ABSTRACT: The performance of timber structures is greatly influenced by the capacity of the connections, in terms of both strength and stiffness, as well as ductility. Reliable estimations of the structural behaviour of timber buildings is possible through a full understanding of the joint behaviour. At present there is not a standard method that allows to identify the mechanical behaviour of timber connections. To fill this gap, in this paper, a procedure for the classification in terms of strength and stiffness of beam-to-column joints in timber structures is presented. The method is inspired to that one related to steel connections according to Eurocode 3. Then, with reference to a number of experimental studies available in the scientific literature on several timber beam-to-column joints, the proposed classification method is applied on typical configurations, evidencing that common joints can be classified as pinned or semi-rigid.

KEYWORDS: Timber structures, moment resisting frames, beam-to-column joints, joint mechanical classification.

1 INTRODUCTION

In timber constructions, joints have great influence on both local and global structural behaviours. Indeed they realize the constraints and restraints conditions of the structural systems, which the structural models for a reliable estimation of the internal forces and deformations are based on. Therefore a full understanding of the joint mechanical properties, such as strength, stiffness and also ductility, is essential. It is also worth to notice that timber members sizes can be determined by the number and type of connectors rather than by the strength requirements for members.

With regards to Moment Resisting Frames (MRF), several experimental studies have been recently carried out on common timber beam-to-column joints, aimed at evaluating the strength and stiffness capabilities [1-9].

However, both in national and international standards, there is not a method that allows to identify the mechanical behaviour of timber connections. To this purpose the moment-rotation relationship should be characterized.

In this paper, a procedure for the classification in terms of strength and stiffness of beam-to-column joints for timber structures is presented. The method is inspired by the classification procedure for steel connections, consolidated and well described in the Eurocode 3 part 1.8 [10], conveniently adapted according to timber connections characteristics. Then, with reference to several experimental studies available in the scientific literature, common configurations of timber beam-to-column connections, whose experimental moment rotation curves were available, have been classified in terms of stiffness by means of the proposed method.

2 JOINT MECHANICAL CLASSIFICATION ACCORDING TO EUROCODE 3

As indicated in section 6.1 of EC3 part 1-8 [10] for steel constructions, the mechanical model of a joint may be represented by a rotational spring joining the centre lines of the connected members at the point of intersection, for a single-sided beam-to-column joint configuration. The properties of the spring can be expressed in terms of moment-rotation (M-θ) characteristic that describes the relationship between the bending moment $M_{j,Ed}$ applied to the joint and the corresponding rotation θ_{jEd} between the connected members (referring to the j-th member).

The design moment-rotation characteristic should define the following three main structural properties:

- bending moment resistance ($M_{j,Rd}$);
- rotational stiffness (S_j);
- rotational capacity (θ_j,).

The complex mechanical behaviour of joints in terms of strength, stiffness and rotational capacity can be determined through the component method (section 6.1, [10]). The joint is analysed as an assembly of components, whose mechanical behaviour is studied separately, and the design resistance of the joint is assumed as the resistance of the weakest joint component, with reference to all the possible collapse modes.

According to Eurocode 3, part: 1-8 [10], in order to identify the effects of joint behaviour on the global structural analysis, three simplified joint models can be distinguished (Tab. 1): 1) *simple joints*, the joint may be assumed not to transfer bending moments; 2) *continuous*

Giacomo Iovane, giacomo.iovane@unina.it; Celeste Noviello, ce.noviello@gmail.com; Federico M. Mazzolani, fmm@unina.it; Raffaele Landolfo, landolfo@unina.it; Beatrice Faggiano, faggiano@unina.it; University of Naples Federico II, Department of Structure for Engineering and Architecture, Via Claudio 21, 80125, Naples, Italy

https://doi.org/10.52202/069179-0390

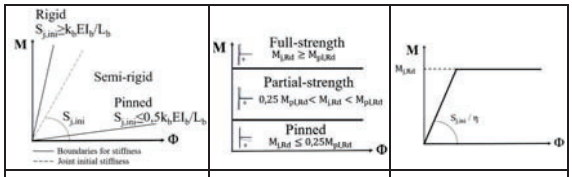
joint, the joint may be assumed to transfer the bending moments; 3) *semi-continuous joints*, the joint transfers the bending moments in some extents according to the joint rotational stiffness.

***Table 1**: Type of joint model [10].*

Method of analysis	**Classification of joint**		
Elastic	Nominally pinned	Rigid	Semi-rigid
Rigid-plastic		Full-strength	Partial-strength
Elastic-plastic		Rigid and full-strength	Semi-rigid and partial-strength; Semi-rigid and full-strength; Rigid and partial-strength
	Simple	*Continuous*	*Semi-continuous*
Type of joint model			

With reference to the Moment-rotation (M-θ) relationship, beam-to-column connections can be classified considering three different methods of structural analysis:

a) *elastic analysis*, based on a linear Moment-rotation (M-θ) relationship, where joints are classified according to rotational stiffness S_j (Fig. 1a);
b) *rigid-plastic analysis*, where joints are classified according to strength, provided that they are able to develop suitable plastic rotation (Fig. 1b);
c) *elastic-plastic analysis*, based on a bi-linear M-θ relationship, in which joints are classified according to both stiffness and strength, considering also the rotational capacity (Fig. 1c).



a) b) c)

***Figure 1:** The EC3 joint classification in terms of a) stiffness, b) strength and c) stiffness and strength.*

It is worth noted that the stiffness of the connection should be compared to the stiffness of the connected members. Therefore the joint classification by stiffness can be expressed in terms of a non-dimensional stiffness parameter $\bar{k}$ (eq. 1), depending on the ratio between the initial joint rotational stiffness $S_{j,ini}$ and the bending stiffness of the connected beam (Fig. 1a):

$$\bar{k} = \frac{S_{j,ini}}{\left(\frac{E_S \cdot I_b}{L_b}\right)} \quad (1)$$

where $S_{j,ini}$ corresponds to the elastic bending moment $M_{j,el}$, not exceeding 2/3 $M_{j,Rd}$ ($M_{j,Rd}$ being the design bending strength of the joint), and to the rotation at the elastic limit $\theta_{j,el}$, L_b is the beam span, E_s is the steel elastic modulus and I_b is the beam cross-section moment of inertia. Therefore a joint can be classified as nominally pinned if $\bar{k} \leq 0.5$; semi-rigid if $0.5 < \bar{k} < k_b$; rigid if $\bar{k} \geq k_b$, with $k_b = 8$ for braced frames and $k_b = 25$ for moment resisting frames (Tab. 1). A nominally pinned joint shall be capable of allowing rotations due to design loads and transmitting internal forces, without developing significant bending moments; a rigid joint shall be capable of having a sufficient rotational stiffness to assume the continuity; a joint which does not meet the criteria for a rigid or a nominally pinned joint should be classified as a semi-rigid joint (Fig. 1a).
A joint is classified by strength (rigid-plastic analysis), depending on the ratio between the bending strength $M_{j,Rd}$ of the joint and the bending strength of the connected beam $M_{b,Rd}$ (Fig. 1b; eq. 2), namely the non-dimensional moment resistance parameter (eq. 2):

$$\bar{m} = \frac{M_{j,Rd}}{M_{b,Rd}} \quad (2)$$

Therefore, a joint can be classified as nominally pinned if $M_{j,Rd} \leq 0.25\ M_{b,Rd}$, partial strength if $0.25\ M_{b,Rd} < M_{j,Rd} < M_{b,Rd}$ ($0.25 < \bar{m} < 1$), full strength if $M_{j,Rd} \geq M_{b,Rd}$ ($\bar{m} \geq 1$, Tab. 1).
In a joint classification according to both stiffness and strength (elastic-plastic analysis), as a simplification of the non-linear moment-rotation behaviour, a bi-linear design moment-rotation characteristic may be adopted (Fig. 1c). Therefore, a joint can be classified as semi-rigid and partial-strength; semi-rigid and full-strength or rigid and partial-strength (Tab. 1). As a simplification, the rotational stiffness can be evaluated as $S_{j,ini}/\eta$ (Table 5.2, section 5.1.2 [10]), where η is a coefficient reliant on the connection type.

3 CLASSIFICATION BY STIFFNESS OF TYPICAL TIMBER BEAM-TO-COLUMN JOINTS

3.1 PROPOSED CLASSIFICATION METHOD FOR TIMBER BEAM-TO-COLUMN JOINTS

For the classification of timber joints, it is possible to apply the same method used for steel connections, conveniently modified to consider the timber material characteristics. In particular, the extension of the EC3 classification to timber joints is based on considering the elastic bending strength of the timber beam, $M_{b,el}$, and the timber elastic modulus, E_T.
The steel EC3 formulations for the joint classification in terms of stiffness ($S_{j,ini}$) and strength ($M_{j,el}$) can be suitably revised, by defining the non-dimensional stiffness and strength parameters $\bar{k}$ and $\bar{m}$, as it follows (Eq. 3, 4):

$$\bar{k} = \frac{S_{j,ini} \cdot L_b}{E_T \cdot I_b} \quad (3)$$

$$\bar{m} = \frac{M_{j,Rd}}{M_{b,el}} \quad (4)$$

where $S_{j,ini}$, $M_{j,el}$, $M_{j,Rd}$, $M_{b,el}$ and L_b have been previously defined, E_T is the timber elastic modulus, I_b is the timber beam cross-section moment of inertia.

https://doi.org/10.52202/069179-0390

3.2 APPLICATION OF THE PROPOSED CLASSIFICATION METHOD TO LITERATURE TIMBER BEAM-TO-COLUMN JOINTS

3.2.1 Case studies of beam-to-column joints

From the literature review on experimental campaigns, four recurring types of timber beam-to-column joints can be identified (Fig. 2, 3, 4):

Type 1. Connection with internal or lateral vertical steel plate (rectangular- or T-shaped) and connectors (generally bolts, screws or pins; [3-5, 11-14])

Type 2. Connection with circular arrangement of connectors (generally bolts or screws; [5, 15]);

Type 3. Connection with top and bottom plates or brackets and connectors (generally bolts or screws; [1, 16]);

Type 4. Timber joint equipped with steel link [2, 17, 18].

A total of 46 joints are examined. In particular, for each joint type, the specimens are represented in Figures 2-4 and the number of tests carried out for each type, as well as the beam and column members sizes are provided in Table 2.

Among Type 1 joints, Wang et al. [4] have studied a beam to column joint with internal T-shaped 9.5mm thick steel plate (S235 steel grade) and bolts (M20, 8.8 steel grade), as base specimen S1, specimen S2 reinforced with screws orthogonal to the grains of the beam and column; specimen S3 locally made with cross-laminated glulam timber. The S2 and S3 specimens show increased stiffness and strength as respect to S1. A similar beam to column joint with internal T-shaped 10mm thick steel plate (S235 steel grade) and M16 bolt (8.8 grade), is studied by He and Liu [3], as base specimen S1, specimen S2 reinforced with bars, specimen S3 reinforced with self-tapping screws, in both cases arranged orthogonal to the grains of beam and column. The stiffnesses result quite similar. He et al. [12] analysed the same joint reinforced with hollow PVC tubes in the holes of the timber elements and with screws orthogonal to the grains. These reinforcements led to an increase in strength and stiffness as respect to the non-reinforced specimen. Beltran [5] tested a beam to column joint configuration with internal T-shaped 6.35mm thick steel plate (ASTM A36 steel grade) and connected bolts in a rectangular arrangement (M12, ASTM A325 steel grade). Salem and Petrycki [13] studied a beam to column joint with two external steel plates for evaluating the influence of the number of bolts (M20, ASTM A325 steel grade) and of the edge distance on the strength and stiffness. In particular, four different types of connection have been tested: edge distance equal to 4ϕ (where ϕ is the bolt diameter) and 3x4 bolts (in a rectangular arrangement); edge distance equal to 4ϕ and 3x6 bolts; edge distance equal to 5ϕ and 3x4 bolts; edge distance equal to 5ϕ and 3x6 bolts. The same specimens are tested by using a T-shaped steel plate by Salem [14]. The variation of the edge distance from 4 to 5 ϕ provides a larger increase of bending moment resistance than the variation of the bolts number from 4 to 6. The reverse happens with the internal steel plate. However, in general, from the test results, a low variation of stiffness among the specimen can be observed.

Wang et al. [11] have studied a post-tensioned (PT) energy dissipating beam to column joint, to provide self-centering capacity, connected with a T-shaped steel plate and bolts (M16-20). In particular, two specimens are tested, by varying the post-tensioned force applied to the steel strand (S1=40kN; S2=60kN). The joints shown similar stiffnesses (Fig. 2).

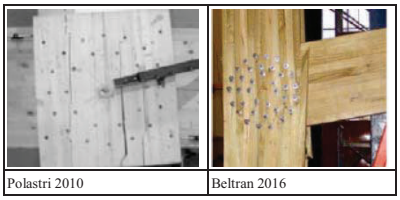
	He et al. 2016	
Salem and Petrycki 2016	Salem et al. 2016	Wang et al. 2016

Figure 2: *Type 1 literature beam-to-column testing joints .*

Among Type 2 joints, Polastri [15] have tested different types of connection: beam to column joint configuration connected with pins (M12, 14, 16) in single (T01) and double (T08, T09) circular arrangements, with glued bars in single (T06) and double (T10) circular arrangements, as well as with a glued connection between timber members (T07). As a result, the glued connections (T06, T10) show higher stiffness and strength as respect to the other connection types. Beltran [5] have tested a beam-to-column joint with two different types of connection: bolts in a circular arrangement (M9, ASTM A307 steel grade); internal T-shaped 6.35mm thick steel plate (ASTM A36 steel grade) connected with bolts with different diameter, steel grade and arrangement (Fig. 3).



Polastri 2010	Beltran 2016

Figure 3: *Type 2 literature beam-to-column testing joints.*

Among Type 3 joints, Kasal et al. [1, 16] have tested a beam to column joint with two L-shaped aluminium angles located at the beam end top and bottom, connected to the beam through inclined self-tapping screws and to the column with horizontal self-tapping screws (Φ6.5-12mm), and a beam to column joint with two timber

https://doi.org/10.52202/069179-0390

rectangular-shaped plates connected to the beam end top and bottom through inclined self-tapping screws and to the column with horizontal self-tapping screws (Φ6.5-12mm). Both the connections have shown good values of stiffness and strength (Fig. 4).

Type 4 joints have been conceived for seismic dissipative structures to delegate the dissipation capacity to the steel link, avoiding the failure of connections and timber members, which should remain in elastic field in case of earthquake. By integrating the timber technology with steel devices, some authors have proposed different solutions. Andreolli [17] have focused on 8 beam to column joint assemblages equipped with steel link (HE120B profile) connected to the beam by means of 4 glued threaded bars (M16, 6.8 grade, 540mm long), for investigating the joint behaviour with variable end-plate thicknesses (6-8-10-15-20mm). At the end of the tests, joints with large thickness of steel plate have reached higher stiffness and dissipative capacity through the plastic combined tensile-bending deformation of the bars and the bending deformation of the end-plate. Nakatani et al. [2] have tested a beam to column joint equipped with a box steel link connected by means of lag-screw-bolts embedded into the beam parallel to the grain and into the column in 3 different configurations: perpendicular to the grain; perpendicular and with a skew angle as respect to the grain; with a skew angle as respect to the grain. Joints with greater connector inclination have exhibited increased stiffness and strength, with a bolts pull-out failure. Gohlich and Erochko [18] have studied a beam to column joint equipped with steel link connected to the timber members by means of inclined screws, also varying the link profile and the inclination of connectors: dog-bone W250x28 steel profile with 45° inclination screws (Φ10,12mm SWG ASSY); dog-bone W250x28 steel profile with 30° inclination double screws; W200x25 steel profile with 45° inclination screws; W200x25 steel profile with 30° inclination double screws . The joints with dog-bone profile have shown a better performance in terms of both stiffness and ductility than the other connection types (Fig. 5).

Figure 5: *Type 4 literature beam-to-column testing joints .*

3.2.2 Classification of the joint case studies

For the study joints, the initial rotational stiffness ($S_{j,ini}$), the joint elastic bending moment ($M_{j,el}$) and the corresponding rotation ($\theta_{j,el}$) are evaluated starting from the Moment-rotation (M-θ) experimental curves from literature, according to the proposed method. The mechanical parameters are indicated in Table 3.

Moreover, the reference initial rotational stiffnesses for a pinned joint $S_{j,pinned}$ (eq. 5) and a rigid joint $S_{j,rigid}$ of a moment resisting frames (eq. 6) are calculated as it follows and given in Table 3:

$$S_{j,pinned} = \frac{0.5 E_T I_b}{L_b} \quad (5)$$

$$S_{j,rigid} = \frac{25 E_T I_b}{L_b} \quad (6)$$

Therefore, a joint can be classified by comparing the initial rotational stiffness of the joint with the reference ones as it follows:

$S_{j,ini} \leq S_{j,pinned}$ Nominally pinned;

$S_{j,pinned} < S_{j,ini} < S_{j,rigid}$ Semi-rigid;

$S_{j,ini} \geq S_{j,rigid}$ Rigid.

The joint classification by stiffness is also presented in terms of non-dimensional parameters, through the Moment-rotation ($\bar{m}$-$\bar{\theta}$) curves, which are defined based on the following equations (eq. 7, 8):

$$\bar{m} = \frac{M_{j,Rd}}{M_{b,el}} \quad (7)$$

$$\bar{\theta} = \theta_{j,Rd} \frac{E_T \cdot I_b}{L_b \cdot M_{b,el}} \quad (8)$$

where $\theta_{j,Rd}$ is the joint rotation corresponding to $M_{j,Rd}$, evaluated as $M_{j,Rd}/S_{j,ini}$.

The results of the proposed joints classification by stiffness in terms of $\bar{m}$-$\bar{\theta}$ curves are reported in Figure 6.

Pinned joint
Semi-rigid joint

3.3 ANALYSIS OF JOINTS CLASSIFICATION

As a result of the classification, for a total of 46 joints examined, 22 are pinned, while 24 are semi-rigid.

Among Type 1 joints, most connections are classified as pinned joints [3-5, 11-14], except one specimen [5], characterized by an internal T-shaped steel plate connected to the beam with a circular arrangement of screws and to the column with a rectangular arrangement of bolts, which is classified as semi-rigid joint.

Among Type 2 joints, the connections tested by Polastri [15], characterized by beam with double column and a circular arrangement of pins, or glued bars, or glued connection between timber members, are classified as semi-rigid joints, while the two specimens tested by Beltran [5], characterized by beam with double column and a circular arrangement of bolts, are classified as pinned joint.

Among Type 3 joints, the connection tested by Kasal et al. [1], characterized by two aluminium L-shaped plates and screws, as well as the connection tested by Kasal et al. [16], characterized by two timber rectangular-shaped plates and screws, are both classified as semi-rigid joints.

All timber joints equipped with steel link (Type 4) are classified as semi-rigid joints [2, 17, 18].

In particular, among the semirigid category, for Type 1, the beam-to-column joint tested by Beltran [5] with internal steel plate connected at the beam with a circular arrangement of screws and at the column with a rectangular arrangement of bolts is the only semi-rigid joint. It is worth noticed that it shows the lowest initial stiffness ($S_{C,ini}$=2149.7kNm/rad) than all the other studied semi-rigid joints. For Type 2, the joint with the greatest initial stiffness is the T07 specimen ($S_{T07,ini}$=60912kNm/rad) tested by Polastri [15], which is configured as a glued joint, characterized by the complete gluing of the timber members, confirming the lower deformation of the glued joints compared to the traditional ones. For Type 3, the joint specimen tested by Kasal et al. [16], which has two timber rectangular-shaped plates connected to the beam end top and bottom, shows a higher initial stiffness ($S_{A,ini}$=20976.7kNm/rad) than the joint specimen tested by Kasal et al. [1], which has angles located at the beam end top and bottom ($S_{A,ini}$=146.15kNm/rad). For Type 4, the joint with the greatest initial stiffness is the P20, followed by the P15-10 ($S_{P20,ini}$=4036.3kNm/rad; $S_{P15,ini}$= 3858.3kNm/rad; $S_{P10,ini}$=3700kNm/rad) beam-to-column joints equipped with steel link tested by Andreolli [17], with steel end-plate thicknesses equal to 20-15-10mm respectively and the connecting threaded bars glued in the beam. Next, the beam-to-column joints tested by Nakatani et al. [2], which have a box steel link connected to the timber beam and column with glued threaded rods, follows in the stiffness classification (S_{ini}=2000.0kNm/rad). At last, all beam-to-column joints equipped with steel link profile and dog-bone profile, tested by Golich and Erochko [18] ($S_{MC-1A,ini}$=13888.9; $S_{MC-1B,ini}$=12244.4kNm/rad), are classified as semi-rigid joints, showing high initial stiffness values.

4 CONCLUSIVE REMARKS

The paper focuses on the proposal of a method for the

https://doi.org/10.52202/069179-0390

mechanical classification of timber beam-to-column joints. In particular, the procedure for the mechanical classification of beam-to-column joints in timber MR framed structures is a suitable and efficient adaptation of that one related to steel joints presented in the Eurocode 3 part: 1-8, taking into account the timber structural features. The classification procedure, in terms of stiffness, has been applied to 46 joints studied through experimental tests in the scientific literature. Specifically, four types of joints have been identified: connection with internal or lateral vertical steel plate and connectors (Type 1); connection with connectors in circular arrangement (Type 2); connection with top and bottom plates or brackets and connectors (Type 3); timber joint equipped with steel link (Type 4). The classification of the joints in terms of stiffness has evidenced that 48% of the joints can be classified as pinned joints, while 52% of the joints can be classified as semi-rigid joints.

In particular, in semirigid joints category, beam-to-column joints with glued connection, such as the beam-to-column joint with glued connection between timber members tested by Polastri [15] and the beam-to-column joint equipped with steel link by means of 4 glued threaded bars tested by Andreolli [17], show higher stiffness values than the other joints tested:.

The study is in progress toward the application of the classification method to other beam-to-column joint types and configurations, whose moment-rotation curves have been achieved through experimental tests or even numerical investigations on well refined models, selected from the scientific literature. Moreover where the joints descriptions are completed of every mechanical details, the component method will be applied to better understand the contribution of the connection components features on the mechanical properties of the joints.

SECOND GENERATION OF EUROCODE 5-2 ON TIMBER BRIDGES, AN OVERVIEW

Matthias Gerold [1], Hauke Burkart [2]

ABSTRACT: The Eurocodes are design standards published by CEN that are being updated. The first generation was published between 2002 and 2007. Work on the second generation is at different stages, with a common implementation expected in 2027/2028. Design rules on Timber Bridges is published as EN 1995-2.

The second generation implements new knowledge gained the last 20 years. Within timber structures this is quite a fair amount. The mandate given by the European Union, being a large financier of the work, was to improve the structure and clarity of the code, reduction of nationally determined parameters and reduction of alternative equivalent application rules and procedures, removal of rules that are little in use and explanation of the mechanical background of formulas.

Consolidation on design practice has been a great part of the work. Though calculating timber bridges has been conducted in a common way, protecting the timber is as much tradition as it is architectural taste. A timber bridge according to the Eurocode is expected to endure for its design service life independent on being located far south or far north in Europe. The term protected timber bridge is introduced, where weathering is not expected to govern the service life.

All parts of EN 1995-2 have been examined and updated if needed, as here presented.

KEYWORDS: Timber Bridges, Design rules, Eurocode

1 INTRODUCTION

In 2004, the EU and several EFTA states introduced uniform design codes, the so-called EUROCODEs (EC). The goal of the European Committee for Standardization (Comité Européen de Normalisation, CEN) here was to replace the member states' differing or even missing design guidelines by a common set of technical rules that provide the same level of safety and thereby to further minimise barriers within Europe. In 2012, the European Commission issued a mandate for the development of a second generation of the Eurocodes to ensure their long-term applicability and reflect the constant technical developments and knowledge gains (see Figure 1).

Figure 1: *European design codes – Eurocodes*
Source: European Commission, 2021

In the work of 2nd generation Eurocodes updates in Eurocode 0 and 1 forced updates for the other parts. For the series of standards "EN 1995 – Design of timber structures," (EC 5) experts regularly prepare drafts for specific topics in timber construction. To this purpose, six project teams (PT) have been convened from 2015 to 2022. Today, their work is continued by ten working groups (WG), which before the start of project teams conducted a review of existing content of the EC5, in cooperation and coordination with the national standardisation bodies. After extensive revision of the entire Eurocode 5 series, new versions will be available for all members states for enquiry September 2023, following expected formal vote in 2025 and publication around 2027.

2 SUSTAINABLE TIMBER BRIDGE CONSTRUCTION

One of the main topics of editing EN 1995-2 was the implementation of the specifications of EN 1990 and EN 1991-2, in particular requirements for reaching a design service life of 100 years. Since construction professionals speak the language of implementation planning, a new Annex is suggested with simplified figures exemplifies how timber bridges can be protected given proper service. Service is topic in another new suggested annex covering inspection and maintenance of timber bridges. Both

[1] Matthias Gerold, Harrer Ingenieure, Karlsruhe, Germany, m.gerold@harrer-ing.net
[2] Hauke Burkart, Standards Norway, Norway, hbu@standard.no

https://doi.org/10.52202/069179-0391

annexes are informative and may be subject to changes nationally.
Like the building construction code, the code for timber bridges was extended to include requirements and regulations for the durability of structures, taking into account the issues of corrosion protection, deck plates, and timber-concrete composites. The creep factors for concrete in timber-concrete composite bridges are different from those in known building constructions, as the cross-sections are significantly larger. Accordingly, a new normative Annex A of prEN 1995-2 provides relevant conditional equations. prEN 1995-1-1 shall stipulate requirements for numeric analyses (keyword Finite Element Method, or FEM for short).
Eurocode 8, Part 2 ("Design of structures for earthquake resistance"), will in 2nd generation take timber bridges into account. In an Informative Annex, additional hints for the design of bearings are given. It is also relevant to point to the Informative Annex E, which contains suggestions to be considered in view of deformations and dimensional changes of timber constructions under changing environmental conditions such as temperature or timber moisture, and notes on transversely prestressed timber deck plates (among other things for the "cupping" of the deck sides).
Most regulations on deck plates (timber decks) were added to one normative and one informative Annex of prEN 1995-1-1, as these regulations can also be applied to, e.g., nail-laminated timber constructions.
With the technical work basically being done, the document is being translated into German and French before being sent on public Enquiry for 16 weeks starting September 2023. The remaining steps of the standardisation process are shown in [1] and [2].

3 PROTECTION AND SERVICE LIFE

3.1 DURABILITY OF WOODEN MEMBERS

General requirements regarding expected service life, i.e. design service life T_{lf}, form the basis for all bridge design in Eurocodes are given in EN 1990 A.2. Together with requirements on Quality Management are the requirements on Maintenance and Durability that form the basis of bridge building. The latter are defined as:

Maintenance
set of activities performed during the service life of the structure so that it fulfils the requirements for reliability

Durability
Ability of a structure or structural member to satisfy, with planned maintenance, its design performance requirements over the design service life

Based on this, different categories are defined for expected service life. For bridges 100 years is the basic option or choice, and is expected independent of material types. Lower service life may be relevant for simple bridges used for instance in recreational purposes where consequence of failure is very little, but still 50 years are expected. Further lower service life is given for replaceable and temporary structures.
For timber bridges, achieving 50 years, which is the same as building structures and thus the design requirements in the general part of Eurocode 5 are to be used. Requirements for 100 years service life are outlined in the bridge part, comprising:
- Requirements on design;
- Recommendations on structural protection;
- Requirements membranes;
- Requirements on steel protection embedded in timber structures.

Environmental actions, i.e. expected moisture variations and thermal actions, are included in simplified calculation models depending on member size. General information on moisture variations are given in the main part.

For the design of durable timber bridges the term protected and unprotected member are included. Protected member is defined as:

Protected Member
structural member not exposed to direct weathering such as rain, snow, or other sources of moisture ingress

Examples of protected members are given see Figure 2, see also [3]

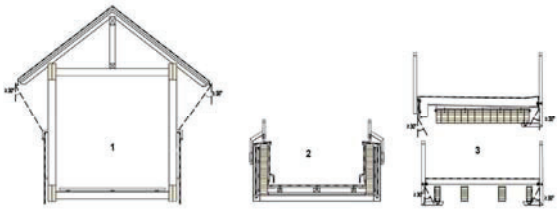

Figure 2: *Examples of protected timber bridges*

Key

membrane or weather-resistant layer

Unprotected member is defined as:

Unprotected Member
structural member that is not protected or partially unprotected from weathering but is within the limits of Service Class (SC) 3

The methodology is that a protected timber bridge is expected to last for 100 years. When parts of a structures are not within the definition of a protected member these must either be easily replaceable, or the expected design service life will be less than 100 years.
Durability and thus sustainability ensure the economic viability of timber structures. Therefore, the following so-called "magic triangle" must be observed:

https://doi.org/10.52202/069179-0391

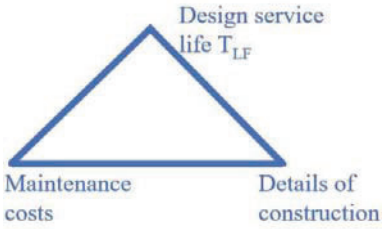

Figure 3: *Important considerations on design*

Requirements on basic structural protection are given in EN 1995-1-1 and EN 1995-2, in some countries with additional national requirements. This leads to a higher robustness of the expected service life, expecting to lower maintenance costs.

2nd generation of EN 1995-2 includes detailing by figures in Annex how timber bridges can generally be protected. Five possibilities for basic structural timber protections are given (see e.g. Figure 4), together with more detailed examples on expansion joints (three methods; see e.g. Figure 5) and bridge caps (2 examples).

Furthermore, a suggested monitoring scheme is included as monitoring timber bridges may be a useful addition to inspection, in some European countries mandatory. Currently an arch bridge is taken as example showing which parts of the bridge are expected to be critical and thus wise instrumenting, also with regard to the Use Class according to EN 355.

Because of translation of European standards all figures are language neutral, creating rather lengthy keys to each figure.

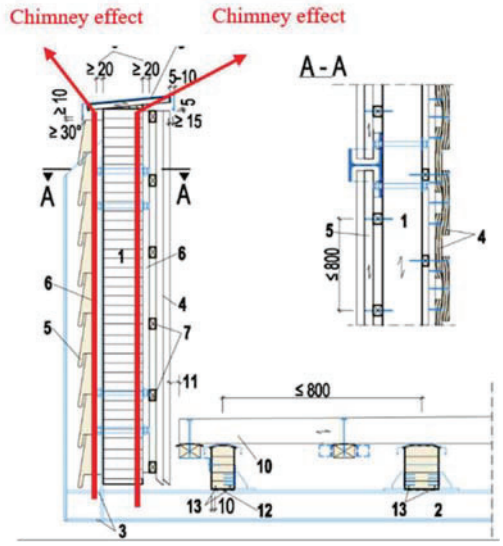

Figure 4: *Example of detailing figure with explanation text on ventilation in red*

Key

A-A	Section A – A
1	Main girder
2	Steel frame
3	Borehole in top and bottom flange
4	Cladding (generally outside)
5	Vertical weather boarding (outside)
6	Vertical battens
7	Horizontal battens
8	Ventilation openings, horizontal ≥ 100 cm²/m, vertical ≥ 50 cm²/m

3.2 DURABILITY OF STEEL MEMBERS

For steel members the updated standard gives requirements of protection of steel members in wooden structures by declaring a timber exposure category class T_E. Different protection levels depending on atmospheric exposure C_E, service class SC and expected design service life results in different recommendations of minimum protection either by steel grade or zinc coverage. Requirements of protection of steel in general is covered by Eurocode 3.

Situation	*Timber exposure category* [a] T_E	*Atmospheric exposure category* [b] C_E	*Typical atmospheric exposure* [c] *(informative)*	*Examples of minimum*	
				zinc thickness [d]	*stainless steel grade (type)* [e]
Protected outdoor with access of pollution (SC2 and SC3)	T_E3/T_E4	C_E2	L_{sea} > 10 km L_{street} > 100 m and/or low polluted area (< 5 µg/m³ of SO_2)	T_R3: 40 µm [f] (n/a [g]) if T_E4) [20 µm [f] (55 µm if T_E4)] [h]	CRC II (e.g. 1.4301)
	T_E3/T_E4	C_E3	10 km > L_{sea} > 3 km 100 m > L_{street} > 10 m and/or medium polluted area (5 µg/m³ ≤ SO_2 ≤ 30 µm/m³)	C_R3: 110 µm [80 µm] [h]	CRC III (e.g. 1.4401)
	T_E3/T_E4	C_E4	3 km > L_{sea} > 0,25 km L_{street} < 10 m and/or high polluted area (30 µg/m³ < SO_2 ≤ 90 µm/m³)	C_R4 [b]: n/a [g] [110 µm] [h]	CRC III (e.g. 1.4401)
	T_E3/T_E4	C_E5	L_{sea} < 0,25 km and/or very high polluted area (90 µg/m³ < SO_2)	C_R5 [b]: n/a [g]	CRC III (e.g. 1.4529)
Permanent in contact with ground- or fresh-water (SC4) [i]	T_E5	n/a [g]	For T_E5/SC4 especially in case of seawater each case should evaluated individually.	C_R5 [b]: n/a [g]	CRC III to CRC V

[a] *Timber exposure categories T_E3, T_E4 and T_E5 are according to prEN 1995-1-1:202x, Table 6.1*

[b] *Atmospheric exposure categories C_E2, C_E3, C_E4 and C_E5 are according to prEN 1995-1-1:202x, Table 6.2 and Table 6.3*

[c] *The specified values for SO_2 are references values only and may vary.*

L_{sea} indicates distance from the sea. The actual exposure depends on the prevailing wind direction and the topography of the coast to saltwater seas e.g. Atlantic Ocean, North Sea, Baltic Sea, Mediterranean See, Black Sea, Irish Sea

L_{street} indicates distance from roads with heavy traffic with de-icing salt

[d] *pure zinc coating and hot-dipped galvanized coating*

T_R3 is the timber resistance class according to prEN 1995-1-1:202x, 6.3

C_R are the resistance classes for metal fastener or connector made of carbon steel to corrosion according to prEN 1995-1-1:202x, 6.3

Figure 6: *Current proposal on protection of steel members embedded in timber in prEN 1995-2. Numbers in red are for 50 years, other values 100 years.*

4 TIMBER DECK PLATES

Timber deck plates comprise decks made of solid-wood beams arranged side by side in the direction of span, clamped together. As a result, the (punctual) wheel loads can be distributed over several beams (see prEN 1995-1-1 Figure U.3). Nowadays, these deck plates (timber decks) are largely used in Scandinavian and Baltic states often using glued laminated timber (GL) as beams and stressed together with steel rods. Requirements regarding these structures have been updated representing state of the art including newer research on the topics. This also includes requirements on modelling of the bridge decks using Finite Elements Software (see prEN 1995-1-1 Annex V) as well as updated recommendations on friction coefficients and requirements to minimum stress forces.

https://doi.org/10.52202/069179-0391

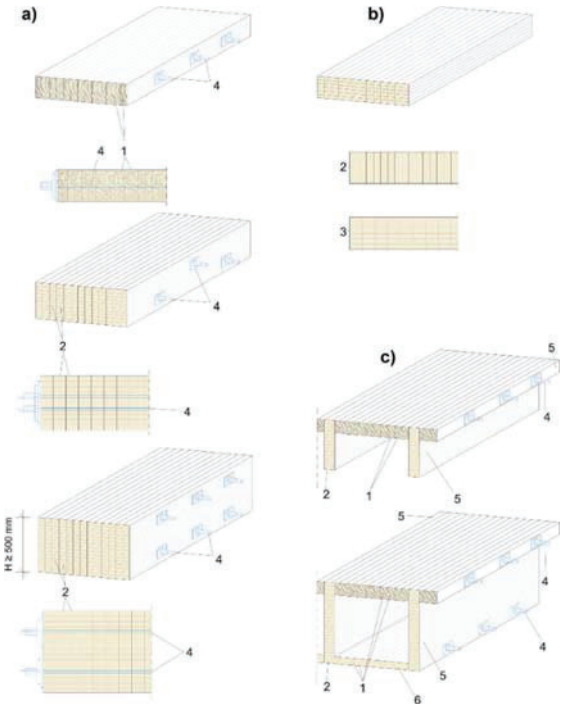

Figure 7: *Examples of timber bridge decks covered in prEN 1995-2*

5 TIMBER-CONCETE COMPOSITE (TCC) AND INTEGRAL ABUTMENTS

TCC decks are included in the updated bridge standard, giving requirements on design and recommendations on durability and design. Creep must be evaluated carefully and as such this is also topic in the updated draft. For a more detailed presentation on the topic see [5] presentation from Mr. Prof. Dr.-Ing. Jörg Schänzlin

Integral timber bridges, bridges with a flexural connection to a concrete abutment, have gained some experience and are also included in the timber bridge code.

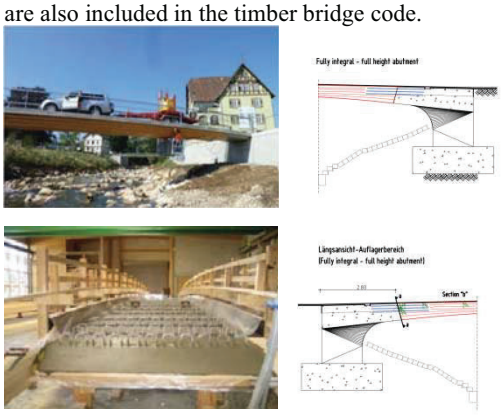

Figure 8: *Examples of integral timber bridge designs.*

6 SERVICE LIMIT STATE

6.1 DEFLECTIONS AND DEFORMATIONS

Requirements on deflections due to traffic-load and wind-force have been updated. These actions should be verified and limited in order to prevent unwanted dynamic impact due to traffic, infringe of required clearances and cracking of surfacing layer, ensuring also sufficient run-off from standing water (see [2]).

6.2 OSCILLATIONS AND DAMPING

A rather large update has been conducted on the subjects oscillations and damping. Simplification regarding requirements given in other parts of Eurocodes are introduced in the timber bridge part. An example is shown in figure 9, where different requirements are gathered in one requirement, see black line in figure 9.

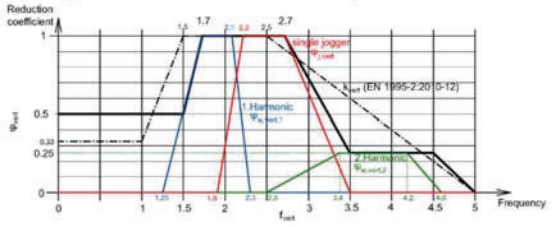

Figure 9: *Examples of integral timber bridge designs.*

7 FATIGUE

It was decided to move fatigue requirements into the general part as these may be necessary also for buildings with cyclic loads, such as crane structures, wind turbine tower, highway traffic sign posts, or bell towers. This means that in EN 1995-2, only those parts were kept that are relevant for timber bridges, in particular:

- some general parts concerning the fatigue assessment of timber structures;
- parts of the document that deal with fatigue load models;
- a simplified fatigue verification model especially for bridges.

Basis in fatigue verification is the stress ratio R_T as the arithmetical minimum stress to the maximum stress of a particular stress cycle in timber design. Since the factor representing the reduction of fatigue strength with number of load cycles k_{fat} values depend on RT, a simplification is also required to offer a real advantage over the 'full' k_{fat} verification. Therefore, it is proposed to consider only whether the fatigue loading is alternating or not and to use the k_{fat} values for $R_T = 0$ or $R_T = -1$, respectively.

The k_{fat} values were evaluated for two lanes and 2*106 cycles (trucks), giving anticipated 100 years design service life using an ß-factor equal to 3 (substantial consequences). This yields a design load cycle number of $1.2*10^9$.

8 PERSPECTIVE

The completion of the work on the European timber construction standards is scheduled for 2026/2027, which still seems far-off. Current status for the timber bridge code is that it is made ready for public Enquiry by september 2023 together will all other parts on timber structures (i.e. part 1-1 General rules and rules for buildings, part 1-2 Fire design and part -3 Execution). After Enquriry no new technical content will be added, only changes to what is suggested will be made, thus most of the essential changes are already known. The scope of the standard will inevitably grow, as new timber construction products need to be considered and known design approaches need to be extended and optimised. The update is guided by the central interest of increasing the user-friendliness – not only by profiting from digital availability and efficient search options but also by restructuring, homogenising, and simplifying the regulations. Nevertheless, as with the adjustment of the first generation of Eurocode 5, an additional process of learning, training, and education will be necessary, with this process starting already prior to the final publication. In conclusion, it may be stated: the second generation of Eurocode 5 is not a revolution but an evolution that consistently builds on the experiences and principles of the previous version.

ACKNOWLEDGEMENT

The authors would like to acknowledge the work done by members of both project team 6 and working group 6 of CEN/TC 250/SC 5 to their contributions over a very long period. In total more than 30 experts have contributed to this work.

TALL WOOD BUILDINGS WITHIN THE 2020 NATIONAL BUILDING CODE OF CANADA

Marc Alam[1], Rodney McPhee[1]

ABSTRACT: In the past decade, many examples have been seen where large and tall buildings of mass timber construction have been built around the world, including here in North America. This paper summarizes the approved provisions within the 2020 National Building Code of Canada (NBC) to allow tall wood buildings up to 12 storeys. The paper will include discussion about the historical precedent of moving away from the NBC prescriptive approach of recognizing only two primary types of construction ─ combustible and noncombustible construction ─ and provide details introducing a new third type of construction called 'encapsulated mass timber construction' (EMTC), which is required to be used for these tall wood buildings. This includes details on current fire research on mass timber construction and the proposed new prescriptive fire protection requirements introducing EMTC within the 2020 NBC.

KEYWORDS: Tall wood buildings, 2020 National Building Code of Canada, Encapsulated mass timber construction

1 INTRODUCTION

The Canadian Commission on Building and Fire Codes (CCBFC), approved changes in the 2020 National Building Code (NBC) to allow construction of tall wood buildings up to 12 storeys in height. This proposal includes a new construction type called 'encapsulated mass timber construction' (EMTC). EMTC is generally defined as a type of construction where a degree of safety is attained through a combination of prescribed minimum sizes of structural mass timber elements and a minimum time for these elements to be protected from fire (encapsulated) using a noncombustible protective membrane.

2 NBC CONSTRUCTION TYPES

2.1 EXISTING CONSTRUCTION TYPES

The 2015 NBC contained two primary construction types: noncombustible and combustible construction. These construction types have been in the NBC since the 1960s. 'Noncombustible construction' means '*that type of construction in which a degree of fire safety is attained by the use of noncombustible materials for structural members and other building assemblies*' [1] (e.g., concrete, steel, masonry). 'Combustible construction' means '*that type of construction that does not meet the requirements for noncombustible construction*' [1] (e.g., wood frame, masonry joist, etc.). There is a subset of combustible construction referenced in the NBC known as 'Heavy Timber Construction' that is defined as '*that type of combustible construction in which a degree of fire safety is attained by placing limitations on the sizes of wood structural members and on the thickness and composition of wood floors and roofs and by the avoidance of concealed spaces under floors and roofs*' [1].

Buildings of noncombustible construction can be of unlimited height and unlimited area when they are designed with a 2-hour structural fire-resistance rating and sprinklered throughout. Buildings of combustible construction are limited to a maximum building height of six storeys, with a maximum six storey building area of 1,500 m^2 (16,145 ft^2) for residential occupancies or 3,000 m^2 (32,290 ft^2) for business and personal services occupancies, when they are designed with a 1-hour structural fire-resistance rating and sprinklered throughout.

2.2 NEW CONSTRUCTION TYPE

The Canadian Wood Council submitted a Code Change Request (CCR) package to the CCBFC in 2016 to introduce provisions in the NBC permitting tall wood buildings above six storeys when constructed with a new construction type called 'Encapsulated Mass Timber Construction' (EMTC). The CCR package was reviewed by the CCBFC Standing Committee on Fire Protection (SC-FP). The SC-FP is made up of volunteers chosen for their fire protection expertise to represent all facets of the construction industry from across Canada. Following lengthy discussions and analysis, the SC-FP developed revised wordings for the proposed changes, which were posted for review and comment as part of three public reviews in 2017, 2018, and 2019. In resolving the public comments, the final wording of the changes were

[1]Marc Alam, Canadian Wood Council, Canada, malam@cwc.ca
[1]Rodney McPhee, Canadian Wood Council, Canada, rmcphee@cwc.ca

https://doi.org/10.52202/069179-0392

approved by the SC-FP and recommended to the CCBFC to be included in the 2020 NBC.

EMTC means '*that type of construction in which a degree of fire safety is attained by the use of encapsulated mass timber elements with an encapsulation rating and minimum dimensions for the structural timber members and other building assemblies*' [2]. In simple terms, EMTC is defined as the combination of two components: encapsulation rating and minimum dimensions of structural mass timber members.

2.2.1 Encapsulation Rating

The first component of EMTC, the 'encapsulation rating', is defined as '*the time in minutes that a material or assembly of materials will delay the ignition and combustion of encapsulated mass timber elements when it is exposed to fire under specified conditions of test and performance criteria, or as otherwise prescribed by this Code*' [2]. The encapsulation rating is determined using a new standard fire test method, CAN/ULC-S146 "*Standard Method of Test for the Evaluation of Encapsulation Materials and Assemblies of Materials for the Protection of Mass Timber Structural Members and Assemblies*" [3]. The fire exposure conditions used in this new test method is the same as the standard time-temperature curve (see Figure 1) from CAN/ULC-S101, "*Standard Methods of Fire Endurance Tests of Building Construction and Materials*" [4]. This is the same time-temperature curve from ASTM E119, "*Standard Test Methods for Fire Tests of Building Construction and Materials*" [5], and similar to time-temperature curve from ISO 834, "*Fire-Resistance Tests*" [6] (see Figure 1).

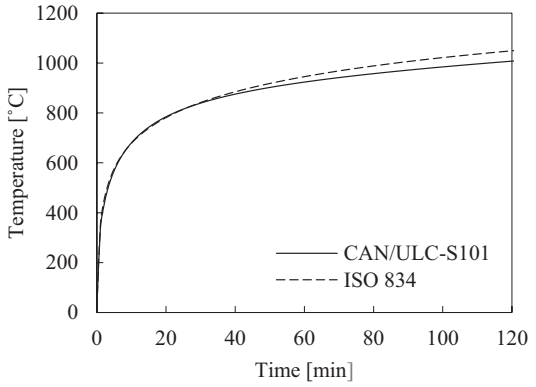

Figure 1: *CAN/ULC-S101 and ISO 834 standard time-temperature curves*

In CAN/ULC-S146, the encapsulation material or assembly of materials are applied to a timber substate and tested within a horizontal furnace with a minimum specimen size of 3.66 m (12 ft) x 3.66 m (12 ft). Unless otherwise prescribed, the encapsulation material or assembly of materials must be noncombustible and is assigned an encapsulation rating that relates to the lesser of the times at which an average temperature rise of 250°C (482°F) or a maximum temperature rise of 270°C (518°F) is recorded at the interface (see Figure 2) of the encapsulation material(s) and the wood substrate that is part of the test specimen.

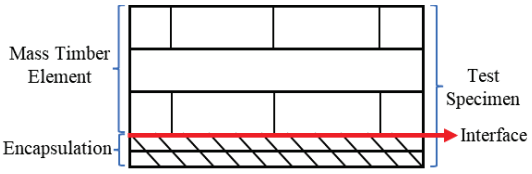

Figure 2: *Temperature interface location in the test specimen*

The minimum encapsulation rating prescribed by the NBC for EMTC is 50 minutes, but in some special cases, a 25-minute rating is permitted. The 2020 NBC provisions also include specifications that describe generic materials that are otherwise deemed to meet the 50-minute encapsulation rating: 2 layers of not less than 12.7 mm (1/2 in) thick Type X gypsum board and not less than 38 mm (1-1/2 in) thick gypsum-concrete or concrete topping. Type X gypsum board, conforming to ASTM C1396 "*Standard Specification for Gypsum Board*" [5], is a fire-resistant board that is manufactured with glass fibre reinforcements and other additives to help limit thermal degradation due to fire exposure [8].

2.2.2 Minimum Dimensions for Timber Members

The second component of EMTC, the minimum dimensions required for the structural mass timber members are shown in Table 1:

Table 1: *Minimum dimensions of mass timber elements*

Structural Wood Elements	Minimum Thickness, mm	Minimum Width × Depth, mm × mm
Wall that is a fire separation or exterior wall (1-sided exposure)	96	-
Wall that requires a fire-resistance rating but is not a fire separation (2-sided exposure)	192	-
Floors and Roofs (1-sided exposure)	96	-
Beams, columns and arches (2- or 3-sided fire exposure)	-	192 × 192
Beams, columns and arches (4-sided fire exposure)	-	224 × 224

Note: Fire separation means a construction assembly that acts as a barrier against the spread of fire [2].

These minimum dimensions are prescribed to increase the likelihood that the timber elements, once they are burning, will exhibit the fire performance characteristics of mass timber rather than of lightweight, small-dimensioned wood elements. This means that after initiation of charring, the timber elements will still be thermally thick for the required fire-resistance rating period [7].

3 CODE REQUIREMENTS

3.1 HEIGHTS AND AREA

The 2020 NBC provisions prescribe the height and area limits for buildings constructed of EMTC. Building height (in storeys) is defined as '*the number of storeys contained*

https://doi.org/10.52202/069179-0392

between the roof and the floor of the first storey.' [1] The building height limit is 12 storeys, with a 42-meter (138-foot) physical height limit (see Figure 3) that is also mandated for the building, which is measured between the floor of the first storey and the uppermost floor level. The first storey is defined as '*the uppermost storey having its floor level not more than 2 m (6.5 ft) above the lowest of the average levels of finished ground adjoining each exterior wall of the building.*'

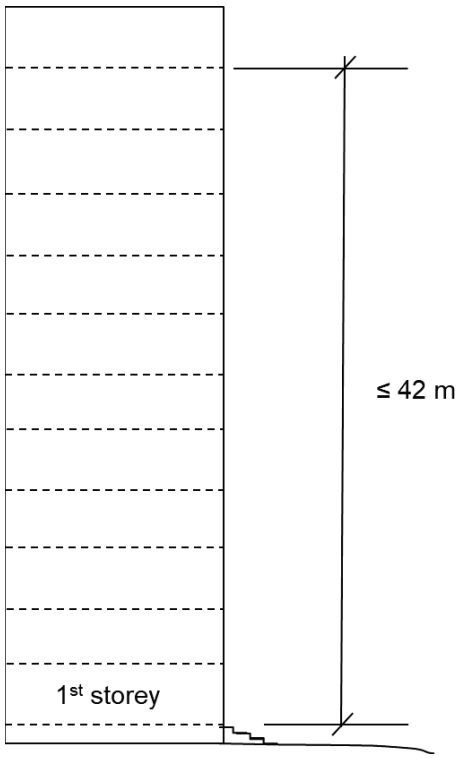

Figure 3: *Physical height limit of EMTC buildings*

Building area means '*the greatest horizontal area of a building above grade within the outside surface of exterior walls or within the outside surface of exterior walls and the centre line of firewalls'* [1]. For buildings constructed of EMTC, the maximum building area for any building height is 6,000 m^2 (64,585 ft^2) for a residential occupancy and 7,200 m^2 (77,500 ft^2) for a business and personal services occupancy.

3.2 FIRE-RESISTANCE AND SPRINKLERING

Fire-resistance ratings within the NBC are determined on the basis of results of standard fire tests conducted in conformance with CAN/ULC-S101 [4]. Within buildings constructed of EMTC, floor assemblies are required to be fire separations, with a fire-resistance rating of not less than 2 hours, and mezzanines shall have a fire-resistance rating of at least 1 hour. Loadbearing walls, columns and arches shall have a fire-resistance rating not less than that required for the supported assembly.

Buildings constructed of EMTC are required to be sprinklered throughout, with the automatic sprinkler system designed in accordance with NFPA 13, "*Standard for the Installation of Sprinkler Systems*" [8].

3.3 OCCUPANCY TYPES

The NBC classifies occupancy (building use) types within 6 different Groups. The main occupancy types permitted on all storeys in buildings constructed of EMTC are Group C, residential and Group D, business and personal services occupancies. Other occupancy types are permitted on the lower storeys as follows: Group E, mercantile occupancy, on the first and second storey, Group A2, assembly occupancy, up to the third storey, and storage garages up to the fourth storey. In addition, Group F2 and F3, medium- and low-hazard industrial occupancies are permitted on the first and second storeys of buildings with a Group D occupancy (See Figure 4).

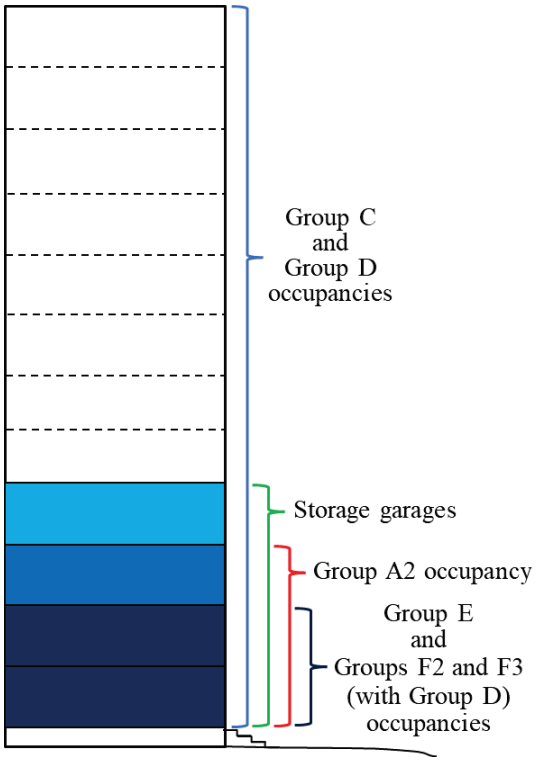

Figure 4: *Allowable occupancy type locations*

3.4 COMBUSTIBLE MATERIALS PERMITTED

Combustible materials are permitted within buildings of EMTC. These include combustible roofing materials, window sashes and frames, exterior cladding, components in exterior walls, nailing elements, stairs, interior finishes, elements in partitions, raised wood floors, concealed spaces, and non-loadbearing wood frame partitions. The provisions regarding combustible components that require more detail are explained below.

3.4.1 Exterior Cladding

Generally, exterior walls and cladding on a building constructed of EMTC shall be noncombustible. Cladding on wall assemblies tested in accordance with CAN/ULC-

https://doi.org/10.52202/069179-0392

S134, "*Fire Test of Exterior Wall Assemblies*" [11] is also permitted, along with some very limited amounts of combustible cladding that are arranged in accordance with three specific design approaches.

CAN/ULC-S134

The CAN/ULC-S134 methodology is a full-scale standard fire test for exterior walls. This fire test evaluates fire spread on the exterior of buildings that have combustible cladding or other combustible components within the exterior wall.

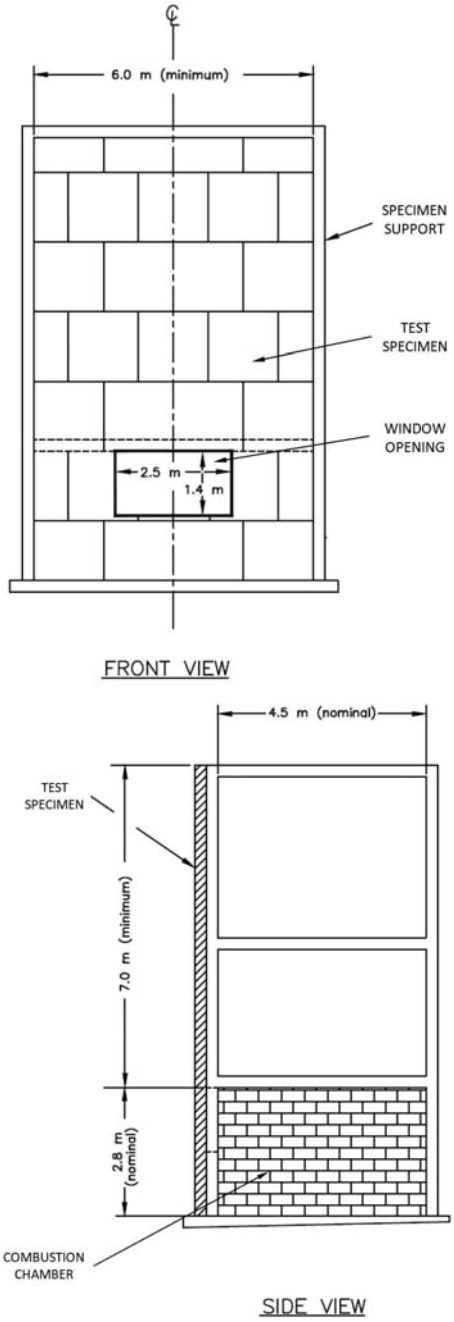

Figure 5: *Typical CAN/ULC-S134 test facility* [11]

The test facility (see Figures 5 and 7) consists of a façade with a minimum 6 m (19.7 ft) width and 9.5 m (31.2 ft) height. The burn room located on the lowest level is 6 m (19.7 ft) wide by 4.5 m (14.8 ft) deep by 2.8 m (9.2 ft) high with a 2.5 m (8.2 ft) wide by 1.4 m (4.6 ft) high window opening. The mass flow rate of gas (shown in Figure 6) shall be adjusted throughout a period of 25 min followed by an observation period of 35 min. From the start of the test (ignition), the gas flow is increased linearly for 5 min, followed by a 15 min steady state period, followed by another 5 min period of linear decrease to zero.

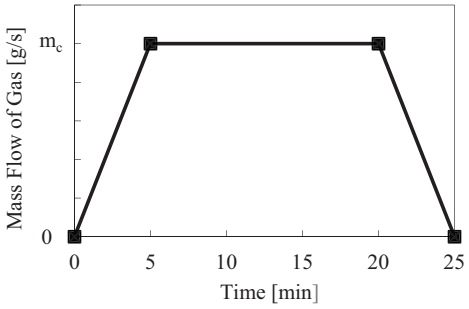

Figure 6: *Mass flow of gas vs time* [11]

The steady mass flow rate of gas, m_c, consists of flames emerging from the opening exposing the outer face of the wall to a heat flux density of 45 ± 3 kW/m^2 at 0.5 m above the top of the opening and 27 ± 2 kW/m^2 at 1.5 m above the top of the opening.

Figure 7: *Example CAN/ULC-S134 test*

Exterior combustible cladding and combustible exterior wall assemblies tested in accordance with CAN/ULC-S134 shall be permitted in buildings constructed of EMTC if they satisfy the following criteria: flaming on or in the

https://doi.org/10.52202/069179-0392

wall assembly does not spread more than 5 m (16.4 ft) above the opening and the heat flux during the flame exposure on the wall assembly is not more than 35 kW/m^2 measure at 3.5 m (11.5 ft) above the opening [1]. The 2020 NBC will include descriptions of generic exterior wall assemblies deemed to satisfy the criteria. These assemblies are shown in Table 2.

Table 2: *Generic CAN/ULC-S134 exterior wall assemblies* [2]

Structural Members	Absorptive Material	Sheathing	Cladding
38 mm × 89 mm wood studs spaced at 400 mm o.c.	89 mm thick rock or slag fibre in cavities formed by studs	-	12.7 mm thick fire-retardant-treated plywood siding
140 mm thick rock or slag fibre in cavities formed by studs	140 mm thick rock or slag fibre in cavities formed by studs	Gypsum sheathing ≥ 12.7 mm thick	Noncombustible exterior cladding
38 mm × 140 mm wood studs spaced at 400 mm o.c.	140 mm thick rock or slag fibre in cavities formed by studs	15.9 mm thick fire-retardant-treated plywood	Noncombustible exterior cladding
38 mm × 140 mm wood studs spaced at 600 mm o.c. attached CLT wall panels ≥ 38 mm thick	140 mm thick glass, rock or slag fibre in cavities formed by studs	Gypsum sheathing ≥ 12.7 mm thick	Noncombustible exterior cladding
89 mm horizontal Z-bars spaced at 600 mm o.c. attached to CLT wall panels ≥ 105 mm thick	89 mm thick rock or slag fibre in cavities formed by Z-bars	-	Noncombustible exterior cladding attached to 19 mm vertical hat channels spaced at 600 mm o.c.

Combustible Cladding

As noted earlier, along with noncombustible cladding and cladding on walls tested in accordance with CAN/ULC-S134, the 2020 NBC will permit three approaches to allow the use of combustible cladding on exterior walls of buildings constructed of EMTC.

The first approach allows for not more than a 10% portion of the exterior cladding on each storey to be combustible and any such portion shall not be contiguous over more than 4 storeys. With this approach, each contiguous combustible cladding portion shall have a maximum width of 1.2 m (3.9 ft). They must also be separated from other portions on the same storey by a horizontal distance of not less than 1.2 m (3.9 ft) and from other portions on the adjacent storeys by a horizontal distance of not less than 2.4 m (7.9 ft). The combustible cladding shall have a flame-spread rating of 75 when tested to CAN/ULC-S102, "*Standard Method of Test for Surface Burning Characteristics of Building Materials and Assemblies*" [12]. Flame-spread rating means '*an index or classification indicating the extent of spread-of-flame on the surface of a material or an assembly of materials as determined in the standard fire test*' [1].

The second approach also allows for not more than a 10% portion of the exterior cladding on each storey to be combustible, and does not impose the 1.2 m width limit, but any such portion shall not be contiguous across adjacent storeys. As such, the maximum total width of any portion (aggregate width for multiple portions on the same storey) is limited to 10% of the storey width. For portions on adjacent storeys, they shall be separated by a distance of not less than 2.4 m (7.9 ft). Similarly, the combustible cladding shall have a flame-spread rating of 75 when tested to CAN/ULC-S102.

The third approach allows for up to 100% of the cladding on exterior walls of the first storey, provided all of the combustible cladding can be directly accessed and are located not more than 15 m (49.2 ft) from a street or access route, measured horizontally from the face of the building [2].

These approaches can be applied individually or in combination as shown in Figure 8. All other portions of cladding that are not combustible are required to be noncombustible or tested in accordance with CAN/ULC-S134.

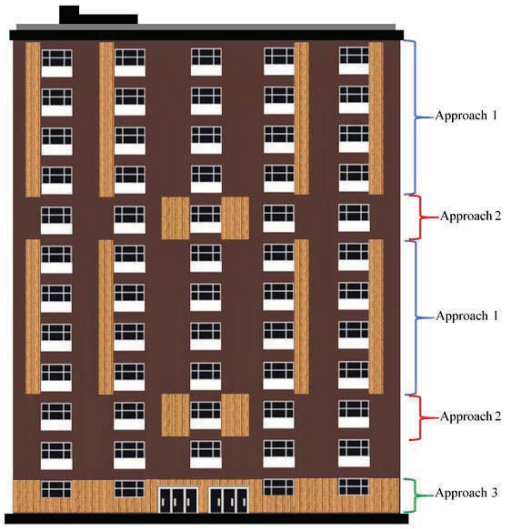

Figure 8: *Example of combustible cladding approaches on buildings constructed of EMTC*

3.4.2 Concealed Spaces

Concealed spaces within structural mass timber elements are permitted in buildings constructed of EMTC. For one example, see Figure 9, where the two mass timber floor slabs are separated by mass timber beams creating a concealed space.

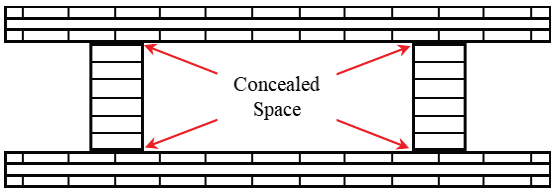

Figure 9: *Example of concealed space in mass timber elements*

These concealed spaces shall be provided with one of the following protective measures set out in the 2020 NBC [2]:

https://doi.org/10.52202/069179-0392

1. Sprinklered and divided into compartments by fire blocks.
2. Completely filled with rock or slag fibre insulation conforming to CAN/ULC-S702, "*Mineral Fibre Thermal Insulation for Buildings*," [13] and having a density of not less than 32 kg/m^3.
3. If horizontal (e.g., floor element), lined with not less than one layer of 12.7 mm (1/2 in) Type X gypsum board or noncombustible material providing an encapsulation rating of not less than 25 min.
4. If vertical (e.g., wall element), lined with not less than one layer of 12.7 mm (1/2 in) Type X gypsum board or noncombustible material providing an encapsulation rating of not less than 25 min and vertically divided into compartments by fire blocks.

Concealed spaces are also permitted where wood nailing elements are used for the attachment of a material or assembly of materials to provide an encapsulation rating in a building constructed of EMTC, provided the concealed space created by the wood nailing elements is not more than 25 mm (1 in) deep as shown in Figure 10.

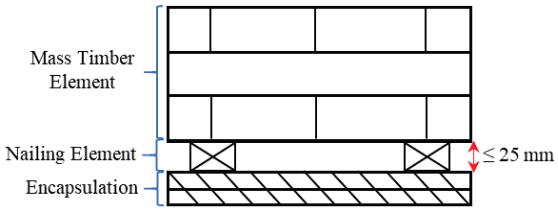

Figure 10: *Maximum depth of concealed space created by wood nailing elements*

Unlike any concealed spaces found within mass timber elements, these concealed spaces will not need to be protected.

3.4.3 Combustible Elements in Partitions

Combustible partitions, which do not enclose exits or vertical service spaces, are permitted in buildings constructed of EMTC. The partitions shall consist of solid lumber not less than 38 mm (1.5 in) thick or wood framing. Protection shall be provided on each face of the partitions. The protection shall consist of one layer of 12.7 mm (1/2 in) thick Type X gypsum board, with all joints either backed or taped and filled, or one layer of 19 mm (3/4 in) thick fire-retardant-treated wood. If fire-retardant-treated wood is used on partitions containing wood framing, the wood stud cavities shall be filled with noncombustible insulation.

3.5 DAMAGE OR REMOVED ENCAPSULATION MATERIAL

In the 2020 National Fire Code of Canada (NFC) [14], there is a new requirement for buildings constructed of EMTC for encapsulation material or assembly of materials if they are damaged or removed such that their integrity is compromised. The 2020 NFC requires that these damaged or removed encapsulation materials or assembly of materials be repaired or replaced in conformance with the 2020 NBC to restore their encapsulation rating.

3.6 PROTECTION DURING CONSTRUCTION

To address safety during construction, the 2020 NFC requires that protective encapsulation be installed in different locations within buildings constructed of EMTC. The encapsulation material or assembly or materials will need to provide an encapsulation rating of not less than 25 min. This rating can be met with one layer of not less than 12.7 mm (1/2 in) thick Type X gypsum board.

The encapsulation will be required to be installed on 100% of the interior side of mass timber stairways and vertical service spaces, and on each face of solid lumber, mass timber or wood framing partitions. In addition, 80% of the area of the underside of the mass timber floor assembly on each storey and 65% of the total area of structural mass timber within the storey will need to be encapsulated during construction [14].

To allow for quick construction of buildings of EMTC, the NFC permits that not more than the four uppermost contiguous storeys to be unprotected during construction. For example, for a 7 storey EMTC building under construction, the first 3 storeys would need to be encapsulated and top 4 storeys can be unprotected. To be able to construct the 8th storey, the first 4 storeys would be protected.

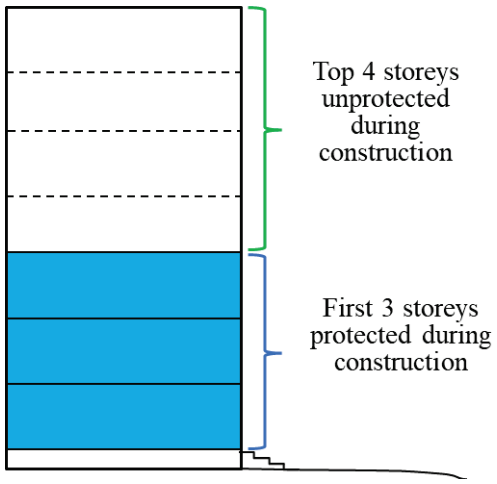

Figure 11: *Example of protection during construction*

3.7 EXPOSED MASS TIMBER

Exposed mass timber elements are permitted in buildings constructed of EMTC. There are limits to the percentage of exposed mass timber walls, beams, columns, arches, and ceilings that may be within either suites or fire compartments within the buildings. A suite means "*a single room or series of rooms of complementary use, operated under a single tenancy, and includes dwelling units, individual guest rooms in motels, hotels, boarding houses, rooming houses and dormitories as well as individual stores and individual or complementary rooms*

https://doi.org/10.52202/069179-0392

for business and personal services occupancies" and a fire compartment means "*an enclosed space in a building that is separated from all other parts of the building by enclosing construction providing a fire separation having a required fire-resistance rating*" [1].

For exposed surfaces of mass timber walls within a suite, they need not be protected if their aggregate surface area does not exceed 35% of the total wall area of the perimeter of the suite in which they are located and each exposed surface faces the same direction [2]. An example of a residential suite with exposed mass timber walls is shown in Figure 12. The surrounding blue rectangle is considered the perimeter of the suite and the total wall area around the perimeter would be used to find the percent of exposed mass timber permitted within the suite. The green lines are the location of the exposed walls within the suite. They represent less than 35% of the total wall area of the perimeter of the suite. Also, the exposed surfaces all face the same direction, as represented in Figure 12 where the green lines are drawn on the right side of each wall.

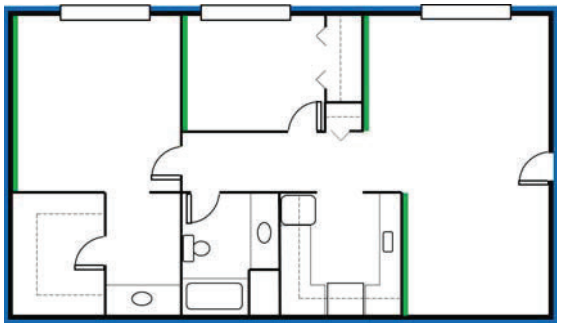

Figure 12: *Example of residential suite with exposed mass timber walls*

The exposed mass timber walls will also be required to have a flame-spread rating not more than 150.

Similarly, exposed surfaces of mass timber beams, columns, and arches within either a suite or fire compartment can be unprotected if their combined aggregate surface area does not exceed 10% of the total wall area of the perimeter of the suite or fire compartment [2]. They also will be required to have a flame-spread rating not more than 150.

The combined exposed surfaces of mass timber walls, beams, columns, and arches within a suite shall not exceed 35% of the total wall area of the perimeter of the suite. For example, if the suite has exposed mass timber beams, columns, and arches that represent the maximum 10% of the total wall area of the perimeter of the suite, then exposed mass timber walls are only permitted to have the remaining 25% of the total wall area of the perimeter of the suite be exposed, for a total of 35%.

Exposed surfaces of mass timber ceilings will have two options to allow for them to be unprotected within suites. The first option for exposed surfaces of mass timber ceilings is where the aggregate area does not exceed 10% of the total ceiling area of the suite and the exposed surfaces have a flame-spread rating not more than 150. In this case, mass timber walls, beams, columns, and arches within the suite are permitted to be exposed as described. The second option for exposed surfaces of mass timber ceilings is where the aggregate area does not exceed 25% of the total ceiling area of the suite and the exposed surfaces have a flame-spread rating not more than 75. With the higher percent of exposed ceilings, no mass timber walls are permitted to be exposed, but exposed beams, columns, and arches are still permitted [2].

A summary of exposed mass timber requirements for buildings constructed of EMTC is shown in Table 3.

Table 3: *Summary of exposed mass timber elements* [2]

Exposed mass timber element	Max aggregate surface area as a percentage of the total		Flame spread rating	Other requirements
	Wall area of the perimeter of the suite	Ceiling area of the suite		
Walls	35%	-	150	Surfaces face the same direction
Beams, columns, and arches	10%	-	150	Also permitted in a fire compartment
Combined walls, beams, columns, and arches	35%	-	150	Wall surfaces face the same direction
Ceilings (option 1)	-	10%	150	Exposed W/B/C/A permitted
Ceilings (option 2)	-	25%	75	No exposed walls

The exceptions to allow surfaces of mass timber elements to be exposed within buildings constructed of EMTC is, in part, based on cross-laminated timber (CLT) room burn research conducted at Carleton University in 2013 [13] and 2014 [14]. In the CLT room burn tests, without automatic sprinkler protection, the fire duration was influenced by the amount of exposed mass timber, the re-radiation between opposing/facing walls, and the char fall-off of CLT. This research limited the percent of exposed mass timber and required all exposed wall surfaces to face the same direction in buildings constructed of EMTC.

In 2018, after the 2020 NBC EMTC exposed mass timber percentages were initially accepted by the SC-FP of the CCBFC, the National Research Council Canada (NRC) undertook two research projects on fire testing of mass timber compartments without sprinkler systems and with exposed mass timber surfaces:

1. Fire Testing of Rooms with Exposed Wood Surfaces in Encapsulated Mass Timber Construction [15]
2. Nail Laminated Timber Compartment Fire Tests [16]

In the first NRC research project, the walls and roof of the test compartment were built from second generation CLT, which meets the 2018 version of ANSI/APA PRG 320, "*Standard for Performance-Rated Cross-Laminated Timber*" [17]. The adhesives used in the CLT conform to

https://doi.org/10.52202/069179-0392

the elevated temperature performance requirements in the standard, which exclude the use of adhesives that permit premature CLT char layer fall-off resulting in fire regrowth during the cooling phase of fully developed fire [17]. In the second NRC research project, the walls and roof of the test compartment were built from nail laminated timber (NLT) made on site at NRC. Several of the compartments in both research projects also included some percentage of exposed glued laminated timber beams and columns.

In most cases, the exposed surfaces of mass timber walls, beams, columns, and ceilings within the compartments exceeded the maximum allowances that have been chosen and approved for buildings constructed of EMTC in the 2020 NBC. These research projects show that the percentages of the acceptable exposed mass timber within EMTC buildings are conservative and can be increased. A new CCR has been submitted to increase these percentages in the 2025 edition of the NBC and is under review by the SC-FP.

4 CONCLUSIONS

This paper summarizes the code changes that were proposed to allow for the construction of tall wood buildings up to 12 storeys within the 2020 National Building Code of Canada. A description of the new construction type used for these tall wood buildings called encapsulated mass timber construction (EMTC) was also introduced. Details of the two main components of EMTC, encapsulation rating and minimum dimensions for timber members were explained. Detailed information about the code requirements on the different components of these tall wood buildings within the 2020 National Building and Fire Codes were shown. Specifics on current research projects on fire testing of mass timber compartments with exposed mass timber surfaces are included.

BEARING SUPPORTS REINFORCED WITH SCREWS: EXPERIMENTAL INVESTIGATION AND DISCUSSION OF THE DESIGN MODELS IN EUROCODE 5

Roberto Tomasi[1], Angelo Aloisio[2], Ebenezer Ussher[1], Kari Ryen Thunber[1], Eldbjørg Aaraas Hånde[1], Harald Liven[3]

ABSTRACT: This experimental investigation has been undertaken with the aim to discuss the current model for compression perpendicular to grain (CPG) proposed in the new Eurocode 5 draft. The current draft present two approaches proposed to assess load-carrying capacity of timber members subjected to CPG with reinforcement (Proposed reinforcement approach) and without reinforcement (New Model). The predictions of existing capacity models are compared to the experimental results of 39 timber specimens, distinguished by different load, screw and geometric configurations. Current capacity models for CPG with reinforcement assume two failure mechanisms, mainly characterized by their location, i.e. the contact area of the applied load (first mode) or the screw tips (second mode). However, the experimental tests reveal that the second mode never occurs despite the model predicting the occurrence of the second mode in more than half of the tested specimens. Additionally, the experimental tests show the fallacy of existing models in accurately estimating the capacity associated with the second failure mode. Parallelly, the model appears to be relatively conservative for the first failure mode.

KEYWORDS: Compression perpendicular to the grain, reinforcement with screws, experimental test

1 INTRODUCTION

The direction of the grain influences mechanical properties of wood, e.g. perpendicularly to the grain it presents considerable lower strength and stiffness [1]
Compression perpendicular to grain (CPG) failure leads to a collapse of the cellular tubes and acts as a failure transversely to the tubular layers.
Therefore, the CPG failure is a crucial problem, especially in the case of permanent deformation in the structures [2], even in the case when they do not cause structural failure.
In the case of CPG without reinforcement, the design approach proposed for the current draft of the new Eurocode 5 is based on the yield slip-line model, see Leijten [3].
Studies have also identified various techniques in improving the member strength in compression perpendicular to the grain (CPG) such as glued-in threaded rods and glued-on plywood plates. Alternatively, screws with uninterrupted threads have been observed to be economically viable in improving CPG capacity of timber members.
Therefore, the current draft of the consolidated version of the new Eurocode 5 on the table for discussion provides additional guidelines for implementing CPG with reinforcement [4].
The proposed design approach is based on the investigation made by Bejtka in 2005 [5], who observed three failure modes in timber subjected to CPG with reinforcement:

- the first failure mode is associated with pushing the reinforcing screws into the timber. It is observed with supports enhanced with short screws and the pushing-in capacity is assumed equal to the withdrawal capacity;
- the second failure mode occurs when slender screws are employed in reinforcing a member against CPG and it is characterised by buckling of the screws;
- the third failure mode is also associated with short screws in which a deformation is observed in a plane formed by the tips of the screws.

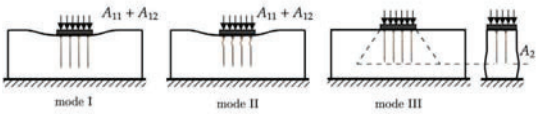

Figure 1: *Failure modes for CPG with reinforcements*

The minimum predicted value is considered to be the limit state to which the demand on a member in CPG may be compared for design. The candidate design approach still presents some gaps in knowledge concerning the test data that strengthen and validate the calculation model. Thus, Tomasi et al [6] experimentally investigated the CPG of

reinforced specimens, with the object of validating the standards approach, whose findings are summarized in this paper.

2 STANDARDS PROPOSAL

2.1 CGP WITHOUT REINFORCEMENT

The CPG model presented in [3] is based on the assumption that the compressive stresses spread as in an isotropic material with a degree depending on the deformations. The standard version of the model is given in Table 1.

Table 1: *Design model of non-reinforced members under CPG*

$$\sigma_{c,90,d} \leq k_p \cdot k_{c,90} \cdot f_{c,90,d} = B_1 \quad (1)$$

$$k_{c,90} = \sqrt{\frac{l_{ef}}{l_c}} \leq 4 \quad (2)$$

Where $k_{c,90}$ is a load arrangement factor, l_{ef} is the effective spreading length of the compressive stresses estimated by assuming a 45° diffusion angle, l_c is the contact length of the applied force, k_p takes into account the material behaviour and the deformation perpendicular to the grain (the factor accounts for the increased stiffness when the deformation increases).

2.2 CGP WITH REINFORCEMENT

Based on the failure modes described above, the capacity model proposed by Bejtka and Blass for CPG with reinforcement [7], is formulated as the minimum resistance associated with two following failure mechanisms (see Table 2):

- The first failure mode, labelled A_1, corresponds to the specimen failure by the contact area of the load. It is obtained by adding the timber and screw contributions, named A_{11} and A_{12} respectively. A_{11} accounts for the crushing of wood member at the support contact surface, adopting an effective length $l_{ef,1}$ higher than the contact length of the applied force, and k_{pr} for the material behaviour and the deformation perpendicular to the grain. A_{12} accounts for the pushing-in capacity of the screw including buckling effect.
- Second failure mode labelled A_2, considers failure of wood member with an effective length along a plane at the tip of the screws, which is determined adopting an effective length $l_{ef,2}$ calculated assuming a 45° diffusion angle.

The wood contribution A_{11} is coherent with the current guidelines in the Eurocode 5 for assessing unreinforced CPG in a member, which depends on the loading situation and the effective contact loading length due to the rope effect of contributing fibres adjacent to the loaded area.

Table 2: *Design model of reinforced members under CPG*

$$F_{c,90,Rk} = min\begin{cases} A_{11} + n \cdot A_{12} = A_1 \\ A_2 \end{cases} \quad (3)$$

where

$$A_{11} = k_{pr} \cdot b_c \cdot l_{ef,1} \cdot f_{c,90,k}$$

$$A_{12} = min\{F_{w,k}, F_{c,k}\}$$

$$A_2 = b \cdot l_{ef,2} \cdot f_{c,90,k}$$

$$l_{ef,1} = l_c + \min\{30\text{mm}, l_c\} + \min\{30\text{mm}, l_c, l_e\} \quad (4)$$

$$l_{ef,2} = l_r + (n_0 - 1) \cdot a_1 + \min\{l_r, a_{3,c}\} \quad (5)$$

The screw withdrawal strength can be calculated in function of the shear strength $f_{w,k}$ distributed along the screw surface areas according to this formula:

$$F_{w,k} = \pi \cdot d \cdot l_w \cdot f_{w,k}, \quad (6)$$

Where $f_{w,k}$ can be assumed as:

$$f_{w,k} = 8.2 \cdot k_w \cdot k_{mat} \cdot d^{-0.33} \cdot \left(\frac{\rho_k}{350}\right)^{k_\rho} \quad (7)$$

The screw buckling resistance is determined in function of an instability coefficient κ_c based on the model of a Winkler elastic beam in an elastic subgrade.

$$F_{c,k} = \frac{\gamma_R}{\gamma_{M1}} \cdot \kappa_c \cdot N_{pl,k} \quad (8)$$

where $N_{pl,k} = \pi \cdot \frac{d_1^2}{4} \cdot f_{y,k}$ and $\frac{\gamma_R}{\gamma_{M1}} \approx 1.18\ (*)$

*) $\frac{\gamma_R}{\gamma_{M1}}$ can be assumed equal to one for estimating the mean value of the buckling resistance.

3 EXPERIMENTAL CAMPAIGN

3.1 MATERIAL AND METHODS

The test specimens are glue-laminated timber of service class GL30 C, with dimensions of 800 × 140 × 225 or 1200 × 140 × 540 mm (length × width × height) with screw reinforcement produced by Rothoblaas and SFS. Figure 3 shows the considered load cases, tested with and without reinforcement, following the EN408 and ISO 6891 recommendations. The test procedure agrees with the one followed by Leijten [2], who investigated similar load cases without reinforcement.

Figure 2 show a schematic overview of the different screws, with the effective screw length applied in the design model. The screws are fully threaded self-tapping screws, except for the WT-T screw, which is double-threaded (in this case an effective screw length of 130 mm is used in the calculation). Each specimen is labelled with a unique name composed of its screw arrangement, screw

diameter, screw length, load case, and test number, see right Figure 2. All specimens were pre-drilled with a diameter 4.5 mm in a length of approximately 50 mm by using a bench pillar drill machine. The pre-drilling ensured having a straight hole, following the producer's recommendations for the diameter and length.
The screws are used in four arrangements according to Figure 4.

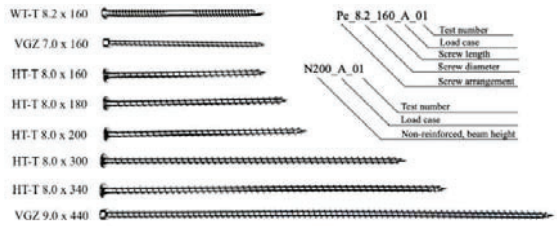

Figure 2: *Screws geometry and description of the labels for reinforced and non-reinforced test specimens.*

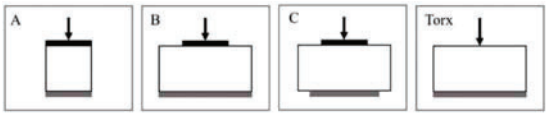

Figure 3: *Load cases*

It must be remarked that the experimental values cannot be compared with the characteristic resistance $F_{c,90,k}$ proposed in Equation (3). This is because the authors did not repeat each configuration multiple times to achieve a statistical description of the specific case. Therefore, an unbiased comparison with the experimental data requires estimating the predicted mean of the capacity. Hence, the mean of the resistance perpendicular to grain and yielding steel strength replaced the formulation's characteristic values in Table 2. The mean CPG timber strength is considered equal to $F_{c,90,m} = 3\,MPa$, following [8]. Conversely, the mean yielding strength of steel is set equal to 1000 MPa, based on separate experimental tests on the screws. The mass density of timber is assumed equal to $\rho_m = 390\ kg/m^3$. The load cases are graphically described in Figure 3.

- **Load case A** represents the block test of the specimens according to EN 408. For the reinforced samples, the predicted failure mode is the second, i.e. collapse by the screws' tips. Conversely, in the case of non-reinforced samples, the failure appears right below the load application area following to the first mode.
- **Load case B** considers a uniformly distributed load and corresponds to the case of the beam on continuous support (see left case in Figure 3).
- **Load case C** has direct loading on the opposite face. The support is a loading area of 140 x 180 mm (width x length). The goal is to investigate the failure in the reinforced area. Hence, the loading area is greater compared to the support (360 x 140 mm).
- **Torx:** This test directly loads the screw head and achieves the failure of the screw alone. The predicted failure mode is buckling for all screws, except for the shorter screws, where the effective screw length equals 130 mm. According to the theory of an elastic beam in elastic subgrade, the buckling capacity is not dependent on the screw length [9].

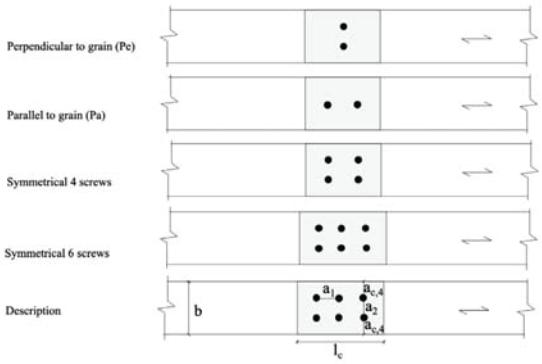

Figure 4: *Screw arrangement.*

3.1.1 Specimen preparation

The specimens were delivered as long beams by Moelven Limtre. The specimens were stored at the laboratory of wood technology at the material test laboratory of the Norwegian University of Life Sciences (NMBU). The relative humidity and the temperature during the storage are equal to 50% and 20° respectively. In a second step, the beams were cut into smaller pieces with a chainsaw to get the correct dimensions. The pre-drilling and insertion of the screw were done using electric drills produced by Bosch and Makita. The screws were drilled with a right angle, and the head was in all cases flush with the timber surface.

3.1.2 Testing procedure

The specimens are subjected to a compressive force by the load cell of the ZwickRoell Z1200 UTM (Universal Testing Machine). The deformation is measured by an integrated sensor in the load cell and external sensors. During the test execution, two horizontal and two vertical sensors are used, see Figure 5. The horizontal sensors are placed on each long side of the specimen corresponding to the screw tip. All estimations are carried out following EN408 and ISO6891 recommendations.

3.1.3 Loading protocol

There is no standard procedure for testing members subjected to CPG with screw reinforcement. However, the tests are executed on the basis of EN408 and ISO6891. In the ISO6891 procedure of loading the estimated load, F_{est} is determined as the minimum between A_1 and A_2. In the case of non-reinforced members for load cases B and C, the force is estimated with k_p equal to 1.0.
The test consists of four phases. Phases 1,2 and 3 are based on load rates, while the fourth is displacement-driven. Phases 1 and 2 follow the ISO6891 and aim to avoid residual initial deformations and stabilize the

https://doi.org/10.52202/069179-0393

loading area. The specimen is loaded up to 40% of the estimated resistance F_{est}, held for 30 seconds before the load decreases to 10% of F_{est}, and then held for 30 seconds. The load rate in phases 1 and 2 is determined as the ratio between 40% and 10% of F_{est} respectively, and 60 seconds. The actual load-displacement curves used in the analyses correspond to phase 3. Phase 3 follows the EN408. Hence, the maximum force will be reached within 300 ± 120 seconds. Phase 4 has a 1mm/min deformation rate, following Dietsch [10]. The test will stop automatically if the load reduces to 20% or the level of deformation reaches 12%.

In load cases A and Torx, the tests are executed with the first three phases, while load cases B and C are executed following the entire protocol. The Torx test is executed by connecting a Torx bit to the load cell through a steel plate. The mean moisture content of the specimens measured by a Delmhorts RDM3 instrument was 12.3%.

3.1.4 Estimation of the experimental capacity

The failure load for non-reinforced specimens has been estimated using an iterative procedure similar to the one described in EN 408 to estimate the compressive strength. Based on the load-displacement curves the line referring to the plausible elastic range between 10% and 40% of the estimated capacity is translate in a new parallel line, with 1% offset to the gauge length. The intersection between this second line 2 and the load-deformation curve determines the estimated capacity (F_{est}). If this value is within 5% of the predicted one $F_{c,90,est}$, it is considered valid. Otherwise, the process is repeated until the value is within the 5% tolerance.

3.2 EXPERIMENTAL RESULTS

he authors reported 31 tests with eight different screws in four loading conditions. The load-displacement curves exhibit an initial linear elastic behaviour, see Figure 5. The slope of the curves reduces when the load approaches the maximum load. After this point, the load decreases. This range corresponds to the failure of the screws and the local crushing of timber. After the screw failure, there is a slight increase in capacity after a certain point. This growth is related to the activation of the timber contribution. In the elastic range, the load-displacement curve has the same trend. Beyond the plastic range, the load-deformation curve depends on the specific failure mode. The horizontal expansion is below 2 mm for all cases, except for load case A, although it does not represent a design situation.

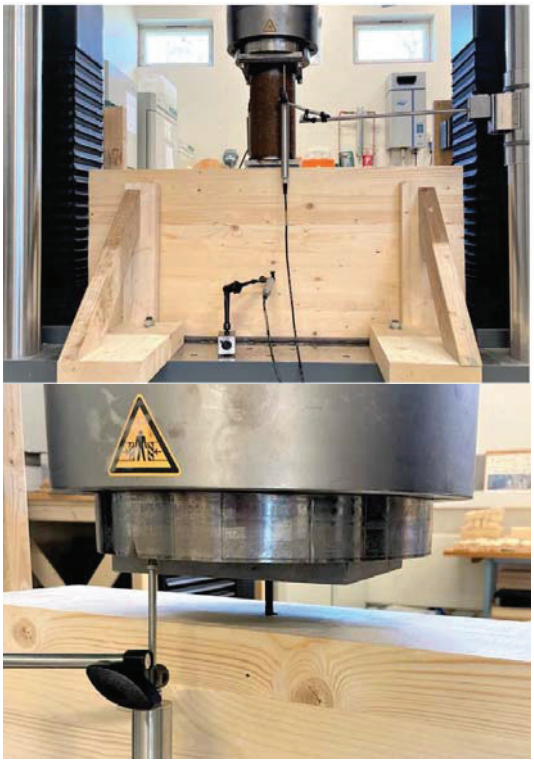

Figure 5: *Setup of specimen with height 540 mm in ZwickRoell Z1200- Setup of Torx test.*

Figure 6 plots all experimental results for load cases A (block test) B and C for the specimen with H = 225 mm, while Figure 7 plot the torx test results. The relevant experimental outcomes are resumed in ***Table 3*** and Table 4. The tables collects the test label, the failure mode, the maximum force (for torx test) and that corresponding to 1% deformation. The column 'increase' reports the percentage increment in capacity due to the presence of screws compared to the specimen without reinforcement.

The major aspects are:

Case A: The capacity increases slightly with the reinforcement. The observed failure mode is the timber failure, despite the significant deformation of the screws. The load-displacement curves are close to each other. As expected, the elastic stiffness of the reinforced model is higher. Theoretically, the effective diffusion length of the reinforced specimen is not fully exploited due to the specimen's geometry.

Case B: The failure modes are buckling and withdrawal. The horizontal displacement is below 1 mm for all cases, except for S6_7.0_160_B, where the horizontal displacement is 1.50 mm. Test Pa_7.0_160_B and Pe_7.0_160_B exhibited the same resistance at 1% deformation. The difference between the configurations is the screw arrangement. The curves of the reinforced specimens have a peak and then decrease, while those of the non-reinforced ones monotonically increase. As expected, the reinforcement causes a higher stiffness. The configuration S6_7.0_160_B shows a significant increase

in capacity. However, the configuration has a considerable number of screws, and the contact area is increased to 140 x 360 mm (width x length). For the configuration S6_9.0_440_B, the horizontal displacement is greater than 1 mm; otherwise, the horizontal displacement is below 1 mm. In the configurations with a 540 mm height, the predicted failure mode, A_1, is confirmed by the test results, except for S6_9.0_440_B. The capacity model yields a 20% overestimation of the test results. Interestingly, no differences emerged between the two configurations with different orientations of the screws (perpendicular or parallel to the grain direction). The predicted failure mode of the screws in the 540 mm specimen is buckling, except for the screw WT-T 8.2 x 160 mm, where withdrawal is reported.

In contrast to the predictions, all screws with a 160 mm length failed due to withdrawal.

In the case of 2 x HT-T 8.0 x 180 mm screws, the failure mechanism is both withdrawal and buckling.

4 x HT-T 8.0 x 180 mm has an apparent withdrawal failure. Similarly, HT-T 8.0 x 200 mm changes the failure mode with the number of screws. Considering a constant load area, the capacity variation between the load configurations may be due to screw length, diameters, and timber imperfections.

Case C: A steel plate with dimensions 360 x 140 mm (length x width) is applied on the non-reinforced side. The capacity of the test specimens increases with the reinforcement. The horizontal displacement is approximately 1-2mm for all cases. The configuration with 2x VGZ 7.0 x 160 mm had a higher capacity than 2 x WT-T 8.2 x 160 mm. The curves of reinforced specimens have a peak and then decrease. The capacity increases with the number of screws. For 225 mm specimens, the failure mode is withdrawal, despite the predictions. The distinction in capacity between A_1 and A_2 is minor.

Torx: The failure modes of the screws are withdrawal and buckling, see Figure 8. The load increases with the length of the screw, except when the size of the screw is 200 mm. In this case, the capacity decreases. All curves exhibit a clear peak. With the VGZ 7.0 screw, the capacity is higher compared to the HT-T 8.0 screw. However, the failure is reached at a smaller displacement. Contrary to the previously reviewed tests, the maximum force achieved is estimated. The predicted failure mode corresponds to the test results, except for VGZ 7.0 x 160 mm, where the failure mode is withdrawal. The design model's decisive capacity is consistently lower than the test results. The mean ratio between the test results and the predicted capacity is 1.55. The impact of the slenderness is considered by testing the HT-T screw with a constant diameter and different lengths. In all cases, the screw failed due to buckling.

3.3 DISCUSSION

The screw and timber contribution to the capacity of the reinforced specimens can be isolated using the outcomes of the Torx tests. Since the timber contribution in the Torx test can be assumed negligible, the Torx tests provide the contribution of a single screw. Accordingly, the role of timber can be estimated by subtracting from the force associated with 1% deformation the capacity obtained from the Torx test multiplied by the number of screws. The timber contribution to the capacity according to the failure mechanism A_1 , named A_{11}, reads:

$$A_{11} = \left(F_{1\%,def} - n \cdot F_{max}\right) \quad (9)$$

Parallelly, the average screw contribution to the capacity, named A_{12}, can be obtained from the $F_{\max}$ of the Torx tests as follows:

$$A_{12} = F_{max} \quad (10)$$

The main aspects emerging from the experimental results are the following:

- The timber contribution to the capacity of the reinforced specimen is approximately 73% and 51% for the samples with two and four screws, respectively. This fact proves that using four rather than two screws reduces the timber contribution by nearly 20%.
- The timber contribution moderately varies if the screw length increases from 160 mm to 440 mm. The A_{11} contribution is on average, 110 for 160 mm screws and 137 for 440 mm.
- The model significantly underestimates the screw contribution by 42% on average. Conversely, the disparity in terms of timber contribution is lower. On average, it is 2% for the two-screws specimens and -22% for the four screws. On the contrary, in this case, the design model overestimates the timber contribution for the four screws specimens. The mean timber contribution from test results is 72% and 51% with two and four screws, respectively. In the design model is 72% and 45%, with two and four screws.
- According to the standard proposal, k_{pr} should be 1.5 for load case B and 1 for load case C. Still, the experimental data contradict these assumptions. The test results for load cases B and C with identical screw arrangements (except for the size of the steel plates) are within the same range of capacity. The dissimilarity is insignificant and lower than 10% in most cases and on average 2%. Therefore, this fact proves that the capacity of the two load cases can be predicted with the same k_{pr} coefficient.

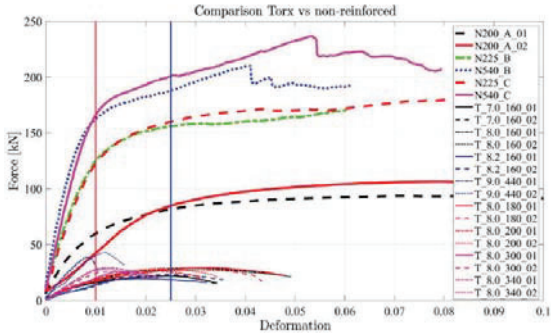

Figure 7: *Comparison between the torx tests on the single screws and those on non-reinforced specimens.*

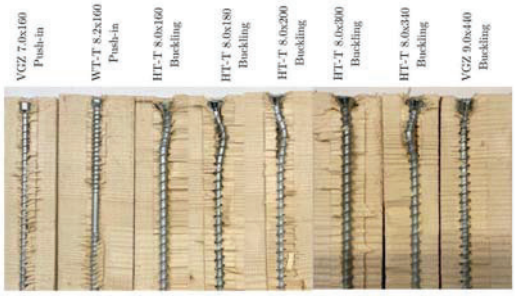

Figure 8: *Failure modes of the tested screws.*

Figure 9 plots the experimental capacity ($F_{1\%,def}$) and A_1, A_2 obtained from the design model. The most relevant aspect is that while A_1 and the experimental capacity are in good agreement, except for case C, A_2 is mostly lower than $F_{1\%,def}$ and exhibits a high scatter.

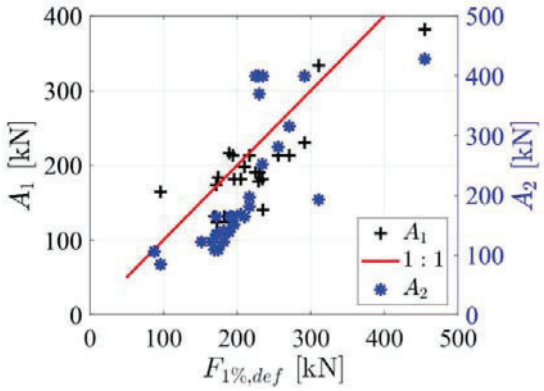

Figure 9:*. Experimental vs model predictions for the first (A1) and second (A2) failure mechanism,*

The failure mode achieved for all tests is according to A_1 for load cases B and C. However, some of the predicted failure modes appear to be different from the results of the experimental campaign. For example, in the event of shorter screws, the expected failure mode is mostly buckling, while the achieved failure mode is withdrawal. This evidence further proves that the specimen's failure corresponds to the A_1 mechanism. Additionally, it suggests that the A_2 model might be inaccurate and possibly underestimate the timber contribution by the screw tips. Consequently, it can be assumed that the capacity of A_2 is higher than the test results for load cases B and C. This fallacy possibly originates from the definition of the spreading length.

This failure mode A_2 is observed by Bejtka with small loading areas and short screws[5]. At the end of the screw, the force is transferred to the timber. The maximum pressure in the timber emerges at the screw tip and depends on the effective dispersion length and width. The effective length depends on the length of the screws, the screw arrangement, and the design situation.

This experimental outcome encourages researchers to study this aspect further to derive a reliable expression for the spreading length in predicting the capacity associated with the A_2 failure mechanism. Notably, the predictions for load case C are biased. The model underestimates the capacity, as a consequence of assuming $k_{pr} = 1$, as above remarked.

The timber contribution to resistance corresponds to the 1% deformation, while the screw contribution corresponds to the screw resistance, taken as the minimum between the buckling and the push-in resistances. However, this hypothesis is valid if the resistance of the screws is approximately reached at 1% deformation. Yet, the main difficulty behind this verification is the correct computation of the deformation in the Torx tests. While the specimen deformation in the non-reinforced specimens can be estimated as the ratio between the vertical displacement and the specimen height, this calculation might not be correct in the case of the Torx. During the push-in or buckling of the screws, the measured displacement does not result in the deformation of the entire specimen since only the

https://doi.org/10.52202/069179-0393

cylindrical layer wrapping the screw is affected by the deformation.

Therefore, the timber deformation associated with the Torx tests could be defined as the ratio between the vertical displacement and the screw length. Figure 7 compares the force-deformation curves of the non-reinforced and Torx tests, where the deformation in the non-reinforced specimens is computed as the ratio between the measured vertical displacement of the timber plate and the specimen height. The force-deformation curves of the non-reinforced samples are almost alike, showing a bend almost to the 1% deformation. The Torx tests exhibit a similar behaviour since the plastic branch approximately occurs between 0.01 and 0.02 deformation. Therefore, given the excellent estimation of the screw contribution A_{12} highlighted in the previous paragraphs, the authors conclude that the additivity hypothesis can be considered a reasonable assumption for a Standard. It must be remarked that the comparison in Figure 7 is only based on non-reinforced specimens to exclude all possible interaction phenomena occurring in the reinforced samples. The timber and screw contribution are already summed in the reinforced specimens. Thus, it is challenging to divide them and verify the additivity hypothesis.

4 CONCLUSIONS

This paper discusses experimental tests of timber specimens with screw reinforcement under compression perpendicular to the grain (CPG). In detail, the CPG tests comprise 31 structural arrangements different for the number and placement of the screws, specimens geometry and load pattern. The experimental capacities are used to validate the accuracy of the design model proposed in the next generation of Eurocodes. The experimental results show that using threaded screws as reinforcement effectively increases the capacity of timber subjected to CPG. However, the measured capacities do not entirely agree with the design model predictions. The current predictive model assumes two failure mechanisms, mainly distinguished by their location: the applied load's contact area (first mode A_1) or screw tips (second mode A_2). The first model is based on the mere summation of the timber and screw contributions. The failure modes achieved in the tests confirm the accuracy of the A_1. These tests ascertain the additivity hypotheses behind the predictive model. The experimental tests reveal that the second mode never occurs despite the model predicting the occurrence of the second mode in more than half of the tested specimens.

Conversely, the estimates corresponding to the failure mechanism A_1 agree with the test results. Yet, the predicted capacity is a bit lower for load case C. This might depend on the k_{pr} coefficient, assumed 1.5 and 1 for load cases B and C, respectively. The overall predicted failure mode of A_1 is mainly confirmed, except for the shorter screws.

The paper shows that the model predictions significantly improve if the same $k_{pr} = 1.5$ is assumed for all load configurations. Nonetheless, the additivity hypotheses for the A_1 failure mode can be considered sufficiently accurate for standards.

MODIFICATION OF PARTIAL SAFETY FACTORS FOR A SEMI-PROBABILISTIC EVALUATION OF EXISTING TIMBER STRUCTURES

Maria Loebjinski[1], Wolfgang Rug[2/3], Hartmut Pasternak[4]

ABSTRACT: The evaluation of the load-bearing capacity of existing structures is a central and important part in the work of structural engineers. At state, engineers are confronted with the challenge of applying design rules developed for new structures in the evaluation of existing ones as no specific recommendations exist on a European level. This task needs to be addressed in the development of common codes and standards. As a contribution, a first step of this study is the evaluation of the reliability level of timber elements subjected to common limit states. Based on these analyses, a modification of the target reliability for existing structures is discussed and a suggestion for different levels is given. In another step, this contribution presents a proposal for a stepwise procedure for the evaluation of the load-bearing capacity of structural timber in existing structures considering different levels of available information. Focus is set on the provision of a flexible semi-probabilistic evaluation concept; modified partial safety factors are calibrated on the resistance side for selected limit states. Additionally, options to consider updated material parameters from a survey on site supported by technical devices are discussed and further need for research is identified.

KEYWORDS: existing timber structures, evaluation, partial safety factor, code calibration

1 INTRODUCTION

Eurocodes form the basis of design and verification of structures. At state, rules for the design of new structures are applied for the evaluation of the load-bearing capacity of existing structures. The newly introduced Technical Specification *CEN/TS 17440:2020-10* [1] as a first common specification for the evaluation of existing structures offers new paths: qualitative evaluation, quantitative evaluation or a combination of both. A qualitative evaluation is based on past performance of the structure. For a quantitative evaluation, the *Partial Factor Method* is recommended, reliability-based methods and risk-informed methods can be applied additionally. The assessment should verify that the structure has adequate reliability. Target values can be taken from *EN 1990* [2] or may be defined in National Annexes. As the target reliability is defined based on an optimisation of failure consequences and efficiency of safety measures (see *ISO 2394:2015* [3] or *SIA 269/2011* [4]), an altered definition for existing structures is possible. Annex C of [1] formulates that "The target reliability level for existing structures can be lower than that for new structures as the relative cost of safety measures to increase the reliability of an existing structure is greater than that for a new structure." (C.3.(4) Note 2). Thus, *CEN/TS 17440:2020-10* [1] opens new ways for the adjustment of the well-proven semi-probabilistic verification format of the Eurocodes for their application on the special demands in the evaluation of existing structures. Basis for an evaluation of the load-bearing capacity of an existing structure is a careful and detailed investigation including an assessment in situ. For existing structures, different national recommendations, on an international level *ISO 13822:2010* [5] and with special focus on existing timber structures *EN 17121:2019* [6] provide the basis for a qualified assessment. Updated information from an assessment on site should be considered in the modified semi-probabilistic evaluation. Results are always specific for the structure at hand what complicates standardisation. Thus, a structured process including options to modify safety elements is needed to systematize the use of updated information in the evaluation.

2 METHODOLOGY

Loads and material parameters are subjected to a natural variability. Besides, model uncertainties have to be considered. Thus, the resulting reliability of different limit states varies depending on the input variables. Hence, a standard cannot provide a reliability level that is most optimal for all kinds of limit states [7], safety elements are defined by optimisation. What is more, [8] emphasizes that reliability indices can hardly serve as indicators without direct link to the model parameters used to calculate them. The calculation of the implicit safety level of current design is hence a good and goal-oriented option to produce reliable values. This approach presupposes that

built structures satisfy public safety requirements [9]. The reliability index β is thus a comparative value of the actual analysis and should not be used separated from the underlying model assumptions.

Based on these considerations, the following path is chosen: Timber members in common limit states are designed for a 100% utilisation of the semi-probabilistic design-check equations with current partial safety factors (PSF) from EC 1 [10] and EC 5 [11] ($\gamma_G = 1.35$ for permanent loads, $\gamma_Q = 1.5$ for variable loads, $\gamma_M = 1.3$ for structural timber strength properties) and evaluated by reliability analyses. The resulting reliability level is determined for a set of limit states, load ratios and a range of the coefficient of variation (*cov*) of the material strength. Based on the obtained reliability level, PSF are calibrated for chosen limit states aiming for an optimised verification of existing timber structures with dominating limit states clearly defined. Besides, options to update PSF based on new information are discussed. Finally, a proposal for a stepwise evaluation procedure is presented. Selected limit states for the analyses are given in Figure 1. The numbering is used in the presentation of results.

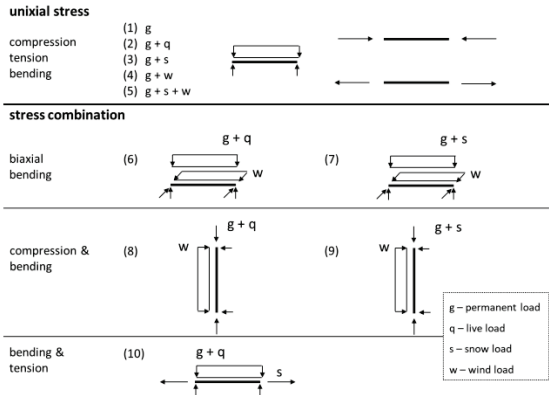

Figure 1: *Loads, load directions and stresses*

The general formulation of the limit state function (LSF) is given by eq. (1)

$$g_i(R, G, Q_1, Q_2, \theta_R, \theta_G, \theta_{Q1}, \theta_{Q2}) = z_d \theta_R R - LA_G \theta_G G - (1 - a_G)\left(LA_{Q1}\theta_{Q1}E_1 \cdot (1 - LA_{Q1})\theta_{Q2}E_2\right) \stackrel{!}{=} 0 \quad (1)$$

with R the resistance variable and θ_G its model uncertainty, G the permanent action and θ_G the model uncertainty associated with it. Q_1 and Q_2 are two variable actions, θ_{Q1} and θ_{Q2} their model uncertainty variables. LA_G is the load ratio of the permanent action and LA_{Q1} is the load ratio of the first variable action in relation to the total variable load. Variable loads are combined using the *Ferry Borges & Castanheta* combination rule [12]. What is more, z_d is the design parameter to ensure a one-hundred percent utilisation of the semi-probabilistic design equation, see [13]. It can be calculated by eq. (2) for one an eq. (3) for two variable actions

$$z_d \frac{k_{mod} \cdot f_k}{\gamma_M} - \gamma_G LA_G g_k - \gamma_Q (1 - LA_G) q_k \stackrel{!}{=} 0 \quad (2)$$

$$z_d \frac{k_{mod} \cdot f_k}{\gamma_M} - \gamma_G LA_G g_k - \gamma_Q (1 - LA_G)\left(LA_{Q1} q_{1,k} + (1 - LA_{Q1}) q_{2,k}\right) \stackrel{!}{=} 0 \quad (3)$$

with k_{mod} the modification factor for load duration and service class, f_k, g_k and q_k the characteristic values for the material strength, permanent and variable loads respectively. Limit states have been formulated according to EC 5-1 [11]. Probabilistic parameters are given in Table 1. The *cov's* of the material strength are based on [14] and a broad literature study in [15]. The influence of alterations of the material *cov* are studied. *Cov's* for live loads are based on own calculations applying [16, 17], see [15]. Parameters for snow and wind loads are based on [17] (wind) and [18] (snow). Load change rates have been oriented on [13] and adopted for German climatic conditions. Please note that in the current version of the JRC documentation "*Reliability background in the Eurocodes*" (unpublished) a higher variability of snow and wind loads has been documented. This especially affects the time-invariant part (taken here with $V_\theta = 0.10$). Besides, the variability of the bending strength is lower in the mentioned report ($V_{fm} = 0.20$) than in the present study ($V_{fm} = 0.25$). As the report was not published at the time of preparation of this contribution, values have been assumed based on the official background documentation of *DIN 1055-100* [18] and the *JCSS PMC* [14, 17].

The reliability analyses are performed by *First Order Reliability Method (FORM)* [19] in MATLAB® [20]. Calculations have been double-checked by exemplary hand calculations with the help of [21] and a selection of *Monte Carlo Simulations* (*MCS*) in MATLAB® [20]. To study the influence of the variables on the calculated reliability, sensitivity factors for selected configurations are shown. Based on the results, a proposal for the target reliability is worked out. γ_M is then calibrated for a set of limit states by *FORM*. As permanent loads can be updated on site, an update of permanent actions as suggested in *SIA 269/2011* [4] is considered in the modification of γ_G and an adjustment of the stochastic properties in the calibration. To avoid systematic programming errors, the

verification is done by *Monte Carlo Simulation* (*MCS*). All calculations have been performed on single structural components. Calibrated PSF and a suggestion for the update of γ_M based on a reference property are structured in an evaluation procedure for practical application. All calculations have been performed for $T_{ref} = 50\ years$.

3 RESULTS

3.1 Reliability analyses

3.1.1 Permanent loads (1)

Figure 2 and Table 2 show the results for permanent load with three different *cov's*. The blue line indicates the target of EN 1990 Annex C ($T_{ref} = 50\ years$) and consequence class (CC) 2. The sensitivity factors confirm the dominating influence of the structural resistance on the reliability. Please note that $\sum \alpha^2 = 1$; an α-value close to 1 shows a great influence of the considered value on the calculated reliability. For $V_G \geq 0.10$ the calculated reliability is lower than the target from EC 0, Annex C.

3.1.2 Permanent and one variable load (2), (3) & (4)

The analyses have been performed for one variable load with $V_Q = 0.25$ (Figure 3, Table 3). The reliability analyses show lower reliabilities than the target. Sensitivity factors reveal the increasing influence of the variable load with increasing load ratio.

Further analyses have been performed for one variable load (wind load) with $V_W = 0.16$ (Figure 4, Table 4). Recent analyses on wind load modelling can be found in [22]. Further studies indicate that the total wind load could be modelled using *cov's* in the range $V_{W,50} = 0.20...0.25$, see e.g. [23, 24]. For further calculations in this study $V_{W,50} = 0.16$ for the time invariant part based on the calculation applying the coefficients in [17] as indicated above and with regard to studies in [25, 26] and $V_{W,\theta} = 0.10$ for the time-invariant part is assumed.

3.1.3 Permanent, snow and wind load (5)

Figure 5 illustrates the reliability for flexural stress from combinations of permanent, snow and wind load. An analysis for Germany showed that for roof angles 30° < α < 75° the load ratio of permanent loads is approximately 50% for normal roof weights (comparison of mean values, coastal areas excluded). Thus, exemplary sensitivity factors for $LA_G = 0.5$ and two different *cov's* of the material strength are given in Table 5**.** Due to the assumed low variability of the wind load its influence on the reliability is rather small. Note that these values are exemplary for $LA_G = 0.5$ and the influence of variable loads increases with greater load ratio.

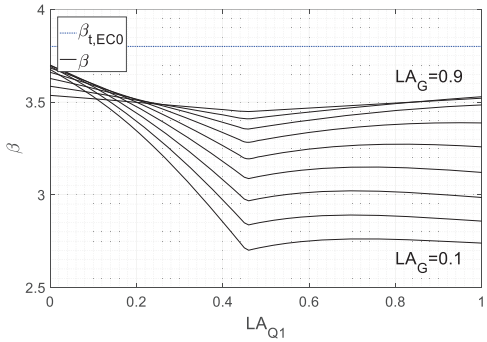

Figure 5: *Reliability index for permanent and variable load 1 (snow) and variable load 2 (wind) with $V_R = 0.25$, uniaxial stress (5)*

3.1.4 Biaxial bending (6) & (7)

Biaxial flexural stress from permanent load and snow (6) or live (7) load in one direction and wind load in the other direction, as relevant for e.g. purlins or half-timber walls, have been analysed, considering different load presence time n_p and load change rate n_r. Flexural strengths in both directions are correlated with $\rho = 0.8$. The ratio of width and height has been assumed $b/h = 1/2$; a ratio was needed to calculate the design parameter z_d. However, the influence of the latter has been turned out to be rather small. A load distribution factor $k_m = 0.7$ for rectangular cross sections has been applied according to EC 5-1 [11]. Figure 6 and Figure 7 show the results. It has turned out that the difference to one-axial bending is rather small for the considered configurations. Sensitivity factors are very similar to Table 5 and thus not repeated here, details can be found in [15].

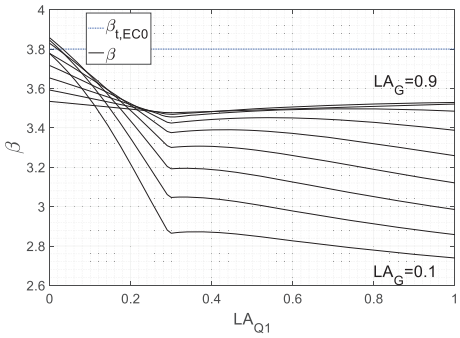

Figure 6: *Reliability index for permanent and variable load 1 (snow) and variable load 2 (wind) with $V_R = 0.25$, biaxial bending (6)*

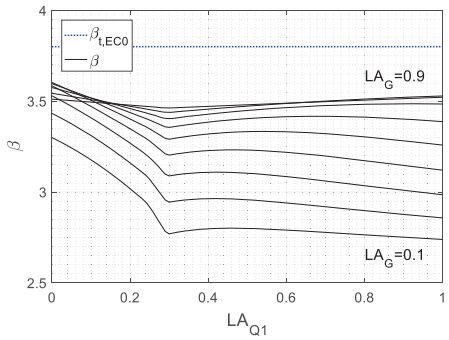

Figure 7: *Reliability index for permanent and variable load 1 (live load) and variable load 2 (wind) with $V_R = 0.25$, biaxial bending (7)*

3.1.5 Compression + bending (8) & (9)

The combination of compression and flexural stress has been analysed for compression from permanent and snow load (8) / live load (9) and bending from wind load as e.g. relevant for struts in roof structures of half-timbered walls. Strength properties are correlated with $\rho = 0.8$. The ratio of width and height is $b/h = 1/2$. Figure 8 and Figure 9 show the reliability. The analyses show that for LA_{Q1} the reliability is rather constant for an increasing ratio of variable load one (snow in (8); live load in (9)). Table 6 and Table 7 sensitivity factors for $LA_G = 0.5$.

3.1.6 Tension + bending (10)

The combination tension and flexural stress has been analysed for tension from permanent/snow load and bending from live load (e.g. tension beams in collar beam roof structures). Strength values are correlated ($\rho = 0.8$). The ratio of width/height is $b/h = 1/2$. Figure 10 shows the reliability, Table 8 shows exemplary sensitivity factors, that reveal the dominating influence of the combination of snow load and tension stress. The reliability has been found out to be comparatively low, which is due to the disadvantageous combinations of variables with a high variability. However, it has to be noted that in existing roof structures this limit state for the mentioned elements is commonly not characterised by a utilisation of 100 %.

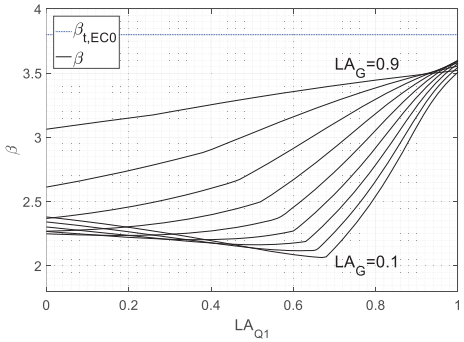

Figure 10: *Reliability index for tension from permanent and variable load 1 (snow) and bending from variable load 2 (live load) with $V_{R,m} = 0.25$, $V_{R,t} = 0.30$ (10)*

3.2 Summary and discussion of target reliability

The analyses of these rather simple limit states result in significant lower reliability indices than the target from *EC 0 Annex C* [2] for consequence class CC2 ($\beta = 3.8$, $T_{ref} = 50\ years$). The aim of the present study is to work out a proposal for an adjusted semi-probabilistic verification format for existing timber structures. As a basis it is assumed that current design fulfils public safety requirements and can thus serve as a basis to define target values. This assumption is justified as no increased number of failure events has been documented for these common limit states. Thus, it is suggested to take the average reliability level from the presented analyses as a target value. The combination of tension and bending can be excluded as these members mostly do not show a utilisation of 100%; verification is often governed by connections which is not in the focus of this work. Based on the presented analyses $\beta_{t,exis} = 3.2$ is suggested.

According to [27] two levels are needed for the evaluation of existing structures: a minimum level and a target level. For the evaluation of existing members in structures not affected by structural changes and supposed to clearly defined dominating limit states it is suggested to apply a target reliability, that considers aspects of economic optimisation. [28] suggest to apply $\Delta\beta = -0.5$ for a target reliability of existing structures and $\Delta\beta = -1.5$ for a minimum reliability. [29] suggests to move one line higher for the relative costs of safety measures from *ISO 2394:2015* [3] what results in $\Delta\beta = -0.2 \ldots -0.9$. Based on the results of the analyses, $\beta_{t,eval} = 2.9$ is suggested as a target for members in service ($T_{ref} = 50\ years$) that

https://doi.org/10.52202/069179-0394

are not affected by damages or major changes. During calibration of partial safety factors, a scatter around the target will occur. During the calibration for the defined target, the reliability should not fall below the minimum level $\beta_0 = 2.5$. which is the minimum reliability level under economic optimisation in [30]. Alterations of structural members should be verified using the same safety elements as for new structures.

3.3 Calibration of partial safety factors

3.3.1 Method

The major work in engineering practice is performed applying the semi-probabilistic safety format using partial safety factors (PSF). For the limit states (1) – (9) (Figure 1) and the target reliability levels proposed above the PSF $\gamma_{M,opt}$ for the material strength has been calibrated. The general optimisation procedure is described in [3, 31, 32] and given in eq. (4)

$$min\, D\,(\gamma_M) = \sum_i w_i w_{pen} (\beta_i - \beta_t)^2 \qquad (4)$$

with w_i the weighting factor for the LSF and w_{pen} a penalty factor, penalising a reliability lower than the target more than a higher one [9]. Different penalty functions have been investigated in [13]. For this work, penalty factors from eq. (5) have been applied.

$$w_{pen} = \begin{cases} 1 & for \quad \beta_i \geq \beta_t \\ 1 + (\beta_i - \beta_t) & for \quad \beta_i < \beta_t \end{cases} \qquad (5)$$

All considered load combinations of snow and wind load have been weighted equally, as studies indicated that they vary a lot depending on location and roof angle and no clear weighting could be identified [15]. For permanent and live load, the weighting factors in Table 9 have been considered and compared to results assuming $LA_G = 0.5$ and $V_N = 0.25$ only. Results of the three options have turned out to lead to similar results.

Table 9: *Weighting factor w_i for permanent and live loads*

	V_N	LA_Q	w_i		Remarks
			a	**b**	
1)	0,25 (A > 20m²)	0,3	0,50	0,35	*Live load categories office, lobby and living room with A > 20m², and hotel and class rooms.*
2)	0,25 (A > 20m²)	0,5	0,40	0,50	*Live load categories office, lobby and living room with A > 20m², and hotel and class rooms.*
3)	0,40 (A ≤ 20m²)	0,5	0,10	0,15	*Live load categories office, lobby and living room with A ≤ 20m², and hospital rooms.*
			$\Sigma = 1$	$\Sigma = 1$	

During calibration the PSF for permanent and variable loads have been fixed to $\gamma_G = 1.20$ and $\gamma_Q = 1.50$, respectively. The value $\gamma_G = 1.20$ takes into account a reduced variability of permanent loads obtained in a survey on site and is chosen based on [4]. The reduced variability is also considered by a reduced variability of permanent actions of 7% instead of 10% to consider an investigation on site. The results are based on a load ratio of permanent loads of $LA_G = 0,5$ and further statistical parameters given in Table 1.

3.3.2 Results

Table 10 and Table 11 show the results for the suggested reliability index for the evaluation level. In [15] results for further reliability indices can be found.

Table 10: *Calibration results $\gamma_{M,opt}$ for the proposed evaluation level and uniaxial stresses*

$V_{R,m}$ – coefficient of variation (cov) of the bending strength. cov of compression strength correlated by $\rho = 0.8$

3.3.3 Summary and Proposal

Keeping in mind practical applicability, the number of PSF should be limited. Thus, a simplified set of optimised PSF $\gamma_{M,opt}$ is proposed that considers the inhomogeneity and anisotropy of timber as structural material but keeps the intended ease of use of the semi-probabilistic design / evaluation format, (Table 12). As $\gamma_Q = 1.5$ for all variable loads, $\gamma_{M,opt}$ also depends on the considered loads. The application of different PSF for different variable loads to consider their statistical properties properly would help to reach a more uniform reliability level.

Table 12: *Proposal for a set $\gamma_{M,opt}$ for the evaluation level*

stress	**loads**	
	perma-nent	combinations with variable loads
compression parallel to grain	1.15	1.20
bending, two-axial bending, comp.& bending	1.20	1.20
tension parallel to grain	1.30	1.30

Remarks: Calibration for $\beta_{t,eval} = 2{,}9$, live load categories A and B, snow and wind loads, load ratio of permanent load $LA_G \geq 0.5$, $\gamma_{G,up} = 1.20$, $\gamma_Q = 1.50$

In order to apply the results (Table 10, Table 11) for an updated material variability from material tests, a sufficient number of tests has to be considered. A proposal in [26] introduces a conversion factor to account for a limited number of tests. For rehabilitation measures PSF as for new structures should be applied in accordance with [33] where it is stated that structural members directly affected by changes should be verified applying the same requirements as for new structural members.

3.3.4 Verification of PSF

The verification of results is an important part of scientific work. While the calibration of modified PSF has been performed with *FORM*, the verification has been performed by *MSC* (crude *Monte Carlo Sampling*) to avoid systematic programming errors. Results have been double checked with *FORM* analyses. Exemplary results are presented in Figure 11 to Figure 16 (graphs produced applying *FORM* after double check with *MCS)*. All analyses are performed for $T_{ref} = 50\ years$. All figures are based on a 100% utilisation of the semi-probabilistic design-check equation. PSF are $\gamma_{G,up} = 1.20$, $\gamma_Q = 1.50$, $\gamma_{M,opt} = 1.20$.

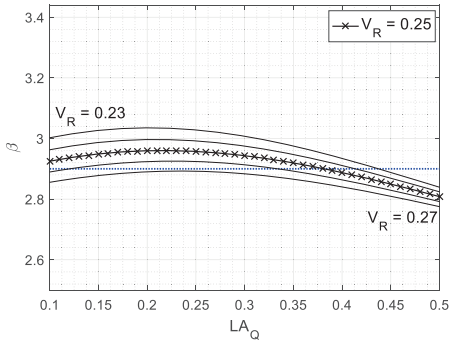

Figure 11: *Reliability index for uniaxial stress, permanent and one variable load with* $V_Q = 0.25$

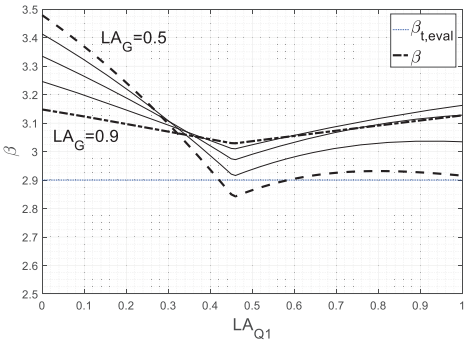

Figure 12: *Reliability index for uniaxial stress, permanent, snow and wind load,* $V_R = 0.20$

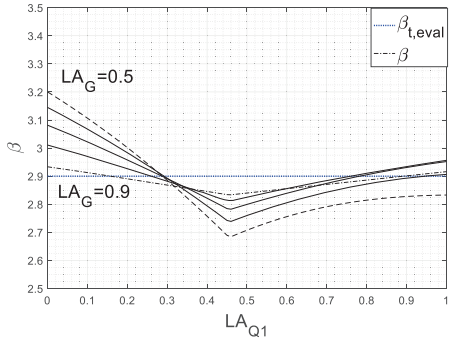

Figure 13: *Reliability index for uniaxial stress, permanent, snow and wind load,*$V_R = 0.25$

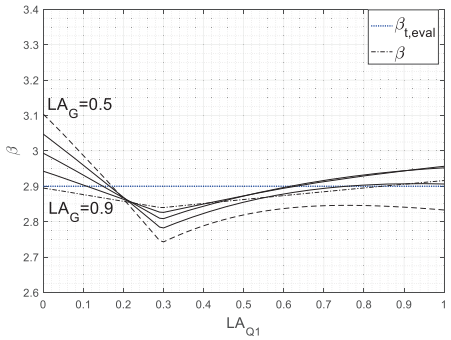

Figure 14: *Reliability index for two-axial bending, permanent, snow and wind load,* $V_R = 0.25$

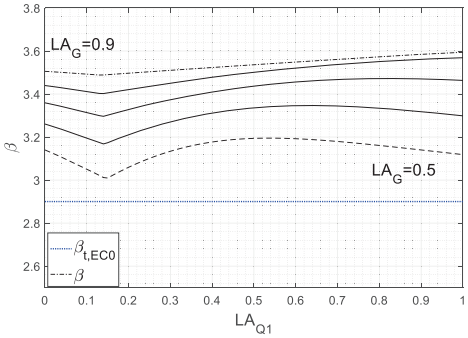

Figure 15: *Reliability index for compression and bending, permanent, snow and wind load,*$V_{R,m} = 0.25$, $V_{R,c} = 0.20$

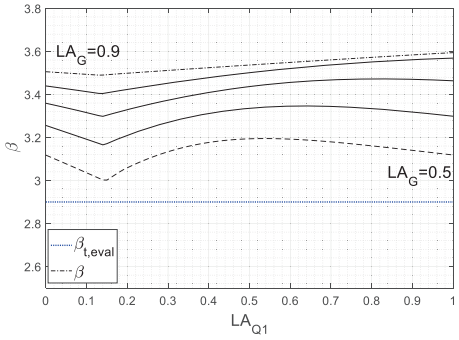

Figure 16: *Reliability index for compression and bending, permanent and live and wind load,*$V_{R,m} = 0.25$, $V_{R,c} = 0.20$

Neglectable differences between results of FORM and MCS have been identified. Thus, for the investigated limit states a sufficient accuracy of the approximation by FORM is given and systematic errors are not present.

The results show that the calibration target $\beta_{t,eval} = 2.9$ (indicated by blue horizontal line) has kept in the majority of analyses. The scatter results from the selection of a limit number of PSF. Thus, the calibration has been successful for the chosen target. However, the target reliability index is chosen based on the analyses presented and needs further discussion by the scientific community and relevant authorities. Results for further targets in the range $2.5 \leq \beta \leq 3.2$ can be found in [15].

https://doi.org/10.52202/069179-0394

3.4 Update of Partial Safety Factors based on Material Update

A great potential when analysing the load-bearing capacity of an existing structure is that it exists in tangible form. Updated material models can be built combining on-site tests and analyses in the laboratory, see e.g. [34]. Different options for the consideration of updated material properties in the semi-probabilistic safety format can be described. One is the application of an improved strength grading supported by technical means, see e.g. [35]. This is, however, not in the focus of this work.

Another option is the consideration of reduced uncertainties due to a detailed investigation in situ by adjusted safety elements. Here also two options can be discussed. The first one is the modification of PSF based on a reduced material variability by direct update of the variable. Adjusted PSF can be calculated applying the *Design Value Method* (DVM) or the *Adjusted Partial Safety Factor Method* (APFM) as described in [36]. Additional to knowledge concerning the special material variability at hand, a target reliability that has been agreed upon and sensitivity factors are needed. Simplified sensitivity factors can be taken from [2]. However, sensitivity factors are factors considering the influence of the change of a certain variable in the limit state on the reliability. Thus, the application of simplified sensitivity factors ignores the advantage of the availability of more detailed information concerning the actual load and material properties at hand and the governing limit state. Hence, updated sensitivity factors for certain limit states as outcome of the presented reliability analyses can be applied. Note that these sensitivity factors are only applicable if updated PSF are also applied for the loads by updated sensitivity factors to keep the intended reliability.

The second option is the update of the PSF on the material side using an updated reference variable. A proposal is described in [37] and presented shortly hereinafter.

The mean value $\mu_{y|x_{meas}}$ and the standard deviation $\sigma_{y|x_{meas}}$ of a target property y dependent on a reference variable x are defined by eq. (6) and (7), respectively, see [38]. $\mu_{y,code}$ and $V_{y,code}$ are the mean value and the *cov* of the target variable as defined in prior information (e.g. a code), respectively. $\mu_{x,code}$ and $V_{x,code}$ are the mean value and the *cov* of the reference variable as defined by prior information, $\rho_{x,y}$ is the correlation coefficient.

$$\mu_{y|x_{meas}} = \mu_{y,code} \cdot \left(1 + \rho_{x,y} \cdot V_{y,code} \cdot \frac{x_{meas} - \mu_{x,code}}{\mu_{x,code} \cdot V_{x,code}}\right) \quad (6)$$

$$\sigma_{y|x_{meas}} = V_{y,code} \cdot \mu_{y,code} \cdot \sqrt{1 - \rho_{x,y}^2} \quad (7)$$

Eq. (8) is derived from eq. (6) and (7).

$$V_{y|x_{meas}} = \frac{\sigma_{y|x_{meas}}}{\mu_{y|x_{meas}}} \quad (8)$$

$$V_{y|x_{meas}} = \frac{V_{y,code} \cdot \sqrt{1 - \rho_{x,y}^2}}{\left(1 + \rho_{x,y} \cdot V_{y,code} \cdot \frac{x_{meas} - \mu_{x,code}}{\mu_{x,code} \cdot V_{x,code}}\right)}$$

with eq. (9) for the PSF of a lognormal distributed resistance variable, the updated PSF $\gamma_{m,\mathrm{up}}$ can be calculated according to eq. (10). Here α_R is the sensitivity factor of the resistance variable, β is the target reliability and q is the quantile of the distributed used to define the characteristic value for semi-probabilistic design.

$$\gamma_m = exp\left(V_R \cdot \left(\alpha_R \cdot \beta + \Phi^{-1}(q)\right)\right) \quad (9)$$

$$\gamma_{m,\mathrm{up}} = exp\left(\frac{V_{y,code} \cdot \sqrt{1-\rho_{x,y}^2}}{\left(1+\rho_{x,y} \cdot V_{y,code} \cdot \frac{x_{meas}-\mu_{x,code}}{\mu_{x,code} \cdot V_{x,code}}\right)} \cdot \left(\alpha_R \cdot \beta + \Phi^{-1}(q)\right)\right) \quad (10)$$

The model uncertainty factor γ_{Rd} is considered by eq.(11).

$$\gamma_{M,\mathrm{up}} = \gamma_{Rd} \cdot \gamma_{m,\mathrm{up}} \quad (11)$$

Application examples can be found in [38, 39]. Please note that uncertainties determining the reference variable, e.g. measurement errors are not considered in this approach. An option is the consideration of an additional error term as described in [40] and left to further work.

3.5 Suggestion of a stepwise evaluation procedure

An evaluation procedure for existing structures needs to be flexible in terms of applicability for the actual circumstances at hand. That includes availability of information, consequences of failure and economic considerations. Thus, a procedure is needed that embraces levels with lower degree of information and an evaluation more on the safe side and different options to include updated information that comes along with higher efforts in terms of time and costs. A proposal has been presented in [41]. The stepwise evaluation procedure embraces three *Knowledge Levels* (terminology based on [30]) including an evaluation without update (*KL 1*), a level including a modified semi-probabilistic evaluation divided into three sublevels (*KL 2*) and a level for advanced probabilistic methods (*KL 3*), see Table 13. With increasing level, the information becomes more detailed as well as the evaluation format does. These levels are connected to a proposal for strength grading levels (*SGL*), see [35]. An application example can e.g. be found in [39].

Table 13: *Proposal for a stepwise evaluation procedure*

<table>
<tr><th colspan="3">semi-probabilistic <u>without</u> update - KL 1</th></tr>
<tr><td colspan="3">visual grading in situ
partial safety factors from
EN 1990, EN 1995-1-1, EN 1995-1-1/NA</td></tr>
<tr><th colspan="3">semi-probabilistic <u>with</u> update - KL 2</th></tr>
<tr><td>KL 2a)</td><td>KL 2b)</td><td>KL 2c)</td></tr>
<tr><td colspan="3">update of permanent loads: $\gamma_{G,up} = 1{,}20$ (unfavourable)</td></tr>
<tr><td colspan="3">variable loads: $\gamma_Q = 1{,}50$</td></tr>

</table>

Please note that the calibration results for $\gamma_{M,opt}$ are only applicable under the given requirements and the intended limit states and load ratios. As results are given depending on the *cov* of the material strength, an updated of material properties leading to e.g. a reduction of the scatter can be considered by choosing the results for the adjusted value. Note that for the update of material properties a sufficient number of tests and strong correlation of target and reference variable are required. As a first orientation, correlation coefficients should be $\rho > 0.6$.

4 CONCLUSION

A responsible use of energy and resources are important elements of the development of a sustainable economy. The preservation of existing structures plays a central role that has never been more important than today. Thus, code calibration cannot only focus on the necessary further development of codes in the context of the design of structures and their application on innovative structural materials. The evaluation of existing structures needs to be integrated in the concept of Eurocodes considering the special requirements that come along with this challenge. In this context, rules and requirements need to be flexible so that they can be adopted for different structural tasks.

The presented works contains analyses of the reliability of timber members according to current standards. The analyses show a scatter of the reliability depending on the considered LSF. Sensitivity factors indicate a great influence of the material strength on the calculated reliability. Based on these results, the target reliability is discussed and modified PSF depending on the LSF and, as a second option, considering an update of material properties are presented.

However, more studies considering further and more complex limit states and further detailing concerning the update of target properties based on in situ measured reference properties have to carried out to enlarge the concept for a wider range of practical cases. Besides, further studies need to embrace the reliability of historic connections, also carpenters' connections. What is more, new information on the modelling of variable actions should be considered, see e.g. [23, 24] for wind loads. Calculating the implicit reliability level of design codes, this might have an influence on the resulting reliability level. However, as the target value for the calibration has been defined based on this calculated implicit level, the evaluation of the influence on the calibration of PSF is left to further work. However, a centrals task in the development of codes and standards for existing structures, it has to be discussed how the target reliability has to be be defined for a calibration of PSF for existing structures.

ACKNOWLEDGEMENT

A major part of the content has been developed in a funding period of *The German Federal Environmental Foundation* (*DBU*, project no. 20015/409, 2016-2018). The authors thank the institution for the generous support.

World Conference on Timber Engineering Oslo 2023

REVIEW OF THE CODE DEVELOPMENT EFFORTS FOR TALL MASS TIMBER BUILDINGS IN THE US

Lori Koch[1], Matthew Hunter[2], M. Omar Amini[3]

ABSTRACT: The 2021 International Building Code (IBC) is the current edition of the predominant model building code adopted for use in the United States. For the first time in the history of US model code development, the 2021 IBC recognizes tall mass timber buildings. With the addition of three new types of construction, US designers can design tall mass timber structures up to 18 stories in height. These provisions are the culmination of a nearly five-year effort by stakeholders participating in the code development process. A brief history of this effort is presented in this paper, including the formation of the International Code Council's (ICC) Tall Wood Ad Hoc Committee. Four (4) work groups, namely, Definitions and Standards, Fire, Structural, and Codes were convened to formulate science-based code change language that led to the current provisions. Analysis of the fire testing completed in support of the code changes is presented and a brief discussion of current research and testing, as well as proposed code changes for future editions of the IBC is also discussed.

KEYWORDS: Cross-laminated Timber, Building Codes, Tall Mass Timber

1 INTRODUCTION

1.1 IBC/IRC

Structural building design in the United States most commonly falls under the jurisdiction of one of two model codes developed by the International Code Council (ICC): the International Residential Code® (IRC®) or the International Building Code®(IBC®). The IRC addresses the design and construction of one- and two-family dwellings and townhouses not more than three stories above grade. The IBC is applicable to all buildings, apart from structures designed to meet the requirements of the IRC. States or other localities across the US regularly adopt updated versions of these standards as their building code – sometimes without alterations, other times with deletions or amendments as the locality deems necessary. The process of code adoption varies from state to state, as evidenced by the map in Figure 1. Some states use a statewide adoption process, while others allow local authorities to adopt updated codes at their discretion. The IBC and IRC both have top-to-bottom provisions for the design and construction of buildings of various structural materials and systems. This paper focuses on the IBC provisions related to structural design and fire safety for mass timber structures.

1.2 NDS/SDPWS

Within the IBC and IRC are dozens of referenced standards produced by relevant organizations. The referenced standard for structural design of wood buildings is the *National Design Specification*® (NDS) *for Wood Construction*. Lateral force resisting systems in wood structures subject to wind or seismic loads are governed by the provisions of the *Special Design Provisions for Wind and Seismic*® (SDPWS), also a referenced standard in the IBC and IRC. Both the NDS and SDPWS are published by the American Wood Council (AWC), a not-for-profit trade association representing North American wood products manufacturers. AWC is accredited by the American National Standards Institute (ANSI) and develops state-of-the-art engineering data, technology, and standards on structural wood products for use by design professionals and building officials.

The NDS is AWC's longest tenured standard, providing structural and fire design provisions for solid sawn and engineered wood products as well as connections in these wood products. In the 2015 edition [1] of the NDS, structural and fire design provisions for cross-laminated timber (CLT) were added. Codified lateral design provisions for CLT diaphragm and CLT shear wall systems were subsequently introduced in the 2021 edition of SDPWS [2].

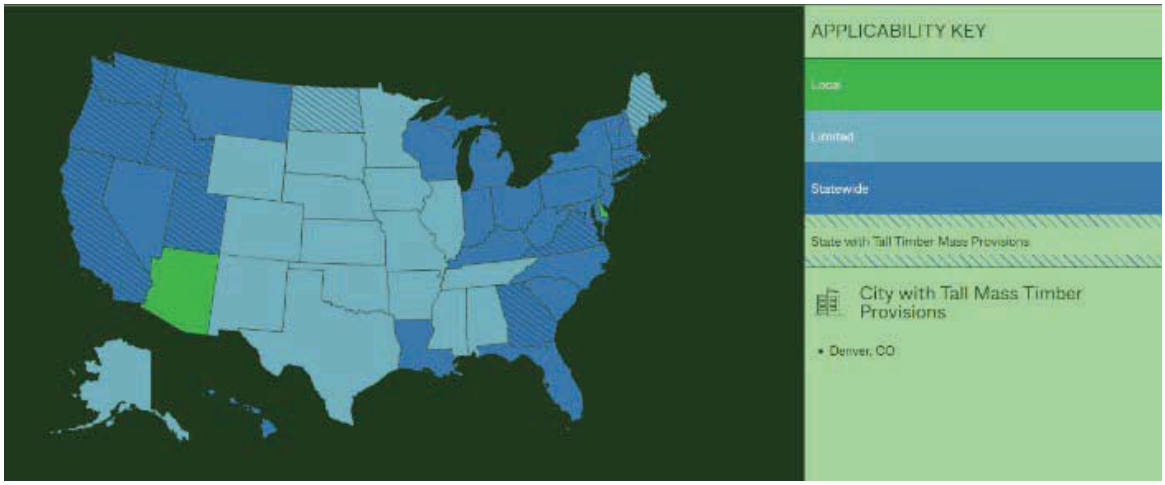

Figure 1. *Code Adoption Map*

2 WOOD BUILDING CODES PRIOR TO 2015

Type IV-HT Heavy Timber construction (referred to as Type IV prior to the adoption of the 2021 IBC [3] Tall Mass Timber provisions) have been present not only through the entire history of the IBC, but also in the historic "legacy" codes used prior to 2000 throughout the US. The definition of Type IV-HT is as follows: "*Type IV construction (Heavy Timber, HT) is that type of construction in which the exterior walls are of noncombustible materials and the interior building elements are of solid wood or laminated wood without concealed spaces…Minimum solid sawn dimensions are required for structures built using Type IV construction (HT)…"* [4].

The story and height limits for Type IV-HT - Heavy Timber construction under the 2015 IBC [4] (and previous editions) is 6 stories and 26m (85 ft) height. Buildings classified as Type IV construction have non-combustible exteriors, and the timber primary structural frame is required to meet minimum dimensional criteria (nominal 6" x 8"/153mm x 203mm for columns and nominal 6" x 10"/153mm x 254mm for beams or joists).

In historic heavy timber buildings (Figure 2a), the robust cross sections of the members stand in stark contrast to the smaller members used in conventional repetitive light-frame wood construction (Figure 2b). Repetitive light-frame buildings in the US can refer to both Type III or Type V construction. Type III construction is defined in the IBC as follows: "*Type III construction is that type of construction in which the exterior walls are of non-combustible materials and the interior building elements are of any materials permitted by this code. Fire-retardant treated wood framing and sheathing complying with Section 2303.2 shall be permitted within exterior wall assemblies of a 2-hour rating or less."* Type V construction is defined as: *Type V construction is that type of construction in which the structural elements, exterior walls and interior walls are of any materials permitted by this code* [4].

In some instances, Type III-A can match the building height of Type IV-HT buildings (85' feet/26m) but may permit fewer stories due to occupancy type restrictions and sprinkler system configurations. Additionally, until all the passive and active fire protection and fire-resistance rated construction is complete, repetitive light frame buildings are typically more susceptible to threats from fire than Type IV-HT structures. The inherent structural mass of Heavy Timber imparts fire resistance to the primary structural frame because of the ability of wood to slowly char over time, versus sudden catastrophic structural collapse of other construction materials that are exposed to fire.

The term *cross-laminated timber* appears for the first time in the US codes in the 2015 edition of the IBC [4]. It is defined therein as: *a prefabricated engineered wood product consisting of not less than three layers of solid-sawn lumber or structural composite lumber where the adjacent layers are cross oriented and bonded with structural adhesive to form a solid wood element*. The manufacturing standard for cross-laminated timber, ANSI/APA PRG-320 [5] also makes its first appearance in the 2015 IBC. This permitted the use of CLT as a building element in Type III, IV and V construction. These two changes in the 2015 IBC were instrumental towards the eventual adoption of Tall Mass Timber/Tall Wood Building changes in the 2021 IBC [3].

Following the definition of cross-laminated timber and the manufacturing standard in the 2015 IBC, changes to the 2018 IBC were more intended as a reorganization of terms, content, and referenced standards associated with wood construction. Content describing Heavy Timber that was originally contained within Chapter 6 (Types of Construction) was relocated to Chapter 23 (Wood chapter). Chapter 23 received many new entries specific to cross-laminated timber. A Table was created to call out dimensions for heavy timber structural components comprised of solid sawn lumber, structural glued laminated timber (Glulam), and structural composite lumber (SCL) for column, floor, beam, girder, and roof framing members. Prior to the adoption of the 2021 IBC terms like *mass timber* and *tall mass timber* were not defined.

3 ICC TALL WOOD BUILDING AD-HOC COMMITTEE

In late December of 2015, industry members and other interested parties petitioned the ICC to explore the science of tall wood buildings and take action to develop the necessary code changes to support this new construction type. The ICC determined this effort was valid and formed an Ad-Hoc Committee to evaluate the potential for new mass timber construction types in the IBC. The Tall Wood Building Ad-Hoc Committee, or TWBAH as it became known, was formed under the leadership of ICC [6]. Over eighty individuals volunteered to serve on the TWBAH, and this consensus-based committee was comprised of representatives from building material industries (including members from concrete, steel, and masonry industries), respected building and fire officials, registered professional architects and structural engineers, fire protection experts, and other industry related stakeholders.

Due to the tremendous volume of data that required review, the TWBAH appointed four work groups: Definitions and Standards, Fire, Structural, and Codes. These work groups immediately identified several key performance objectives that guided their development of any proposed code changes:

- No collapse under reasonable scenarios of complete burn-out of fuel without automatic sprinkler protection being considered.
- No unusually high radiation exposure from the subject building to adjoining properties to present a risk of ignition under reasonably severe fire scenarios.
- No unusual response from typical radiation exposure from adjacent properties to present a risk of ignition of the subject building under reasonably severe fire scenarios.
- No unusual fire department access issues.
- Egress systems designed to protect building occupants during design escape time, plus a factor of safety.
- Highly reliable fire suppression systems to reduce risk of failure during reasonably expected fire. Degree of reliability proportional to evacuation time (height) and risk of collapse.

The TWBAH worked for almost 5 years to analyze data and research from across the globe on CLT and mass timber buildings. The Fire Work group had arguably the most challenging task of identifying realistic fire test scenarios to validate the increased story and overall heights proposed by the TWBAH. Fortunately, several notable fire tests of cross-laminated timber had been conducted prior to the formation of the committee [7]. In 2012, an ASTM E119 [8] test was conducted on a 5-ply CLT wall panel assembly that was loaded with 87,000 pounds (39,462 kg). The intent of the test was to have the assembly obtain a two-hour fire-resistance rating. The test was concluded when flame front penetration was observed through the assembly at three-hours and six minutes.

Additional compartment fire testing was conducted at the Southwest Research Institute (SWRI) in 2015 [9], the research and fire test labs at NIST (National Institute of Science and Technology) in the National Research Council of Canada in 2017[10]. Follow-up testing of heat resistant adhesives to ensure the layers of CLT did not delaminate during fire conditions were also conducted at SWRI in 2017 [11]. All the data from previous fire tests was taken into consideration to design the fire tests that were conducted on the two-story test structure at the US ATF (Bureau of Alcohol, Tobacco, Firearms and Explosives) laboratory in direct support of the proposed Tall Mass Timber code change proposals in the 2021 IBC.

The five fire test scenarios conducted at ATF [7, 12] are described in Table 1.

https://doi.org/10.52202/069179-0395

Table 1: *Summary of ATF Fire Tests*

Test	Description	Date	Duration
1	All mass timber surfaces protected with 2-layers of 15.9 mm (5/8 in.) Type X GWB – establishes baseline	5/23/17	3 hours
2	30% of CLT ceiling area in living room and bedroom exposed – represents maximum exposure in Type IV-B	5/31/17	4 hours
3	Two opposing CLT walls exposed – one in bedroom and one in living room (there is a partition wall) – Type IV-B	6/20/17	4 hours
4	All mass timber surfaces fully exposed in bedroom and living room. Sprinklered – normal activation	6/27/17	6 minutes
5	All mass timber surfaces fully exposed in bedroom and living room (except bathroom). Sprinklered – 23 min delayed activation	6/29/17	30 minutes

Figure 3: *Fire Test 1 test progression photos*

All the fire tests conducted at the ATF laboratory were designed to replicate the actual conditions as permitted under the proposed Tall Mass Timber code change proposals. These fire tests validated the fire performance of CLT and the ability of the material to withstand flame and sustained high temperatures (over 1000°C and 18 and 23 megawatts of energy release) generated by the room and contents fire without any contribution of the fire sprinkler system.

It should be noted that the CLT panels tested at the ATF were not manufactured with adhesives that are required under the most current CLT manufacturing standard, ANSI/APA PRG320-18 [5]. The use of fire-resistant adhesives only increased the robust fire performance of CLT as proven in follow on testing conducted at the Research Institute of Sweden (RISE) in 2020 [13].

A total of five additional compartment tests were conducted at RISE [13], all with the primary objective of exposing increasing amounts of exposed CLT ceiling surfaces. A secondary objective was to model the performance of exposed ceiling and wall intersections.

The robust fire resistance of CLT panels manufactured in accordance with ANSI/APA PRG 320-18 [5] was again validated during the RISE tests. The testing proved that CLT constructed with heat-resistant adhesives did not lead to fire regrowth conditions or result in elevated ceiling temperatures greater that 600°C after the decay phase.

4 CLT SHEAR WALL DESIGN REQUIREMENTS

Seismic design based on the equivalent lateral force procedure in the IBC relies on factors from referenced standard ASCE/SEI 7 – *Minimum Design Loads and Associated Criteria for Buildings and Other Structures* [14]. The design requirements are provided in ANSI/AWC *Special Design Provisions for Wind and Seismic* 2021 edition (SDPWS-21) [2]. The SDPWS-21 is referenced in the 2021 IBC [3], and both SDPWS-21 and ASCE 7-22 will be referenced in the 2024 IBC.

The two defined CLT shear wall system types in SDPWS-21 are: (a) *CLT shear wall system* and (b) *CLT shear wall system with shear resistance provided by high aspect ratio panels only*. Both have seismic design factors (i.e., R, Ω_0, C_d) provided in ASCE 7-22 Table 12.2-1. Seismic performance factors and structural height limits appearing in ASCE 7-22 are summarized in Table 2.

Individual CLT panels of CLT shear walls are expected to exhibit rocking, as shown in Figure 4, with the strength of the system controlled by nailed connections. Typical CLT shear wall configurations with the corresponding components are shown in Figure 5. Prescribed nailed connectors are shown at the bottoms and tops of panels and at adjoining vertical panel edges. For multi-panel configurations, free-body diagrams for the tension end panel and compression end panels are shown in Figure 6.

To ensure rocking behavior, as shown in Figure 4, and development of the nailed connection strength, design requirements include: (1) use of CLT panels of prescribed aspect ratios; (2) use of prescribed nailed connectors at bottoms of panels, tops of panels, and adjoining vertical edge(s) of multi-panel shear walls; (3) strength requirements for overturning tension devices (e.g., hold-downs); and (4) compression zone length requirements. Design requirements also include equations for calculating nominal unit shear capacity provided by the prescribed nailed connectors and for calculating the CLT shear wall deflection. The structural design of the CLT panels for resistance to tension, compression, bending, and shear, as well as the design of connections to CLT panels, is required to be in accordance with the NDS. Requirements for the design of CLT diaphragms are also provided in SDPWS.

https://doi.org/10.52202/069179-0395

Table 2: *Design Coefficients and Factors for CLT Seismic Force-Resisting Systems (appearing in ASCE/SEI 7-22 Table 12.2-1)*

Seismic Force-Resisting System	Detailing Requirements, ASCE/SEI 7-22 Section	R	Ω_0	C_d	Structural Height, h_n, Limit Seismic Design Category B, C, D, E & F
Cross-laminated timber shear walls	14.5	3	3	3	20 m [65 ft]
Cross-laminated timber shear walls with shear resistance provided by high aspect ratio panels only	14.5	4	3	4	20 m [65 ft]

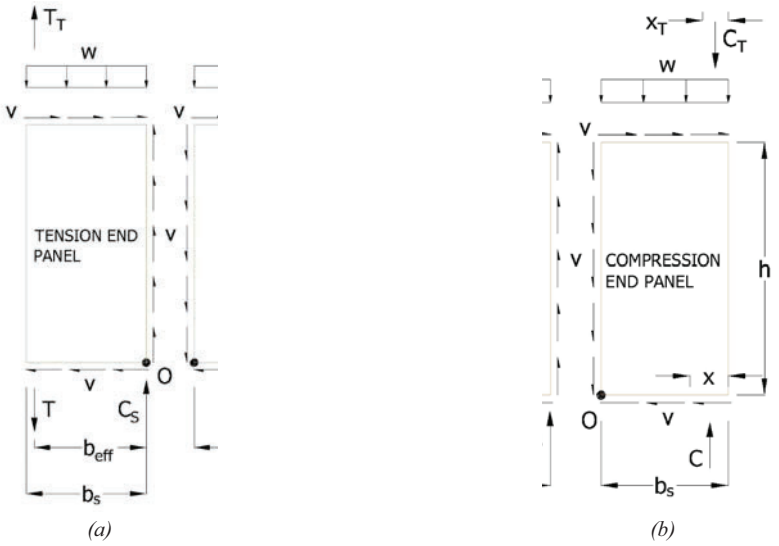

Figure 6: *Free-body Diagram for (a) the Tension End Panel and (b) the Compression End Panel of the CLT Multi-panel Shear Wall*

Additional Resources for Seismic Requirements

Background information on the development of the CLT shear wall system is available in General Technical Report FPL-GTR-281 *Determination of Seismic Performance Factors for Cross-Laminated Timber Shear Walls Based on the FEMA P695 Methodology* [15]. The report includes testing, modeling, and archetypes that led to the development of seismic design coefficients for the CLT shear wall system.

The NEHRP Recommended Seismic Provisions for New Buildings and Other Structures, Volume I: Part 1 Provisions and Part 2 Commentary, 2020 Edition, FEMA P-2082-1 [16] includes design requirements for CLT shear walls. As a predecessor to requirements in ASCE 7-22 and SDPWS, the NEHRP requirements are similar but not identical to those appearing in SDPWS. The 2020 NEHRP *Recommended Seismic Provisions: Design Examples, Training Materials, and Design Flow Charts*, FEMA P-2192 [17], contain design examples based on the 2020 NEHRP Provisions. FEMA P-2192 includes an approximate 25-page example of the CLT shear wall system following the requirements of ASCE 7-22 and SDPWS. The example features the seismic design of cross-laminated timber shear walls used in a three-story, six-unit townhouse cross-laminated timber building of platform construction.

5 2021 IBC FINAL PRODUCT – CODE CHANGE SUMMARY (Type IV-A, IV-B, IV-C)

5.1 2021 IBC

The efforts led by the TWBAH Committee resulted in the inclusion of tall mass timber provisions in the 2021 IBC [3]. Three new building types were added to the IBC, called Type IV-A, IV-B, and IV-C construction, permitting the tallest ever code accepted wood construction in the US. A brief summary of the maximum story limits and building heights allowed in the 2021 IBC is presented in Table 3.

Table 3: *New 2021 IBC Building Types and Height Limits*

Building Type	IV-A	IV-B	IV-C
Maximum # Stories[1]	18	12	9
Maximum Building Height	82m/ 270ft	55m/ 180ft	26m/ 85ft

[1] Based on Occupancy Use of the building

These building code provisions have already been adopted by several state and local jurisdictions, and will continue to be adopted by municipalities across the US.

5.2 2018 NDS

A product chapter for CLT was introduced in the 2015 NDS and updated in the 2018 NDS [18]. Reference to the 2018 NDS was updated in the 2018 IBC and is retained in the 2021 IBC. The NDS specifies that the design procedures for CLT are only applicable to materials manufactured in accordance with production standard ANSI/APA PRG-320 [5] and includes provisions on structural design, connection design, and fire design. The NDS allows designers to choose one of two design methods, Allowable Stress Design (ASD) or Load and Resistance Factor Design (LRFD) for CLT structural and connection designs. However, it limits fire design provisions to ASD designs only.

5.3 2021 SDPWS

The 2021 SDPWS [2] is the first edition of the standard to include provisions for CLT-based lateral-force resisting systems (LFRS). Coupled with the previously discussed seismic factors published in ASCE 7-22 [11], designers

can use CLT diaphragms and shear walls to resist loads due to wind and seismic forces. SDPWS allows for designs using both ASD and LRFD.

6 FUTURE PLANS

6.1 2024 IBC Approved Code Change

The TWBAH Committee established early on during the 2021 IBC development process that only criteria based upon actual tests would be utilized to evaluate the fire performance of CLT. Over 600 data collection points were utilized during the ATF Fire Tests. This extensive data collection was done in part, to facilitate additional follow-up testing. The conservative, relatively small, unprotected portions of both walls and ceilings were justified under the testing criteria performed at the ATF laboratory because the CLT utilized for all five tests was not fabricated with fire-resistant adhesives per the ANSI/APA PRG320-18 standard [5]. In fact, the standard had not even been drafted in 2017 during the time of the ATF tests. The fire-resistant adhesive requirements of ANSI/APA PRG320-18 prevent failure at the glue line of the CLT within the test compartment. Pursuant to the previous fire tests at ATF, recorded compartment temperatures decayed below the point at which reignition of exposed CLT would occur (572°F/300°C). A successful test meant that the compartment temperature dropped below 300°C prior to the conclusion of testing at 240 minutes.

Based on recent RISE tests, a code change proposal, submitted and approved under the ICC governmental consensus process for the development of the 2024 IBC, will permit mass timber ceilings to be exposed for ceiling areas not to exceed 100% of the floor area in Type IV-B Construction. For design professionals to take advantage of this provision, the walls must retain the non-combustible sheathing requirements (typically a minimum of two layers of 5/8 in. or 16mm Type X gypsum board) for the Type IV-B Construction. Additionally, all other stringent active and passive fire protection requirements would apply for these structures which are permitted to be up to twelve (12) stories and one-hundred and eighty feet (180 ft/55 m). This code change permits design professionals to showcase the aesthetically pleasing properties of wood, without sacrificing any reduction in fire performance.

IMPROVEMENT OF THE DURABILITY OF TIMBER BRIDGES BY INTELLIGENT DESIGN AND RESPONSIBLE MAINTENANCE

Antje Simon[1], Markus Jahreis[2], Johannes Koch[3]

ABSTRACT: Timber bridges may contribute to climate protection due to their carbon sink capability and substitutional effect. One basic requirement for the increased application of timber as an ecological and sustainable construction material is long-term durability. This can only be achieved by consistently using structural protection measures in all stages of planning, construction and service life. The paper presents sample drawings for the design of structurally protected timber bridges and provides recommendations for useful maintenance measures. Using standardized drawings increases effectiveness and efficiency in engineering offices and reduces the danger of serious errors in planning. Regarding their ecological and sustainable advantages, a significant increase in the market share of timber bridges is to be expected in Germany. Aesthetic, well-protected and durable timber bridges of a high-quality standard will characterise the landscape in the future.

KEYWORDS: timber bridges, durability, design, sample drawings, details, maintenance

1 INTRODUCTION

Timber bridges have a centuries-old tradition. A few very old, well-protected bridges demonstrate the potential of timber as a natural structural material (Figure 1). However, the specifics of this orthotropic and hygroscopic material need to be considered in general timber construction and that of bridges in particular. Careful observance to the structural details is required. The material must be protected against moisture ingress. The strength and stiffness of wood decrease with increasing moisture content. Timber starts to swell and shrink with changing moisture, causing internal stress and cracks. Furthermore, a higher moisture content enables insects and fungi to attack and destroy the structure.

Figure 1: *Old covered bridge in Aarberg (Switzerland), built in 1568 (photo: A. Simon)*

If the specific requirements are ignored, there is high-risk potential for destruction, and the maintenance costs significantly increase. Inspections of several bridges in Germany have confirmed that most defects are caused by faulty design and a lack of protection and maintenance measures. The long-term durability of timber bridges can only be achieved by consistently using structural protection measures in all stages of planning, construction and service life. Therefore, the research project "Protected timber bridges (ProTimB)" was initiated to define a new standard for durable timber bridges. The results of the project have been published in a research report [1].

2 THE RESEARCH PROJECT PROTIMB

2.1 OVERVIEW

The outcome of the project is a set of technical guidelines for the design, construction and maintenance of protected timber bridges (Figure 2). Formally, it is inspired by the existing sets of rules for other materials established by the German Federal Highway Research Institute (BASt) to facilitate their application in practice.

The design rules [2] consist of references for planning, samples for structural analysis and 36 new sample drawings (MuZ-HolzBr). In addition, "Recommendations for technical contractual terms for timber bridges (ETV-HolzBr)" have been developed for construction [3].

https://doi.org/10.52202/069179-0396

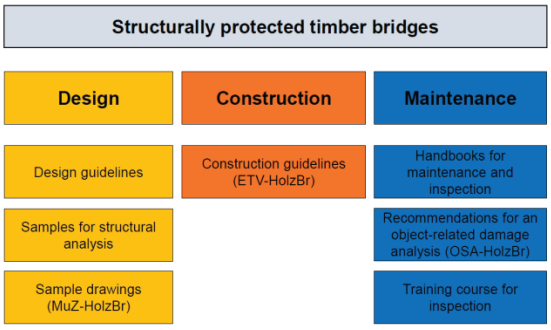

Figure 2: *Overview of the new guidelines and project results*

Sample handbooks have been written for the maintenance and inspection of timber bridges and recommendations for an object-related damage analysis (OSA-HolzBr) have been compiled. Furthermore, an advanced training course has been conceptualised for timber bridge inspectors. Additionally, nine protected timber bridges crossing rivers were comprehensively monitored [4]. The most important guidelines for design and maintenance will be presented in the following. For further details see [1].

2.2 DESIGN

2.2.1 Overview

A set of new sample drawings [5] has been developed for the design of timber bridges. It is based on older drawing sets [6] and [7], which it updates and extends. The 36 new drawings illustrate durable and proven solutions for special structural details (Table 1).

Table 1: *Contents of the sample drawings for protected timber bridges*

Drawing	Contents
H-Belag 1-4	Variants of decks and their mounting (closed surfaces as asphalt sealings, concrete- and natural stone slabs and open surfaces using wooden planks)
H-Dicht 1-3	Design of sealings for the timber-superstructure
H-Gel 1-5	Variants of parapets and their fastening
H-Kap 1-2	Mounting of concrete caps on timber structures
H-Lag 1-3	Details for bearings
H-Schutz 1-8	Structural protection measures (covering, cladding, ventilation distances, protrusion)
H-Trog 1-2	Design of cross frames and bracing structures for trough bridges
H-Übe 1-4	Transition structures and expansion joints
H-Was 1-3	Details for drainage and dewatering
H-Zug 1	Accessibility of substructure

They are closely related to the familiar drawings of the German Federal Highway Research Institute (BASt) [8]. Annex D of the new version of the European Code for Timber Bridges EC5-2 [9] also shows sample drawings inspired by the results of the ProTimB project.

The drawings focus on the critical points of timber bridges such as decks, sealings, parapets, bearings and expansion joints. Special attention was paid to the structural protection measures including recommendations for covering, cladding, ventilation distances and protrusion. In Germany, structural protection takes precedence over chemical treatment. All load-bearing members must be structurally protected. Secondary structural members may remain unprotected but should then be regarded as "maintenance elements" with a lower service life of 10 to 20 years.

This strategy is also followed by the next edition of Eurocode [9].

According to this new code, timber bridges will be divided into four categories to define their design service life. For protected timber bridges in category 1, a design service life of 100 years is expected. To achieve this design service life analogously to bridges made of other materials, the main structural components shall be designed with structural protection. Category 2 includes timber bridges whose main structural members are protected for a 50-year design service life. Replaceable structural parts of protected bridges (category 3) should achieve a design service life of 25 years. For temporary structures (category 4), a maximum design service life of 10 years is expected. Unprotected timber bridges belong to category 4.

As a basis for planning protection measures, the use class (UC) has to be defined for every single timber member (Figure 3) according to [10].

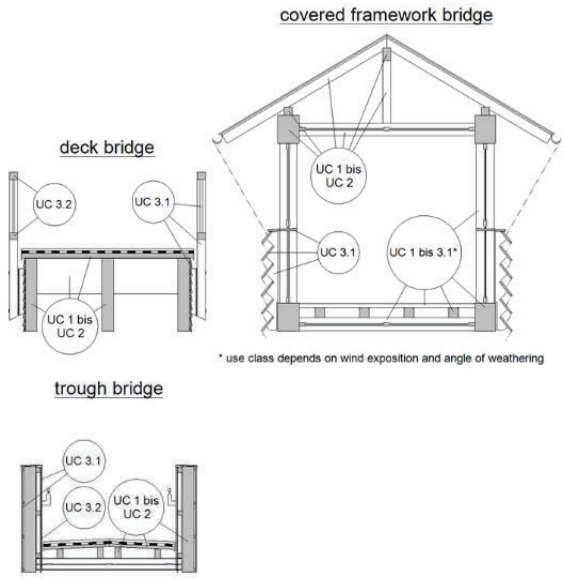

Figure 3: *Assignment of timber members to use classes (UC) in different exposure situations*

Appropriate structural protection measures and wood species, based on their durability class, should be derived from the use class. Analogously to the procedure according to [11], the main objective is to achieve use class 0 to avoid chemical treatment. For every single timber member, the classifications and protection measures should be summarised in a separate design plan as shown in Table D.1 of [9].
One special feature of the sample drawings is the definition of maintenance elements. If non-load-bearing or easily replaceable timber components are exposed to weathering (e.g. railings, cladding and planks), a significantly shorter service life is to be assumed for these components compared to the service life of the protected main load-bearing structure. Weathered timber components must be regularly maintained and replaced if their stability, traffic safety or durability is impaired. Therefore, these components are explicitly marked as maintenance elements.
The following will offer important design advice and present and explain examples of the drawings.

2.2.2 Bridge deck surfaces and sealings

In principle, a closed deck is preferable to an open deck, as the main girders located under the deck are structurally well protected by a dense layer. Bridges over roads and railway lines should generally be provided with a closed deck.
For a closed deck, an under-ventilated construction is recommended. In contrast to the direct arrangement of the sealing on the main supporting structure, an under-ventilated structure enables direct checking for leaks, creates a second sealing level and reduces blistering during asphalt paving. An under-ventilated construction can also be more easily repaired. The following setup should be used (H-Belag 1 (Figure 4) in connection with H-Dicht 1):

- Top layer: mastic asphalt, 25 – 45 mm thickness,
- Protection layer: mastic asphalt, 25 mm thickness, mounting temperature 180 – 200°C,
- Sealing: polymer-bitumen water-proofing membrane fixed to timber deck,
- Epoxy resin-based primer,
- Wood-based panel on squared timber as spacer for under-ventilation, minimum surface inclination 2.5 %,
- Protective layer, diffusion-open,
- Timber deck, minimum surface inclination 2.5 %.

In the case of open decks, the planks must be fastened to a separate decking beam placed next to the main beam (H-Belag 3 and H-Belag 4). Direct fastening of the planks to the main girder is not permissible, as the fasteners penetrate the sealing arranged above the main girder and thus impair structural timber protection. The decking planks and the decking beam are maintenance elements with a shorter service life, as they are exposed to direct weathering and dirt through use. A sheet metal cover on the top side and a nail sealing strip (H-Belag 3) or a plastic membrane extend the service life of the separate decking beam. In the case of open decks, the joint between the end of the superstructure and the chamber wall must be closed to prevent dirt, grit, leaves or similar from falling through and remaining on the support bench (H-Belag 3 and H-Übe 4).

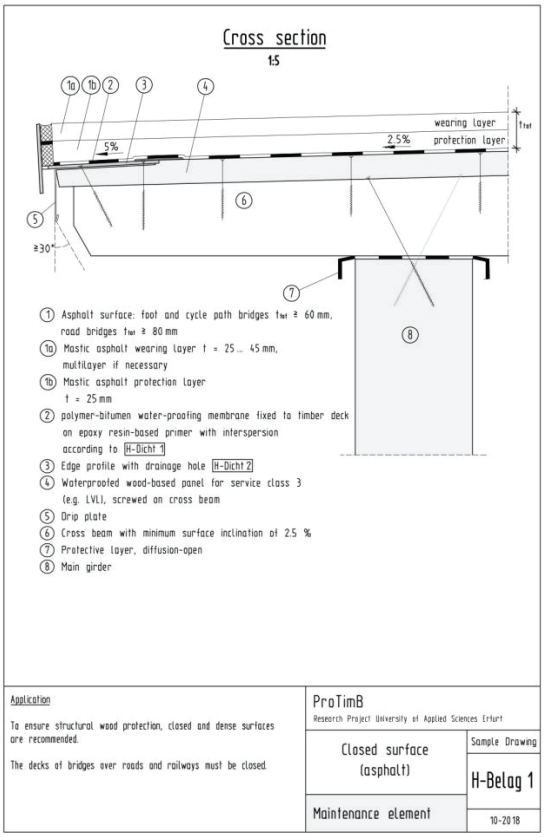

Figure 4: *Sample drawing H-Belag 1 showing the surface layers and the sealing*

2.2.3 Railings

Weathered wooden railings are maintenance elements with a shorter service life. They need to be replaced after 10 to 20 years.
Knots on the surfaces of wooden planks and handrails can lead to break-outs and increase rotting. Therefore, the components of wooden railings should contain as few knots as possible.
Architecturally interesting alternatives to wooden railings are steel railings with wooden handrails. For the handrail, the use of acetylated or other modified wood is recommended due to its higher durability and low tendency to crack and deform.
When fixing the railing to the main beam, it is important to make sure that the structural wood protection of the main beam is maintained. Water must not be led to the main girder via the fastening elements (pos. 5 of H-Gel 5, see Figure 5).

https://doi.org/10.52202/069179-0396

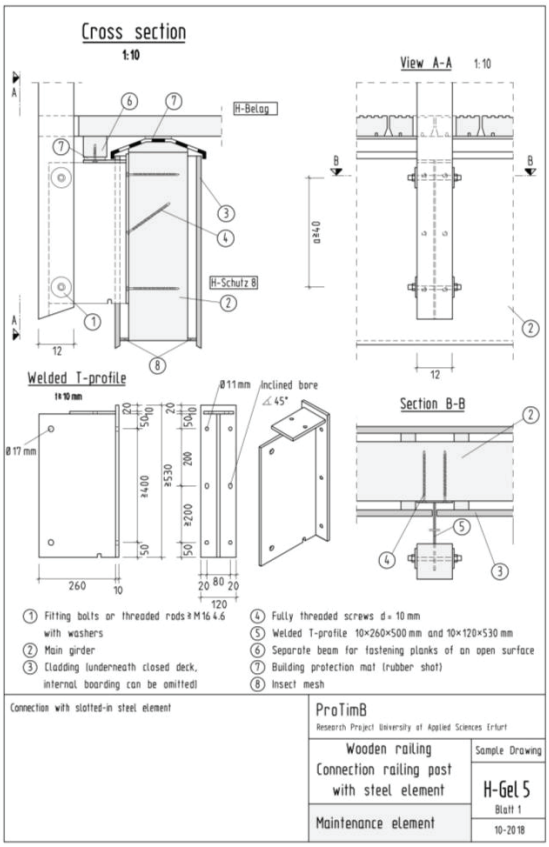

Figure 5: *Sample drawing H-Gel 5 explaining the connection of a railing post by a steel element*

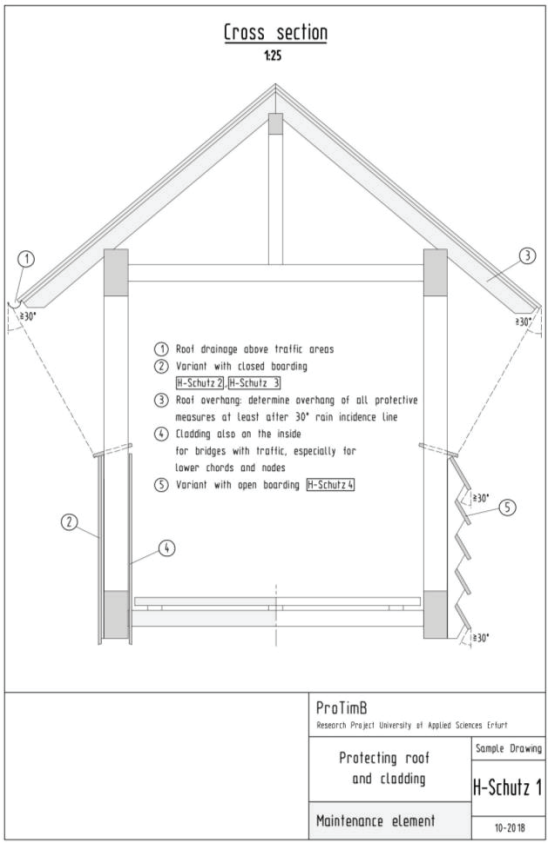

Figure 6: *Sample drawing H-Schutz 1 explaining general structural protection measures*

For pedestrian bridges, the minimum height of the railings is 1.00 m. If bridges are used by cyclists, the railings must be at least 1.30 m high.

2.2.4 Structural protection measures

The sample drawings in H-Schutz regulate details of structural timber protection as the most important basis for durability.

Structural timber protection can be attained by using a closed surface or a sufficient roof overhang and/or by cladding. Any covering must protrude at least far enough to prevent rain falling at an angle of 30° from the vertical from reaching the load-bearing timber structure (H-Schutz 1, see Figure 6). At wind-exposed locations, a significantly larger angle of rain incidence can occur. In this case, the protective measures must be extended. Lower chords of trusses are particularly at risk, as water can penetrate the connecting details, nodes and horizontal cracks and cannot run off. If wind exposure is unknown, it is recommended to plan load reserves in the static calculation for the subsequent installation of additional cladding. Alternatively, it is possible to calculate the main structure with reduced strength in service class 3 (as necessary for unprotected members) instead of service class 2 (as permitted for protected members).

Construction with a sufficient lateral overhang is preferable to cladding, as hands-on inspection of the main structure is easier. Open claddings (H-Schutz 4) facilitate hands-on inspection (Figure 7).

Figure 7: *Swiss timber bridge structurally protected by a roof and an open cladding (photo: A. Simon)*

Closed cladding should be easily removable or hinged to improve the inspection of the construction behind (H-

Schutz 6, see Figure 8). Due to better water drainage, vertical cladding is preferred to horizontal cladding (H-Schutz 2). Inside trough bridges, horizontal boards can be advantageous, as individual horizontal lamellas could be more easily replaced in the splash water area.

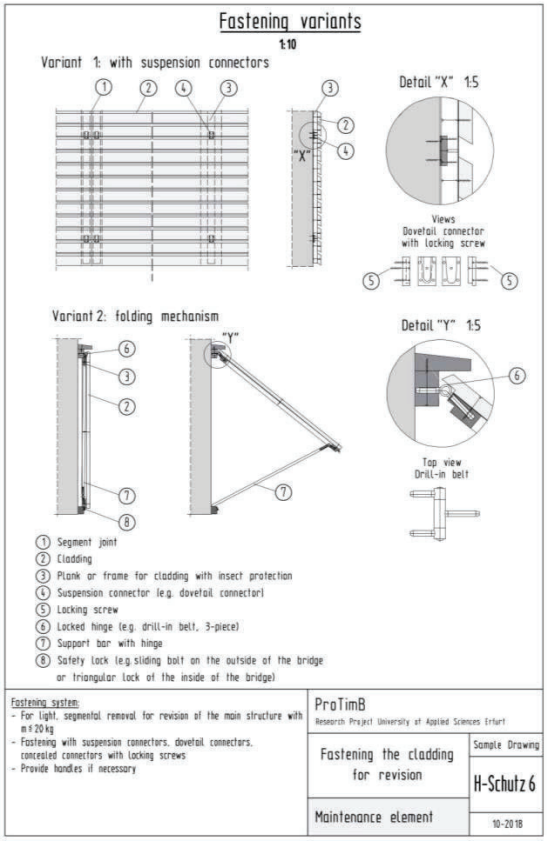

Figure 8: *Sample drawing H-Schutz 6 showing a removable cladding for inspection*

The following basic and special measures for structural timber protection should be observed in timber bridge construction:

- Wooden bridges should be designed for low-maintenance (e.g. by integral structures, watertight expansion joints, closed surfaces) or in a maintenance-friendly manner (facilitation of cleaning and inspection by sufficiently large distances between the components).
- During assembly, the moisture content of the wood should correspond to the expected moisture content on site (approx. 16 to 18 M%).
- Wooden components and their connections must always be designed in such a way that precipitation is deflected by weather protection. Alternatively, it has to be drained away so fast that no increase in wood moisture can occur and no moisture accumulation takes place. Timber components shall be installed with air circulation at an appropriate distance from other building components and from the terrain to avoid moisture transfer or moisture accumulation and to allow rapid drying. Direct weathering must be effectively prevented during transport, storage and the construction phase (e.g. by covering with foil).
- Insect infestation must be precluded (e.g. by using kiln-dried timber, insect-impermeable covers, coloured heartwood with sapwood content $\leq$ 10 % or open arrangement of timber members with regular inspection).

2.2.5 Accessibility

In order to facilitate the bridge-inspection, minimum distances should be maintained between the superstructure and the substructure as well as the surrounding terrain (H-Zug 1, see Figure 9). Sufficient distances also guarantee air ventilation and prevent the influence of spray water and vegetation.

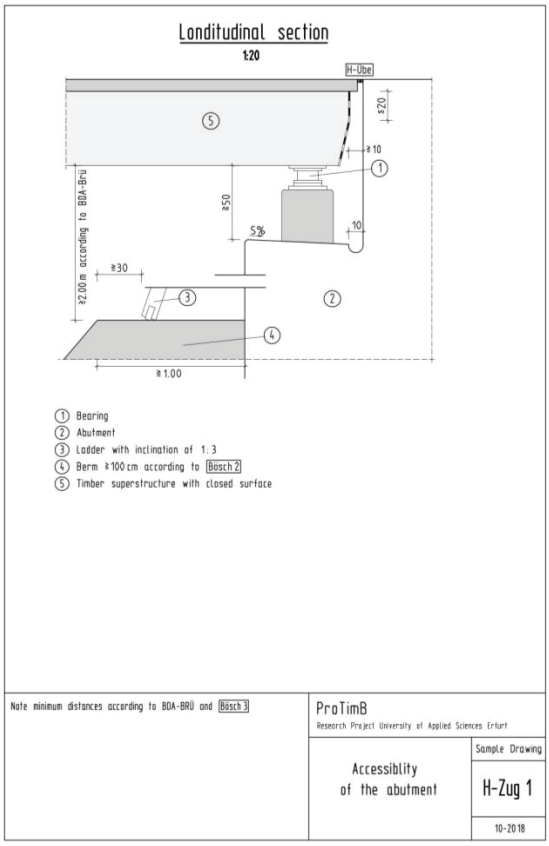

Figure 9: *Sample drawing H-Zug 1 showing minimum distances for good ventilation and easy inspection*

Special protection of the end-grain surfaces is necessary, e.g. by arranging waterproof transition joints, arranging rear-ventilated sheets or boards or by means of diffusion-open paint or membrane. Ventilation and accessibility of the end-grain surfaces can be ensured by chamfering the beam's ends and maintaining a distance to the chamber wall of at least 0.10 m.

https://doi.org/10.52202/069179-0396

A clear distance between the superstructure and the support bench of at least 0.50 m enables the bearings to be easily checked. In addition, the wooden main beams are prevented from being affected by water and dirt on the support bench. Manual cleaning of the support bench is also facilitated. A sufficiently wide and plane area in front of the abutment and a clear height of at least 2 m enable the inspection of the superstructure's underside (Figure 10).

Figure 10: *Bottom view of a timber-concrete composite bridge (Birkbergbridge, Germany) showing a sufficient distance between superstructure, support bench and ground for good ventilation and easy inspection (photo: A. Simon)*

2.3 CONSTRUCTION

"Recommendations for technical contractual terms for timber bridges (ETV-HolzBr)" have been developed for construction [3]. This document defines basic material requirements for the timber, engineered wood products, thermally and chemically modified wood, adhesives and steel components. Specifications are given for minimum dimensions, surface qualities and limits for deformation due to shrinkage and swelling. The production, storage, delivery, quality control and assembly of structural timber elements are regulated. For the purposes of quality control, the document defines limits for dimensional and moisture tolerances, cracks and surface qualities at the factory and at the construction site. Furthermore, it contains necessary measures to be taken for structural timber protection and the corrosion protection of steel components in timber bridges. Suggestions for the design of timber-concrete composite bridges and of wildlife bridges complete these guidelines. With the extension of the Eurocode for timber structures [11], execution rules will also be normatively regulated in the future.

2.4 MAINTENANCE

Respecting the principles of structural protection is mandatory but not sufficient for durable timber bridges. Their intended service life of 60 to 100 years can only be achieved in combination with regular maintenance and inspection. Manuals for maintenance and inspection have been developed within the ProTimB project [1].

The maintenance manual explains useful service measures, their necessary intervals, the required technical equipment and means of access to facilitate economical maintenance. Service measures include:

- the cleaning of the superstructure, benching, road surface, bridge drains and drainage channels,
- the removal of vegetation all around the bridge in a radius of at least 2 m,
- the renewal of coatings, sealants, joints,
- the repair of planks, asphalt layer, cladding, cover plates and parapet members.

An interval is recommended for every measure, taking the structural element's service life and seasonal weathering and pollution into account. In addition, a continuous monitoring of the timber moisture content is advised.

2.5 BRIDGE INSPECTION

Independently of maintenance, bridges must be regularly inspected in Germany. Every bridge has to be visited twice a year and checked once a year. Additionally, the basic inspection and main inspection have to be performed alternately every three years. The main inspection requires a hands-on check of every structural component and is therefore the most complex and expensive. For special types of timber bridges such as framework bridges, cable-stayed bridges or bridges for wildlife, an inspection manual supplements the maintenance manual. The inspection manual explains the tasks for continuous observation (usually twice a year) and the annual survey as well as for the basic and the main inspection in detail.

It is recommended to use the checklists for continuous observation and survey, which are part of the inspection manual, in parallel to the maintenance manual. The following aspects have to be checked during the annual observation:

- All structural protection measures have to be checked for functionality (covering, sealings, cladding).
- All accessible members have to be checked for sufficient protection from moisture and dirt (marks of running water, timber with earth contact, growth of moss and algae).
- The timber moisture content has to be measured in damp and vulnerable areas.
- All accessible members have to be checked for wood-destroying fungi, incipient rot and wood-destroying insects.
- Protruding connectors have to be observed (screws in planks, dowels in knot areas).

https://doi.org/10.52202/069179-0396

It is recommended to record damage and compare it with the condition of the previous observation. On this basis, necessary conservation measures can be derived to ensure economical bridge maintenance and to achieve long durability.

The inspection manual contains the recommended measuring methods and provides special hints for organisation, accessibility, documentation and traffic security during the inspection. Regarding individual structural characteristics, the regular inspection of every timber bridge can be optimised and performed economically. If a regular inspection reveals complex damage of unclear cause or unclear dimension of defects, further recommendations are given for the implementation of an object-related damage analysis.

3 CONCLUSIONS

Technical guidelines guarantee professional state of the art design and construction standards.

The sample drawings for timber bridges describe recommended structural details for the planning, calculation and execution of timber bridges. They represent proven and durable solutions for recurring technical tasks and reflect the respective state of the art. Intelligent design and responsible regular maintenance improve the durability of timber structures, enabling bridges made of timber to achieve the service lives of concrete and steel bridges.

Aesthetic, well-protected and durable timber bridges of a high-quality standard will characterise our landscape in the future.

ACKNOWLEDGEMENT

The new guidelines for protected timber bridges were developed within the research project “Protected Timber Bridges (ProTimB)”. The research has been supported and funded by the Federal Ministry of Education and Research of Germany, the companies of the Qualitätsgemeinschaft Holzbrückenbau e. V. (Schaffitzel Holzindustrie GmbH + Co. KG, Schmees & Lühn Holz- und Stahlingenieurbau GmbH, Grossmann Bau GmbH) and Setzpfandt Beratende Ingenieure GmbH & Co. KG. The authors thank all partners and supporters for their technical and financial support.

World Conference on Timber Engineering Oslo 2023

WOOD DURABILITY BASED IN THE NEW BRAZILIAN TIMBER STRUCTURES CODE ABNT NBR 7190: 2022

Leandro Dussarrat Brito[1], Everaldo Pletz[2], Carlito Calil Junior[3].

ABSTRACT: The ABNT NBR 7190:1997 standard has recently undergone a revision process. Thus, this paper treats of the Chapter 12 wood durability of the standard revision project Brazilian, Design of Timber Structures code ABNT NBR 7190: 2022. Wood is an organic material and it must receive a prior analysis of the conditions in which it will be applied to identify the need for specific preservative treatment, seeking to obtain durability and resistance to wood biodeterioration agents, such as fungi, xylophagous insects and marine bores. Similar to Chapter 12 Wood durability of the ABNT NBR 7190: 2022 standard revision project, ABNT NBR 16143: 2013 complements regarding the wood preservation treatment, where it also establishes the system with six Use Categories for wood, with an emphasis on treatment preservative to increase the durability of construction systems. A very important aspect that must be considered is the elaboration of a project in which the durability is assured. Thus the purpose of the Use Categories System is to offer a simplified tool for decision making regarding the rational and intelligent use of wood, through a systemic approach to the producer and user, which ensures greater durability of constructions.

KEYWORDS: Brazilian Design of Timber Structures code, Timber structures, Wood durability.

1 INTRODUCTION

Wood is an organic material that can have biodeterioration.

To develop the design of a timber structure, it is necessary to ensure a minimum durability compatible with its purpose and with the investment to be made (ABNT NBR7190: 1997) [1].

Usually a good performance of the structural member is expected throughout its useful life. The key element to identify wood performance over time is durability (CALIL et al, 2006; CALIL JUNIOR & BRITO 2010) [2, 4].

Thus, durability is the capacity of a product to maintain its performance above pre-established minimum values in line with users under expected conditions of use (CALIL JUNIOR et al, 2006) [2].

2 BRIEF HISTORIC

The first Brazilian Code of Timber Structures was published in 1951 under the name of NB 11 - Design and Construction of Timber Structures [5], with a deterministic design method.

In February 1982 it was renamed ABNT NBR 7190:1982 without any modification.

As of 1992, a new study of this standard was started using the semi-probabilistic method of dimensioning in limit states.

As long as the research and scientific work evolved in the country, starting from the Technical Bulletin BT/PEF/9602/USP Fusco et al (1996)[6] updated the published standard revision project to version ABNT NBR 7190:1997 [1] with emphasis in the use of noble woods. In this version of the standard, topics on wood durability were introduced according to the Biodeterioration Risk Classes.

When developing the design of a timber structure, it is necessary to ensure a minimum durability compatible with its purpose and with the investment to be made.

The structural members of a timber construction can be exposed to different Risk Classes of biodeterioration depending of the biotic organisms present in the local and the environmental conditions that may favor the attack (FUSCO et al 1996)[6].

From the draft standard carried out by Fusco et al (1996) [6], Annex D of the ABNT NBR 7190: 1997 [1] was added, which is informative and deals with recommendations on the durability of wood.

In this Annex D of NBR 7190:1997 [1], five situations of Biodeterioration Risk Classes were presented to be considered in the design of timber structures (CALIL JUNIOR et al, 2003) [7].

Brazolin et al (2004) [8] proposed the elaboration of a standard of wood preservation to help producers and users of the civil construction sector to increase the durability of timber construction systems. In this work, a systematic approach was presented on the subject of biodeterioration and wood preservative treatment called the System of Risk Classes, which now has six situations of these classes (BRAZOLIN et al 2004) [8].

Calil Junior et al (2006) [2] presented six Risk Classes, when from Brito (2010) [3] it started to be called Use Classes. The term “risk” was replaced by “use” in order not to depreciate the use of wood.

[1]Leandro Dussarrat Brito, LaMEM/SET/EESC/USP University of São Paulo, Brazil, dussarrat@sc.usp.br
[2]Everaldo Pletz, Department of Structures, UEL State University of Londrina, Brazil, pletz@uel.br
[3]Carlito Calil Junior, LaMEM/SET/EESC/USP University of São Paulo, Brazil, calil@sc.usp.br

https://doi.org/10.52202/069179-0397

In 2013, a new revision of NBR 7190 began, based on new research and work carried out by the CB-002 committee and in parallel with the revision project of this standard, ABNT NBR 16143:2013 Wood Preservation – Use Categories System [9] was prepared, when the term Use Categories was officially changed.
Thus, in the NBR 7190:2022 standard revision project, it now has the six Use Categories [10].
It is worth noting that the ABNT NBR 16143:2013 was prepared by the Brazilian Wood Committee (ABNT/CB-31), by the Wood Preservation Study Committee (CE-31: 000.15) [9].
While the revision of the ABNT NBR 7190-1:2022 standard was elaborated in the Brazilian Civil Construction Committee (ABNT/CB-002), by the Commission for the Study of Timber Structures (CE-002:126.010)[10].

3 WOOD DURABILITY

The Chapter 12 of the new version of the ABNT NBR 7190:2022 treat with the theme "Durability of wood".
Among the various materials intended for civil construction, wood has exceptional qualities that elect it, in many respects, especially under the criterion of sustainability, as a high-performance building material (ABNT NBR 7190:2022).
However, wood is an organic material and must receive prior analysis of the conditions in which it will be applied, in order to identify the need for specific preservative treatment, seeking to obtain the best result in terms of durability and resistance to biodeteriorating agents of wood, such as fungis, xylophagous insects and marine borers (NBR 7190:2022).
The structural classification provides a connection between the timber structural members and their expected performance when they come into service (CALIL JUNIOR. et al, 2003; CALIL JUNIOR et al, 2006; CALIL JUNIOR & BRITO, 2010; CALIL JUNIOR et al, 2015) [2, 4, 7, 11].
Usually, good performance is expected over the entire useful life of the structural member (CALIL JUNIOR. et al, 2003; CALIL JUNIOR et al, 2006; CALIL JUNIOR & BRITO, 2010; CALIL JUNIOR et al, 2015) [2, 4, 7, 11].
The key element for this prediction is its durability, defined as the ability of a product to maintain its performance above pre-established minimum values, on consonance with users, under the intended conditions of use (CALIL JUNIOR. et al, 2003; CALIL JUNIOR et al, 2006; CALIL JUNIOR & BRITO, 2010); (CALIL JUNIOR et al, 2015) [2, 4, 7, 11].
A large number of biotic agents and abiotic agents have the potential to reduce wood performance over time (CALIL JUNIOR. et al, 2003; CALIL JUNIOR et al, 2006; CALIL JUNIOR & BRITO, 2010; CALIL JUNIOR et al, 2015) [2, 4, 7, 11].
The structural designer, however, can guarantee durability using a combination of three factors [2, 4, 7, 11]:

- Better design detailing;
- Preservative treatment;
- Inspection, maintenance and repairs.

An important aspect is to always record the works carried out for later verifications (CALIL JUNIOR. et al, 2006) [2].

4 WOOD PRESERVATION – USE CATEGORIES SYSTEM

According to the ABNT NBR 7190: 2022 wood preservation is the set of preventive and curative recommendations adopted to control biological agents (fungi, xylophagous insects and marine bores), physical and chemical that affect the properties of wood, adopted in the development and maintenance of wood components in the built environment.
Initially proposed by Brazolin et al (2004) [8] as Risk Category System, currently the normative term of ABNT NBR 7190:2022 becomes Use Category System.
The purpose of the Use Categories System is to offer a simplified tool for decision making regarding the rational and intelligent use of wood, through a systemic approach to the producer and user, which ensures greater durability of constructions.
The creation of the set of use categories was based on the principle of valuing the project as the first and most important preventive tool to be used with the objective of obtaining a wooden construction endowed with durability.
The system consists of establishing six Use Categories based on the conditions of exposure or use of the wood, on the expected performance of the component and on the possible biodeteriorators agents present (ABNT NBR 16143: 2013; ABNT NBR 7190: 2022) [9, 10].
In the design of timber structures, the following use categories should be considered [9, 10]:

- **Use Category 1:** Inside buildings, out of contact with the soil, foundations or masonry, protected from weathering, internal sources of moisture and local free from access by subterranean termites or arboreal.

- **Use Category 2:** Interior of buildings, in contact with the masonry, without contact with the soil or foundations, protected from the weather and indoor sources of moisture.

- **Use Category 3:** Interior of buildings, out of contact with the soil and protected from the weather, which can, occasionally be exposed to sources of moisture.

- **Use Category 4:** Outside use, out of contact with the soil and subject to the weathering.

- **Use Category 5:** Contact with soil, fresh water and other situations favorable to deterioration, such as setting in concrete and masonry.

- **Use Category 6:** Exposure to salt water or brackish.

Thus, in the current Brazilian standard ABNT NBR 7190: 2022, depending on the service condition in which the wood of the structure will be exposed, each corresponding

https://doi.org/10.52202/069179-0397

use category is susceptible to attack by biodeteriorating organisms, as listed [9, 10]:

- **Use Category 1:** drywood termite, wood borer beetle;
- **Use Category 2:** drywood termite; wood borer beetle; subterranean termite, arboreal termite;
- **Use Category 3:** drywood termite; wood borer beetle; subterranean termite; arboreal termite; mold fungis; stain fungis; decay fungis;
- **Use Category 4:** drywood termite; wood borer beetle; subterranean termite; arboreal termite; mold fungis; stain fungis; decay fungis;
- **Use Category 5:** drywood termite; wood borer beetle; subterranean termite; arboreal termite; mold fungis; stain fungis; decay fungis;
- **Use Category 6:** marine borers; mold fungis; stain fungis; decay fungis.

The figure 1 illustrates some examples of biodeterioration risk situations for each corresponding use category, taking a residence as an example.

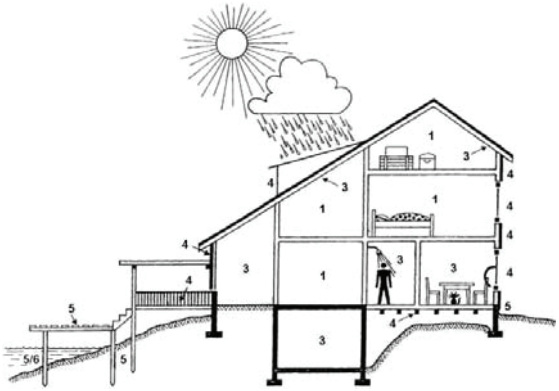

Figure 1: *Use Categories, depending on the situation of biodeterioration risk in a residence. Source: (BRITO (2010); CALIL & BRITO (2010); BRITO (2014)[3,4,12].*

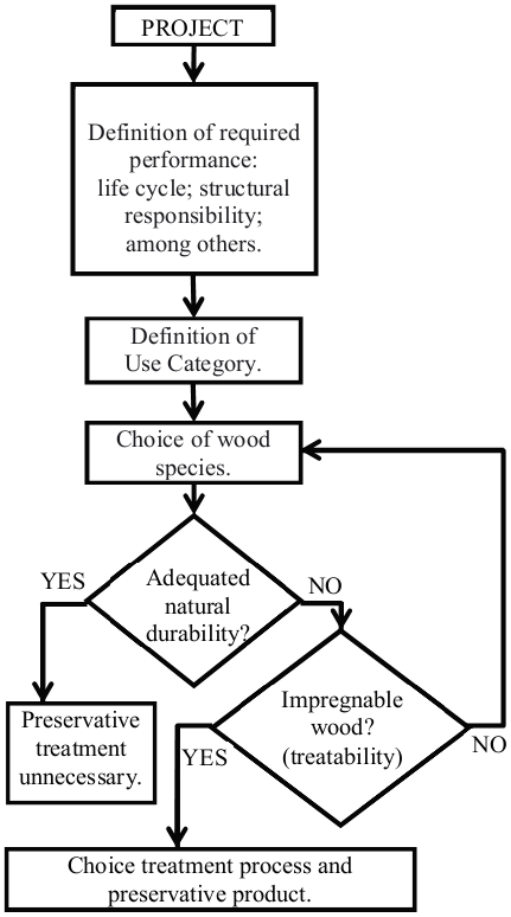
Due to the chemical nature of the preservative products recommended for the treatment of wood, in the construction components of structures, which may be in direct contact with people or animals, it is recommended to use suitable finishes, such as "stains", varnishes and/or paints, to prevent migration and/or leaching of the preservative product. (CALIL JUNIOR. et al, 2006) [2].

5 APPLICATION OF THE USE CATEGORIES SYSTEM

The Use Category System defines recommendations that must be adopted during the design phase of a construction with wooden components, helping to choose the preservative treatment of wood - product and process (ABNT NBR 16143: 2013; ABNT NBR 7190: 2022) [9, 10]. This decision process is represented by the Flowchart 1 of the Figure 34 in ABNT NBR 7190: 2022 [10].



Flowchart 1: *Choice of treatment and wood species in the project. Fonte:* ***Figure 34 in ABNT NBR 7190:2022****.*

Thus, when using wood as an engineering material, the following steps must be considered mandatory (ABNT NBR 16143: 2013; ABNT NBR 7190: 2022) [9,10]:

a) Definition of the required performance level for the wooden component or structure, such as: useful life, structural responsibility and commercial and legal guarantees;

b) Evaluation of the biological risks to which the wood will be subjected during its useful life – attack by fungis, xylophagous insects and/or marine borers;

c) Definition of the wood species suitable for use and the need for preservative treatment considering: natural durability of the species, treatability, treatment process and available preservative products. The preservative

treatment is necessary if the chosen species is not naturally durable for the category of use considered and/or if the wood contains sapwood, a portion naturally susceptible to attack by xylophagous organisms;

d) Selection of the appropriate wood treatment process and preservative product.

6 USE CATEGORIES: TIMBER STRUCTURAL AND CONSTRUTIVE ELEMENTS

With a focus on preservative treatment to increase durability in the useful life of structural member and constructive wooden, ABNT NBR 16143:2013 Wood Preservation - Use Categories System [9] - complements the system of six use categories of the current version of ABNT NBR 7190: 2022 Projects of Wooden Structures [10].
Tables 1 to 4 list the possible applications of lumber wood, roundwood, glulam, and wood panels as engineering material, with the six use categories of probable, according to ABNT NBR 16143: 2013 [9].

Table 1: *Lumber wood. Fontes: BRASOLIN et. al (2004); ABNT NBR 16143:2013; [8, 9].*

Application	**Probable Use Category**
Floor	2 e 3
Doors and Windows	2, 3 e 4
Floor beam	2 e 3
Door Jambs	2, 3, 4 e 5
Reel	1, 2, 3 e 4

Tiles shingles	4
Roof (undercover)	2 e 3
Plywood box beam	2, 3 e 4

7 CONCLUSIONS

The Use Categories System defines the indications that must be taken in the design phase of a construction with wooden elements, thus helping to choose the most appropriate treatment for wood preservation.

Once the Use Categories are defined at the design step, the structural designer resorts to the ABNT NBR 16143:2013 standard and defines which will be the most appropriate preservative treatment to be used for each timber structural members.

The Annex D (informative) of ABNT NBR 7190:1997 dealt with recommendations on the durability of wood.

In the revised version of the ABNT NBR 7190:2022 standard, the content ceases to be informative and becomes normative and mandatory, available in Chapter 12 Durability of wood.

World Conference on Timber Engineering Oslo 2023

UPDATING EUROCODE 5 – DESIGN GUIDANCE FOR INCREASING THE ROBUSTNESS OF TIMBER STRUCTURES

Pedro Palma [1], Jørgen Munch-Andersen [2], and Philipp Dietsch [3]

ABSTRACT: The European structural timber design standard EN 1995-1-1 *Eurocode 5* is currently under an extensive revision and the latest draft includes a new Informative Annex on *Additional guidance for increasing the robustness of timber structures*. The design rules in this new Annex are focused on direct design methods that provide explicit verifications for specific scenarios of assumed local failure: i) design for resistance to removal of load-carrying elements and; ii) design for segmentation using fuse elements. Dynamic effects related to a sudden loss of a load-carrying element are considered through dynamic amplification factors, which are provisionally prescribed as $\gamma_{dyn} = 2.0$. The design of fuse elements is based on limiting their load-carrying capacity, ensuring that they fail under certain damage scenarios. The upper values of the load-carrying capacity of connections are very dependent on the specific type of connection, but a over-strength factor $4 = R_{k,0.95}/R_{k,0.05}$ is provisionally prescribed.

KEYWORDS: robustness, progressive collapse, EN 1995-1-1, Eurocode 5, element-removal analyses, fuse elements

1 INTRODUCTION

1.1 BACKGROUND

Twenty years after their initial publication, the structural Eurocodes are currently under revision. A new topic that is now explicitly considered in the latest draft version of FprEN 1990:2022 *Eurocode 0 Basis of structural design* [1] is resistance to disproportionate collapse. This draft includes an Informative Annex E with additional guidance for enhancing the robustness of buildings and bridges. This Annex E, however, provides only very general guidance and does not provide a clear hierarchy of design strategies to prevent disproportionate collapses. The European standardisation committee CEN/TC 250/SC 5, responsible for EN 1995-1-1 *Eurocode 5 Design of timber structures* [2] took on the task of developing specific design guidance for increasing the robustness of timber structures. This work has been carried out by members of its Working Group 10 and the outcome is a new Informative Annex to the latest draft of prEN 1995-1-1 Eurocode 5.

1.2 SCOPE AND OBJECTIVES

This paper presents the new Annex A *Additional guidance for increasing the robustness of timber structures* of prEN 1995-1-1 Eurocode 5. It gives an overview of design strategies to increase resistance to disproportionate collapse, focusing on timber structures [3–5] and including lessons learned from past accidents [6,7]. Advantages and shortcomings of the different strategies are discussed. The design rules in the new Annex A are presented, alongside with their background. Aspects that need to be further investigated are also highlighted

1.3 DISCLAIMER

The opinions expressed in this paper are those of the authors and do not necessarily represent the official position of the Technical Committee CEN/TC 250/SC 5 or the opinion of its other members.

2 DEFINITIONS

FprEN 1990:2022 Eurocode 0 [1] defines *robustness* as the "ability of a structure to withstand adverse and unforeseen events without being damaged to an extent disproportionate to the original cause". The Swiss standard SIA 260:2013 *Basis of Structural Design* [8] uses a somewhat different formulation and defines robustness as the "ability of a structure and its members to keep the amount of deterioration or failure within reasonable limits in relation to the cause". These definitions of robustness coincide with what has been more broadly defined as *resistance to disproportionate collapse* or *collapse resistance* [9,10,3]. The definition of robustness adopted in this paper is instead *insensitivity to initial damage*, which is one of the aspects of *collapse resistance* (Figure 1), alongside with *vulnerability* (susceptibility of a structural component to be damaged

by an abnormal event) and *exposure* (abnormal events, not explicitly considered in ordinary design) [11]. A robust structure is, therefore, less prone to disproportionate collapses. Finally, a disproportionate collapse might not be *progressive*, as statically determinate structures will most likely collapse after the failure of a single component.

The main difference between design for robustness and design for accidental situations [12] is that the latter assumes identified and quantified abnormal actions (e.g. far-field blasts or vehicle impacts), against which the structure can be explicitly designed, so that a specified reliability level is reached. Design for robustness, on the other hand, deals with exposures that cannot be identified and/or quantified. These can be errors in the design, construction, or use of the structure that lead to structural deficiencies, or external man-made (e.g. accidental or deliberate blast, impact, or fire) or natural events (e.g. extreme snow or wind loads, or degradation of the structure)Design for robustness deals mostly with threat-independent scenarios that assume an initial notional damage (e.g. sudden removal of a load-carrying member). The corresponding robustness-related design strategies are focused on limiting damage propagation through redundancy and/or segmentation.

3 DESIGN FRAMEWORK FOR RESISTANCE TO DISPROPORTIONATE COLLAPSE

Starossek's [11] design framework for resistance to disproportionate collapse (Figure 2) can be divided into the following main parts [13]:

i) risk assessment/classification of the structure;
ii) specification of hazard scenarios;
iii) specification of performance objectives;
iv) selection of design strategies
v) carrying out of verification procedures.

The level of *design requirements* should be based on the risk assessment of building. This can be achieved by undertaking the risk assessment and building classification frameworks described, e.g. in Section 4.1. The specification of *hazardous scenario*s, such as threat-specific (e.g. impact of a car in a ground-floor column) or non-threat-specific events (e.g. notional damage such as a sudden removal of a structural component), and *performance objectives* (i.e. the acceptable level of damage/consequences) should involve other stakeholders besides the owner and the design team, namely the relevant civil and building authorities and even insurance companies. For major projects, the specification of hazardous scenarios requires some experience, since the creation of general rules is difficult due to the many possible scenarios and the project-specific nature of many of them. Once the hazard scenarios are considered and the performance objectives are set, the structural design team then selects the *design strategies* (e.g. protection or overdesign measures to prevent local damage, robustness measures to limit damage propagation) and the *design verification procedures* (e.g. based on structural analysis models or even testing). A schematic overview of this design framework for resistance to disproportionate collapse is given in Figure 2.

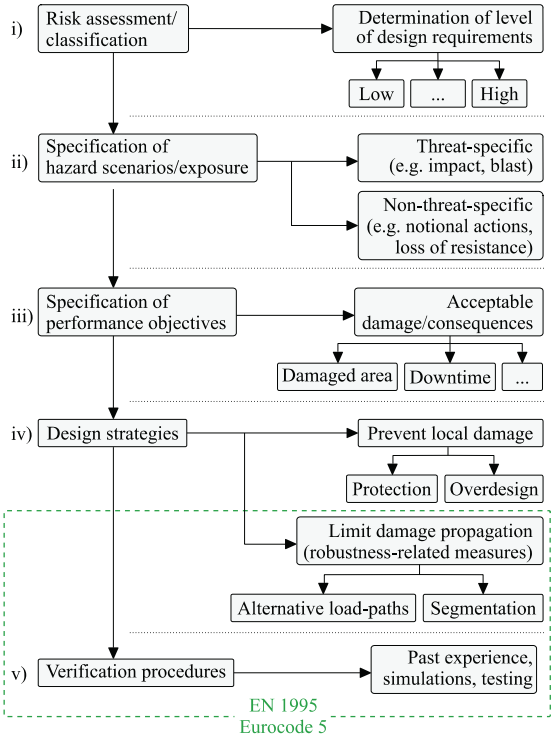

Figure 2: *Design framework for resistance to disproportionate collapse, based on Starossek [11], and the scope of prEN 1995-1-1 Eurocode 5.*

https://doi.org/10.52202/069179-0398

For buildings with low importance and exposure, it should be possible to achieve an adequate level of resistance to disproportionate collapse without any explicit design verifications. However increasingly complex verifications are often required for buildings of high importance and/or exposure.

4 DESIGN IN ACCORDANCE WITH THE STRUCTURAL EUROCODES

4.1 APPROACH

The structural Eurocodes in their current and upcoming versions, as well as most other current structural design codes, adopt a limit-state design approach, based on a probabilistic representation of the design parameters so that predefined appropriate reliability levels are reached. EN 1990 *Eurocode 0* establishes the design principles, based mostly on the partial factor method, EN 1991 *Eurocode 1* specifies the actions and their values, and timber-specific aspects are addressed in EN 1995 *Eurocode 5*. (Figure 3).

FprEN 1990:2022 *Eurocode 0* [1] recommends that structures "be designed to have an adequate level of robustness" and states that "for most structures, design in accordance with the Eurocodes is assumed to provide an adequate level of robustness without the need for any additional design measures". This statement might be based on the fact that not so many disproportionate collapses have been observed [14] and that it has been traditionally accepted that "structural codes may consider these [progressive collapse] requirements satisfied if all other requirements can be fulfilled" [15,16]. However, assuming that designing in accordance with the Eurocodes automatically provides an adequate level of robustness is a rather "optimistic" view and has been shown not to be true in some cases, as some studies on multi-storey timber buildings have shown [17].

As other design frameworks for resistance to disproportionate collapse [18,19], FprEN 1990:2022 *Eurocode 0* [1] starts by assessing the *importance* of the building, i.e. the *direct* and *indirect* risks or consequences of a collapse, and its *exposure*, i.e. the probability of occurrence of a hazardous event (e.g. accident, malicious or unintentional actions). FprEN 1990:2022 Eurocode 0 [1] establishes five consequence classes (Table 1), based on an indicative qualification of consequences (loss of human life or personal injury and economic, social or environmental consequences). The exposure of the structure, i.e. the level of threat, is not explicitly accounted for (or it is assumed to be proportional to the importance of the building) [13].

FprEN 1990:2022 Eurocode 0 [1] then allows for the design method for "providing enhanced robustness" to be selected based on the consequence class (CC) of the structure (Table 2).

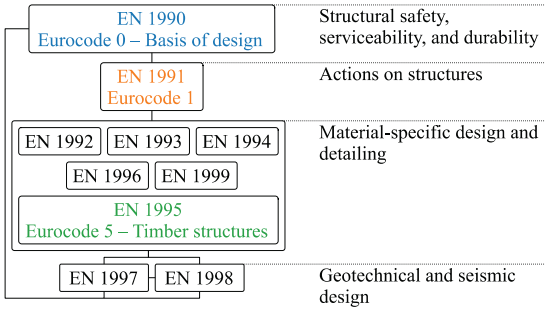

Figure 3: *Links between the Eurocodes (https://eurocodes.jrc.ec.europa.eu/showpage.php?id=13)*

4.2 SHORTCOMINGS

One of the shortcoming regarding resistance to disproportionate collapse is that design verifications are made only on the local (component) level, following an element-by-element approach.It is hereby assumed that the reliability of the structure is not much smaller than the reliability of each member or connection [20]. However, the response of a structure to an initial local damage is dependent not only on the behaviour of its components in

Table 1: *Qualification of consequence classes (FprEN 1990 2022* ***[1]****). Assignment of structures to consequences classes is a Nationally Determined Parameter (NDP), i.e. it can be defined at a national level by regulatory authorities in each Member State.*

Consequence class (CC)	Indicative qualification of consequences	
	Loss of human life or personal injury [a]	Economic, social or environmental consequences [a]
CC0 – Lowest	Very low	Insignificant
CC1 – Lower	Low	Small
CC2 – Normal	Medium	Considerable
CC3 – Higher	High	Very great
CC4 – Highest	Extreme	Huge

[a] The consequence class is chosen based on the more severe of these two columns.

Table 2: *Indicative design methods for "enhancing robustness" taken from FprEN 1990 2022 [1].*

Consequence class	Design methods
CC1 – Lower	No design methods to provide enhanced robustness need be applied.
CC2 – Normal	When specified by the relevant authority or as agreed for a specific project by the relevant parties, either: a) For buildings: use of prescriptive design rules for ties to provide integrity, ductility and alternative load paths; or b) Design of particular structural members as 'Key members'; and/or c) Segmentation.
CC3 – Higher	Satisfy the requirements for CC2 appropriately adapted and in addition consider, where appropriate: a) potential initial failure events; b) propagation of failure; c) resulting consequences; d) risks.

https://doi.org/10.52202/069179-0398

isolation, but on their arrangement and connectivity to the structure and the requirements for the reliability of the components should depend on the characteristics of the structure [20].

Another issue of the current approach regarding design for resistance to disproportionate collapse is the difficulty in dealing with extreme risks, i.e. low probability/high consequence events, such as a disproportionate collapse, due to the lack of statistical data [11]. Strategies to enhance resistance to disproportionate collapse are "not generally associated with a target level of reliability as in structural member design against identified actions and could involve consideration of a conditional reliability" [1]. Therefore, these events cannot easily be handled within the current reliability-based framework, even though target reliability levels have been set in the past for ultimate limit states corresponding to progressive collapse [15,16].

As mentioned above, it is difficult to judge the resistance of a structure to disproportionate collapse simply based on the individual behaviour of its elements and neglecting the structure's sensitivity to initial damage. Tests on a medium-rise multi-storey platform-frame building, with structural walls and floors constructed from small section timber studs and cladded with wood-based panels, showed that such buildings had "significant inherent robustness and capacity to span over removed panels" [21–23]. On the other hand advanced mechanical simulations, which also took into account the variability of mechanical properties, of a medium-rise cross-laminated timber building showed that simple compliance with building codes [4] (both the Eurocodes and the *National Building Code of Canada* and CSA O86-09:2010) led to a probability of disproportionate collapse as high as 32% after removal of a load-carrying element [17].

Finally, the indicative design methods for "enhancing robustness" prescribed by FprEN 1990:2022 *Eurocode 0* [1] (Table 2) are not actually focused on increasing robustness, i.e. insensitivity to initial damage, and can hence be misleading. Strategies such as the overdesign of "key members" reduce the local *vulnerability* of the structure, but do not necessarily lead to increased *robustness* (Figure 1). Prescriptive design rules (e.g. providing ties or imposing failure modes with sufficient ductility in the connections) might, in some cases, promote rather than prevent collapse progression [7,11].

5 DESIGN STRATEGIES AGAINST DISPROPORTIONATE COLLAPSE

Given that different structures are vulnerable to disproportionate collapse in different degrees, design for resistance to disproportionate collapse cannot be completely independent of the specifics of each project. Hence, it should be considered in the early (i.e. conceptual) stages of the design process [4,5]. For structures in higher consequence classes, resistance to disproportionate collapse should be based on more detailed analyses that include explicit *direct* design verifications for specific scenarios (e.g. element-removal analyses). This *direct* approach is more compatible with architectural complexity and design procedures that allow evaluating the global structural behaviour as a function of the behaviour of single elements. It can give valuable insights regarding resistance to disproportionate collapse of the structure. However, the required time, skill, and computational effort is greater than with the *indirect* approach. In any case, design for resistance to disproportionate collapse should not be interpreted as "simply applying rules" as this could lead to these aspects being addressed too late in the design process, hence limiting the applicable strategies or involving considerable costs. Rather should design for resistance to disproportionate collapse be addressed in the conceptual design of the structures.

Resistance to disproportionate collapse can be achieved at different levels (Figures 1 and 2):

- preventing local failures by
  - *adopting protective measures* to reduce the probability, extent or mitigate the exposure of the structure to abnormal events, or by
  - *overdesigning key elements* to reduce the probability of damage in case of a hazardous event, i.e. reduce the vulnerability of key elements and increase safety against initial failure;
- assuming local failure and limiting damage propagation (robustness-related measures to increase insensitivity to initial damage), through
  - *redundancy*, e.g. through alternative load paths and/or
  - *segmentation*, e.g. ensuring that collapsing parts are isolated from the rest of the structure.

Design strategies based on adopting *protective measures* often fall outside the scope of structural design (e.g. vehicle barriers, access control, active fire protection). Strategies based on *overdesigning key elements* should be a last resort [3,5,25,26], used only in cases where other alternatives are not viable or too costly. Design of key elements follows the common design procedure, even if the considered hazards and assumed actions are anything but common, like blast and impact, and the corresponding structural design can often be done in accordance with available guidance [4,12].

The *redundancy* strategy is based on providing an alternative load path (ALP) for the forces previously transmitted through load-carrying components that are assumed to have failed. It is based on assessing the behaviour of the remaining structure after an initial notional damage. A commonly assumed initial damage is the notional removal of one or several components of the structure. Then a so-called *element-removal analysis* is performed, with the objective of evaluating if the

[4] The building was not designed for earthquake resistance, only for a 1.0 kPa horizontal wind action. Explicit design for earthquake resistance could have indirectly increased the resistance to disproportionate collapse.

https://doi.org/10.52202/069179-0398

remaining structure is able to accommodate the damage. Redundancy on its own might not be suitable to avoid disproportionate collapse. In the case of repetitive structures, systematic design or execution errors can compromise the ability of a structure to redistribute loads and lead to progressive collapse [6,7], as the alternative load paths are all affected by a common-cause failure.

In these cases, *segmentation* can be an adequate design strategy. The objective of this strategy is to compartmentalise the structure in a way that collapse progression after an initial damage is halted at predefined locations, i.e. at the segment's borders, either through fuse-type elements or by having control joints at which the segments are physically separated. Most common solutions for *vertical segmentation* rely on providing shock-absorbing zones with high energy dissipation capacity. Examples of vertical segmentation are scarce, however, the 14-storey timber building "Treet", in Norway, includes a paradigmatic example [27]: this building has two "power storeys" that carry a prefabricated concrete slab on top of which four levels of residential modules are stacked; these "power storeys" should be able to halt a progressive collapse of the stacked residential modules, limiting the extent of collapse.

6 DESIGN FOR ROBUSTNESS IN prEN 1995-1-1 EUROCODE 5

6.1 SCOPE

As already discussed in Section 2, mistaking robustness with resistance to disproportionate collapse is a common misconception. Robustness-related strategies assume that damage has occurred and focus on limiting the extent of the damage, whereas increasing resistance to disproportionate collapse can be achieved through other strategies that are not related to robustness. Two other common misconceptions on the scope of prEN 1995-1-1 Eurocode 5 are that it should specify: i) *hazardous scenarios*, e.g. impact of a car in a ground-floor column, or a notional removal of a load-carrying component; and ii) *performance objectives*, e.g. allowed collapsed/ damaged area. However, as discussed in Section 3, these aspects are not to be addressed by the structural design team alone and must involve other stakeholders, such as the owner, the authorities, and other relevant parties.

The simple application of prescriptive design rules does not imply that performance requirements are met [11], hence they are therefore not addressed in prEN 1995-1-1 Eurocode 5. Preventing local failures by adopting protective measures also falls outside of the scope of structural design codes. Overdesigning key elements can be done within the normal design framework of the Eurocodes [4,12], even if the design actions are arbitrarily determined instead of statistically assessed (Section 5). In addition, even if overdesigning identified key elements contributes to increasing the resistance to disproportionate collapse, it is mostly unrelated to increasing robustness.

Ensuring robustness cannot simply be based on "applying rules". Choosing an adequate structural concept is as important for robustness as it is for seismic design. The new Annex A of prEN 1995-1-1 Eurocode 5 is focused on direct design methods, in which robustness can be explicitly demonstrated for specified initial damage scenarios (e.g. loss of one or more columns) and performance requirements (e.g. acceptable extent of collapse as a percentage of floor area, volume, or costs). This can only be achieved for design strategies based on *assuming local failure* and limiting the damage that follows, namely *redundancy* through alternative load paths and/or segmentation through fuse elements.

6.2 DRAFT CLAUSES IN prEN 1995-1-1

6.2.1 Overview

The members of Working Group (WG) 10 *Basis of design and materials*, of the European standardisation Technical Committee CEN/TC 250/SC 5 *Eurocode 5* have drafted robustness-related clauses for the upcoming revised version of Eurocode 5. A note in the main part of the standard highlights that designing for robustness is more related to the structural concept, redundancy, adequate choice of structural materials, and structural detailing than to complex analyses. More detailed provisions are given in informative Annex A *Additional guidance for increasing the robustness of timber structures*.

Annex A contains provisions for design strategies to increase robustness based on limiting the total damage following assumed scenarios of initial local failure (Figures 2 and 4), namely:

i) creation of alternative load paths (*redundancy* strategy); and
ii) segmentation of the structure into distinct parts that are able to collapse without inducing structural failures in other parts, by means of fuse elements.

Annex A is based on the assumption that the design will be based on linear-elastic structural analyses, as the other parts of Eurocode 5. Therefore, non-linear and dynamic effects have to be considered through adequate factors imposed on actions, resistances, and stiffnesses. It is not yet clear if enough data is available to derive all these factors, or if its application will be limited specific types of elements and connections.

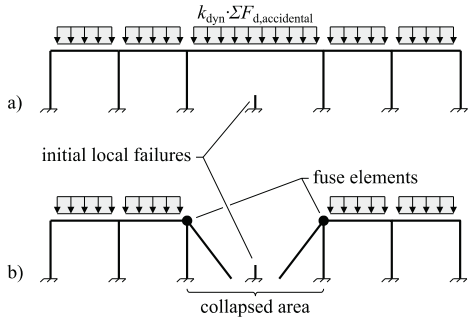

Figure 4: *Design strategies in the latest draft of Annex A of the prEN 1995-1-1 Eurocode 5: a) design for removal of load-carrying elements; b) design for segmentation using fuse elements.*

https://doi.org/10.52202/069179-0398

6.2.2 Design for removal of structural elements

The design verifications for *resistance to removal of load-carrying elements* includes two scenarios:

i) failure of a structural element including dynamic effects and impact of falling debris; and
ii) remaining structure, without the failed structural element.

In the first scenario, the dynamic effects corresponding to the sudden failure of a load-carrying element are considered by applying a partial factor γ_{dyn} on the actions. Different values have been proposed for such dynamic amplification factors. Grantham and Enjily [23] propose a modification factor of 2.0 (for timber-frame walls). Mpidi Bita et al. [17] state that for a 12-storey CLT building the forces from the dynamic simulation were about 1.5 times higher than the outcome from static analysis. Dietsch and Kreuzinger [28] determine dynamic amplification factors due to brittle failures in timber elements with shear reinforcement in form of self-tapping screws around 1.2. Cheng et al. [29] performed dynamic element-removal experiments on small-scale beam-column frames and report dynamic amplification factors between 1.3 and 1.7 for frames with ductile connections and above 2.0 for frames with brittle connections. Stevens et al. [30,31] present results that show a range of dynamic amplification factors from 1.20 to 1.85 for steel buildings and from 1.00 to 1.40 for concrete buildings. In the current draft of Annex A, a single provisional value $\gamma_{dyn} = 2.0$ is recommended, but it is still under discussion whether different values should be given depending on the type of structure and connections.

In this first scenario, the prescribed mechanical properties are those corresponding to an *instantaneous* load-duration class in EN 1995-1-1:2004 Eurocode 5 [2]. The prescribed combination of actions is that for accidental design situations [1].

Some element-removal scenarios might not impose dynamic effects on the structure (e.g. gradual loss of an element during a fire, excessive settlement of a foundation). In such cases, only the second design scenario is relevant. It is also important to note that whenever an alternative load path is mobilised, the failure might go unnoticed if the structure does not exhibit visible deflections or extensive cracking. Such a situation can eventually lead to a progressive collapse. This is particularly important in the case of very stiff secondary systems [6,7].

6.2.3 Design for segmentation using fuse elements

Robustness can be increased by designing for segmentation, e.g by isolating collapsing parts of the structure. Segmentation by interrupting the structural continuity is particularly important to limit the extent of damage in the case of systematic flaws that reduce the resistance of the structure at many locations, namely in repetitive structures.

Design for segmentation may be achieved by limiting the upper value of the load-carrying capacity of fuse elements, which are structural elements that are presumed to fail under certain damage scenarios in order to halt a progressive collapse. Given the large variability exhibited by the mechanical properties of timber, the fuse elements should be connections and the upper design value of their load-carrying capacity $R_{d,sup}$ should be smaller than the design effect of the action that it will carry in the case of a collapse $E_{d,fuse}$

$$R_{d,sup} \leq E_{d,fuse}. \quad (1)$$

In the current draft of Annex A, the upper design value of the load-carrying capacity of the fuse element $R_{d,sup}$ is calculated using the 95th-percentile value $R_{k,0.95}$ of the load-carrying capacity. Partial safety factors γ_M or γ_R are those for accidental design situations. The strength modification factor k_{mod} to be used is that for actions assigned to the *instantaneous* load duration class.

The values of $R_{k,0.95}$ are very dependent on the specific type of connection. In the absence of more ac-curate information, it is proposed that $R_{k,0.95} = 4 \cdot R_{k,0.05}$ is used. In a more recent experimental study on nailed and screwed steel-to-timber connections, Munch-Andersen [32] found an over-strength factor (ratio between the 95th-and the 5th-percentile values) of about 2.2. Connections with laterally-loaded dowel-type fasteners are prone to have considerable over-strength due to a possible pronounced rope-effect, which might complicate their use as fuse elements.

The design effect of the action $E_{d,fuse}$ is typically based on analyses of specific scenarios of initial local failure and includes relevant dynamic effects. In many cases, $E_{d,fuse}$ is mainly dependent on the self-weight of the part of the structure that is assumed to collapse. The fuse elements can also be conceptualised as in the example given in Figure 5 (not applicable in seismic regions), in which the rotations during failure lead to the detachment of failing and attached member.

It is in any case important to ensure that the remaining structure is able to carry relevant horizontal loads and that its members are adequately braced.

Design for segmentation and design for removal of structural elements can be used in combination, e.g. the structure can be segmented and alternative load paths can be provided within the segments.

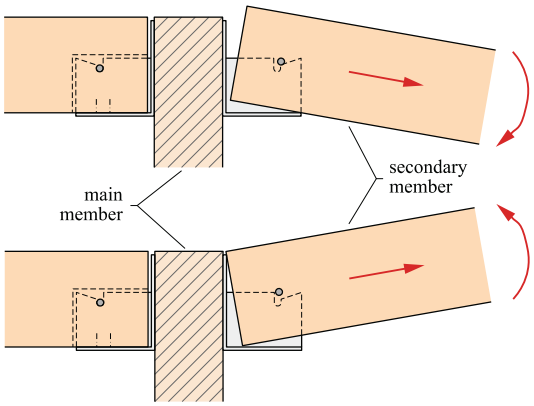

Figure 5: *Example of fuse element by Waidelich [33].*

https://doi.org/10.52202/069179-0398

7 CONCLUSIONS

Codification of resistance to disproportionate collapse of timber structures within the framework of the Eurocodes is not straightforward, in particular due to the lack of well-established design procedures. Designing for robustness (which is a part of the resistance to disproportionate collapse) shall primarily be considered in the early stages of design, e.g. by choosing an adequate structural concept, materials, and detailing.

The new Annex A of prEN 1995-1-1 Eurocode 5 is focused on direct design methods, in which *robustness* can be explicitly demonstrated for specified initial damage scenarios and performance requirements. Annex A contains provisions for design strategies to increase robustness based on limiting the total damage following assumed scenarios of initial local failure, namely the creation of alternative load paths and segmentation using fuse elements. Dynamic effects related to a sudden loss of a load-carrying element are considered through dynamic amplification factors, which are provisionally prescribed as $\gamma_{dyn} = 2.0$. The design of fuse elements is based on limiting their load-carrying capacity, and an over-strength factor $4 = R_{k,0.95}/R_{k,0.05}$ is provisionally recommended.

THE NEW BRAZILIAN TIMBER STRUCTURES CODE NBR7190: 2022

Carlito Calil Junior[1], Felipe Hideyoshi Icimoto[2], Leandro Dussarrat Brito[3]

ABSTRACT: The first Brazilian Timber Structures Code was published in 1951 under the name of NB11: Design and construction of timber structures, with a deterministic design method and composed of 16 pages without annex. In February of 1982, it was renamed NBR7190: 1982 without any modifications. In 1992 start the new study of this code using the limit states design method. This version, using the load and resistance factored design (LRFD), was published in 1997 by the Brazilian Association of Technical Standards with the emphasis on the utilization of hardwoods. A new study started in 2013 in order to consider all the new wood composite industrialized materials and connections. Considering the huge amount of hardwoods in Brazil, new test methods were developed in order to calibrate the new materials. This paper aims to present the New Brazilian Code for Timber Structures Design, NBR7190: 2022, relating the new revision for structural grading recommendations for softwoods and hardwoods planted in Brazil. Details of structural and constructive systems, Glulam, CLT, fire and preservation recommendations for design and new types of connections are also presented.

The New Brazilian Timber Structures Design Code NBR7190: 2022 is composed of 7 parts, that are: Part 1: Design criteria; Part 2: Test Methods for visual and mechanical grading of structural lumber; Part 3: Test Methods for characterization of defect-free specimens for native timber; Part 4: Test Methods for characterization of structural lumber; Part 5: Test Methods for determination of strength and stiffness of connections; Part 6: Test Methods for characterization of glued laminated timber; Part 7: Test Methods for characterization of cross laminated timber.

These six test methods for structural properties, grading, quality control of Glulam and CLT, and connections are also presented in related papers. Part of these codes is based on international codes such as EUROCODE and ISO.

KEYWORDS: Brazilian timber design code, timber structures, timber structural properties

1 INTRODUCTION

The Brazilian Timber Design Code is based on the Limit States Design concept used with the partial factor method, moving from an Allowable Stress Design of 1982 to a Probabilistic Limit States Design in 1997 using a calibration coefficient to convert tabulated medium strength properties to characteristic 5% values of load effects and resistances.

This paper aims to present the New Brazilian Code for Timber Structures Design, NBR7190: 2022, relating the new revision for structural grading recommendations for softwoods and hardwoods planted in Brazil. Details of structural and constructive systems, Glulam, CLT, fire and preservation recommendations for design and new types of connections are presented.

The global objective of the code is to fix the general conditions that must be followed in the design, construction and control of current timber structures, namely: bridges, buildings, roofs, decks and formworks.

2 MATERIAL PROPERTIES

The properties to consider in the design of timber structures are: density, strength, stiffness and moisture content. The specified properties of strength and stiffness correspond to the class of moisture content of 12%, that is 20 degrees Celsius and 65% of relative humidity.

2.1 CHARACTERIZATION OF TIMBER PROPERTIES

The new code considers two types of characterization of material properties based on defect-free specimens for native wood and structural samples for reforestation and

[1] Carlito Calil Junior, LaMEM/SET/EESC/USP, University of São Paulo, São Paulo, Brazil, calil@sc.usp.br

https://doi.org/10.52202/069179-0399

native species. The second type corresponds to the characterization of structural lumber based on the commercial lumber with all the defects like knots, fissures, slope of grain, warp, etc.

2.2 STRENGTH CLASSES

The two types of strength classes are simply a group of species/strength grade combinations that have similar properties. For native hardwoods five classes are defined: D20, D30, D40, D50 and D60. These numbers represent the characteristic value of compression parallel to grain stress for each strength class based on the characterization of small defect-free specimens. These strength classes represent the values of the strength and stiffness properties of forty-two tropical hardwood timbers grown in Brazil with adequate statistical analysis according to researches since 1980's to define the five classes for hardwoods, as we can observe in Table 1.

Table 1: *Strength classes of native wood defined with clear samples.*

Classes	$f_{c0,k}$ MPa	$f_{v0,k}$ MPa	$E_{c0,m}$ MPa	Density (12%) kg/m³
D20	20	4	10 000	500
D30	30	5	12 000	625
D40	40	6	14 500	750
D50	50	7	16 500	850
D60	60	8	19 500	1 000

Source: ABNT NBR 7190: 2022

For reforestation species, the strength classes are based on tests of structural lumber as an alternative for native timber. The strength classes are based on bending strength with 12 strength classes for softwoods and 8 strength classes for hardwoods according to Table 2 and Table 3.

Table 2: *Strength classes for C14 to C24 softwoods.*

2.3 DESIGN CRITERIA

The new code adopts the stability design criteria based on the EUROCODE 5 EN 1995-1-1:2009: Design of timber structures.

Representative Strength and Stiffness Values

The design values X_d of one wood property is obtained from the characteristic value X_k by the following formulae:

$$X_d = K_{mod} \frac{X_k}{\gamma_w} \quad (1)$$

Where γ_w the partial safety is factor of wood properties and K_{mod} is the modification factor that considers the influences that are not accounted in factor γ_w.

Modification Factors
The global modification factors K_{mod} is composed by the product of two partial modification factors, that is:

$$k_{mod} = k_{mod1} \cdot k_{mod2} \quad (2)$$

The partial modification factor number $K_{mod,1}$ consider the load classes and types of materials used, according to Table 5.

Table 5: *Values of* k_{mod1}.

Load class	Load duration	Wood type: Sawn wood Roundwood Glulam CLT LVL	Wood type: Recomposed wood
Permanent	More than 10 years	0,60	0,30
Long duration	Six months to 10 years	0,70	0,45
Medium duration	One week to 6 months	0,80	0,65
Short duration	Less one week	0,90	0,90
Instantaneous	Momentary	1,10	1,10

Source: ABNT NBR 7190: 2022

The partial modification factor number K_{mod2}, consider the classes of moisture content and types of materials used, according to Table 6.

Table 6: *Values of* K_{mod2}.

Wood moisture class	Wood type: Sawn wood Roundwood Glulam CLT LVL	Wood type: Recomposed wood
(1)	1,00	1,00
(2)	0,90	0,95
(3)	0,80	0,93
(4)	0,70*	0,90

*It is not allowed to use MLCC for humidity class 4.

Source: ABNT NBR 7190: 2022

2.3.1 Partial strength coefficients for Ultimate Limit States

The partial coefficient γ_w for Ultimate Limit States due the normal stresses has the basic value $\gamma_w = 1,4$. The partial coefficient for Ultimate Limit States due to shear stresses has the basic value $\gamma_w = 1,8$.

2.3.2 Partial coefficient for Serviceability Limit States.

The partial coefficient for Serviceability Limit States has the basic value $\gamma_w = 1,0$.

Partial Safety Factors for Ultimate Limit States: - the partial factor for compression parallel and normal to grain is $\gamma_{wc} = 1,4$, - the partial factor for tension parallel to grain is $\gamma_{wt} = 1,8$, - the partial factor for shear is $\gamma_{wv} = 1,8$, Stiffness The design analysis that the safety depends of wood stiffness like the instability in compression elements the elasticity modulus parallel to grain must be taken as:

$$E_{co,ef} = k_{mod1} \cdot k_{mod2} \cdot E_{o,med} \quad (3)$$

And the transversal modulus as:

$$G_{med} = \frac{E_{co,med}}{16} \quad (4)$$

https://doi.org/10.52202/069179-0399

Design Considerations in Stability of Compression Elements

In the compression design process, slenderness structural elements, may be subject of accidental eccentricity loads and geometrical lumber imperfections and this situation is considered in the code by applying an accidental eccentricity value of L/300. This mean that all the compression members with $\lambda > 40$ must be designed for bending and compression forces, where the bending forces appeared by eccentricity of L/300 multiply by the normal load. The formulas to be applied in the design of compression members are:

$$\sigma_{\mathrm{Nc,d}} = \frac{\mathrm{N}_{c,d}}{A} < \mathrm{f}_{\mathrm{co,d}} \quad (5)$$

3 TIMBER CONNECTIONS

The old code considers only two models for the design of connections using steel dowels, that is, embedment and bending.
The proposed code adopt the models used in EUROCODE 5 EN 1995-1-1:2009: Design of timber structures.
The modes for one and two shear sections using wood-wood and one and two shear sections using steel plate-wood and wood-steel plate-wood.
The main types of connections presented are nails, bolts and steel rings.

4 TEST METHODS

The New Brazilian Timber Structures Design Code NBR7190: 2022 is composed of 6 tests methods, that is:

Test Methods for visual and mechanical grading of structural lumber;

This Part 2 of the code establishes the criteria for visual and mechanical grading of lumber pieces of softwood and hardwood from planted forests for structural use. It aims to assign a strength class to each of the pieces that make up the batch of wood to be used classification by piece. This Part applies to wood pieces whose maximum dimensions of the cross section do not exceed the limits of 60 mm for the smallest dimension and 300 mm for the largest dimension.

Test Methods for characterization of defect-free specimens for timber of native timber;

This Part 3 of the code specifies the test method for characterizing defect-free specimens for wood from native forests. This Part applies to the determination of strength and stiffness properties in order to design of timber structures of native wood, related to complete, minimal and simplified characterization of sawn wood from native forests. Include the clear wood tests of bending, compression parallel and perpendicular, tension parallel and perpendicular, shear, toughness and embedment parallel and perpendicular to grain.

Test Methods for characterization of structural lumber;

This Part 4 of the code specifies test method for sampling and characterization of structural lumber for determining the medium and characteristic values of the structural properties of sawn timber of rectangular cross-section. Includes the tests of bending, compression parallel and perpendicular, tension parallel and perpendicular, shear and the determination of the transversal elasticity G value

Test Methods for determination of strength and stiffness of connections;

This Part 5 of the code specifies methods for the determination of the strength and stiffness of joints with mechanical fasteners used in timber structures (metal-dowel, timber dowel, screws, nails, stamped connectors and rings). It does not apply to the detailed procedures for each type of mechanical connector.

Test Methods for characterization of glued laminated timber;

This Part 6 of the code presents the test methods for the characterization of glued laminated timber (Glulam). The tests available are delamination tests for external and internal exposure, shear test of glue line, tensile strength parallel to the grain of the finger joints, and the amount of adhesive applied. In addition, provides some guidance for the production of finger joints. The delamination and shear of the glue line tests were based on the EN 14080 [4] with some adaptations. On the other hand, the tensile strength parallel to the grain test was based on EN 408 [5], whereas the failure mode of the finger joints was based on ASTM D4688/D4688 [6].

Test Methods for characterization of cross laminated timber

This Part 7 of the code presents the tests for CLT panels, its concepts and fundamental bases, that in part, was based in international codes like European Norms and ISO. Aiming at international standardization of quality control and characterization of CLT panels, some tests were based on established methodologies in the literature and European standards, the most advanced on the subject. Several academic works have been carried out to use international testing methods for Brazilian products, thus validating such methods. The main tests of this part are: strength and effective stiffness to bending perpendicular to the plane test and delamination test.

https://doi.org/10.52202/069179-0399

5 TIMBER STRUCTURES IN FIRE SITUATION

The new version considers the normal fire that represents the temperature elevation as a function of time defined by the Brazilian Code NBR 5628 given by the expression:

$$\theta g = \theta o + 345 \log (8t + 1). \quad (6)$$

The structural safety related to the limit states of fire will be imposed by the safety analysis given by:

$$S_{fi,d} \leq R_{fi,d} \quad (7)$$

Where $S_{fi,d}$ is obtained by exceptional combinations of actions defined by ABNT NBR 8681 or may be designed considering 60% of the design actions in normal situations (20 °C), that is, $S_{fi,d}$ = 0,60 Sd. The value of $R_{fi,d}$ is determined according to:

$$R_{fi,d} = k_{mod,fi} \frac{R_{0,2}}{\gamma_{w,fi}} \quad (8)$$

$k_{mod,fi}$ is 1,0 and includes the effects of the strength reduction and stiffness of wood; $\gamma_{w,fi}$ is 1,0 and $R_{0,2}$ must be designed by the normal design at normal temperature, however considering the area reduction and the mechanical properties substituted by the amount of 20% (20 percentile), that is:

$$f_{0,2} = k_{fi} f_k \quad (9)$$

$$E_{0,2} = k_{fi} E_{0,05} \quad (10)$$

Where k_{fi} is given in a table.

6 WOOD DURABILITY: USE CATEGORIES

According to the ABNT NBR 7190: 2022 wood preservation is a set of preventive and curative measures adopted to control biological agents (fungi, xylophages insects and marine bores), physical and chemical that affect the properties of wood, adopted in the development and maintenance of wood components
in the built environment.

In the design of timber structures, the following use categories should be considered:

Use Category 1: Inside buildings, out of contact with the soil, foundations or masonry, protected from weathering, internal sources of moisture and local free from access by subterranean termites or arboreal.

Use Category 2: Interior of buildings, in contact with the masonry, without contact with the soil or foundations, protected from the weather and indoor sources of moisture.

Use Category 3: Interior of buildings, out of contact with the soil and protected from the weather, which can, occasionally be exposed to sources of moisture.

Use Category 4: Outside use, out of contact with the soil and subject to the weathering.

Use Category 5: Contact with soil, fresh water and other situations favorable to deterioration, such as setting in concrete and masonry.

Use Category 6: Exposure to salt water or brackish.

In this way depending on the service condition in which the wood of the structure will be exposed, each corresponding use category must be considered and the susceptibility of attack by bio deteriorating organisms.

Each use category of durability has the correspondent treatment process and preservative product recommended.

7 CONCLUSIONS

The New Brazilian Code for Timber Structures Design, NBR7199: 2022, a load and resistance factored design (LRFD) code considers the structural grading recommendations for softwoods and hardwoods planted in South America with special attention for the production and design for Glulam structural elements. Rules for grading and gluing with the reforestation species are also presented. This new version adopts the connections models design used in EUROCODE 5 EN 1995-1-1:2009: Design of timber structures. The principal idea was to have a very similar code for all the countries of South America.

EVALUATION OF CLT SHEAR WALLS FOR INCREASED STRUCTURAL HEIGHT LIMIT AND FOR EFFECT OF VARYING PANEL ASPECT RATIO

M. Omar Amini[1], Philip Line[2], John W. van de Lindt[3], Doug Rammer[4], Francisco Flores[5]

ABSTRACT: In the US, two CLT shear wall systems are defined in SDPWS 2021 and ASCE 7-22, *CLT shear wall* with CLT panel aspect ratio ranging from 2:1 to 4:1 (*CLT-R3*) and *CLT shear wall with shear resistance provided by high aspect ratio panels only* (*CLT-R4*). Both of these systems are applicable up to a structural height of 19.8 meters [65 feet] in Seismic Design Categories B through F, thus limiting some applications. To increase usability of this system, two analytical study cases are presented in this paper: Study Case 1, increase in structural height limit for *CLT-R3* and *CLT-R4* systems in moderate seismic regions (i.e., SDC C_{max}); and Study Case 2, panel aspect ratio range for *CLT-R4* system. This evaluation was performed using the FEMA P695 methodology on several archetypes that were prototypical representation of the CLT shear wall system. For both study cases the archetypes passed the collapse performance objective of FEMA P695 indicating that *CLT-R3* and *CLT-R4* systems up to and including 8 stories can be used in SDC C_{max} and *CLT-R4* system with CLT panel aspect ratio ranging from 3.5:1 to 4.5:1 can be used in SDC D_{max}.

KEYWORDS: Cross-laminated timber (CLT), seismic performance factors, FEMA P695

1 INTRODUCTION

There has been a recent increase in the number of studies geared towards investigating CLT system behavior and performance under cyclic and dynamic loading. Most of these studies originated in Europe (e.g., Dujic et al. [1]; Ceccotti [2]; Hristovski et al. [3]), in North America (e.g., Popovski et al. [4]; Pei et al., 2013 [5]; Popovski and Gavric [6], van de Lindt et al. [7]) and in Japan (e.g., Okabe et al. [8]; Tsuchimoto et al. [9]). While some studies aimed to provide a novel contribution to the developing body of knowledge in this new area of engineering and construction, some of the studies have adopted a systematic approach to investigating seismic behavior of CLT with the eventual goal of obtaining seismic performance factors or codification of some kind. A review of some of these studies is provided in Pei et al. [10] and a more recent comprehensive review of seismic behavior of CLT can be found in Izzi et al. [11].

In the US, the cross-laminated timber (CLT) shear wall seismic force resisting system was recognized in building code reference standards for the first time with inclusion of seismic design requirements in 2021 Special Design Provisions for Wind and Seismic (SDPWS) [12] and in ASCE 7-22 Minimum Design Loads and Associated Criteria for Buildings and Other Structures [13].

Seismic performance factors, namely, the response modification factor, R, deflection amplification factor, C_d, and overstrength factor, Ω, were developed by applying the FEMA P695 [14] methodology to the CLT shear wall system [7, 15, 16]. The evaluation process is summarized in Figure 1 with the details explained in Amini et al. [15]. The methodology consists of experimental testing, development of a design methodology, archetype development, numerical modelling, nonlinear analyses, and peer panel review. The process was applied to a number of archetypes that were prototypical representations of the seismic force resisting system. These analyses resulted in computing the so-called "margin against collapse" of each archetype and hence the CLT shear wall system with specific requirements dictated by FEMA P695. The methodology takes into account uncertainties inherent in the test data and modelling methods as well as inherent variability in the suite of ground motion records.

Two CLT shear wall systems are defined and recognized by SDPWS and ASCE 7; *CLT shear wall* with CLT panel aspect ratio ranging from 2:1 to 4:1 with R=3, C_d=3, and Ω = 3; and *CLT shear wall with shear resistance provided by high aspect ratio panels only* with CLT panel aspect ratio equal to 4:1 with R=4, C_d=4, and Ω = 3; hereafter referred to as *CLT-R3* and *CLT-R4*, respectively. Both

systems have a structural height limit of 19.8 meters [65 feet] in Seismic Design Category (SDC) B through F. Seismic performance factors and structural height limits appearing in ASCE 7-22 [13] are summarized in Table 1. This paper summarizes results of application of the FEMA P965 method to increase usability of the CLT shear wall systems defined in SDPWS. In one study, an increase in the structural height limit beyond the current limit of 19.8 meters [65 feet] in moderate seismic hazard areas (i.e., SDC C_{max}) is evaluated. In a separate study, an expanded aspect ratio range between 3.5:1 and 4.5:1 is evaluated for *CLT-R4* as a replacement for the existing exact limit of 4:1.

2 DESIGN METHODOLOGY

The design of the CLT shear wall system in accordance with SDPWS [7] includes requirements for use of CLT panels meeting aspect ratio requirements, prescribed connections (i.e., nails and connectors) at the bottom and top of the walls and at vertical edges of multi-panel shear walls, and tie-downs to transfer overturning induced tension forces. These requirements result in combined bending yield and pull-out of the nails from the CLT panels which exhibit rocking and sliding behaviour under in-plane shear loading. Example single-panel and multi-panel CLT shear wall configurations are shown in Figure 2.

Table 1: *Design Coefficients and Factors for CLT Seismic Force-Resisting Systems (appearing in ASCE/SEI 7-22 Table 12.2-1)*

Seismic Force-Resisting System	Detailing Requirements, ASCE/SEI 7-22 Section	*R*	Ω_0	C_d	Structural Height, h_n, Limit Seismic Design Category B, C, D, E & F
Cross-laminated timber shear walls	14.5	3	3	3	19.8 meters [65 feet]
Cross-laminated timber shear walls with shear resistance provided by high aspect ratio panels only	14.5	4	3	4	19.8 meters [65 feet]

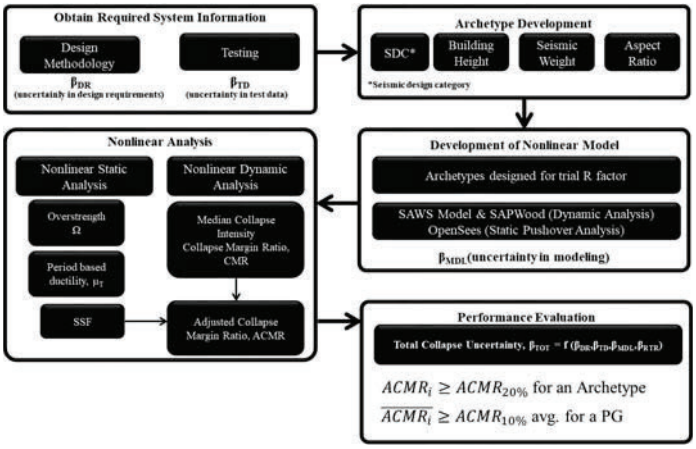

Figure 1: *CLT Shear Wall System Evaluation Process (van de Lindt et al., 2020)*

3 ARCHETYPES

A floor plan for an example index building with the extracted archetypes highlighted in red dashed lines is shown in Figure 3. While prior studies [7, 16] evaluated 72 archetypes (extracted from index buildings) for a full comprehensive study on CLT shear wall system, a reduced number of archetypes is analysed for this study based on prior findings that collapse probabilities are correlated to pushover strength (V_{max}/W) with superior collapse performance associated with increased strength. This study conservatively evaluated archetypes associated with smaller values of pushover strength. Study cases are shown in Table 2. For increased structural height limit for

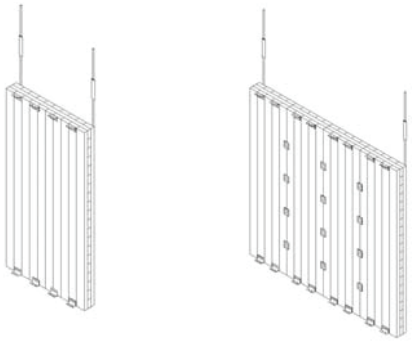

Figure 2: *(a) Single panel configuration (b) Multi-panel configuration*

https://doi.org/10.52202/069179-0400

CLT-R3 system, 8-story archetypes are considered and designed for SDC C_{max}. These were then grouped into two performance groups, PG-1 and PG-2 based on the CLT panel aspect ratio. For the evaluation of aspect ratio range for *CLT-R4* system, archetypes of 2-6 stories were considered and designed for SDC D_{max}. These were also grouped into two performance groups, PG-3 and PG-4 based on the CLT panel aspect ratio. Both study cases were with high gravity load and shear wall line length of 6.1m-18.3m extracted from the index buildings. In total 18 archetypes were considered in this study.

Table 2: *Study cases*

	CLT shear wall system	**Seismic Design Load Level**
Increased structural height limit (25.91 meters [85 feet])	*CLT-R3* *CLT-R4*	SDC C_{max}
Expanded aspect ratio range (3.5:1 – 4.5:1)	*CLT-R4*	SDC D_{max} /SDC D_{min}

The FEMA P-695 methodology requires archetypes to be designed for the Design Earthquake (DE) and then evaluated for the Maximum Considered Earthquake (MCE). Seismic loads are defined in terms of seismic design category (SDC) and occupancy category of the structure. Based on the methodology, structures are considered Occupancy Category I or II and receive an importance factor equal to 1.0. For Study Case 1 (increased structural height limit) the archetypes were designed for the Design Earthquake (DE) in SDC C_{max}, S_s= 0.55g, S_1=0.132g, F_a=1.36 and F_v=2.28. For Study Case 2 (expanded aspect ratio range) the archetypes were designed for SDC D_{max}, S_s= 1.50g, S_1=0.6g, F_a=1 and F_v=1.5, since the highest SDC governs the performance.
The building period was calculated in accordance with FEMA P-695 where it was taken as the product of coefficient for the upper limit (Table 12.8-1, ASCE 7-16 [17]) and the approximate fundamental period, Section 12.8.2.1 of ASCE 7-16. Designs were based on the ELF procedure explained in Sec 12.8 of ASCE 7-16 using R of 3 and 4 for Study Cases 1 and 2, respectively.
The selected archetypes were designed to ensure over-strength (i.e., provided shear capacity over shear demand) was minimized. After the design, the as-designed archetypes were then evaluated via numerical modeling for a set of predefined ground motions. Performance groups, archetypes and their corresponding seismic design parameters are provided in Table 3.

4 NUMERICAL MODELLING

In order to match prior study analysis methods, CLT shear wall behavior is characterized using the phenomenological CUREE-SAWS model [18]. This 10-parameter model defines force, stiffness and degradation as part of the hysteretic behaviour. The 10-parameters used for CLT shear walls are based on CLT shear wall test results which incorporated tension rods for overturning, and the prescribed shear connections in accordance with the design method in SDPWS 2021 [12]. This hysteretic fitting is discussed in van de Lindt et al. [7] and an example of the SAWS model fitted to the test data is shown in Figure 4. In Study Case 2, for CLT panels with aspect ratios of 3.5:1 and 4.5:1, parameters were scaled based on test data for CLT shear walls with panel aspect ratio of 2:1 and CLT shear wall with panel aspect ratio of 4:1. The effect of this scaling was seen in terms of peak strength and deformation capacity. An example for the two panel multi-panel configuration is shown in Figure 5. Looking at Figure 5, the lower aspect ratio (3.5:1) configuration has a larger strength but smaller deformation capacity while the higher aspect ratio panel case (4.5:1) has a lower strength but a gentler slope for the post peak behavior.
Nonlinear static pushover and incremental dynamic analysis (IDA) (Vamvatsikos and Cornell [19]) were performed in OpenSees [20] assuming that the structure is composed of rigid diaphragms attached to shear walls that are represented by nonlinear hysteretic springs. P-Delta effects were also included using a leaning column.
Static pushover was performed for each archetype to determine maximum base shear resistance, V_{max}, and ultimate displacement, δ_u. The results of these analyses were then used to determine overstrength factor, Ω, and period-based ductility, μ_T. The former is defined as the ratio of maximum base shear over design base shear and the latter is obtained from the pushover analyses using the following equation.

$$\mu_T = \frac{\delta_u}{\delta_{y,eff}} \quad (1)$$

where δ_u is the roof displacement corresponding to 80% post peak load ($0.8V_{max}$) and $\delta_{y,eff}$ is the effective yield roof displacement.

				18	6	0.60	0.63	328.89 (73.94)	1323.72 (297.6)	1.49

IDA [19] was performed for a set of 22 bi-axial ground motions (44 records) termed "Far-Field" in FEMA P695 [14]. The ground motion scaling was performed in accordance with the FEMA P695 methodology where a record set is scaled by a single factor such that the median response spectrum of the normalized set matches the spectral acceleration of interest at the fundamental period of the building. According to the FEMA P695 methodology, the damping can be in the range of 2% to 5% of critical damping and for the purpose of this study the conservative lower bound of 2% critical damping was assumed. This damping was applied based on classic Rayleigh damping using the mass matrix and the initial stiffness matrix.

IDA results were used to generate fragility curves which were then used to determine median collapse spectral acceleration ($\hat{S}_{CT}$) defined as the spectral acceleration at which half the ground motions cause collapse (Ibarra et al. [21]). The non-simulated collapse criteria based on an inter-story drift ratio of 4.5% and 5.5% (specified limit

https://doi.org/10.52202/069179-0400

state) were used for cases of low aspect ratio panels (2:1) and high aspect ratio panels (4:1), respectively. These are discussed in detail in van de Lindt et al. [7]. A sample fragility obtained based on the CLT shear wall collapse criteria is shown in Figure 6. For Study Case 2, the non-simulated collapse criteria were scaled to reflect the corresponding deformation capacities. Inter-story drift ratio of 5.25% and 5.75% were used for the two high aspect ratio panel cases of 3.5:1 and 4.5:1, respectively.

5 PERFORMANCE EVALUATION

Collapse Margin Ratio (CMR) for each archetype was calculated as the ratio of median collapse intensity, $\hat{S}_{CT}$, to MCE ground motion intensity, S_{MT}. CMR was then adjusted to an Adjusted Collapse Margin Ratio (ACMR) using the Spectral Shape Factor (SSF) to account for the effects of spectral shape.

$$ACMR = CMR * SSF \quad (2)$$

SSF was determined based on the SDC for which the archetype was designed, and the period-based ductility obtained from the pushover analysis. ACMR is then compared with the acceptable ACMR that is calculated considering the uncertainties corresponding to the record-to-record variability (β_{RTR}), design requirements (β_{DR}), test data (β_{TD}), and modelling (β_{MDL}). The methodology accounts for these uncertainties using total system collapse uncertainly, β_{TOT}, given by the following equation:

$$\beta_{TOT} = \sqrt{\beta_{RTR}^2 + \beta_{DR}^2 + \beta_{TD}^2 + \beta_{MDL}^2} \quad (3)$$

These β values are based on qualitative ratings that are then translated to quantitative values. The ratings used for evaluation in this study are provided in Table 4. Considering the completeness of design requirements, β_{DR} of 0.10 was used in this study which is smaller than 0.20 used in the original study [7]. A detailed discussion on consideration of uncertainties on collapse evaluation is provided in Chapter 7 of FEMA P695 [14] and van de Lindt et al. [7]. The effect of total system collapse uncertainty on the fragility curve is demonstrated in Figure 6 shown earlier. While the median remains unchanged, additional uncertainty flattens the curve resulting in higher probability of collapse at MCE spectral intensity.

For performance evaluation all the individual archetypes needed to pass the $ACMR_{20\%}$ criteria (FEMA P695 criteria for an individual archetype to pass) and the average of the performance groups exceed the $ACMR_{10\%}$ criteria (FEMA P695 criteria for a performance group) for the performance groups. The results are provided in Table 5. Looking at the table, all the individual archetypes and performance groups for both study cases pass their respective collapse criteria. Performance groups results are also summarized in Figure 7 showing all the performance groups passing their corresponding criteria.

6 CONCLUSIONS

The evaluation of increased structural height limit for both CLT shear wall systems defined in SDPWS, namely *CLT-R3* and *CLT-R4*, showed that archetypes up to and including 8 stories met the collpase performance objective of FEMA P695 for use in SDC C_{max}. The evaluation of expanded aspect ratio for *CLT-R4* system, showed that archetypes of 1-6 stories with CLT panel aspect ratio ranging from 3.5:1 - 4.5:1 met the collapse perfromance objective of FEMA P695 for use in SDC D_{max}.

Table 4: *Quality ratings used for evaluation*

Uncertainty	Quality rating value	Description
Record-to-record (β_{RTR})	0.40	$\beta_{RTR} = 0.1 + \mu_T \leq 0.40$
Design requirements (β_{DR})	0.10	Superior: High in completeness and robustness and high confidence
Test data (β_{TD})	0.20	Good: Medium in completeness and robustness and high confidence
Modeling (β_{MDL})	0.20	Good: Medium in completeness and robustness and high confidence

BEAVER: A PARAMETRIC DESIGN FRAMEWORK FOR TIMBER ENGINEERING

Renan Prandini[1], João Tavares Pini[2], Márcio Sartorelli Venâncio de Souza[3]

ABSTRACT: Developments in digital modelling tools and requirements for low-carbon buildings have produced increased complexity in the field of timber structural engineering. This paper presents advancements and applications of the on-going development of Beaver, an open-source plugin for Rhino3D and Grasshopper environment, which allows live-fed parametric analysis and design of timber structures (elements and connections) according to "Eurocode 5 – Design of Timber Structures". With the help of Grasshopper and finite element analysis plugins such as *Karamba3D*, structural data can be fed to Beaver for integrated timber ULS and SLS analysis allowing a Performance-Based Design (PBD) and therefore integrates structural conception and timber structural engineering in a single decision-making step.

Case studies are presented using the proposed framework to discuss about how timber engineering practice can benefit from a computational engineering toolbox when integrated to a variety of design methods such as form-finding, genetic algorithms and spatially associative problems to explore various design possibilities and while ensuring structural safety.

KEYWORDS: parametric design, timber engineering, Eurocode 5, engineering software, beaver, grasshopper, karamba3d, moment-stiff, semi-rigid, timber design, timber connections, performance-based design, structural optimization, genetic algorithm, form-finding.

1. INTRODUCTION

Generative processes have marked the current avant-garde experimentations in architecture and engineering. Contemporary tools have allowed designers to explore new spatial tectonics in architecture, which is also presented as an added layer of geometrical complexity to the physical behaviour of structures. To deal with these non-standard solutions, engineers have increasingly adopted parametric tools for the design and analysis of structures. Although many computational methods are available for handling complex geometry, timber-engineering design is still identified as setback on the interdisciplinary design-to-production process to data exchange [1].

In that context, a commonly used tool for dealing with early-stage design validation is Karamba3D [2], a Grasshopper finite element analysis plug-in used to analyse structures such as: spatial trusses, frames or shell structures. With a simple algorithm, it allows the designer to explore a range of structural arrangements and instantly have structural feedback on the design. The live-fed structural output is one of the key features of Karamba which allow for further spatial explorations and information-aided design, such as cost or environmental impact of the designed structure.

Although the structural data output from Karamba and other visual programming tools are decisive for validation of concepts, it also relies on the experience of the structural designer to develop further parametric routines to evaluate if the output renders a valid result in terms of building structural safety codes.

In a previous paper [3], the authors proposed a beta version of Beaver: a Grasshopper plugin developed to evaluate the necessary safety Eurocode 5 checks, which assists the design of feasible timber-framed structures and the exploration of optimal solutions in terms of topology, aesthetics, costs and global structural behaviour.

Beaver is now presented in its first official version, with an improved workflow that allows a more straightforward usage of the tool as it is now completely integrated with Karamba3d, requiring minimal steps to connect both tools. Beaver software architecture was recreated to enable coupling of Beaver functionality not only inside Grasshopper, but also any other .NET application. The tool is now open sourced to promote the collaboration between professionals on the field as well as for research and educational purposes.

2. BOUNDING STRUCTURAL ENGINEERING AND SOFTWARE DEVELOPMENT

One of the main issues in the practical field of structural engineering and design is mainly due to compatibility between computational models. It is difficult or almost impossible to find end-to-end solutions to design, analysis and detail buildings. Common practice is to transfer models between different software applications specialized to their needs, which can be detailing, structural analysis, thermal analysis, and so on. This is a well know issue of CAD (Computer Aided Design) and CAE (Computer Aided Engineering) systems. Most of integration issues relate to loss of data, compatibility during the process and lack of automation [4]. Those issues arise due the different characteristics between the processes. A CAD model is mainly a computational representation of the geometry, not necessarily having attributes and properties. These features are crucial inside CAE environment, as it needs data such as material properties, physical interfaces, and element types.

Grasshopper3d appeared as a good candidate to enable integration between CAD/CAE systems. It offers a convenient way to create scripts for geometry processing and automation in a powerful CAD environment, and many research is being applied in developing CAE systems inside it, such as Karamba3D [2], Kiwi3D [5] and BATS [6] for structural analysis, Ladybug [7] for Thermal/Solar Analysis, Butterfly [7] and Eddy3d [8] for CFD analysis.

Beaver first conception was to overcome one of the limitations of structural design inside of Grasshopper which was the lack of structural design tools according to valid design codes [3]. Its beta version was composed of a series of Grasshopper components that worked based on element internal forces and displacements provided by a structural frame analysis software. Generic routines were conceived in C# in order to evaluate the Limit States according to Eurocode 5 procedures [9]. As inputs, along with internal forces and displacements, the nominal strength, modification coefficients for load duration, service class and material uncertainties are considered. As outputs one can access actions and resistance ratios and considered analysis information such as failure mode of elements or fasteners, along with specific evaluation reports.

However, this implementation has shown some limitations. All design check routines were implemented individually in a series of Grasshopper components that communicate thought the connection of many individual parameters, which made quite challenging to transfer data between components as well as to implement new features, such as new design codes and direct integration with Grasshopper structural analysis plugins. The lack of structured data also made it demanding to filter values such as utilization data, based on combination and/or design check type, making it difficult to select data to display in colour and display graphs.

Also, while parametric design environments display great advantages for integrated structural design and analysis, the development of a C# library for the design of timber structures could also be beneficial to many other .NET applications. This is particularly important since many modern engineering companies are promoting in-house software development teams, both by dedicated software engineers but also by use of structural engineers with software development skills. This also may support the extension and creation of structural analysis software for academic purposes.

To overcome those limitations, a full refactor of Beaver software architecture was made. The first decision was to make Beaver functionality independent from Rhino and Grasshopper API's, creating a .NET Standard library named *BeaverCore* [10]. This library provides an object-oriented-model to assign and evaluate structural design checks.

On top of that layer sits BeaverGrasshopper [11], which is the actual Grasshopper plug-in. It provides data wrappers to pass BeaverCore objects between Grasshopper components, making the design process simpler and with less Grasshopper components. Also, a Beaver object-oriented model enables the conversion of structural analysis models, such as Karamba3d models, into an evaluated Beaver model in a simple straight-forward manner.

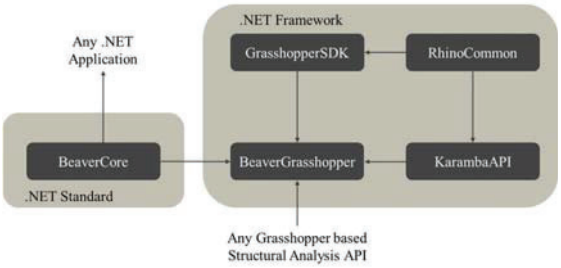

Figure 1: *Beaver dependencies flowchart*

1.1 BeaverCore: A open-source .NET library for structural timber engineering design

BeaverCore is a .NET library that contains an object model to properly assign structural members and its internal forces to apply the desirable design checks for timber members and connections.

Beaver functionality was split from the original GH plug-in to easen the development of additional features on design checks and proper structural models independent from any platform. This enables the use of BeaverCore in any other .NET application, such as FEA software and web/cloud-based platforms. BeaverCore has its code totally open-sourced, in a wish to assist designers to potentially enhance its functionality for other design codes, national annexes and further developments regarding other timber-based structural materials. The reliability of the tool is promoted by the development of unit tests that assures that the results provided by Beaver

https://doi.org/10.52202/069179-0401

can be verified by the community and allow awareness of the methods and algorithms used in its formulation.

1.2 BeaverGrasshopper: A Grasshopper plugin for parametric timber design

BeaverGrasshopper is a Grasshopper layer built on top of BeaverCore library to fulfil the original Beaver purpose of enabling parametric structural timber design according to official structural codes. The Grasshopper plug-in now only deals with managing BeaverCore object data between the Grasshopper components, that just queries data from BeaverCore object model. With this object model it is also possible to integrate Beaver fully with third-party FEA plug-ins such as Karamba3d by translating their API object model to BeaverCore model. This makes the use of Beaver way simpler since you can define all properties in your FEA model and automatically check the results of the Eurocode checks.

The presented workflow is integrated to *Karamba3D* by assigning element-related parameters of *Eurocode 5* such as span length, cantilever considerations, service classes, buckling lengths and other necessary parameters to *Karamba* beam elements.

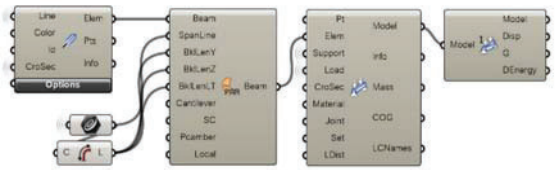

Figure 2: *Typical model setup for Beaver consists in using native Karamba elements and including necessary inputs for EC5 calculations.*

After the FEA analysis is performed by *Karamba*, all Beaver input data can be retrieved directly from *Karamba's* model to allow the final limit state timber analysis and further result displays. It is also possible to filter the load-case and bending direction to be displayed.

Figure 3: *A Karamba3D analysed model can be directly fed into Beaver components for displaying the limit state analysis.*

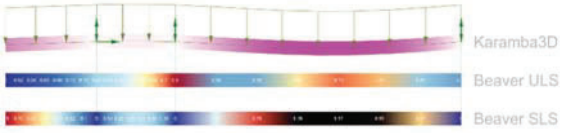

Figure 4: *Example of the ULS and SLS displayed results for a loaded beam with two spans and a cantilever.*

In addition, calculation reports are now available for result checking of Beaver analysis of elements and connections, which avoids the "black-box" perception of users, allows better benchmarking processes and promotes an educational usage of the software.

Figure 5: *A parametric dowel-type moment-stiff connection can be generated and verified in real time*

Having a generic solver for timber structure validation allows for exploration of new tectonics of construction and experimentation on problems whose physical properties are directly associated with geometrical constraints. This is all done through a live-fed calculation with intuitive outputs.

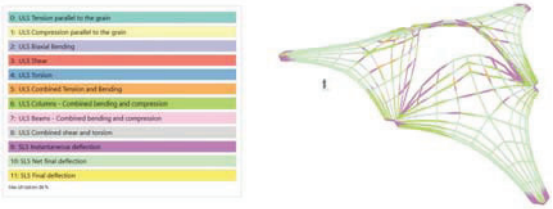

Figure 6: *Dealing with complex geometry requires deeper understanding of the governing checks of the structural analysis.*

Also, parametric processes are generally very useful for designers which perform specific design methods on multiple projects which are not necessarily complex structures. Grasshopper, along with *Karamba3D*, have shown to be increasingly used by the industry in all stages to fasten design processes from the concept to documentation, and a complete timber limit state analysis is also beneficial is this perspective.

https://doi.org/10.52202/069179-0401

3. APPLIED PROBLEM-SOLVING

Three study cases are presented in order to highlight the benefits of computational design approach to timber engineering and to illustrate how specific designs can be achieved through topological optimizations, form finding and integration between connection detailing and global structural behaviour.

1.3 Fishbelly trussed beam form-finding

This structure was designed Ita construtora, Brazil, to be a competitive alternative to typical steel and precast concrete structures usually employed for Boat Hangars located in tropical areas. With modular spans of 6 by 20 meters, permeable façades and lightweight steel sandwich panel roofs, the structural arrangement will mainly be affected by low permanent load case, low imposed load cases, high wind load cases and no earthquake or snow consideration.

To achieve this product, the structural concept goals were:

- *Minimal timber volume*
- *Minimal use of steel*
- *100% CNC machining*

The project started with the intuition that those goals would be achievable with a trussed beam for the long span and secondary beams for the short spans, where the roof sandwich panels are to be attached. Considering critical variable wind load scenarios, all structural elements were conceived in timber, in order to allow both tension and compression resistance.

A Grasshopper algorithm was written to generate multiple trussed beam arrangements. Karamba3D and Beaver were used to allow an on-time Eurocode 5 analysis considering all load case scenarios.

The variable structural arrangement parameters where:

- *Main beam division ratio*
- *Truss height*
- *Elements cross sections*

In terms of main beam division ratio, from a one-post trussed beam to a multiple posts fish-belly beam, there is an optimal cross section for each arrangement in order to employ minimal timber volume. Less posts scenarios generate larger buckling lengths and larger spans on upper chord, resulting in larger cross sections. In the other hand, multiple posts scenarios will allow smaller buckling lengths and chord cross sections, but the volume of the added posts and the number of timber connections will also be incremental.

Also, minimal beam division ratios will generate obtuse angles on lower chord that demand timber segmentation and steel connections, while higher beam division ratios will allow straighter angles that may allow lower chord continuity with the use of a curved glulam beam.

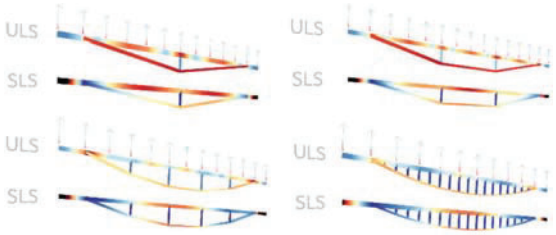

Figure 5: One to multiple posts trussed beam geometries with adjusted acceptable cross sections.

In terms of truss height, considering ULS analysis, a higher truss will allow smaller cross sections by reducing normal forces on upper and lower chords, but will also increment the lower chord length. Considering SLS analysis, higher truss heights will result in less deformation and SLS may be critical, demanding cross sections with higher bending resistance.

Figure 6: *Different truss heights with adjusted acceptable cross sections.*

Based on the presented parameters, this Grasshopper script allows multiple acceptable solutions in terms of structural safety, and the genetic algorithm [12] was used to generate and compare those arrangements in terms of timber volume and safety, resulting in the optimal arrangement bellow.

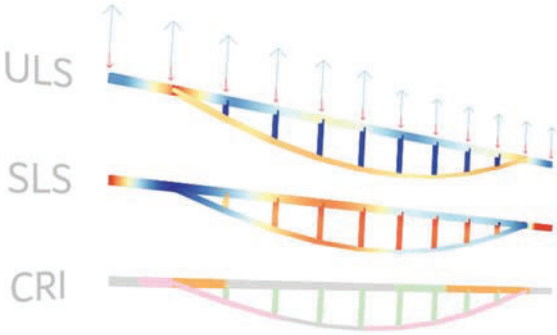

Figure 7: *Optimal genetic algorithm solution considering asymmetrical wind load cases*

Considering the main project goals presented above, minimal timber usage would be achieved with this solution. In the other hand, the minimal use of steel would only be achieved if the lower chord is made of a continuous beam, resulting in only two main connections between lower and upper chord, and this would be easily possible by considering a curved continuous glulam beam.

In the other hand, the third project goal is develop a 100% CNC machined timber structure, and for most production plants this allows only straight timber elements.

https://doi.org/10.52202/069179-0401

Considering those goals, the best concept would be to develop the correct geometry to allow both upper and lower chords to be continuous and also straight members, pretensioned together in pre-assembly process, in a way that curvature will be generated by posts lengths.

Karamba3D is a parametric tool that allows the consideration of imposed curvature strain loads, developed to allow the analysis of timber grid shells, for example. With the of this method, it is possible do model the structure correctly, considering the bending moments generated by the initial imposed curvature. This pretension adds permanent bending moment to both chords, which must be considered at the ULS analysis, and will result in a too high pre-camber that will affect SLS analysis.

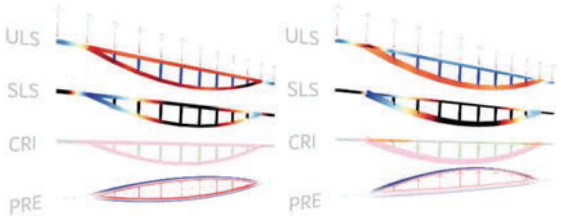

Figure 8: *Imposed curvature bending moment and pre-camber are governed by the inertia relation between upper and lower chords and the overall truss height.*

With this new script that includes pretension forces and deformations for the Beaver ULS and SLS analysis, Grasshopper genetic algorithm should converge to an optimal solution that will meet the main project goals of minimal timber volume, minimal use of steel and 100% CNC machining.

What is interesting about this study-case is that we realized that a very a large spectrum of the inputs will result in not acceptable structures, and depending on the imposed loads the form-finding process will never converge to a possible safe result, because of three main reasons:

- *Higher truss heights will simultaneously result in better SLS ratios and worse ULS ratios due to incremental imposed curvature bending moments.*
- *To generate acceptable imposed pre-camber, the Y-axis inertia relation between upper and lower chord must be drastically different, while section areas tend to be similar due to axial loads.*
- *Incrementing cross sections will not necessarily minimize ULS ratios, since they also increment bending moments due to the imposed curvature loads.*

Thankfully to the minimal loads of this typical scenario, the genetic algorithm found a small spectrum of possible results and could finally reach the optimal relation for the main beam division ratio, truss height and element cross sections.

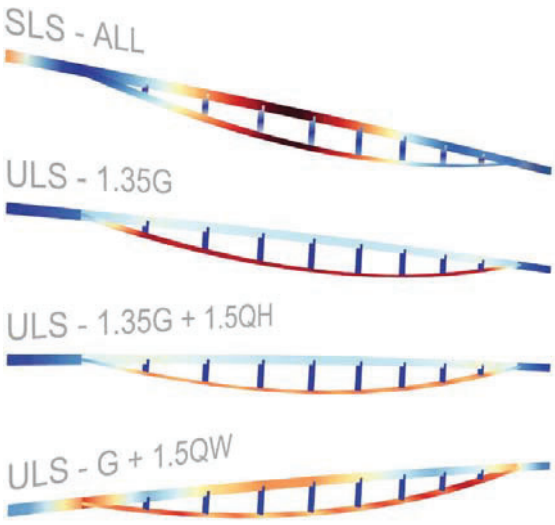

Figure 9: *Design ratios from critical load-cases displayed at the optimal structural arrangement generated by the algorithm. Imposed curvature strain load bending moment and precamber considered, along with and asymmetrical wind load cases.*

But there was one more topic that could be developed for a last optimization. The script was built based on a parabolic curvature, ant that is not perfect since it generates a peak bending moment at the first and last fish belly posts, and this affects directly the lower chord ULS analysis.

A last script was written to allow a fine manipulation of truss height and curvature for the now defined division ratio and cross sections, in order to find the optimal curvature. After this last analysis, a greater safety margin was achieved without incremental production costs.

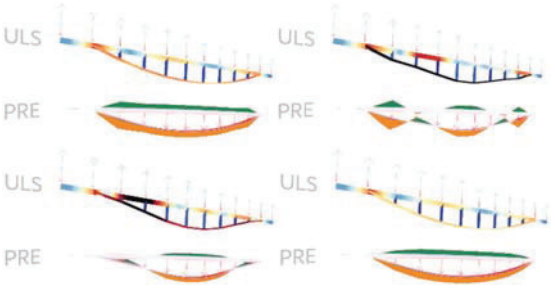

Figure 10: *Genetic algorithm playing with curvature to find the minimal peak bending moment, generated by the imposed curvature strain load.*

With the help of Karamba3D and Beaver, the final structural arrangement was achieved. In the next steps, before reaching the final product, a double check on the structural safety will be made along with the connection detailing. Later, a 1:1 mock-up will be produced to allow an evaluation of pre-assembly process and to be load-tested in order to verify that safety standards are met as expected.

https://doi.org/10.52202/069179-0401

1.4 Doubly curved roof with straight elements

Reciprocal beams have an intimate relationship with structural behaviour and the spatial arrangement of beams. Defining the correct pattern for a structurally sound structure can be a calculation-intensive process with many design possibilities. The roof in Franz Masereel Centre has undergone several topology optimizations based solely on global deflections because workflows regarding structural verifications according to code were be too time-consuming for an integrated design approach [13].

Applying Beaver into a geometrical formulation within Grasshopper will immediately offer feedback on the structural feasibility of the structure, while also allowing for topological optimizations. This is essentially true to reciprocal systems where each element is dependent on each other for achieving global stability and thus have no structural hierarchy between elements.

In the example below, a doubly curved surface is subdivided in a diagrid subdivision to form a reciprocal grid where two subsequent lines of the diagrid are joined together to form one continuous element. A script for moving each start and end node of these joined lines to the middle of the next continuous line was built so that an iterational procedure can occur until a geometrical convergence is reached. This allowed for an approximation of the double curvature surface while maintaining strictly straight elements connecting at middle points of the next element on the reciprocal grid.

A design exploration can take place where the reciprocal grid can vary in terms of subdivision in the u and v domains of the NURBS surface. Different designs are then tested against code in Beaver and a structurally sound solution can be chosen where a balance between number of connections and suitable cross section sizes is achieved.

Figure 11: *Design explorations are possible where the structural arrangement is critical to the final solution.*

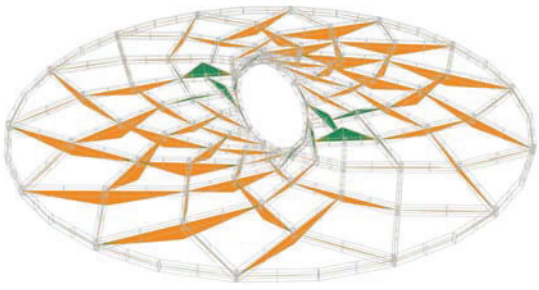

Figure 12: *Bending moment around the y-y axis of each member.*

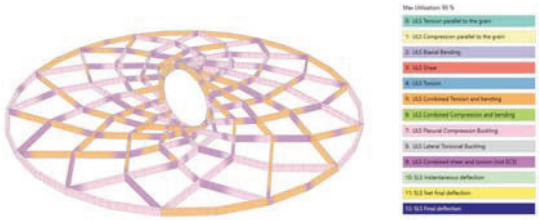

Figure 13: *A Color-coded plot shows the critical SLS or ULS verification according to code for each FE node of the structure.*

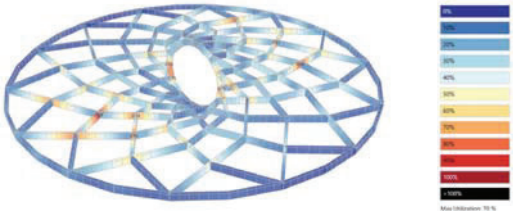

Figure 14: *ULS utilizations according to EC5.*

1.5 Integrated calculation of semi-rigid moment stiff connection

Since serviceability requirements often determine element sections in timber structures, optimization processes can occur by implementing semi-rigid connections in early design stages. On the other hand, engineering practice often neglects the effects of semi-rigid timber connections due to the several iterations needed to ensure proper structural behaviour.

The implementation of rotational stiffness on FE models represent a time-intensive task of the detail design since the resulting moment affects not only the forces acting the connection but also the resistance of each fastener due to a change in the angle between the acting force and the relative angle to the grain in the timber element.

Beaver proposes an integrated process of semi-rigid connection design where the rotational stiffness can be live verified and fed back to the finite element software, resulting in an automated iterative approach on the design of the timber structure and its connections. This integration is particularly important because every change made on the connection design affects the bending moment acting upon it. Since the resistance of each fastener depends on the angle between the grain direction and the fastener force, it is difficult to infer whether a change in the connection design is conservative or not. In most cases, a recalculation of the connection is necessary.

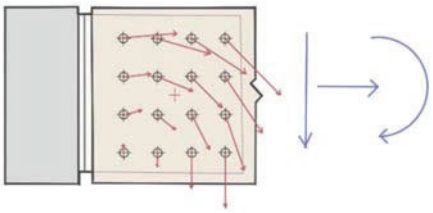

Figure 15: *The resistance of each fastener is calculated separately since the vectorial sum of forces affects the angle between force and grain.*

https://doi.org/10.52202/069179-0401

Designers can often oversee the effects of semi-rigidity of the connections especially when they are designed for pure shear and tension. The choice in arrangement and type of fasteners and number of shear planes affect deeply the behaviour of the connection, which may lead to an undesirable moment-stiffness in the connection. An integration between a global model and the connection detailing is desired to ensure the compliance of the connection to standards.

Figure 16: *Calculated fastener utilization on a simple-span beam for a steel-to-timber connection adopting hinged (left) and semi-rigid (right) hypothesis*

In the previous paper [3], the authors presented another geometrical optimization of a truss system where Beaver was used for an early stage engineering design of a 40m span roof for a horse arena, designed and executed by Ita Construtora, Brazil, in 2020. A benchmark is presented to demonstrate how Beaver is able to produce reliable results also at later-design stages.

Not only optimizations in truss geometry and member cross-section design have been optimized but also the connection design was considered in early stages. Fasteners geometry at the critical multiple shear plane tensile connections affected greatly on section design due to possible block shear failure and there was a concern that the effect of moment semi-rigidity and sliding of the dowels would effect on deformations and on the integrated design of each fastener.

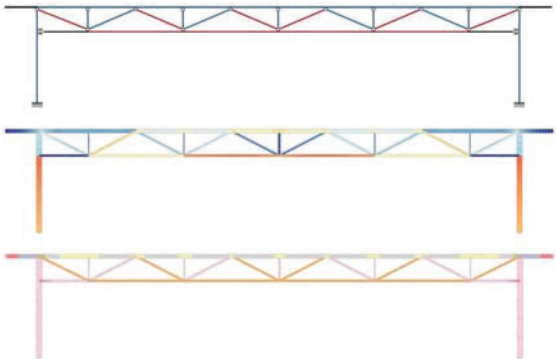

Figure 17: *Structural principles, Beaver utilizations and critical check according to code.*

A high number of fasteners and steel plates were needed to take tensile forces on the connections of the truss, inherently creating a semi-rigid moment-stiff connection between elements. This affects not only global deformations and actions on each member but also the design of the connection, leading to an iterative process on the engineering design.

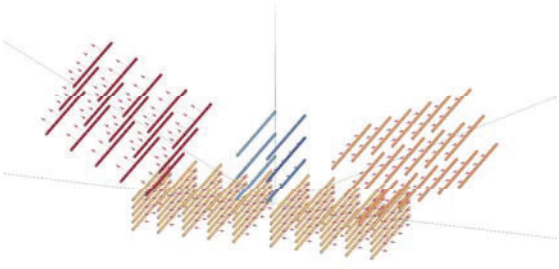

Figure 18: *The connection nodes of the structure were modelled in 3D and verified according to EC5 in real time.*

The workflow adopted integrates both timber engineering member design, connection design and 3D model documentation into one single interface, making sure the fastener arrangement is compatible with the cross-section and facilitates the coordination between draftsmen, engineers and builders.

4. CONCLUSIONS

The framework and case studies presented in this paper display an integration between computational design tools – i.e., evolutionary solvers, multi-objective optimizations and form-finding processes – and timber engineering calculations, allowing for a broad variety of design methods and its associated performance in relation to current standards.

The improved integration with *Karamba3D* allows the designer to evaluate its results easily by performing a structural safety evaluation. By managing *Karamba*'s data directly from a back-end integration, Beaver is able to perform live limit state evaluations, which suits well with computational design workflows and early design phases. Furthermore, Beaver combines the limit state analysis for timber elements and its respective connections in a live-fed calculation, assisting designers to consider a variety of spatially associative problems such as the effects of semi-rigid stiffness and fastener arrangements on global structural behaviour and member design.

After all, Beaver aims to assist designers to integrate geometrical formulations, finite element analysis, safety structural checks and solver algorithms in order to simplify structural design in a parametric environment. The latest improvements of the tool deliver a better user experience of the tool, as well as invite the field to use and collaborate with it by making its core logic open-source, and independent from Grasshopper. The authors hope that this step will provide a tool to develop new systems as well to help improve its features either by professional collaboration as well inside scientific research in the areas of structural engineering and software development.

STRUCTURAL CHARACTERIZATION OF NATIVE SPECIES ACCORDING TO THE NEW BRAZILIAN STANDARD ABNT NBR 7190: 2022 – PART 4

Fabiana Yukiko Moritani[1], Felipe Hideyoshi Icimoto[2], Rodrigo de Souza Nogueira[3], Carlito Calil Junior[4], Lorenzo Lube dos Santos[5], Adriano Wagner Ballarin[6]

ABSTRACT: Timber is a heterogeneous material with high variability in its physical and mechanical characteristics. Therefore, whenever possible, it is essential to grade timber members using results from tests of structural size specimens that better express its structural quality to meet the design requirements. The Brazilian Standard ABNT NBR 7190: 2022 – Part 4, introduced test methods for mechanical characterization and strength grading of sawn timber in structural sizes. This study aimed to perform these mechanical tests for assign strength class for three native species of the Amazon rainforest obtained from trees under sustainable forest management (Caixeta (*Simarouba amara* Aubl.), Cedrinho (*Erisma uncinatum* Warm.), and Goiabão (*Planchonella pachycarpa* Pires.)). The Goiabão species had the highest characteristic value of bending strength and was graded as D60, Cedrinho D24, and Caixeta D18. Results also showed a high correlation ($R^2 = 0.94$) between modulus of elasticity in dynamic and static bending tests.

KEYWORDS: Structural timber, Strength grading, Mechanical properties, Native species.

1 INTRODUCTION

Wood is one of the most used materials in civil construction and it is essential to know the physical and mechanical properties for the best use of the material in timber structures design, mainly alternative species with potential for use in a rational way.

Extraction of wood in the Amazon rainforest is only allowed through forest management (planning practices and conservation principles which ensures the forest's capacity to continuously supply a product or service plans [1]) and authorization of sustainable exploitation. The awareness of the use and preservation of natural resources from Brazilian tropical forests has been applied with the dissemination of sustainable forest management concepts and the marketing of certified wood.

Several native species from forest management are not recognized for commercialization as raw or engineered timber due mainly to the lack of research on its properties or the correct dissemination of knowledge. The main studies on Brazilian native species can be found in [2-4].

The new Brazilian Standard ABNT NBR 7190 [5] for the design of timber structures, has seven parts and presents new topics and concepts, as mechanical tests for connections and detailed design methods and quality control procedures for engineered wood products (*e.g.* glulam and CLT). Following the initiative of other international standards and trying to express the structural quality of wood better, preconizes mechanical characterization and strength grading of sawn timber using structural size specimens, although, in special situations, allows this characterization using small clear specimens. Part 1 of the standard [5] specifies that strength and stiffness properties of timber are, in general, attributed to batches considered homogeneous – classification by batch - and presents the strength classes. ABNT NBR 7190 - Part 4 [6], based on ISO 13910 [7] details the experimental tests for structural size specimens: density, 4-point bending, tensile and compression parallel to the grain, tensile and compression perpendicular to the grain, shear parallel to the grain and, transversal modulus of elasticity.

This study aimed to characterize and grade three native wood species from Amazon rainforest using this new standard: *Simarouba amara* Aubl., *Erisma uncinatum* Warm., and *Planchonella pachycarpa* Pires.

2 MATERIALS AND METHODS

2.1 MATERIALS

Three native species from Amazon rainforest were characterized (Figure 1): Caixeta (*Simarouba amara* Aubl.), Cedrinho (*Erisma uncinatum* Warm.) and, Goiabão (*Planchonella pachycarpa* Pires.). These timber boards were obtained from trees under sustainable forest management. Table 1 presents their apparent densities, nominal section and the sample size of the experimental program.

Figure 1 – Species tested

Table 1 – Experimental program - species and sample size (N)

Species	*Scientific names*	Density (kg/m³)	N	Nominal section (cm)
Goiabão	*Planchonella pachycarpa* Pires.	902	57	4x12
Cedrinho	*Erisma uncinatum* Warm.	606	55	4x12
Caixeta	*Simarouba amara* Aubl.	424	62	4x14

2.2 TEST METHODS FOR MECHANICAL CHARACTERIZATION OF STRUCTURAL TIMBER

The characterization was carried out by mechanical tests in structural size specimens according to the new Brazilian Standard NBR 7190 – Part 4 [6], based on ISO 13910 [7]. Additionally, nondestructive test through 3-point bending test was carried out to obtain the reference static modulus of elasticity, as well as the transverse vibration method was used to determine the dynamic modulus of elasticity.

2.2.1 Nondestructive tests

The dynamic modulus of elasticity in bending was obtained for each timber board with a nondestructive grading through Metriguard model 340. The Metriguard Technolgies Inc. provided and calculated the dynamic modulus of elasticity by Equation (1).

$$E_{dyn} = \frac{f_n^2 . W . L^3}{K . b . h^3} \qquad (1)$$

Where: E_{dyn} is the dynamic bending modulus of elasticity, f_n is the undamped natural frequency, W is weight of the specimen, L is the span length, K is the constant of equipment, b is the width of specimen, and h is the thickness of the specimen.

The nondestructive bending test was carried out through 3-point static bending test (see Figure 2) to obtain the static modulus of elasticity. The boards was placed in flatwise position and loaded at center-point. The modulus of elasticity was determined in linear elastic regime (normally in 10% to 40% to ultimate load). The deflection measurement was taken at the center point while applying incremental load until the deflection reached 40% of ultimate load. The modulus of elasticity was calculated from Equation (2):

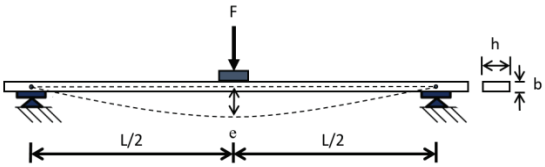

Figure 2 - Non-destructive static bending test [8]

$$E = \frac{1}{4} \cdot \left(\frac{L}{b}\right)^3 \cdot \left(\frac{\Delta F}{\Delta e}\right) \cdot \frac{1}{h} \qquad (2)$$

Where, L (mm): span length; h (mm): height of cross-section; b (mm): width of cross-section; F_{ult}: ultimate load; ΔF (N): incremental load; Δe (mm): incremental deflection.

2.2.2 Characterization tests

Mechanical characterization tests were carried out in structural boards according to the new Brazilian standard ABNT NBR 7190 – Part 4: 2022 [6], which was based on ISO 13910: 2005 [7]. The experimental program consists of: 4-point static bending, tension parallel and perpendicular to the grain, compression parallel and perpendicular to the grain and shear parallel to the grain.

4-point static bending

The 4-point static bending test (see Figure 3) was performed to obtain the static modulus of elasticity and bending strength of structural timber boards. The boards were loaded at two points, spaced *6h* between the ends of each support. To determine the modulus of elasticity in bending (E), the deflection measurement at the center-point was taken while applying incremental load until the deflection reached $L/300$. The bending strength (f_m) was determined by increasing the applied load until the maximum load was reached. The modulus of elasticity and bending strength were calculated from Equations (3) and (4):

https://doi.org/10.52202/069179-0402

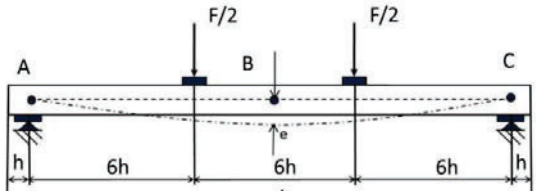

Figure 3 – Bending test [6]

$$E = \frac{23}{108} \cdot \left(\frac{L}{h}\right)^3 \cdot \left(\frac{\Delta F}{\Delta e}\right) \cdot \frac{1}{b} \quad (3)$$

$$f_m = \frac{F_{ult} \cdot L}{b \cdot h^2} \quad (4)$$

Tension parallel to the grain

The tension parallel to the grain test (see Figure 4) was carried out using the Metriguard 422 Tension Proof Testers, which has an 800 kN load capacity. The boards were subjected gradually increasing the applied load until the failure. The tension strength parallel to the grain was determined using Equation (5):

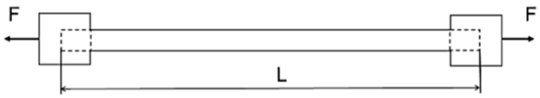

Figure 4 – Tension strength parallel to the grain test [6]

$$f_{t,0} = \frac{F_{ult}}{b \cdot h} \quad (5)$$

Where, $f_{t,0}$ (MPa): tension strength parallel to the grain; F_{ult} (N): ultimate load; h (mm): height of cross-section; b (mm): width of the cross-section.

Tension perpendicular to the grain

The tension perpendicular to the grain test was carried out using alternative method with the EMIC universal testing machine (see Figure 5), which has a load capacity of 30 kN. The specimen was comprised of the full cross-section that was cut the length L_h equal to *h/3* of the timber board. The specimen was submitted to a 3-point bending test and loaded gradually until it failed. Equation (6) was used to calculate the tension strength perpendicular to the grain:

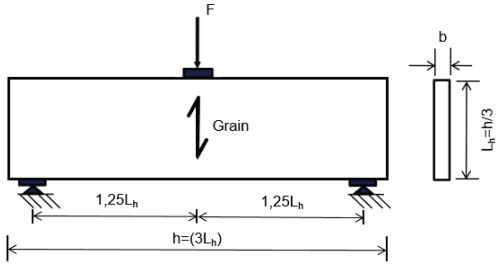

Figure 5 – Tension perpendicular of the grain strength test [6]

$$f_{t,90} = \left(\frac{3{,}75 \cdot F_{ult}}{b \cdot L_h}\right) \cdot \left(\frac{0{,}03 \cdot b \cdot {L_h}^2}{800^3}\right)^{0,2} \quad (6)$$

where, $f_{t,90}$ (MPa): tension strength perpendicular to the grain; F_{ult} (N): ultimate load; h (mm): height of cross-section; b (mm): width of cross-section; L_h (mm): length cut from the specimen; $\left(\frac{0{,}03 \cdot b \cdot {L_h}^2}{800^3}\right)^{0,2}$: a factor that normalized the tension strength to the equivalent value for a timber cube of side length equal to 800 mm.

Compression parallel to the grain

The compression parallel to the grain test (see Figure 6) was executed using the AMSLER universal testing, which has a load capacity of 25000 kgf. Two specimens with *6b* length were compressed axially until failure. The ultimate load F_{ult} was the lower value of the applied load at failure for the two specimens. The compression strength parallel to the grain was calculated from Equation (7):

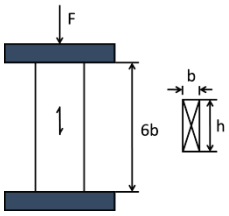

Figure 6 – Compression parallel to the grain test [6]

$$f_{c,0} = \frac{F_{ult}}{b \cdot h} \quad (7)$$

Where, f_{c0} (MPa): compression strength parallel to the grain; F_{ult} (N): ultimate load; h (mm): height of cross-section; b (mm): width of the cross-section.

Compression perpendicular to the grain

The compression strength perpendicular to the grain was obtained using the AMSLER universal and the setup shown in Figure 7. The specimen was cut to a length of *6h*, and then loaded until it either failed or reached a maximum deformation of 0.1 mm. The compression strength perpendicular to the grain was calculated from Equation (8):

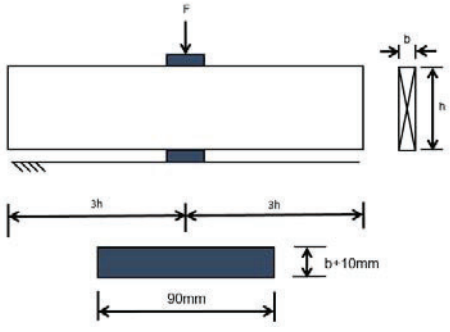

Figure 7 – Compression perpendicular to the grain test [6]

$$f_{c,90} = \frac{F_{ult}}{90 \cdot b} \text{ or } f_{c,90} = \frac{F_{0,1h}}{90 \cdot b} \quad (8)$$

Where f_{c90} (MPa): compression strength perpendicular to the grain; F_{ult} (N): ultimate load; $F_{0,1h}$ (N): load at a deformation of 0.1h mm; b (mm): width of the cross-section.

Shear parallel to the grain

The shear parallel to the grain test was performed according to the setup shown in Figure 8. The specimen was cut to a length of *7h*, and then loaded until it either failed that presented shear failure mode or bending failure mode. However, all results were used to calculate shear strength, regardless of failure mode. The shear strength parallel to the grain was determined from Equation (9):

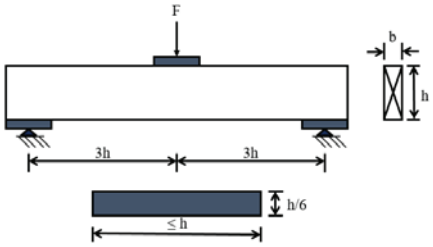

Figure 8 – Shear parallel to the grain test [6]

$$f_v = \frac{0{,}75 \cdot F_{ult}}{b \cdot h} \quad (9)$$

Where, f_v (MPa): shear strength parallel to the grain; F_{ult} (N): ultimate load; h (mm): height of cross-section; b (mm): width of cross-section.

2.2.3 The characteristic value of the strength

The characteristic value of strength properties of each species was calculated assuming they are logarithmically normally distributed according to EN 14358: 2016 [9]. Thus, the mean value, standard deviation and characteristic value were obtained from Equations (10), (11) and (12), respectively:

$$\bar{y} = \frac{1}{n}\sum_{i=1}^{n} \ln m_i \quad (10)$$

$$s_y = max\left\{\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(\ln m_i - \bar{y})^2};\ 0{,}05\right\} \quad (11)$$

$$m_k = \exp(\bar{y} - k_s(n)s_y) \quad (12)$$

Where: $\bar{y}$ is the mean sample value, n is the number of test values, m_i is the individual test value i of stochastic variable m, s_y is the standard deviation, m_k is the 5-percentile value of stochastic variable m, $\bar{y}$ is the sample mean value, s_y is the standard deviation, and $k_s(n)$ is the factor used to determine characteristic value. The factor $k_s(n)$ was calculated from Equation (13):

$$k_s(n) = \frac{6{,}5\ n + 6}{3{,}7\ n - 3} \quad (13)$$

Where: n is the number of test values.

3 RESULTS

3.1 Experimental data

Table 2 presents the maximum, minimum and mean value, standard deviation, and coefficient of variation of physical and mechanical properties for "Caixeta".

Table 2 – Density and mechanical properties of Caixeta

Properties	Min.	Max.	Mean	Std.	CoV (%)
ρ_{ap} (kg/m³)	351	498	424	32	7.54
E_{dyn} (GPa)	7.65	13.44	10.62	1.24	11.63
E_{flat} (GPa)	8.02	13.38	10.70	1.22	11.39

f_{v0} (MPa)	6.1	4.5	35.6

Piter *et al.* (2003) [10] presented mechanical characterization and visual grading of Argentinean *Eucalyptus grandis* with specimens in structural size. The growth characteristics had greater influence reducing strength and stiffness, and obtained different mechanical properties in comparison with strength class system established in EN 338 [11].

When considering the characteristic value of bending strength, mean density, and modulus of elasticity of the "Caixeta" species, the mechanical properties and density of the strength class assigned has significantly lower than the characteristics values of "Caixeta" species. Although the characteristic bending strength was 40 MPa, the low values of modulus of elasticity and density resulted in class D18, which have the lowest strength class in ABNT NBR 7190 [5]. "Cedrinho" species presented characteristics values higher than the properties of the strength class assigned to it, except for the tension strength perpendicular to the grain and shear strength parallel to the grain. It is worth mentioning that "Goiabão" species, with the highest mechanical properties and density, was included in strength classes D60 and also showed characteristics values higher than the mechanical properties of the assigned strength class, except for the tension strength perpendicular to the grain.

Therefore, it is recommended that industries should performed characterization tests for each species they plan to use in their production line, according to well-defined standards. Based on the results of these tests, appropriate strength classes for each species should be established.

3.2 Comparison between dynamic and static modulus of elasticity

Figure 9 shows the association between dynamic and 4-point static modulus of elasticity data for the three species, that the coefficient of determination value (R^2) was 0.9394. Generally, the correlation between the static and dynamic modulus of elasticity is considered high if above 90%. The ABNT NBR 7190 – Part 2 requires that this correlation be above 90%. Morin-Bernard *et al.* (2020) [12] compared the dynamic and static modulus of elasticity of two hardwood species that showed the

coefficient of determination for white ash ($R^2 = 0.94$) and yellow birch ($R^2 = 0.87$).

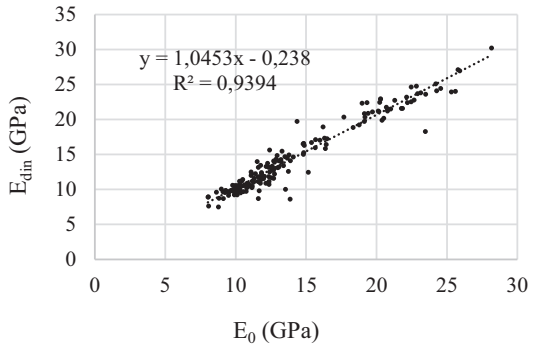

Figure 9 – Dispersion graphic of the static (E_0) and dynamic (E_{din}) modulus of elasticity

Table 8 presents the mean values, the coefficient of variation (%) of the static and dynamic modulus of elasticity for each species and comparative ratios, $\mathbf{E_{flat}/E_{dyn}}$ and $\mathbf{E_{edge}/E_{dyn}}$. The dynamic modulus of elasticity was higher than the static modulus of elasticity for "Cedrinho" and "Goiabão" species. Furthermore, the $\mathbf{E_{edge}/E_{dyn}}$ ratio obtained greater differences, mainly for the "Caixeta" and "Goiabão" species. Sales *et al.* (2009) [13] performed structural grading though nondestructive methods, *i.e*. ultrasound and transverse vibration, and compared to static bending results. The authors evaluated structural members of *Eucalyptus grandis* and *Pinus sp*. The transverse vibration method allowed for modulus of elasticity closer to the values obtained by the static modulus of elasticity that the average percentile variations were 4.42% for *Eucalyptus grandis* and 4.33% for *Pinus sp*.

The modulus of elasticity in flatwise position was closer than edgewise position. The edgewise position is required by ABNT NBR 7190 – Part 4 [5] for the characterization of the 4-point static bending test. However, the dynamic modulus of elasticity through transverse vibration method have been carried out in the flatwise position, the same position required by the Brazilian standard ABNT NBR 7190 – Part 2 [7], for the nondestructive test of the 3-point static bending.

Table 8 – Modulus of elasticity in bending (static and dynamic) and comparison ratio between dynamic and static modulus of elasticity

Properties	Caixeta	Cedrinho	Goiabão
$\mathbf{E_{dyn}}$ **(GPa)**	10.62	12.45	20.92
	11.63%	19.01%	16.28%
$\mathbf{E_{flat}}$ **(GPa)**	10.70	11.97	20.19
	11.39%	14.46%	17.09%
$\mathbf{E_{flat}/E_{dyn}}$	1.01	0.96	0.97
$\mathbf{E_{edge}}$ **(GPa)**	9.74	12.39	18.55
	10.23%	15.36%	9.75%
$\mathbf{E_{edge}/E_{dyn}}$	0.92	0.99	0.87

4 CONCLUSIONS

Mechanical characterization tests were performed in structural size specimens for three native species of the Amazon rainforest obtained from trees under sustainable forest management, *i.e.* Caixeta (*Simarouba amara* Aubl.), Cedrinho (*Erisma uncinatum* Warm.) and, Goiabão (*Planchonella pachycarpa* Pires.). The experimental campaign followed the new Brazilian Standard ABNT NBR 7190 – Part 4 [6] Additionally, non-destructive tests were carried out 3-point static bending test to determine modulus of elasticity and transverse vibration test to determine the dynamic modulus of elasticity. Main highlights are:

- Static and dynamic modulus of elasticity were analysed and the regression presented a high coefficient of determination ($R^2 = 0.9394$).
- The comparison of the static and dynamic modulus of elasticity showed that E_{flat} had closer values to E_{dyn} than E_{edge}, since transverse vibration through Metriguard model 340 requires flatwise position to determine the dynamic modulus of elasticity.
- The species were classified into strength classes by the characteristic value of bending strength and, mean values of static modulus of elasticity and density. "Goiabão" was graded as D60, "Cedrinho" D24, and "Caixeta" D18. However, it was observed that the tension strength perpendicular to the grain and the shear parallel to the grain did not achieve the values presented by the strength classes assigned to these species.

ACKNOWLEDGEMENT

The authors would like to thank WWF-BRASIL (World Wide Fund for Nature), and Wood and Timber Structures Laboratory (LaMEM) of the Department of Structural Engineering (SET) of the São Carlos Engineering School (EESC) - University of São Paulo (USP) for making this work possible. This study was partly financed by FIPAI (Foundation for the Increase of Research and Industrial Improvement), and the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) under Finance Code 001.

PREFABRICATED TIMBER CONCRETE COMPOSITES

Sam Winder[1], Dan Chapman[2], Panayiotis Papastavrou[3], Simon Smith[4], Allan McRobie[5]

ABSTRACT: Timber-concrete composite floor panels offer a lightweight structural floor system that can be used with a panelised construction method. Currently, prefabricated timber-concrete composite (TCC) floor solutions are rare. This is partly due to a lack of knowledge regarding the shear connectors that join the timber and concrete elements and the impact of additional interlayers between the timber and concrete elements is even less well understood. This research project was undertaken as part of the broader work being done for the GenZero initiative by the UK's Department for Education (DfE) working with industrial partners Smith and Wallwork Engineers, Ecosystems Technologies, Thorp Precast, and several others. In particular, the impact of two different shear connectors on the proposed 8m by 1.8m TCC slabs was investigated: a concrete notch and a steel dowel. Full-scale slab and small-scale shear experiments were carried out, supplemented by computational analysis, to establish the properties of specific connectors and their impact on whole slab dynamic and static performance. The inclusion of any interlayer immediately reduced structural performance, but varying the interlayer thickness and build up only had a small impact. A critical feature of shear connector design was found to be the extent to which a connector is vertically restrained.

KEYWORDS: Timber-concrete composites, Off-site manufacturing, Vibration performance, Finite Element modelling

1 INTRODUCTION

Timber-concrete composite floor panels offer a relatively lightweight structural floor system that can be used with a panelised construction method. Currently, prefabricated timber-concrete composite (TCC) floor solutions are rare. This is in part due to a lack of knowledge regarding the shear connectors that join the timber and concrete elements, and the impact of additional interlayers between those timber and concrete elements, which is even less well understood.

This research project was undertaken as part of the broader work being done for the GenZero initiative [1] by the UK's Department for Education (DfE) working with industrial partners Smith and Wallwork Engineers, Ecosystems Technologies, and Thorp Precast.

1.1 GENZERO

The DfE have identified the need to build up to 200 new secondary schools each year in the 2030s. The GenZero initiative looks at how future secondary schools could be designed to meet this demand while aligning with the government's commitment to net zero carbon emissions by 2050. The key aims of the initial GenZero research project was to develop a flexible secondary school design system which could be applied to multiple sites and achieve net zero carbon in both construction and operation.

The DfE aim to pioneer a new method to build these secondary schools, using the principles of Design for Manufacture and Assembly (DfMA) to design a kit of high-performance parts from which new schools can be developed, and then quickly assembled onsite.

An initial prototype of a single classroom was displayed at the COP26 Glasgow summit, which gave the opportunity for testing and improving the understanding of the floor slab solution. Other prototyping projects are ongoing.

1.2 GENZERO FLOOR SLAB

For the majority of the GenZero design a high-performance timber concrete composite floor panel was proposed. These prefabricated panels aimed to meet the structural requirements, as well as provide benefits for fire separation between floors, acoustic separation and thermal mass. The concrete would also provide a hard-wearing architectural finish, reducing the number of on-site trades and would minimise whole life carbon compared to finishes that need to be replaced every few years.

The floor panels span 8m and are 1.8m wide. The panel build-up, Figure 1, is made of a 75mm concrete slab, on top of an acoustic resilient layer (~5mm) supported on a timber boarding layer (24mm) which also acts as a permanent formwork. The concrete then acts compositely with the glulam ribs below. There is one central rib of 200x400mm with two half ribs (100x400mm) at each edge to create a continuous appearance underneath while helping to protect the concrete edges. The glulam is made using UK grown timber with a material grade of GL16+.

1.3 TECHNICAL MOTIVATION

The structural performance of timber or concrete is already well understood. What is less well understood are the methods of joining these materials to form a composite, especially with the inclusion of interlayers. The properties of these connectors have a significant impact on the performance of the overall structure, as the connectors dictate to what extent composite action occurs. This in turn determines the global stiffness of the slab. Then under large loads, the design of the shear connectors will govern the failure mode and the failure load. The key metrics of performance for a shear connector are its slip modulus and failure load, which can then be used to calculate the global slab properties.

There are evidently many methods to join timber and concrete to make a composite connector. The original GenZero research (a literature review and design exercise) identified two connector types to take forward from a literature review: a 20mm flanged steel dowel and a notch 50mm into the timber. See Figure 2. The assessment was based on a balance of structural performance, manufacturability and an attempt to limit the number of connectors for manufacturing ease and reduced noise transmission.

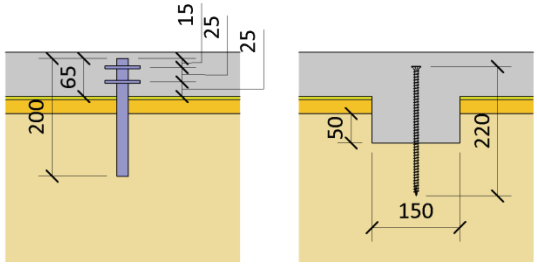

Figure 2: *Composite connectors, flanged dowel on the left, concrete notch on the right*

The two types of composite connector have been researched and tested before. However, the effect of adding interlayers between the concrete and the timber members is not adequately understood. Previous research has given flat reduction factors for strength and slip modulus values for interlayers. Table 1 shows the reduction factors put forward from the 2018 COST report "Design of timber-concrete composite structures" [2], which summarised available research.

Table 1: Reduction factors due to interlayers [2]

	Strength R.F. (%)	Stiffness R.F. (%)
Dowels	8	35
Notches	16	34

It is important to note that the reduction factors given in Table 1 are not a function of the interlayer thickness or interlayer material. It is intuitive to expect a thicker interlayer will have a greater impact on stiffness. The original GenZero prototype includes an interlayer of two materials with a thickness of ~ 30mm. More recent guidance published in March 2022 'Design of Timber Structures. Structural design of timber-concrete composite structures.' [3] is also limited on detail. For example, if the interlayer is as stiff as the timber "The Slip Modulus of dowel-type fasteners may be taken as that for a similar configuration without an interlayer with a reduction factor of 30%." Otherwise "the slip modulus should be determined by tests", which is what this report aims to provide for the GenZero design.

Previous research has typically used higher grade glulam timber, with greater stiffness and strength properties. The GenZero design differs by using softer UK grown glulam timber elements with a grade of GL16+. GL16+ was proposed by Edinburgh Napier University specifically for UK grown timber. Material properties for GL16+ are given in Table 2.

Table 2: *GL16+ timber properties*

Bending strength	$f_{m,g,k}$	22.5	N/mm^2
Tensile strength	$f_{t,0,g,k}$	18.0	N/mm^2
	$f_{t,90,g,k}$	0.5	N/mm^2
Compressive strength	$f_{c,0,g,k}$	22.5	N/mm^2
	$f_{c,90,g,k}$	2.5	N/mm^2
Shear strength	$f_{v,g,k}$	3.5	N/mm^2
	$f_{r,g,k}$	1.2	N/mm^2
Modulus of Elasticity	$E_{0,g,mean}$	8,400	N/mm^2
	$E_{0,g,0.05}$	7,000	N/mm^2
	$E_{90,g,mean}$	300	N/mm^2
Shear modulus	$G_{g,mean}$	650	N/mm^2
	$G_{r,g,mean}$	65	N/mm^2
Density	$\rho_{g,k}$	363	kg/m^3
	$\rho_{g,mean}$	400	kg/m^3

Dynamic performance typically governs the design of long-span timber floors such as the GenZero design. This research focuses on the small strain and dynamic behaviour of the composite shear connectors and full slab, with the aim of informing the development of prefabricated timber-concrete floor panels. This is done by analytical methods, finite element modelling of the shear connectors and the slab unit, small-scale lab testing

https://doi.org/10.52202/069179-0403

comparing different shear connectors and interlayers, and full-scale lab testing of a complete slab focusing on its dynamic properties under footfall excitation.

2 CONNECTOR BEHAVIOUR

This section aims to establish the performance of the individual composite connectors identified for the GenZero prototype and explore the effect of the proposed interlayer. This is done through small scale tests of the connectors and through computational analysis.

2.1 EXPECTED VALUES FROM LITERATURE

The anticipated failure load and stiffness from the literature is given in Table 3. The flanged dowel values are based on existing research [4], with stiffness scaled with the timber density to power of 1.5. Values for the notch are based off guidance in the COST report [2], which gives a flat stiffness value based on notch width, with no relation to timber properties.

Table 3: *Predicted connector properties*

Connector	Predicted failure load, kN	Slip modulus, kN/mm
Flanged dowel	27	109
Flanged dowel w/ interlayer	25	71
Notch	29	120
Notch w/ interlayer	24	76.8

2.2 CONNECTOR SPECIMEN DESIGN

Four test specimens were constructed to cover both connectors and three different interlayers build ups, see Table 4 for a summary. The number of specimens was limited by the availability of UK grown glulam.

Table 4: *Small-scale test specimens (SF = Rothoblaas Silent Floor)*

Test	Shear connector	Interlayer depth, mm	Interlayer Composition
1	Dowel	0	None
2	Dowel	24	OSB
3	Dowel	29	SF + OSB
4	Notch	29	SF + OSB

The specimens were designed for symmetric shear tests with two connectors in each side, so that no additional moments would be placed on the shear connectors.
The geometry of each specimen was designed to replicate the full size GenZero slab, with the same timber dimensions as an outside rib and the same concrete thickness. Where the interlayer thickness is varied the dowel embedment depth is kept the same. The key variation from the full-scale slab is the concrete is unreinforced and has the same width as the beam.

2.2.1 CONCRETE

The GenZero design specified a concrete grade of RC30/37 with a 70% GGBS replacement mix. The concrete mix used for the tests did not include GGBS due to availability, however this should only affect curing times. Concrete test results are given in Table 6, showing the strength requirements were met.
The mix was relatively dry, making it harder to compact leading to concerns that voids may have formed in or near the connectors.

Table 5: *Concrete mix used in shear test specimens.*

Test type	Number of tests	Mean failure load (MPa)
Cube	3	42.4
Cylinder	2	32.7

2.3 SMALL SCALE TESTING METHOD

The small-scale shear tests were completed in accordance with BS EN 26891:1991 [5] to ensure relevance to all stakeholders. The loading regime is shown in Figure 3, specimens are loaded elastically, unloaded, and then loaded to failure. This allows connectors to embed and shows a hysteresis loop for the cycle. Testing was completed with an Instron machine using load control for the initial cycle then displacement control to prevent any sudden failure; Figure 4 shows a photo of the test set up.

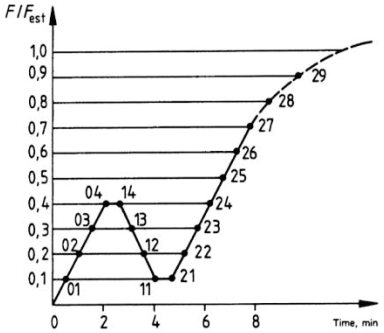

Figure 3: *Loading protocol [5]*

Figure 4: *Test set up, with specimen 1 after failure*

https://doi.org/10.52202/069179-0403

The standard also provides the method to calculate the slip modulus from experimental results. This required calculating an estimate of the failure load for each specimen, which was typically done using values from literature. Test 4 was the exception, which was subjected to the same regime as Test 3 in order for the performance of the two different shear connectors to be better compared.

2.3.1 DIGITAL IMAGE CORRELATION

Digital Image Correlation (DIC), also called Particle Image Velocity (PIC), was used to measure strain in the specimens during testing. This is done by spray painting dots onto the specimen then comparing digital images to track deformations and calculate the strain field.

2.4 COMPUTATIONAL ANALYSIS

SIMSOLID was used to create a Finite Element Model of individual connections to extend the parameter field covered. FEA models were developed for the two connector types. This was proposed by the full-scale slab fabricator as it simpler to manufacture.

The interlayer was modelled as an air gap, to make a lower bound estimate where the interlayer material does not contribute to the stiffness, through friction or restraint.

2.5 RESULTS AND DISCUSSON

2.5.1 EXPERIMENTAL

Table 6 shows the characteristic connector properties calculated using BS EN 26891:1991 for each specimen with four connectors. The results for a single connector are then compared to the expected values from literature in Table 7. Initial impressions of the results show both the capacity and stiffness of the dowel connector drop significantly as the interlayer increases. Also, the notch connector slightly outperforms the dowel connector for the same interlayer.

Compared to the literature the strength values are relatively similar. However, the experimental stiffness values are generally lower by a factor of 10, this is discussed later.

For the flanged dowel the literature gave a stiffness reduction of 35% where the experimental results show reductions of 51% and 62% for the OSB interlayer and the combined OSB and resilient layer interlayer respectively. This shows a flat reduction factor for any interlayer is unsuitable.

Table 7: *Predicted vs experimental connector properties*

Test	1	2	3	4
Predicted failure load, kN	27	25	25	24
Experimental failure load, kN	27	20	17	27
Predicted slip modulus, kN/mm	109	71	71	77
Experimental slip modulus, kN/mm	13.4	6.5	5.1	6.8

However, there is a significant discrepancy between the slip moduli of the experimental and literature values. This discrepancy can't be explained by the interlayer build-up as test 1 which had no interlayer is also significantly lower than the literature, suggesting something is wrong with the specimen design. None of the shear test specimens failed in the shear connectors. In each case there was bearing failure at the base of the specimen first. For example, Figure 4 show the cracking patterns of the concrete in failure of Test 1; note cracking at the base. The onset of this cracking may have reduced the stiffness of the shear connectors in the specimen. Therefore, the results from the small-scale tests are indicative of the relative performance of the shear connectors with given interlayer but are not reflective of the true absolute values of the slip moduli and shear strength.

Table 6: *Experimental specimen properties (4 connectors)*

	Property	Notation	Unit	Test			
				1	2	3	4
1	**Maximum Load**	**F_{max}**	**kN**	**107.5**	**78.9**	**69**	**108**
2	estimated maximum load	F_{est}	kN	100	90	80	80
3	initial slip	v_i	mm	0.88	1.54	1.54	1.41
4	modified initial slip	$v_{i,mod}$	mm	0.74	1.40	1.57	1.19
5	joint settlement	v_s	mm	0.14	0.14	-0.03	0.22
6	elastic slip	v_e	mm	0.57	0.76	1.01	0.45
7	initial slip modulus	k_i	kN/mm	45.3	23.4	20.7	22.7
8	**slip modulus**	**k_s**	**kN/mm**	**53.7**	**25.8**	**20.4**	**27.0**
9	slip at 60% F_{est}	$v_{0.6}$	mm	1.31	2.23	2.51	1.77
10	modified slip at 60% F_{est}	$v_{0.6,\ mod}$	mm	1.15	1.94	2.49	1.49
11	slip at 80% F_{est}	$v_{0.8}$	mm	2.06	2.95	3.91	2.12
12	modified slip at 80% F_{est}	$v_{0.8,\ mod}$	mm	1.90	2.66	3.89	1.83

https://doi.org/10.52202/069179-0403

Only a narrow strip of concrete was used in each specimen, rather than having the concrete overhang to replicate a larger part of the slab. A larger concrete area would increase the crushing failure load. The use of a dry mix, resulting in voids inside the specimen (Section 2.3.6) will have exacerbated this problem. Finally, the concrete was completely un-reinforced. Including a reinforcement mesh would be more representative.

2.5.2 COMPUTATIONAL

The absolute values for slip modulus the FEA produced were substantially higher than the literature and experimental values, see Table 8. This is potentially the result of imperfections in real world samples. For example, within a concrete notch, the concrete face in unlikely to be perfectly smooth, meaning protruding elements are likely to bed into the timber until a sufficient surface area is in contact with the timber, effectively reducing the initial slip modulus. Similarly, this could happen with hole tolerances with the dowel connector.

Table 8: *FEA slip moduli*

Interlayer Thickness, mm	Slip Modulus, kN/mm (Normalised)		
	Rectangular notch	Flanged dowel	Dowel Experimental
0	363 (1.0)	297 (1.0)	13.4 (1.0)
5	225 (0.62)	144 (0.48)	6.5 (0.49)
29	206 (0.57)	93 (0.31)	5.1 (0.38)

More interesting is the normalised slip modulus for each connector type. These are shown for a variety of interlayer thickness in Figure 5. Each connector shows a significant drop in slip modulus as the gap first starts, then a more steady, approximately linear reduction. This indicates a flat reduction factor is suitable for thin interlayers approx. <5mm. However, for larger interlayers the linear drop does become pronounced, showing the limitations of the current literature.

The FEA models and experimental values also show a larger initial reduction compared to the literature values, in particular the dowel reduction is substantially larger. This suggests a larger experimental set with the improvements discussed in Section 2.5.1 is required to fully characterise the behaviour of these connectors.

3 FLOOR SLAB BEHAVIOUR

Two full size GenZero floor slabs were constructed for structural testing as part of the prototype build. Testing included impact vibration tests, and a 3-point bend test with cyclic loading. These tests aimed to verify whether the original design met the structural requirements and to explore the properties of the composite connectors through back calculation of the whole slab's behaviour.

3.1 SLAB DESIGN AND MANUFACTURE

Each slab has the same dimensions and build up with the full interlayer (24mm OSB and 5mm resilient layer), shown in Figure 6. Connector spacing was kept the same for both slabs to ensure a direct comparison. Along each rib connectors were spaced at 1m intervals. In the wider central rib, two dowels were used at each interval and double width notch was used.

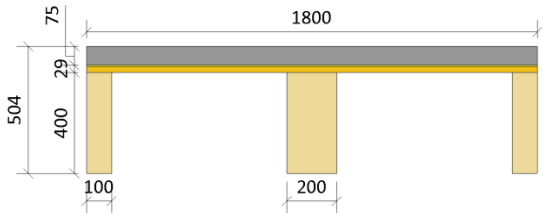

Figure 6: *GenZero slab cross-section*

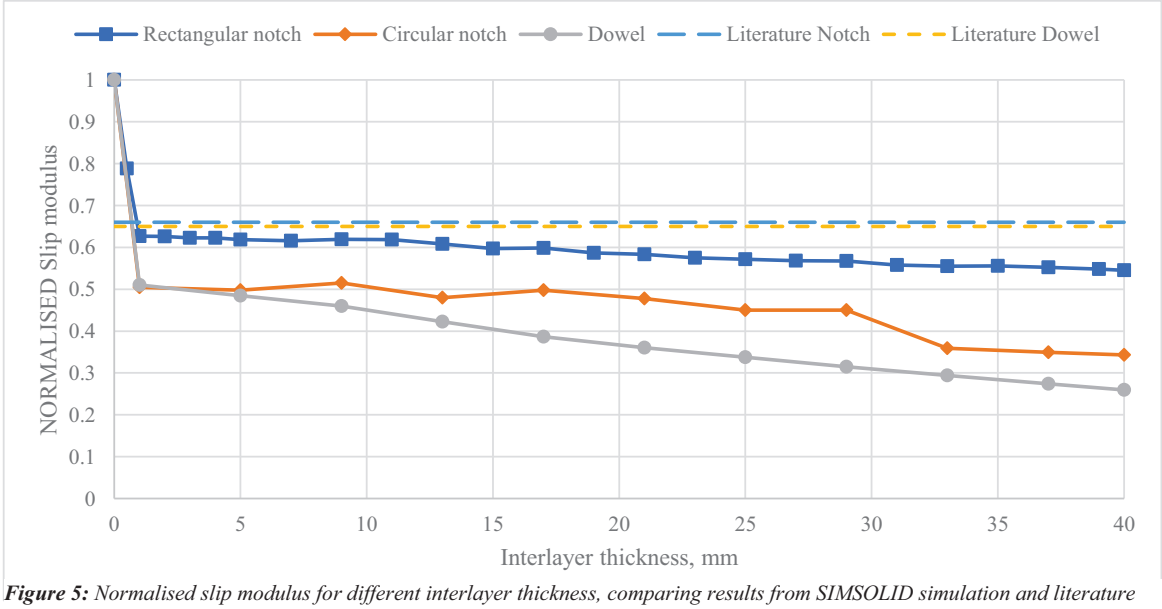

Figure 5: *Normalised slip modulus for different interlayer thickness, comparing results from SIMSOLID simulation and literature*

https://doi.org/10.52202/069179-0403

ECOSystems Technologies fabricated the timber elements, connectors and applied the resilient layer, then the slabs were transported to Thorp Precast to pour and polish the concrete.
The C16+ timber that made up the glulam beams of the prototype outperformed initial expectations of stiffness. Research from Edinburgh Napier University demonstrated that the timber performed closer to a C24 classification, since the modulus of elasticity of the glulam was 11GPa rather than the initially assumed 8GPa. The high GGBS content of the concrete slab made power floating more difficult. The prototype slabs had a slightly curved profile on their surface, with more cover at the edges than in the middle. This meant a few of the steel dowel shear connectors were visible. Variation in the slabs' mass can be seen in Table 9.
The dowel connectors were intended to be glued in; however the epoxy was missed, which could have a significant impact on performance.

Table 9: *Prototype slab masses*

Prototype shear connector	Weight (kN)
Notch	33.28
Dowel	33.33

3.2 VIBRATION TESTING

3.2.1 TEST METHOD

Dynamic testing was completed using an instrumented hammer, see Figure 7, with accelerometers glued to the floor slab. The hammer was used to excite the slab vertically while it was simply supported at each end. This would enable measurement of the fundamental frequency of the slab, which is the most relevant for excitation from walking. The fundamental frequency of the slab is a property of the slab and therefore would be independent of where the hammer blow is struck and where the receiving accelerometer is placed. However, the exception is that a mode will neither be excited by the hammer nor received by the accelerometer if either of those two points on the slab coincide with a nodal point of the vibration in that mode. Therefore, data was collected from a variety of locations to help produce confidence in the nature of the resonant peak being detected. Numerous off-centre impacts from the instrumented hammer and off-centre accelerometer measurements were taken to avoid mistaking any torsional or minor axis flexural modes of vibration for the fundamental mode.

Figure 7: *Instrumented hammers on test slab*

3.2.2 DYNAMIC RESULTS

Figures 8 to 10 show the key frequency data for each slab. Figures 11 and 12 show a spiral plot for the notched connector slab based on the equation of motion:

$$F = m.\ddot{x} + v.\dot{x} = k.x$$

The accelerometer glued to the slab, records the acceleration of the slab, which can be numerically integrated to find the velocity and position. After the initial impact the external force, F = 0. Therefore, if each of the exponents are constant (the slabs' mass, stiffness and damping factor) the equation of motion defines a plane in space on which the oscillations of the slab create an ellipse. As the oscillations decay this ellipse decays into a spiral.
Table 10 shows the key results from these figures, showing the notch connector performs better than the dowel. From these values and the slab masses response factors for a range of input walking frequencies were calculated, using the method from "A Design Guide for Footfall Induced Vibration of Structures" [6], the results are shown in Figures 13 and 14.

Table 10: *Experimental dynamic values*

	Natural Frequency (Hz)	Damping Factor (% critical)
Dowel	8.6	2
Notch	10.2	4.5

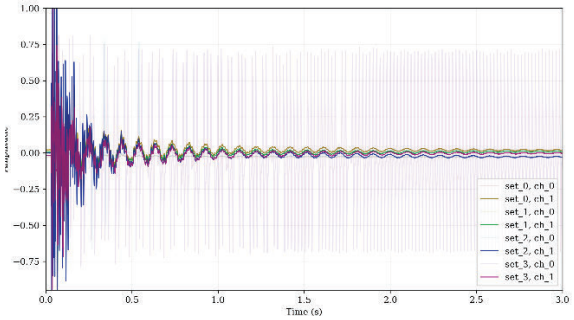

Figure 8: *Time domain data of notch connector slab*

https://doi.org/10.52202/069179-0403

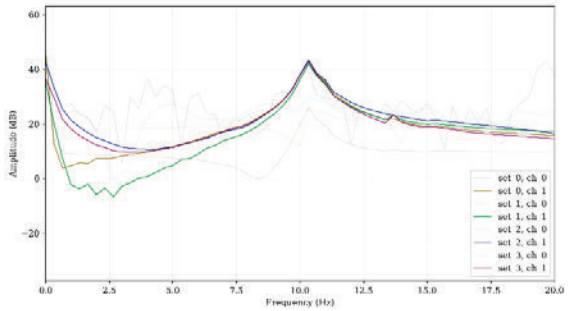

Figure 9: *Frequency domain data for notch connector slab*

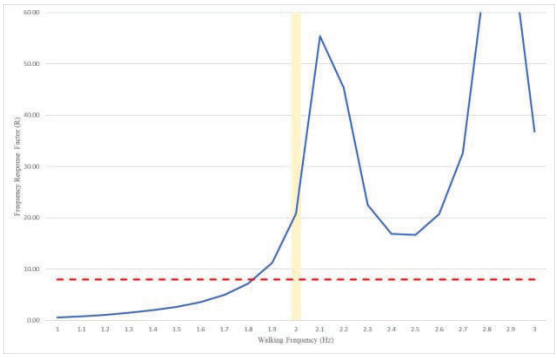

Figure 14: *Response factors for different walking frequencies of the dowel connector slab, the yellow line indicates the max expected walking frequency in a classroom, the red line indicates the max permissible response.*

3.2.3 DISCUSSION OF RESULTS

There is a clear difference between the appearance of the fundamental resonant peak of the notch slab and the equivalent resonant peak in the dowel slab, compare Figures 9 and 10. The clean resonant peak in the notched slab is what one would normally expect to see. The shape of the resonant peak in the dowel slab indicates that there are in fact two resonant peaks at very similar frequencies superimposed on top of one another. One possible explanation would be to suggest that there were two modes present with similar natural frequencies, for example a bending mode and a torsional mode that were both excited at the same time. However, this would be very unlikely given that torsional modes should only occur at higher frequencies due to the long thin shape of the slab. This was confirmed by impacting the slab at different locations. By impacting the slab near the edge, one would expect to excite a torsional mode, whereas impacting the slab along at centre line should excite no torsional modes. In all the above cases the same 8.6Hz peak was present with the same shape, and no torsional modes in the considered frequency range were observed. Instead, the shape of the peak is indicative of an asymmetric slab. If the left half of the slab and the right

https://doi.org/10.52202/069179-0403

half of the slab were built slightly differently, with subtly different masses and stiffnesses, then the left half of the slab would have a subtly different resonant frequency to the right half. Then the two resonant peaks would superimpose and join into one resonant peak with a shape similar to what was observed. This is the most likely explanation since it is consistent with the defects recorded, for example one of the glulam ribs was 10mm thinner in width than specified.

Often a linear damping factor is assumed to simplify analysis, Figures 11 and 12 demonstrate that damping was linear in both slabs. As discussed in Section 3.2.2, if the damping factor, v, was linear the spiral would lie on a plane, as can be seen. However, if the damping factor was non-linear a 'bowl' shape would be observed instead.

The notch shear connected slab performed better than the dowel slab. However, this is not due to the performance of the shear connector alone. The dowel slab had more issues with its manufacture and the dowel connectors were not glued into the timber.

3.3 3-POINT BEND TEST

3.3.1 TEST METHOD

There is no specific standard for testing TCC slabs, therefore a test method was developed based on the protocol for steel concrete composites (SCC). "Design of composite steel and concrete structures" [7] lays out methods for testing both shear connectors and composite slabs. This uses a four-point bend test with an initial cyclic loading phase before the slab is taken to failure.

To test the TCC slabs, a 3-point test is used with an initial phase of 25 cycles to 30% of the estimated failure load. A 3-point bend test was justified as the primary interest of this test is the slab stiffness, and it would make a shear failure more likely which is of greater interest to evaluate the shear connectors. The number of cycles is reduced from the SCC test as steel fatigue is less of an interest here, this is also seen in the small-scale test method where timber connections require a single cycle and SCC connectors require 25.

To collect the data, multiple techniques were used. DIC imaging was used to monitor the slab by the supports. LED monitoring was used to track relative movement of different regions of the slabs. Transducers were placed under each rib, to measure deflection.

3.3.2 RESULTS

Table 11 shows key results from the test. There was a hydraulic fault in the actuator during testing of the notch prototype slab. There was a control error with the hydraulic actuator, resulting in a sudden impact on the notch slab. This made a loud sound, including cracking from the slab. This impact recorded a maximum load of 105kN. However, this value is likely to be an overestimate due to the water hammer pressure excited within the actuator as a result of this sudden load.

The remainder of the test on the notch slab was conducted in displacement control, but the need to adjust the program led to interrupted data acquisition from the actuator.

The initial failure mode of the notch slab was in the shear connectors. The initial failure mode of the dowel slab was in bending.

Table 11: *Experimental slab performance.*

Prototype slab	**Notch**	**Dowel**
Elastic limit (kN)	93	100
Peak load (kN)	117	104
Bending stiffness (N/mm^2 $x10^{12}$)	59.3	23.7

Both slabs had significant post failure strength and ductility. The notch slab was able to resist the full extension of the actuator of approximately 160mm. When the load was removed the slab rebounded, but not to its original height. The dowel slab did not rebound after its final failure at its peak load near the maximum extension of the actuator.

3.3.3 DISCUSSION OF RESULTS

Using the methods of built-up sections, from EC5 [8] it is possible to back-calculate the slip modulus of the shear connectors in a slab from the experimental values of central deflection in bending as shown in Table 12.

Given that a negative slip modulus is impossible, the result indicates that the dowel slab is performing worse than would be expected if no composite action was occurring at all. This cannot be a consequence of the performance of the shear connector alone. Nevertheless, the result demonstrates that the dowel performed very poorly. The calculation was based on the design dimensions of the slab, but as discussed in Section 3.1 the prototype slabs contained defects.

Table 12: *Connector slip moduli calculated from bend test*

Prototype shear connector	Slip modulus (kN/mm)
Notch	45.0
Dowel	-1.1

Table 13: *Revised connector slip moduli calculated from bend test, to account for manufacture*

Prototype shear connector	Slip Modulus (kN/mm)
Notch	69.5
Dowel	1.0

A revised calculation was then performed, reducing the cross-section to match the as built dimension and accommodate for imperfections in manufacture. Specifically, Table 13 was produced by reducing the concrete depth by 10mm to 65mm, as some dowels were partially exposed from the polishing and assuming each rib had been planned by 10mm each on average, reducing to total width of glulam from 400mm to 360mm.

However, this does not account for the fact that the slab with dowel shear connectors was generally in a poorer condition with more defects before the test than the slab with notch shear connectors. This brings the slip modulus value of the notch more in line with the literature value. Due to the construction defects of the dowel slab, in particular the missing glue in the dowel connector, these full-scale results are disregarded.

3.4 DYNAMIC VS BENDING STIFFNESS

The bending stiffness of the two full scale slabs can be back calculated from both the vibration tests and the 3-point bend tests to show the effects of load duration, these are shown in Table 14. As is typically expected both slabs are stiffer during the dynamic tests, by 23% and 119% for the notch and dowel respectively. The greater drop in stiffness of the dowel connector slab suggests it is more susceptible to degradation over time, this may be from increased cracking in the concrete or greater embedment of the dowels into the timber.

Table 14: *Slab bending stiffness*

	Bending stiffness (N/mm^2 $x10^{12}$)
Full composite action	122.3
No composite action	25.4
Notch (static)	59.3
Notch (dynamic)	73.2
Dowel (static)	23.7
Dowel (dynamic)	52.1

3.5 COMPUTATIONAL ANALYSIS

An ABAQUS FEA model of the full-scale slab was created to explore the internal forces acting within the slab to understand what elements are affecting the performance of the concrete slabs.

3.5.1 MODELING UNCERTAINTIES

The glulam was modelled as a homogenous anisotropic material rather than as a built-up section of lamina. The material properties assigned in the test were based on Eurocodes [7] in the case of concrete, this causes some uncertainty as the actual value as is dependent on cracking. Values for the glulam were based on recent research from Edinburgh Napier University, while mean values are used in the model there is still significant natural variation within timber causing more uncertainty.

3.5.2 MODELING INSIGHTS

The key insight provided from modelling was the importance of vertical restraint to the composite connectors. If a shear connector is allowed to lift, it provides much less resistance to shear than if it is held down. Figures 15 and 16 show the normal stress distributions in a TCC slab, for a notch shear connector both with vertical restraint, replicating the fully threaded screw in the connection, and without vertical restraint, no additional screw. When there is no restraint, the connectors lift and the slab provides virtually no structural contribution, Figure 16. In comparison Figure 15 shows the slab stressed, in a pattern consistent with the connector locations.

This also helps explain the particularly poor performance of the experimental dowel slab, because the glue was missed from the dowels meaning there was limited vertical restraint.

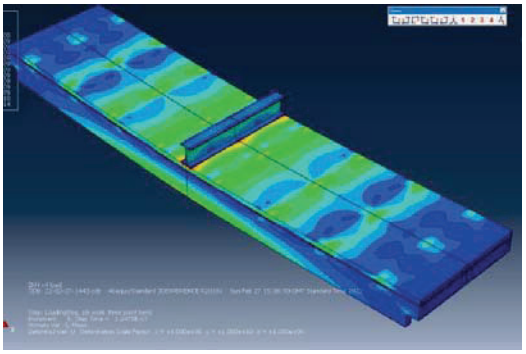

Figure 15: *Notch connector slab with vertical restraint*

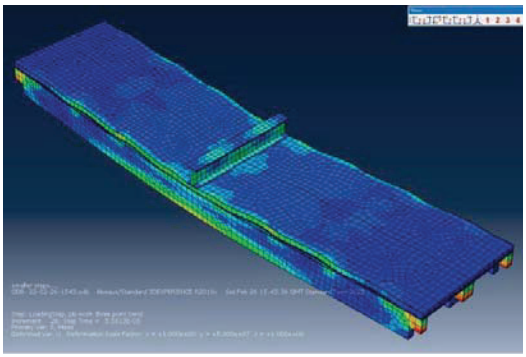

Figure 16: *Notch connector slab without vertical restraint*

4 GENZERO DESIGN EVALUATION

4.1 STRENGTH PERFORMANCE

To meet ULS requirements (G_k =0.5kN/m^2, Q_k=3.8kN/m^2) both slabs must be able to resist an equivalent central point load for bending strength: $P = 46$ kN, and an equivalent central point for shear strength: $P = 92$ kN. Shear failure is the limiting parameter and both slabs pass.

Table 15: *Satisfaction of strength criteria*

	Required Maximum load (kN)	Achieved Maximum load (kN)	Result
Notch	92	117.5	**PASS**
Dowel	92	100.2	**PASS**

4.2 DEFLECTION PERFORMANCE

Under SLS loading, the equivalent central point load, P = 38.9 kN. The instantaneous deflection limit = $span$ / 250 = 32.2mm. Both slabs pass.

Table 16: *Satisfaction of deflection criteria*

	Permitted deflection (mm)	Deflection under load (mm)	Result
Notch	22.4	7.9	**PASS**
Dowel	22.4	12.1	**PASS**

4.3 VIBRATION PERFORMANCE

GenZero put forward two vibration performance criteria, a minimum natural frequency of 8Hz with 10% live load applied, noting however vibration tests were completed with no live load. Then a maximum frequency response of 8 for excitation walking frequencies up to 2Hz as suggested in [6]. Both slabs pass the basic natural frequency test, only the notched connector passes the frequency response test.

Table 17: *Vibration criteria and results*

	Minimum resonance (Hz)	Natural frequency (Hz)	Result
Notch	8.00	10.22	**N/A**
Dowel	8.00	8.56	**N/A**

	Allowable FR	Maximum FR	Result
Notch	8	6.8	**PASS**
Dowel	8	22.1	**FAIL**

5 CONCLUSIONS

There was no case where an interlayer improved structural performance. Each connector saw a large initial drop off before a reduced linear decline. Therefore, in design an interlayer should be avoided. If absolutely required, the thickness of the interlayer should be minimised.

A key attribute of a composite connector is vertical restraint. The full-scale slab modelling and the missing epoxy of the dowels showed the significant impact of removing this restraint.

The notch connector outperformed the dowel in all tests completed. Future work could investigate the effect of notch shape to help simplify manufacture, circular notches are typically easier to cut. Initial modelling of a circular notch with similar dimensions to the rectangular notch produced a less stiff connector.

The GenZero slab design was shown as viable. The full-scale tests can be taken as a lower bound of performance due to the manufacturing imperfections. Key to making this solution a reality would be manufacturing consistency.

NUMERICAL MODELLING OF A CROSS-LAMINATED TIMBER-TO-CONRETE DOWEL-TYPE CONNECTION USING THE BEAM-ON-FOUNDATION MODEL

Joan W. Gikonyo[1], Eva Binder[2], Michael Schweigler[3], Thomas K. Bader[4]

ABSTRACT: The aim of the research presented herein is to investigate the mechanical behaviour of cross-laminated timber (CLT)-to-concrete dowel-type connections. For reliable timber-concrete-composite structures, mechanical connections between the two construction materials are of great importance. This paper investigates the nonlinear load-displacement behaviour, giving access to the stiffness and strength, as well as ductile connection failure modes, of a CLT-to-concrete composite connection using a Beam-on-Foundation (BoF) model. The latter is a numerical model that utilizes non-linear springs for the interaction between the fastener and the surrounding CLT and concrete materials. The influence of: (i) fastener diameter, (ii) initial slip, (iii) concrete embedment properties, and (iv) axial fastener resistance due to friction, on the connection shear capacity and slip modulus, was investigated in a parameter study. The nonlinear load-displacement response, connection stiffness and strength predicted by the BoF model were moreover compared to laboratory tests and the European Yield Model (EYM), which supported the validity of the BoF model. In addition, it was shown that the BoF model could enhance the prediction of the slip modulus compared to the current design regulations in Eurocode 5.

KEYWORDS: Beam-on-Foundation Model, CLT-to-concrete composite connections, connection stiffness

1 INTRODUCTION

The need for energy efficiency in construction has propelled the popularity of timber structures. Apart from exceptionally high mechanical properties in relation to the low weight of the material, timber has low mechanical properties under certain loading conditions and timber structures are prone to vibrations due to the lightweight nature of the material. The use of timber in combination with other construction materials in hybrid structures or structural composite elements, such as Timber Concrete Composites (TCC), can considerably improve the mechanical performance and stability as compared to conventional timber structures [1]. In TCC elements, timber and concrete elements are placed strategically in the tension and compression zones, respectively. Some of the benefits associated with TCC structures compared to timber structures are increased stiffness and load bearing capacity, improved sound insulation, reduced sensitivity to vibrations and improved structural bracing. In order to make use of the composite action in structural elements, efficient shear connections between the tension and compression-resisting components, i.e., between timber and concrete elements, are critical for the realization of the aforementioned benefits [2].

Most of the comprehensive experimental and numerical analyses of timber-concrete composite structures have been carried out with structural timber or glued laminated timber employed as the tension element. In recent years, studies on Cross Laminated Timber (CLT)-concrete composite structures have become increasingly popular. CLT is a pre-engineered timber product with an orthogonal laminar structure composed of an odd number of layers, usually with a maximum of seven layers. The popularity of CLT-to-concrete composite structures is attributed to improved mechanical properties in both longitudinal and transverse directions of CLT. CLT is attractive in development of full-scale wall and floor elements. CLT–concrete hybrid floor systems improve the bending capacity of the pure CLT floor elements by 3-5 times [3]. The suitability of common types of connectors such as, dowel-type fasteners [4], adhesive connections [5] and even novel types of connections [6] for CLT-to-concrete connections have been investigated by various researchers. Though adhesive connections provide an effective way to ensure a rigid shear connection between the concrete and CLT, shrinkage induced deflections of the composite connection render dowel-type connectors more suitable [1]. The stiffness of dowel-type connections in TCC elements depends on the deformation that takes place at the joint. Therefore, design of TCC connections assumes partial composite action, due to the difficulty in achieving full rigidity due to deformation at joints [7]. Ductility of dowel-type steel fasteners used in TCC connections increases the load-bearing capacity as well as the ultimate deformation capacity, because typically the connection shear capacity activates before the member ultimate load is reached [8]. However, ductile behaviour of the connection may not necessarily lead to ductile behaviour of the composite element if the stiffness of the

connection is higher than predicted, as the timber may exhibit brittle failure [2]. This emphasizes the importance of accurately predicting the slip modulus of TCC connections. Dias et al. [9] carried out a comparison between experimental tests on the load-bearing capacity of timber-to-concrete composite connections and the European Yield Model (EYM) by Ehlbeck and Larsen [10] in Eurocode 5 [11] (EC5) for i) timber-to-timber, ii) steel-to-timber and iii) timber-to-timber with a gap. The experimental results showed good agreement with all three EYM models. However, the EYM for steel-to-timber connections showed the best fit with the experimental results. Moreover, Dias et al. [12] compared experimental results for the slip modulus to i) analytical models based on beam-on-elastic foundation, and ii) the Eurocode-based empirical design equation for timber-to-timber connections, multiplied by a factor of two, as suggested in the code. The results showed that both models overestimated the slip modulus obtained in the experiments. Nonetheless, the experimental results showed better agreement with the Eurocode design equation.

The strength and slip modulus of TCC connections is experimentally determined according to EN 26891 [13]. However, Dias [14] showed that the connection slip modulus determined as per EN 26891 was inaccurate due to the pronounced non-linear response of TCC connections. Dias notes that the maximum slip observed in TCC connections is usually less than 8 mm, thus significantly lower than 15 mm indicated in EN 26891 [13], thereby, overestimating the shear capacity. Furthermore, it turns out that factors such as, initial slip [15], dowel diameter [6], concrete stiffness and strength [16] and connector inclination [4], influence the strength and slip modulus of CLT-to-concrete connections. The extent to which such factors influence the global response of CLT-to-concrete connection is largely unknown, which emphasizes the need for suitable design models for the prediction of both slip modulus and load bearing capacity of CLT-to-concrete connections.

The aim of this study is to validate a Beam-on-Foundation (BoF) model of CLT-to-concrete connections, by means of comparing model predictions with experimental results. The model is then applied to investigate the influence of various factors on the shear capacity and slip modulus of CLT-to-concrete connections. The outcome of this study provides experimental and numerical results that can be useful for creating structural design codes for CLT-concrete composite structures.

2 MATERIALS AND METHODS

2.1 Materials

The cross-laminated timber (CLT) elements, produced with boards of strength class C24 according to EN 338 [17], were stored in a climate room under standard climate conditions of 20°C and 65% RH for more than a year and it was assumed that an equilibrium moisture content of approximately 12% was established. The corresponding mean density of the CLT elements was 493 kg/m^3 (CV= 22%, 3 specimens). The prefabricated concrete elements were stored for at least 28 days before the tests, which leads to a stiffness of at least 33 GPa, with a mean density of 2371 kg/m^3 (CV= 1%, 3 specimens). The threaded rods for the connection had an ISO metric thread M24 and a quality of at least 8.8 grade steel.

2.2 Experimental tests on CLT-to-concrete shear connections

CLT-to-concrete connections were tested in a double shear push-out test configuration, see Figures 1 and 2. The tests were performed in a test frame, mounted with a hydraulic piston with a load capacity of up to 500 kN (MTS 210.45 G2, Flex test 60, MTS System Corporation, Sweden). In the test setup, the concrete element in the middle was connected by a threaded rod to two CLT side elements, kept together by a washer (d_{out}= 44 mm and d_{in}= 25 mm) and nut at each end, see Figure 1. The threaded rod was inserted into pre-drilled holes (d= 25 mm) in the timber and a casted hole in the concrete (d= 25 mm). A displacement-controlled load was applied to the concrete at a rate of 3 mm/min. Through a hinge included in the steel loading device, pure vertical loading and an even load distribution was ensured. The loading was stopped when the machine displacement reached 30 mm. The local displacement between concrete and CLT was measured with four linear variable differential transformers (LVDTs) – two on each side of the specimen. The mean local displacement of the LVDT measurements between the concrete and timber, the displacement, and the applied force from the testing machine over time were further processed and considered for the validation of the numerical model.

2.3 Numerical modelling of CLT-to-concrete connection using the BoF model

The 2-dimensional beam-on-foundation (BoF) model, illustrated in Figure 3, was used to simulate the CLT-to-concrete shear connection in the research presented herein. The model has been utilized by various researchers such as, Lemaitre et al. [18] and Schweigler et al. [19] to predict steel-to-timber connection behaviour, while considering non-linear embedment and elasto-plastic steel material behaviour. The model is composed of a deformable beam element that represents the steel fastener and rigid beams that host non-linear springs. These springs describe the local interaction between the steel fastener and the surrounding timber and concrete materials.

The model has four main inputs, a) the geometry of the connection, b) the non-linear load-slip data used to define the interaction between the steel dowel and, the i) concrete and ii) timber, c) the local interaction between washer and timber, and d) the mechanical properties of the steel fastener. Boundary conditions as regards the specimen support and the loading of the connection, as well as a possible lateral support at the washer or for symmetry conditions are specified at the reference nodes of the rigid elements and the fastener, see Figure 3.

2.3.1 Lateral embedment and axial withdrawal behaviour of timber

The non-linear load-slip data for the springs between the steel fastener and the CLT is defined using embedment load-slip data. The 2-dimensional BoF model considers two in-plane force components i) parallel to the fastener, related to the axial withdrawal capacity of the fastener and ii) perpendicular to the fastener, related to the lateral embedment behaviour of the fastener. The BoF model utilizes embedment load-slip data for both loading directions with respect to the grain direction of the timber, parallel and perpendicular to the grain, in the corresponding layers of the CLT. In lieu of experimentally determined embedment data for the connection materials, the analytical formula from Richard and Abbott [20] was used to determine the embedment stress, σ_h, in [MPa] at a particular displacement, u, in [mm] as,

$$\sigma_h(u) = \frac{(k_{f,el} - k_{f,pl}) \cdot u}{\left[1 + \left[\frac{(k_{f,el} - k_{f,pl}) \cdot u}{f_{h,inter}}\right]^a\right]^{\frac{1}{a}}} + k_{f,pl} \cdot u, \quad (1)$$

with the embedment parameters $k_{f,el}$ as the elastic foundation modulus in [N mm^{-3}] , $k_{f,pl}$ as the plastic foundation modulus in [N mm^{-3}], $f_{h,inter}$ as the intersection of the line defined by $k_{f,pl}$ with the y-axis in [MPa], and a as a transition parameter between $k_{f,el}$ and $k_{f,pl}$. The embedment parameters were determined using analytical formulas from a database [21] that includes several timber products, i.e., structural timber, Laminated Veneer Lumber (LVL), plywood and glulam, loaded both parallel and perpendicular to the grain as

$$f_{h,inter,0} = 0.1253 \cdot \rho - 20.32, \quad (2a)$$
$$f_{h,inter,90} = 0.1108 \cdot \rho - 28.47, \quad (2b)$$
$$k_{f,el,0} = 0.1374 \cdot \rho - 12.90, \quad (2c)$$
$$k_{f,el,90} = 0.0922 \cdot \rho - 18.20, \quad (2d)$$
$$k_{f,pl,0} = 0.0047 \cdot \rho - 2.0, \quad (2e)$$
$$k_{f,pl,90} = 0.0084 \cdot \rho - 2.21, \quad (2f)$$

where, ρ is the density of the timber in [kg m^{-3}]. In this study, the mean density of the CLT of 493 kg m^{-3} (see Section 2.1) was used to determine embedment parameters. It should be noted that the embedment parameter, $f_{h,inter,}$ in Equations (2a-b) was determined using the proposed formula for $f_{h,5mm}$ in [21]. Assuming the same dependence of the two parameters ($f_{h,inter,0}$ and $f_{h,inter,90}$) on the density, as for $f_{h,5mm,0}$ and $f_{h,5mm,90}$, might lead to a slight overestimation of the behaviour perpendicular to the grain. Figure 4 illustrates the embedment stress-displacement curves generated from Equations (2a-b) with consideration of the large displacement effect according to Schweigler et al. [19] when coupling the springs parallel and perpendicular to the fastener's axis. Only the component parallel to the loading direction of the connection, for loading parallel and perpendicular to the grain is shown in Figure 4. The non-linear stress-displacement data describing the axial capacity in between the fastener and the wood, was determined according to Schweigler et al. [19] with consideration of a friction coefficient, $\mu = 0.3$.

Once the stress displacement curves for both the embedment and axial (withdrawal) behaviour were determined, the corresponding forces of one embedment element in the model, $F(u)$, at a particular displacement, u, was calculated as,

$$F(u) = \sigma_h(u) \cdot d_{major} \cdot \Delta t \quad (3)$$

with the embedment stress, $\sigma_h(u)$ at that particular displacement, the major diameter of the threaded rod,

https://doi.org/10.52202/069179-0404

d_{major}, and the distance between adjacent springs, Δt. A single linear spring, positioned at the end of the fastener, simulated the axial resistance due to the washer. The stiffness of the axial spring of 3.9 kN/mm was determined, by considering the area of the washer of 994 mm^2 and the characteristic compression strength of the wood, $f_{c,90k}$, of 2.9 MPa, assuming a yield displacement of slightly less than 1 mm. The compressive strength was chosen equivalent to that of timber with an average density of 490 kg m^{-3} as per EN 338 [17], matching the mean density of the CLT. In dowel-type shear connections, and especially for fasteners inserted into pre-casted and pre-drilled holes, a clearance between the fastener and the surrounding material can be observed, which typically leads to an initial slip in the connection's load-displacement behaviour. Moreover, the indentation of the threaded part of the rod into the pre-drilled hole, leads to an initially softer behaviour, before full contact with the surrounding material is established. To consider this, the embedment stress-displacement curve is offset by a certain displacement representing the initial slip. The stiffness of the embedment curve up to the initial slip displacement was assumed to be 1% of the elastic foundation modulus, $k_{f,el}$.

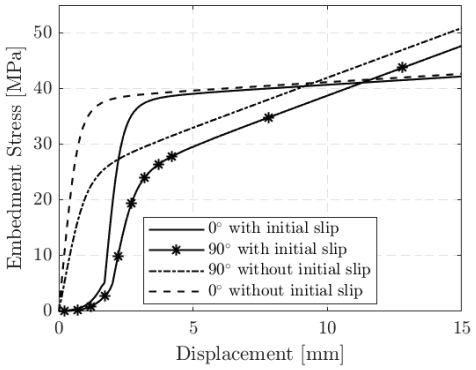

Figure 4: *Embedment stress-displacement curves of timber derived from embedment parameters using Equations (1) and (2).*

2.3.2 Concrete behaviour

The non-linear load-slip data for the interaction between the steel fastener and the concrete was determined as a multiple of the embedment parameters for the parallel loaded layer in the CLT. The values for $f_{h,inter}$ and $k_{f,el}$ were increased threefold, to account for the higher stiffness and compression strength of concrete, while for $k_{f,pl}$ the same values as for timber were used. Additionally, unlike the connectors between the steel fastener and the timber that were coupled, the connector elements parallel and perpendicular to the fastener's axis were uncoupled, since only small displacements were expected in the concrete, and thus, large displacement effects were neglected. In addition, connectors were only specified for the force resistance perpendicular to the fastener's axis, neglecting any possible axial resistance. Equations (1) and (2) were used to determine the stress-displacement curve for these non-linear spring connector elements. Subsequently, Equation (3) was used to determine the corresponding force-displacement data applied in the model.

2.3.3 Steel fastener

For the yield strength, the nominal values for steel quality 8.8 were increased by about 25%, since frequently higher yield and ultimate strength as compared to declared values were observed in connection tests. The remaining material properties of the threaded rod used in the BoF models presented herein were based on the properties of a dowel applied in [22]. Figure 5 shows the stress-strain relationship used in the model. Based on this stress-strain data, moment-rotation (bending angle) curves for various threaded steel rod diameters were determined using a numerical model of a 3-point bending test setup. In this study, consideration was made for both the major and minor diameter. The major diameter includes the depth of the thread while the minor diameter excludes the depth of the thread and thus is the diameter of the shank of the rod. The yield moment, $M_{y,R}$, was determined for a specific bending angle according to EN 409 [23] and further used in the analytical formulas provided in Eurocode 5 to determine the shear capacity of the CLT-to-concrete connections. In cases where the BoF model simulates threaded fasteners, the diameter of the threaded rod in the bending behaviour is specified as the minor diameter.

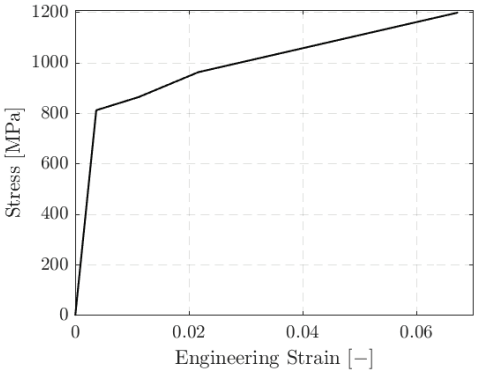

Figure 5: *Elasto-plastic response of the threaded steel rod.*

2.3.4 Evaluation of connection behaviour

After displacement-controlled loading at the reference node 2 in, shown in Figure 3**,** and the calculation of corresponding reaction forces at the support, the output from the BoF model is a force-displacement curve. The shear capacity and the slip modulus were determined according to EN 26891 [13]. Therefore, the shear capacity was defined as the maximum force up until 15 mm displacement. The slip modulus was determined as the gradient between the points at 10% and 40% of the shear capacity.

The results from the BoF model were compared to predictions of the European Yield Model (EYM) given by analytical formulas for the design of timber shear connections in Eurocode 5 (EC5) [11], for connections with a thick steel plate in steel-to-timber connections loaded in shear. This assumes a clamping of the fastener in the concrete (like in the steel) as compared to the considerably weaker behaviour of timber. EC5 determines the shear capacity, $F_{v,R}$, per shear plane for the

three failure modes associated with a thick steel plate for laterally loaded steel-to-timber connections as,

$$F_{v,R,mode1} = f_h t d_{major}, \quad (4a)$$

$$F_{v,R,mode2} = f_h t d_{major}\left(\sqrt{2+\frac{4M_{y,R}}{f_h t^2 d_{major}}}-1\right)+\frac{F_{ax,R}}{4}, \quad (4b)$$

$$F_{v,R,mode3} = 2.3\sqrt{2M_{y,R}f_h d_{major}}+\frac{F_{ax,R}}{4}, \quad (4c)$$

where, f_h is the embedment strength of timber or CLT in [MPa], $M_{y,R}$ is the yield moment of the fastener in [N mm], t is the thickness of the timber or CLT, d is the major diameter of the threaded rod in [mm] and $F_{ax,R}$ is the withdrawal capacity of the fastener. The contribution due to the rope effect, $F_{ax,R}/4$, representing the friction in the shear planes, was neglected as the friction in the shear plane was prevented in the experiments and BoF model. The yield moment, $M_{y,R}$, was determined at a particular angle of rotation, α, in [°] defined in EN 409 as,

$$\alpha = \alpha_1\left(\frac{2.78\cdot\rho}{f_t}\right)^{0.44}+\alpha_2, \quad (5)$$

where α_1 is the rotation angle in [°] dependent on the diameter of the dowel-type fastener, ρ is the density of the timber where the fastener is applied in [kg m^{-3}], f_t, is the tensile strength of the fastener in [MPa] and α_1 is 0° for dowels and bolts. In the standards, Equations (4) and (5) are based on characteristic values in a semi-probabilistic design concept. However, in this study mean values were applied to allow for a comparison with the experimental data and the BoF model predictions. The connection's serviceability slip modulus per shear plane, K_{ser} was determined as proposed in EC5 as,

$$K_{ser} = \frac{\rho_m^{1.5} d_{major}}{23} \quad (6)$$

where d_{major} is the major diameter of the threaded rod in [mm] and ρ_m is the mean density of wood in [kg m^{-3}]. EC5 proposes that for concrete (steel)-to-timber connections K_{ser} be multiplied by two as Equation (6) was derived for timber-to-timber connections.

3 RESULTS AND DISCUSSION

3.1 Model Validation

To validate the BoF model described in Section 2.3 it was used to predict the shear capacity and slip modulus of the experimentally investigated CLT-to-concrete shear connection detailed in Section 2.2. Symmetry and appropriate boundary conditions were used to create the BoF model, illustrated in Figure 3. A comparison of the shear capacity and slip modulus of the connection to i) the EYM and ii) the BoF model, was carried out. Figure 6 summarizes the results from the comparison also indicating the deformed shape of the fastener from the BoF simulations. The global force-displacement behaviour of the connection as predicted by the BoF model showed good agreement with the experimental results. Both the experiments and the BoF model illustrated ductile failure with substantial hardening past the yield point. Figure 6 shows the results from the BoF model, EYM and experiments. The slip modulus and shear capacity from the experiments and the BoF model were determined according to EN 26891 [13], as detailed in Section 2.3.4.

Meanwhile, for comparison to the EYM the embedment strength of CLT, f_h, was determined as the average embedment stress of the parallel and perpendicularly loaded layers (with initial slip from Figure 4) at 15 mm displacement, 44.8 MPa. The major diameter of the steel rod, 24 mm, was used to calculate the embedment force-displacement data of wood. Similarly, when determining the shear capacity according to the EYM, the major diameter was used. However, the minor diameter of the steel rod, 20.3 mm, was assumed to determine the moment resistance of the threaded steel rod, which yielded a plastic moment of $M_{y,R} = 1169$ kN mm. The contribution from the rope effect was neglected as the test set-up ensured no friction occurred between the concrete and CLT surfaces.

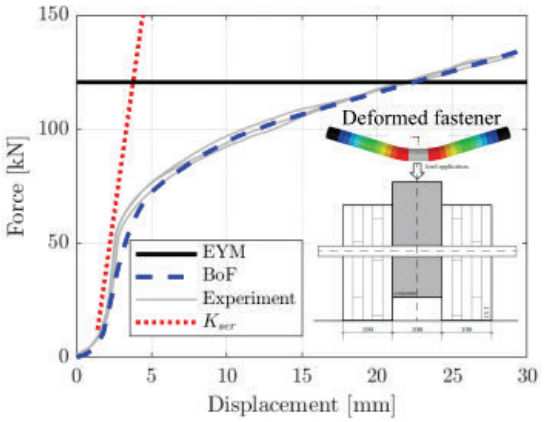

Figure 6: *Comparison of the global force-displacement results from the experiments to the BoF prediction and the EYM according to Eurocode 5.*

The results, summarised in Table 1, revealed that the EYM overestimated the shear capacity of the connection by 13%. On the contrary, the BoF model predicted the shear capacity rather accurately. The EYM assumes full utilization of the plastic moment of the fastener and ideal plastic behaviour of the wood embedment, which in the experiments and BoF model is not reached for all areas along the fastener. The BoF model underestimated the slip modulus by 20%. On the contrary, K_{ser} overestimated the slip modulus by 29%. The overestimation of K_{ser} is similar to what Dias et al. observed in [14]. The underestimation from the BoF model was attributed to the use of the minor diameter instead of the major or effective diameter of the threaded steel rod which results in a lower embedment stiffness and lower yield moment, $M_{y,R}$, of the threaded steel rod, and thus, lower shear capacity and slip modulus. The deformed shapes of the fastener from the BoF model and experiment agreed well with failure mode 2 from EYM, characterized by clamping of the fastener in the concrete with a deformation of the fastener in the CLT.

Table 1: *Comparison of BoF model and the EYM predictions to the experimental results of the CLT-to-concrete connection.*

Shear capacity [kN]			Slip Modulus [kNmm^{-1}]		
EYM	BoF	Experiment	K_{ser}	BoF	Experiment
120.6	106.5	107.2	45.7	28.4	35.5

3.2 Parameter study

A preliminary parameter study was carried out to investigate the influence of dowel diameter, initial slip, concrete stiffness, friction along the fastener, and axial resistance due to the washer on the global force-displacement response of the BoF model prediction discussed in Section 3.1. In this parameter study, only one parameter alteration was done per study, as compared to the reference connection. The results, shown in Figure 7, indicate that altering any of these five parameters resulted in a change in the global force-displacement response of the connection, thereby influencing the connection shear capacity and slip modulus.

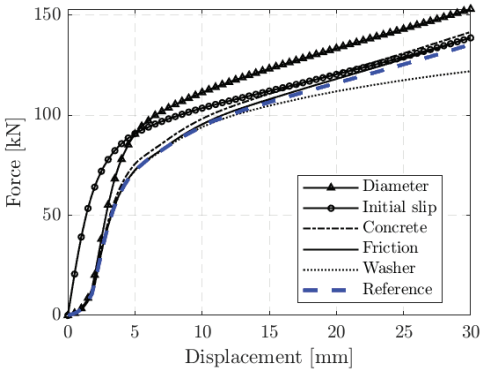

Figure 7: *Initial parameter study of various factors that influence the force-displacement behaviour of the CLT-to-concrete reference shear connections.*

The results from this preliminary parameter study are summarised in Table 2. The slip modulus and shear capacity of the connection were assessed according to EN 26891 [13]. This investigation revealed that assuming the major instead of the minor diameter of the rod yielded the highest increase in shear capacity of the reference connection by up to 16%. Additionally, neglecting initial slip, assuming stiffer and stronger concrete and a higher friction coefficient resulted in 5%, 4% and 1% increase in shear capacity, respectively. However, neglecting the washer yielded a reduction of the shear capacity by 2%. Moreover, the study of the aforementioned parameters shows that, neglecting the initial slip resulted in the highest increase in the slip modulus of 28%. Furthermore, assuming the major instead of the minor diameter, stiffer and stronger concrete and a higher coefficient of friction caused 18%, 6% and 1% increase in the slip modulus, respectively. Neglecting the washer had negligible influence on the slip modulus. However, upon further assessment it was evident that the influence of the washer and friction were more important for the behaviour beyond 15 mm displacement. Furthermore, the effect of the washer is overlaid with the effect of the friction along the fastener between fastener and CLT. A 1% increase in the force due to an increased friction coefficient was found at 9 mm displacement. The force further increased with increased fastener displacement, finally yielding 3% higher force than the reference connection at 30 mm displacement. Similarly, the influence of the withdrawal capacity due to the washer was observable beyond a displacement of 13 mm, where the force was 1% lower than in the reference connection. Increased displacement showed a marked increase of the influence of the washer. At a maximum displacement of 30 mm, neglecting the washer yielded a 10% lower force.

Table 2. *Influence of various parameters on the shear capacity and slip modulus of the reference connection.*

Parameter	Reference Value	New value	Shear capacity	Slip modulus
Diameter	20.3 mm	24 mm	+16%	+18%
Initial slip	2 mm	0 mm	+5%	+28%
Concrete	$3 \cdot f_{h,inter}$ $3 \cdot k_{f,el}$	$4 \cdot f_{h,inter}$ $4 \cdot k_{f,el}$	+4%	+6%
Friction	0.3	0.4	+1%	+1%
Washer	Included	Neglected	-2%	~0%

With these findings, an in-depth parameter study was done to look further into the influence of four out of the five aforementioned parameters. The influence of the washer capacity on the connection shear capacity is not presented since a similar behaviour as for the coefficient of friction was seen. As a reference, the connection illustrated in Figure 3 was used. Three important items should be noted to guide the discussion hereafter regarding the reference connection: i) embedment stress-displacement data was used without the initial slip, see Figure 4, ii) the washer was neglected, and iii) the threaded rod was modelled using the major diameter. All other properties of the BoF model, the elasto-plastic behaviour of the threaded rod and concrete embedment properties were used as specified in Section 2.

3.2.1 Diameter of threaded rod

The diameter of a fastener influences its mechanical properties as the moment resistance increases with increase in the diameter. Therefore, it follows that using the major diameter of the threaded rod will result in increased shear capacity and slip modulus. However, assuming the major diameter, d_{major}, implies that the shank of the threaded rod is larger. To investigate the influence of assuming the yield moment for the minor or major diameter, i.e., d_{minor} or d_{major} for modelling the threaded steel rod, several BoF models were created for various threaded steel rods major diameters, 10 mm $\leq d_{major} \leq$ 30 mm. The ratio of d_{minor} to d_{major} ranged between 0.88 and 0.83. For the BoF simulations, firstly, the threaded steel rod was modelled using d_{major}, like in the reference model, and secondly, variant models of the reference connection were created with the threaded steel rod modelled using the d_{minor}. For both models, the force-displacement data used for the wood in the CLT, determined according to Equation (5), was calculated using the d_{major}. Furthermore, the results were compared to the EYM. In the latter, the rope effect, representing the friction in the shear planes, was neglected as the friction

in the shear plane was prevented in the experiments and BoF model. The yield moment applied in the EYM was determined for the maximum bending angle, α, using i) d_{minor} and ii) d_{major} according to EN 409 [23].

The results showed that assuming the yield moment from d_{minor} resulted in reduced shear capacity and slip modulus for both the BoF model and the EYM, see Figure 8. This was attributed to the reduced mechanical properties of the fastener. A comparison between the BoF model predictions showed that assuming d_{minor} resulted in up to 21% reduction in shear capacity for the 10 mm threaded rod. The reduction in shear capacity was lower for larger diameters of the threaded rod. The BoF model for the 30 mm threaded rod showed 14% reduction in shear capacity.

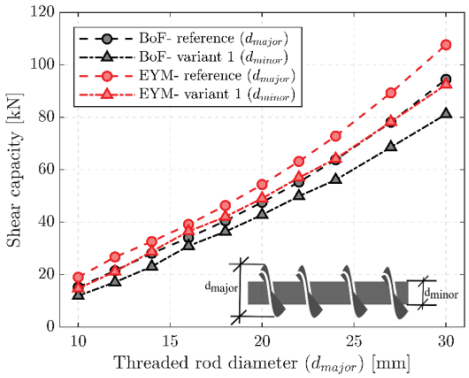

Figure 8: *Comparison of the BoF model and EYM predictions for shear capacity of a CLT-to-concrete connection, per shear plane, while using the minor and major diameter.*

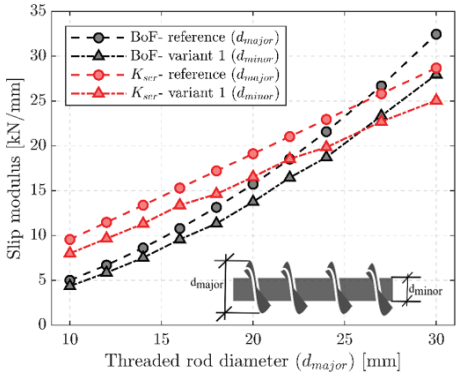

Figure 9: *Comparison of the BoF model and K_{ser} predictions for slip modulus of a CLT-to-concrete connection, per shear plane, while using the minor and major diameter.*

A comparison of the results from the BoF models to the EYM showed that shear capacity predicted from the EYM was on average 15% and 17% higher than the equivalent BoF model predictions utilizing the d_{major} and d_{minor}, respectively. The difference was highest at smaller diameters of the threaded rod with up to 20% and 19% higher shear capacity in the EYM than the BoF model with d_{major} and d_{minor}, respectively. The difference between EYM and BoF model could be because the EYM assumes full utilization of the plastic moment of the fastener and ideal plastic behaviour of the wood embedment, which in the BoF model is not reached for all areas along the fastener. Thus, the EYM will give an upper limit for the connection capacity if the input for the embedment strength is used as assumed in this study. An analysis of the connection's slip modulus showed that BoF models that utilized d_{major} yielded on average 13% higher slip modulus compared to equivalent BoF models that utilized d_{minor}, see Figure 9. The comparison between K_{ser} and BoF model predictions for connection slip modulus showed that K_{ser} yielded higher slip modulus. The difference was highest for small dowel diameters with up to 48% and 56% higher K_{ser} as compared to equivalent BoF models that utilized d_{major} and d_{minor}, respectively. The difference reduced with increased dowel diameter, with models utilizing threaded rod major diameters, d_{major}, ranging between, 24 mm < d_{major} < 26 mm, showing rather good agreement with K_{ser}. However, for threaded rods with diameters, d_{major} > 26 mm, K_{ser} yielded a lower slip modulus of the CLT-to-concrete connection as compared to the BoF model. These findings highlight the disadvantage of K_{ser} being defined independent of the connection failure mode, resulting in a substantial simplification for certain connection layouts.

3.2.2 Initial slip

Initial slip refers to the displacement that occurs between fastener and borehole before full contact is achieved with the surrounding timber matrix. This phenomenon leads to a reduced initial elastic foundation modulus, $k_{f,el}$, for the wood as detailed in Section 2.3.1. Therefore, this parameter study investigates the influence of the initial slip on the shear capacity and slip modulus of CLT-to-concrete connections. Several models of the CLT-to-concrete connection were created for various threaded rod diameters from 10 mm to 30 mm, using the BoF model with embedment stress-displacement data i), without initial slip (reference) and ii) with initial slip (Variant 1), illustrated in Figure 4. The results showed that BoF models of the reference CLT-to-concrete connection with initial slip yielded on average 4% lower shear capacity in comparison to equivalent BoF models without initial slip, see Figure 10. A similar difference was found for the EYM predictions. This was attributed to the reduced embedment strength for the models with the initial slip. Accounting for the initial slip leads to a shift of the embedment curve. Thus, same absolute displacement values give lower embedment stress for the models with initial slip, especially for embedment loading perpendicular to the grain, which shows an increase in embedment stress after yielding. This effect is reflected also in the embedment strength definition, where f_h was determined at 15 mm displacement according to EN 26891 [13]. The comparison of the BoF model with the EYM showed that the EYM yielded a higher connection shear capacity for both models, i.e. variant 1 and reference, on average 16% and 15%, respectively. The EYMs with smaller threaded rod diameters when compared to their equivalent BoF models showed up to 20% higher shear capacity. Similar to the previous study on the diameter of the threaded rod, the difference reduced with increased diameter. The effect of the initial slip on the connection slip modulus was similar to that on the shear capacity, as the initial slip resulted in a reduced slip

https://doi.org/10.52202/069179-0404

modulus, see Figure 11. In addition to an initial weaker overall response of the connection, the lower slip modulus is also given due to reduced shear capacity that determined the points at 10% and 40% of the shear capacity, between which the slip modulus was determined. The lower point at 10% of the shear capacity was found to be located in the initial softer part of the load-displacement curve, which resulted in a reduced slip modulus of the connection. Consideration of the initial slip caused on average 28% reduction in slip modulus. Moreover, an analysis of variant 1 BoF models, that considered initial slip, showed that K_{ser} prediction yielded a higher slip modulus of all variant 1 BoF models of the CLT-to-concrete connection for various threaded rod diameters. The results for the comparison of the reference BoF models and their equivalent EYMs is as detailed in Section 3.2.1.

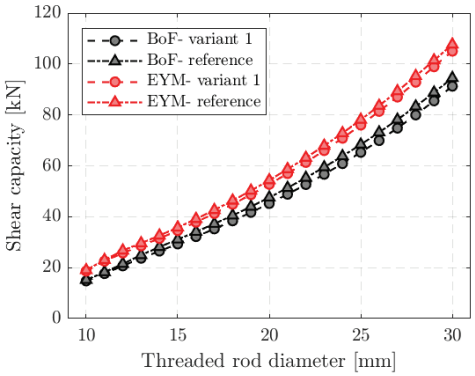

Figure 10: *Comparison of the BoF model and EYM predictions for shear capacity of a CLT-to-concrete connection, per shear plane, to investigate the influence of initial load slip.*

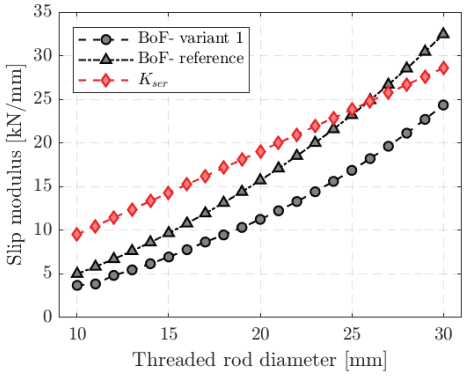

Figure 11: *Comparison of the BoF model and K_{ser} predictions for slip modulus of a CLT-to-concrete connection, per shear plane, to investigate the influence of initial load slip.*

3.2.3 Embedment stiffness and strength of concrete

The stiffness and strength parameters used to determine the load-displacement data for the interaction between the threaded steel rod and the concrete, detailed in Section 2.3.2, were based on the wood properties parallel to the grain and multiplied by a factor of 2 (BoF model variant 1), factor of 3 (reference BoF model) and factor of 4 (BoF model variant 2). The results from this study showed that there was on average 3% increase in shear capacity of the reference connection when the strength and stiffness of the concrete was increased, see Figure 12. Conversely, the shear capacity decreased on average by 6%, with decrease in the concrete strength and stiffness. This difference in the shear capacity due to altering the concrete strength and stiffness was most pronounced for BoF models with diameters less than 13 mm. A comparison of the BoF models with the EYM showed that the EYM yielded a higher shear capacity of 19%, 15% and 12%, than for variant 1, reference connection and variant 2 BoF models, respectively.

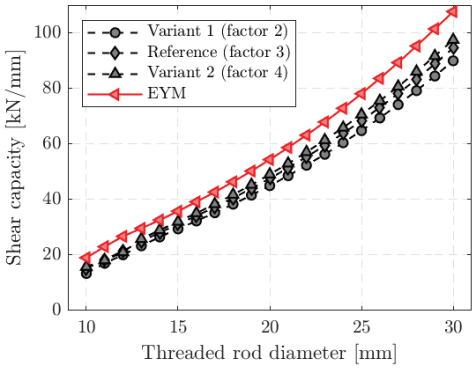

Figure 12: *Comparison of the BoF model and EYM predictions for shear capacity of a CLT-to-concrete connection, per shear plane, to investigate the influence of concrete stiffness and strength.*

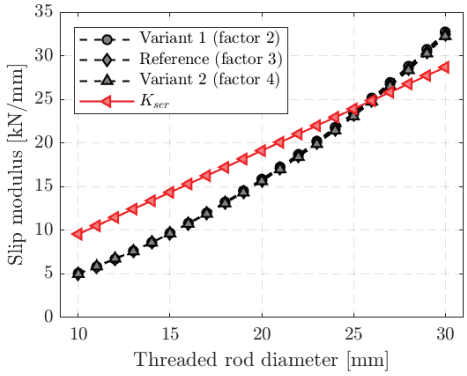

Figure 13: *Comparison of the BoF model and K_{ser} predictions for slip modulus of a CLT-to-concrete connection, per shear plane, to investigate the influence of concrete stiffness and strength.*

The reduction in the difference in the shear capacity between the EYM and the BoF models with increase in concrete strength and stiffness was attributed to increased bending deformation of the fastener within the CLT due to increased clamping. The EYM highlights that the shear capacity is directly linked with the corresponding failure modes [11]. If the side member thickness, in this case concrete, is larger than that of the diameter, failure mode 2 characterized by development of a single plastic hinge in the side member is observed according to the EYM. Therefore, Equation 4(b) was used to determine the shear capacity of the connection. The yield moment associated with this connection was determined for a certain bending angle, α, according to EN 409 [23]. Increasing the concrete stiffness and strength increased the clamping of

the fastener within the concrete whilst increasing the rotation of the fastener in the CLT. Increased fastener rotation led to activation of more spring connector elements in the CLT, and in addition to a larger resistance per spring, due to the larger spring connector displacements, hence increasing the shear capacity. Contrary to the findings on shear capacity, increasing the strength and stiffness of concrete had negligible effect on the slip modulus of the connection, see Figure 13. A comparison of the results from BoF models, variant 1 and variant 2, to equivalent BoF models of the reference connection for varying diameters, showed less than 1% difference. Similar to previous studies, K_{ser} yielded higher slip modulus for most of the BoF models considered. The results were similar to the comparison of reference BoF model to equivalent EYM detailed in Section 3.2.1.

3.2.4 Friction

The influence of friction between the rod and the wood on the shear capacity and slip modulus of CLT-to-concrete connections was investigated for various diameters of the threaded rod. The friction coefficient, μ. was altered, such that for each threaded steel rod considered for this study, two variants of the reference BoF model (μ=0.3), were created. BoF model variant 1 assumed μ=0 and BoF model variant 2 assumed μ=0.6.

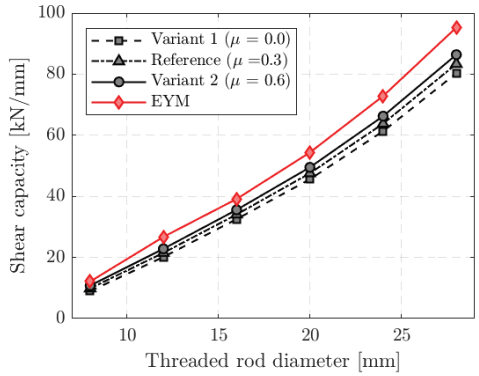

Figure 14: *Comparison of the BoF model and EYM predictions for shear capacity of a CLT-to-concrete connection, per shear plane, to investigate the influence of friction.*

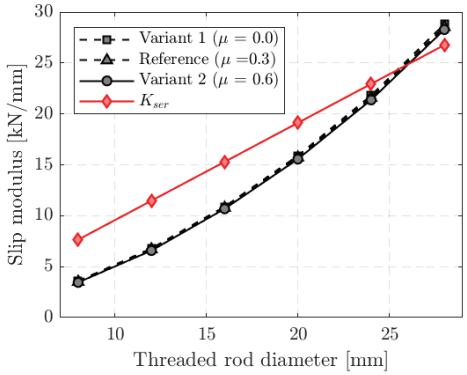

Figure 15: *Comparison of the BoF model and K_{ser} predictions for slip modulus of a CLT-to-concrete connection, per shear plane, to investigate the influence of friction.*

A comparison of the reference BoF model with variant 1 and 2 was carried out. The results showed that increasing the friction coefficient in BoF model variant 2 led to a subsequent increase in the shear capacity. On average, this increase was 5%, with higher relative increase for smaller threaded rod diameters, see Figure 14. Similarly, assuming no friction, i.e., μ=0 in BoF model variant 1 led to a 5% reduction in shear capacity when compared to the reference model. As discussed for the preliminary parameter study in Section 3.2, a considerable large connection displacement is needed to cause a substantial inclination of the fastener, to take an effect of the axial force component caused by friction on the connection shear resistance. The EYM prediction was not influenced by a change in the friction coefficient. On average, the EYM recorded, 18%, 13% and 9% higher shear capacity than BoF model variant 1, reference BoF model and BoF model variant 2, respectively. Similar to the findings in the parameter study on the influence of concrete stiffness and strength, in Section 3.2.3, there was negligible influence of the friction coefficient on the slip modulus of the connection, see Figure 15. These findings are similar to results from a parameter study on the influence of the axial fastener behaviour on the shear capacity of steel-to-timber connections in [19].

4 CONCLUSIONS

The beam-on-foundation (BoF) method was applied herein to predict the shear capacity and slip modulus of CLT-to-concrete connections. The parameter study rests on a validation of the BoF model with experiments on a CLT-to-concrete connection with a single threaded rod. Results indicated validity of the BoF model for this application by a good agreement of the nonlinear load-displacement behaviour, and thus of the shear capacity and slip modulus, between simulations and experiments. From the comprehensive parameter study, it can be concluded that:

- Shear capacity and slip modulus are substantially influenced by the choice of either using the minor or major diameter of the threaded rod for BoF simulations and EYM predictions.
- Consideration of the initial slip in the BoF model results in reduced shear capacity and slip modulus of CLT-to-concrete connections, determined according to EN 26891.
- Varying the friction coefficient between rod and wood between 0-0.6 and varying the embedment properties of concrete had negligible influence on the slip modulus, and only a minor influence on the shear capacity of the investigated CLT-to-concrete connections.
- K_{ser} proposed in EC5 was found to give simplified slip modulus predictions for CLT-to-concrete connections, since the influences of parameters like e.g. the fastener slenderness, are not considered in the design equation, but their impact was shown by the BoF model.

The BoF model was found to be useful in determining both the slip modulus and shear capacity of the connection. Application of the model in engineering

https://doi.org/10.52202/069179-0404

design can lead to more reliable and economic connections in CLT-to concrete composite slabs.

5 ACKNOWLEDGEMENT

The authors would like to acknowledge the support from the Knowledge Foundation through the project 'Improving the competitive advantage of CLT-based building systems through engineering design and reduced carbon footprint' (project number 20190026).

EXPERIMENTAL AND NUMERICAL STUDY OF MOULDED WOOD TECHNOLOGY WITH FIBRE-PLASTIC COMPOSITE NODE ELEMENTS

Siavash Namari[1], Peer Haller[1]

ABSTRACT: The reduction of CO2 emissions and the enhancement of resource efficiency have emerged as significant motivators for research and development activities. One particular area of interest in sustainable building materials is moulded wood tubes, which offer the benefits of wood as a renewable resource and the material efficiency of composite construction. These tubes are well-suited for lightweight structures that are subject to dynamic and static loading. This paper proposes a method for joining thin-walled wooden elements with node elements composed of fibre-reinforced plastic (FRP) that incorporates integrally manufactured multilayer 3D fabrics that are adaptable to the component geometry. The investigation includes both experimental and numerical approaches to establish the load-bearing capacity of such connections. Experimental tests were conducted on specimens of different sizes under tension, while numerical models were developed to assess the load-bearing behaviour of small and large scale tests, as well as perform static verifications. The proposed solution has potential applications in the fabrication of a solar roof demonstrator. The results suggest that the use of FRP for connecting moulded wood tubes is a viable approach.

KEYWORDS: Connections, Composite structure, Moulded wood, Compressed wood, Fibre-reinforced plastics (FRP)

1 INTRODUCTION

The Federal Republic of Germany's industrial policy goals of reducing CO2 emissions and enhancing resource efficiency have served as a catalyst for research and development efforts. These endeavours necessitate the utilization of sophisticated and expensive tools, but the structural mechanical performance remains suboptimal [1].

Besides the use of sustainable building material such as wood, the use of high-performance composite materials instead of traditional metallic construction materials is an efficient way of improving material and energy efficiency while decreasing carbon dioxide consumption. The potential of moulded wood technology in combination with fibre composite materials is particularly relevant in spatial structures which static systems primarily transmit normal forces. Recent studies have shown that the cellular structure of wood can be compressed under the influence of moisture and heat due to its thermo-hydro-mechanical properties [2]. This process is used by researchers to create moulded wooden construction elements formed from thin compressed wood panels, with a tubular cross-section being the simplest form. A tubular cross-section represents the simplest form, combining high structural strength for compression with very low material consumption [3]. Compared to massive solid wood cross-sections typically used in timber construction, moulded wooden tubes combine high structural strength for compression with very low material consumption, enabling a weight-efficient application of the material and saving up to 70% of the raw material [4]. Moulded wooden tubes can be reinforced with high-performance fibres such as carbon or glass to create resource-efficient, high-performance composite wood components [5]. The positive properties of wooden tubes are especially useful in three-dimensional load-bearing structures, where compressive forces predominate due to the static system. These tubes have been used as rod-shaped construction elements in truss or lattice structures, including a 30m high truss structure built as a support for a 10kW wind power plant (see Figure 1) [6], [7].

Figure 1: *Left: Moulded wooden tubes with reinforcements using glass, carbon or aramid fibres, Right: Wind power plant made of moulded wood tubes and steel connecting elements*

Previously, steel joining solutions for construction required heavy castings or expensive, multi-step sheet metal forming. However, this project aims to develop a more efficient manufacturing and assembly process for lightweight timber construction systems. The paper will use moulded wood tubes and fibre-reinforced plastic composite as connection means, which are made of multilayer 3D fabrics. The adhesive connection of the node elements with the shaped wood profiles offers

[1] Siavash Namari, Peer Haller, Technische Universität Dresden (TU Dresden), Institute of Steel and Timber Construction, siavash.namari@tu-dresden.de

https://doi.org/10.52202/069179-0405

constructive advantages compared to mechanical fasteners, which imply a weakening of the cross-section. The combination of moulded wood and fibre-reinforced plastic enables versatile modular construction solutions that meet architectural and structural requirements. This innovative approach aims to remove the significant barriers to sustainable, lighter and architecturally diverse construction methods. After completion, a solar roof will be built as a technology demonstrator. The demonstrator will be characterized by high prefabrication, low dead weight with high load-bearing capacity and material efficiency. The construction should also be able to be implemented in a short assembly time. The final design is a pavilion with a roof made of solar modules that functions as a solar charging station, supported by two moulded wood elements (Figure 2).

Figure 2: *Design of the technology demonstrator*

Tensile testing has been performed on test specimens with varying geometries based on a design featuring 33, 25 and 17 cm long glass fibre-reinforced plastic (GRP) slats. These tests will be modelled using finite element method (FEM) software and compared against the test results. Subsequently, the demonstrator will be modelled in FEM software to showcase the performance of the lightweight wood support system. The load-bearing behaviour of the developed modules will be evaluated under site-typical load scenarios, providing valuable insights into their practical application. Any necessary design optimizations will be identified and incorporated accordingly. Ultimately, a comprehensive recommendation for structural implementation in lightweight timber construction support systems will be presented.

2 MATERIAL

2.1 Thermo-Hydro-Mechanical Treatment

In mechanical wood technology, it is well known that low strength and durability can be improved by treatment with increased temperature and humidity. These processes are known as Thermo-Hydro-Mechanical (THM) processes. Under THM conditions, the amorphous building blocks of the wood structure soften, which enables shaping, compression and bending. The viscoelastic behaviour of the wood is utilized, whereby at low temperatures and low moisture content, the wood behaves like glass, while at high temperatures and high moisture content, it shows entropy-elastic behaviour.

Thermo-hydro-mechanical compression can reduce the cavities in the wood cells, especially in hardwood. Theoretically, wood can be compressed in all directions (longitudinal, tangential, or radial), but compression in the radial direction is the most practical. Due to the porous cell structure, it is possible to contract the cell structure in the compression process with an appropriate process regime without causing microscopic damage to the cell structure. The process of compressing wood typically occurs in a hot press with a constant displacement rate at high temperatures ranging between 120 to 160 ◦C. If the press is opened immediately after the compression process, compressed wood (CW) may exhibit partial springback or return to its original shape. To counteract this, it is necessary to cool the CW specimens down to below 80 ◦C while in the compressed state. Post-treatment may be required subsequently to limit this effect and ensure dimensional stability. Recovery, a characteristic of CW whereby it achieves partial or complete recovery of its original dimensions when exposed to water or high humidity, is known as shape memory. In this project, to avoid CW springback, specimens were cooled to 40 ◦C after compression, thereby ensuring stable dimensions. The research results show that CW and CW connectors offer a significant increase in the strength and stiffness properties compared to normal softwood or hardwood [8].

2.2 Moulded Wood Production

Wood has numerous advantages as a building material, including its eco-friendly properties and environmental friendliness. While wood performs well in most areas, some materials may outperform it in terms of specific properties such as density and Young's modulus. To make the most of wood as a building material, it is crucial to consider both its advantages and disadvantages. For example, wood has lower strength, is anisotropic and is vulnerable to weathering [9]. To maximize wood's positive attributes, it is often used in combination with other materials such as steel, concrete, glass and textiles in sustainable construction methods. Softwood is the most commonly used type of wood in construction because of its straight, long trunks. The development of moulded wood technology also opens up new possibilities for using deciduous trees in construction, contributing to a more sustainable building industry.

In addition to mechanical properties, the structural and economic performance of a cross-section is also important. The sawmill, as the primary step in the value-added chain, plays a crucial role in the provision of full cross-sections from a grown tree. However, the process results in significant material losses and a lack of competitiveness, as only about 60% of the stem wood remains of value [10]. To improve efficiency, material savings must be made during cross-section formation. The yield of raw wood and waste significantly affect the price structure of wood products, favouring tree species with long and straight trunks, such as softwoods like spruce, over hardwoods with branched crowns like beech or oak. The manufacturing of rectangular cross-sections involves traditional machining methods, including sawing, milling,

planning and sanding with minimal energy and force, followed by joining with synthetic binding agents.
The use of round and rectangular solid cross-sections in wood-based materials is commonly accepted in the construction industry [9]. However, compared to other technical profiles made of metal or plastic, the full cross-sections created by traditional processing methods have a lower second-degree moment of Inertia. The compression process creates deformation reserves in the wood, which are later used for bending. With a suitable process regime, depending on temperature, humidity and compression speed, the compression process is reversible and fixable with almost no damage to the cell structure. The compression direction runs in the plane of the plate. In the subsequent moulding process for the production of thin-walled tubular cross-sections, the solid wood panel is shaped into profiles with the addition of heat and moisture and then fixed, as can be seen in Figure 3.

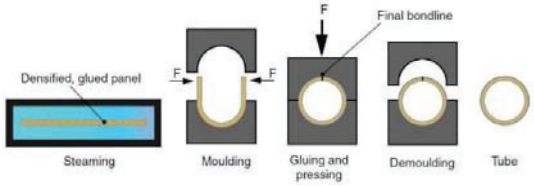

Figure 3: *Schematic production of a wooden tube by shaping* ***[11]***

The ability of cell walls to recall memory means that the folding is reversible and the radius of curvature of the moulded wood tubes depends on the intensity of the previous compression. All open and closed profile shapes with any length and thickness can be produced using this technique. The successful process for manufacturing moulded wood profiles is patented by the Technical University of Dresden. The numerous investigations and derived properties of the moulded wood profiles have shown decisive advantages, including a lower weight compared to the full cross-section, small shrinkage, the use of all types of wood, including deciduous wood of lower quality, low waste in the sawmill, forming instead of machining and the high synergy of the bond with fibres. Product-specific evaluations in comparison with sawn, glued and glued laminated timber have demonstrated the technology's biggest advantages.

2.3 Fibre-Plastic Composite Node Elements

As mentioned, this paper aim to develop new node elements for lightweight structural systems made of moulded wood elements. The aim is to ensure a correct and constructive connection between the moulded wood profiles to transfer stresses caused by load between them. The node elements will be produced from multi-layer fabric and resin systems. Previous material models will be used to calculate the material parameters and the appropriate polymeric resin of the matrix will be selected based on simulations.
The fibre-reinforced plastic node elements offer a multitude of advantages over existing metal connections. For successful use in lightweight support systems, the advantages must be put into practice. The decisive advantages are, among other things, the significantly reduced weight of a node element made of fibre plastic compared to steel alternatives and the resulting lower assembly effort due to the unnecessary use of heavy equipment. This results in the possibility of realizing new supporting structures. A symbolic node element is shown in Figure 4.

Figure 4: *Node element made of carbon fibre* ***[12]***

The connection of moulded wood profiles with fibre-plastic composite node elements is a relatively new field and as such, there is no established calculation method to evaluate the material behaviour of the structural adhesive connection. Therefore, previous material characteristics of glued wooden surfaces must be adapted to the structural adhesive connection. The load-bearing capacity of a structural adhesive connection primarily depends on the shear and transverse tensile stresses occurring in the adhesive surface.

3 EXPERIMENTAL PROGRAM

3.1 Material and methods

The aim of these tests was to use force-displacement diagrams to quantify the load-bearing behaviour and characterize the failure mechanisms. Proportionally reduced test specimens were produced for the uniaxial tensile test and three different test specimen series with different dimensions were produced. Spruce glued laminated timber compressed by around 25% was used as the material and five test specimens were produced per series.
The test specimens were designated according to the length of the lamination and the GRP lamellae. The designation of the test specimen of GRP-H33 shown in Figure 24.

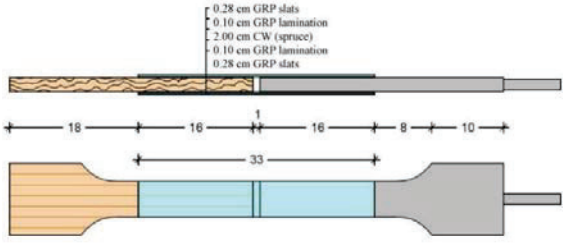

Figure 5: *Test specimen GRP_H33*

Tensile test specimens made of compressed spruce wood, fibreglass lamination, Plexus MA300 adhesive and two Glass Reinforced Plastic (GRP) lamellas. The test

https://doi.org/10.52202/069179-0405

specimens were assembled by sanding and applying a spacer and an adhesive layer, followed by the GRP lamella set. The elastic adhesive connection was used to absorb tensile shear loads that primarily occur in the tensile test. Three different test series with different dimensions were produced for the tensile tests. The results were evaluated based on the force-displacement diagrams.

Table 1 summarizes the properties of the materials used in the test specimens, including the density, tensile strength and Young's modulus of the compressed wood, glue and GRP.

Table 1: *Properties of the materials of the test specimens*

Characteristic		CW	Glue	GRP
density ρ	[g/cm³]	0.61	0.97	1.76
tensile strength R_m	[N/mm²]	55.9	20.7-27.6	319
Young's modulus E	[N/mm²]	15600	931-1137	20500

The tensile test was conducted at room temperature of 20°C and 65% relative humidity, in accordance with ISO 554:1976-07 and The test run corresponds to the loading procedure DIN EN 26891:1991-07. The test setup, involved hanging the test specimens in the testing machine with a steel connector. The ALMEMO 2890-9 precision measuring device and data logger, together with two displacement sensors, were used to measure the applied force and displacement.

3.2 Experimental setup and results

The samples showed a linear load-displacement behaviour until sudden and brittle failure of the fibre reinforcement and wood cross-section, with the specimens failing at an average load of 65 kN.

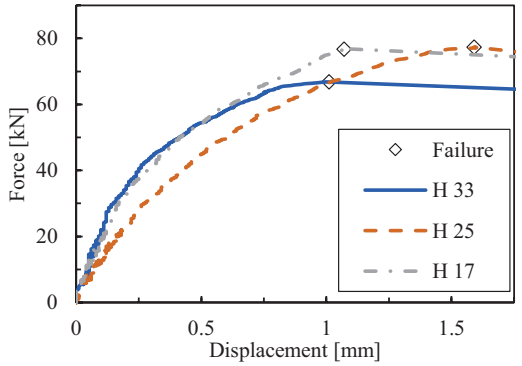

Figure 6: *Force-displacement diagram for the tensile test series*

Test series consists of three test bodies with GRP lamellae of different lengths, one for each previously described test body series. Table 9 summarizes all relevant properties of the test body series for the main conclusions, with values obtained from the mean values of all considered test specimens. The maximum load is greater for the test specimen series with a GRP lamella length of 25 cm, while the displacement is larger for the 33 cm specimens with wooden components. The steel component values have only marginal differences. The smallest displacements at the highest possible maximum loads are achieved for the test specimen series with a GRP lamella length of 17 cm. Although the maximum load and displacement are of secondary importance due to the different test specimen geometries, the expected maximum load of 55.9 kN is exceeded for all test specimen series with wooden components, indicating that the wooden body has a higher tensile strength in the composite.

Table 2: *Maximum loads, displacements of the test series*

Test specimen	H 33	H 25	H 17
F_{max} [kN]	64.79	77.48	73.79
u_{max} [mm]	1.24	1.45	1.05
k_s [kN/mm]	85.50	78.44	99.60

The displacement modulus, denoted as K_s, is a measure of the stiffness of a timber connection and is used to assess its load-bearing capacity and serviceability. It represents the force required to produce a displacement of 1 mm. The DIN EN 26891:1991-07 test procedure is used to determine the displacement modulus for mechanical fasteners. However, since there is no standard for adhesive connections in Euro code 5, this procedure is also used to evaluate the stiffness values of adhesive wood connections, enabling comparison of the test specimens' stiffness values. For mechanical fasteners, the displacement modulus is determined by the load application, structural conditions, connection type, load-bearing capacity and accuracy of fit, characterizing the displacement of the fastener. However, for adhesive connections, determining the displacement modulus is more challenging as it depends on the displacement of the entire adhesive surface and, therefore, the test specimen. The force-displacement relationship is used to derive the stiffness of adhesive connections.

Four different failure modes were identified, with the failure of the lamination being the most critical. For the failure of the lamination, two different failure modes were observed: either the lamination detaches from the wood surface or the wood-side lamination detaches from the adhesive bond but remains attached to the wood surface. The exact differentiation between these two possibilities is not possible due to the overall failure of the lamination. Another type of failure is the breakage of the GRP lamella, which mainly occurs at the connection to the steel member and occurs both vertically and horizontally. The failure of the splice and the fracture of the wooden body are also observed. The irregular fractures of the wooden specimens can be due to irregularities in the wood or knots. Figure 7 shows an example of the failure mechanism of the tensile test.

https://doi.org/10.52202/069179-0405

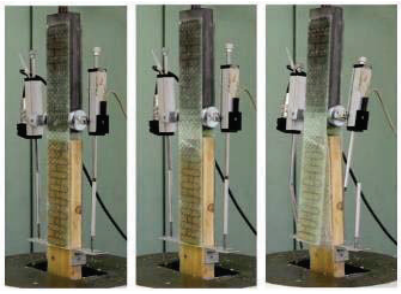

***Figure 7:**, An example of failure mechanism of tensile test*

The lamination failure is evident in almost every test specimen and can be identified as a critical failure. In the test specimen series H33, the failure of the GRP lamella is also identified for all test specimens. There are occasional breaks in the wooden body across all series, but failure mode (d) is not decisive.

For all test specimens of the series with steel components, the breakage of the GRP lamellae is recognizable as the decisive failure. The failure of the adhesive connection only occurs once and can be explained by the insufficient processing of the adhesive and the resulting weak points.

In summary, while the lack of video recordings makes it difficult to fully understand the failures, the images of the test specimens allow for the assessment of the relevant failure mechanisms. The failure of the lamination and the breakage of the GRP lamellae are identified as the critical failures.

4 NUMERICAL MODEL

The modelling of wood is a complex and challenging task due to the many structural parameters and the variable environmental conditions that influence the mechanical properties of the material. Moisture, in particular, has a significant impact on the mechanical behaviour, along with the type of load, duration and temperature. Natural features such as density, knots, aging and orthotropic also affect the material properties.

For Finite Element Method (FEM) models, no universal model exists that can fully and precisely describe the constitutive relationships of wood. Different models and approaches are used, depending on the type of problem to be solved. Fracture mechanics approaches are used for brittle problems, while a combination of the classical flow theory of plasticity with a criterion according to Hill, Hoffman, or Tsai-Wu is used for ductile problems. Physical, mathematical-static and hybrid model approaches can also be used and simplifications related to damage and failure may be applied to ensure reliability.

This article focuses on a mathematical-static model, which has a high degree of reliability but limited scope. The material properties used in the model are selected based on the load and are divided into the elastic range, the transition from elastic to plastic with the associated yield condition and the plastic range with the hardening law. According to the theory of material behaviour modelling, there are four essential building blocks for creating a reliable model. These include a valid material model, loading condition, a hardening law and reliable material data [13], However, modelling materials realistically can be challenging due to various factors. For instance, the yield surface only describes the moment when failure occurred but not the type of failure.

Despite these difficulties, the approaches described serve as a simplified assumption for understanding the material behaviour and subsequent finite element (FE) modelling. Modelling wood as a material is a complex subject influenced by various factors such as moisture, viscoelasticity and so on in addition to elastic and plastic deformation [13]. The ANSYS software, which is a finite element software used to solve linear and nonlinear problems in structural mechanics, is employed to model tensile tests and later the demonstrator. The simulation process used an extensive trial-and-error method until the simulation results matched the experimentally performed tensile tests.

4.1 Material Parameters

The materials of the components and their properties are defined in the technical data. The material properties of the GRP slats are taken from the material data sheet provided. The density, modulus of elasticity and maximum tensile strength are given and a bilinear isotropic hardening model is selected. The yield point and tangent modulus are required to characterize the bilinear isotropic hardening, but there is no data for either property, so assumptions were made and continuously improved during the simulation process. The values summarized in Table 10 are assumed as material properties.

***Table 3:** Material properties of the GRP slats*

Characteristic	Value	Unit
density ρ	1760	kg/m²
Young's modulus E	20500	MPa
Poisson's ratio v	0.18	-
bulk modulus K	10677.08	MPa
shear modulus G	8686.44	MPa
Stretch limit R_p	75	MPa
tangent modulus E_T	8000	MPa
Max Tensile Strength R_m	319	MPa

Similar to the GRP slats, the lamination of wood is made up of a fibre material and resin. The material properties are summarized in Table 4

***Table 4:** Material property of the lamination of the wood*

Characteristic	Value	Unit
density ρ	1760	kg/m²

shear modulus G	7627.12	MPa
Stretch limit R_p	65	MPa
tangent modulus E_T	5000	MPa
Max Tensile Strength R_m	250	MPa

https://doi.org/10.52202/069179-0405

The wood component of the test specimen consists of compressed spruce wood with a degree of compressionV of about 25%. Due to the orthotropic, the orthotropic elasticity is used with three Young's modules, Poisson's ratios and shear moduli. The same values are used for the values in the tangential and radial directions, as these differ only minimally in the specified directions and only the properties perpendicular to the fibre were determined in the tests.

In the model used here, the mesh for all 8 components of the test specimen consists of tetrahedrons, as this was the only way to find a solution due to the geometry of the shoulder stick shape used and the size of the mesh.. Overall, the geometry shown in Figure 8 is meshed with 8938 elements and 20657 nodes.

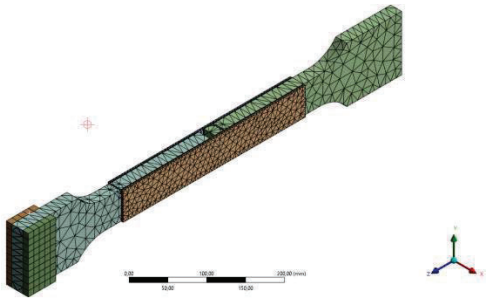

Figure 8: *Meshed geometry of the tensile sample*

4.2 Comparison of the numerical and experimental results

With the described material and simulation parameters, as well as mesh refinement, the force-displacement diagram shown in Figure 9 was obtained. This diagram shows all curves of the tests and the ANSYS model. The model curve is almost identical to that of the tests.

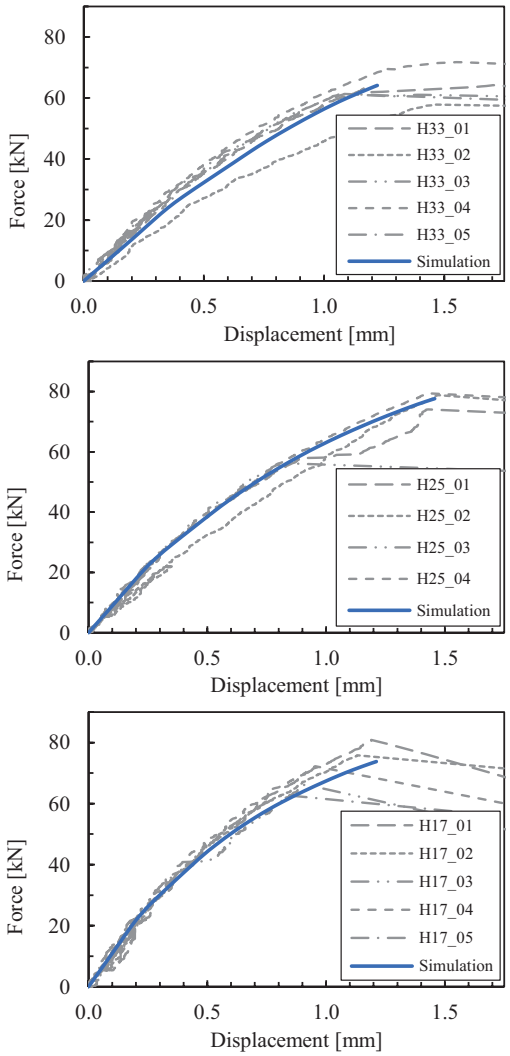

Figure 9: *Comparison of the force-displacement diagrams of test specimen with the numerical model*

For the model of the test specimen with a GRP length of 33 cm, the yield strength of the of the wood was set at 66 MPa based on the test data. To evaluate the model further, the displacement modulus of the tests is compared with that of the model. The displacement modulus is evaluated similarly to the calculation of the displacement modulus of the tests. For a direct comparison, the displacement modulus is evaluated analogously to the expected maximum load of 55.9 kN of the tests.

Figure 10 shows the maximum main stresses of the entire component. The principal normal stress hypothesis is used to predict the failure of brittle materials without yielding.

https://doi.org/10.52202/069179-0405

Positive values indicate tensile stresses and negative values indicate compressive stresses. The highest tensile stress is 305.01 MPa and the highest compressive stress is 59.64 MPa. The exact locations of the maximum stresses are evaluated separately and the GRP lamellae in the transition area from wood to steel components have the highest stress values on the surface.

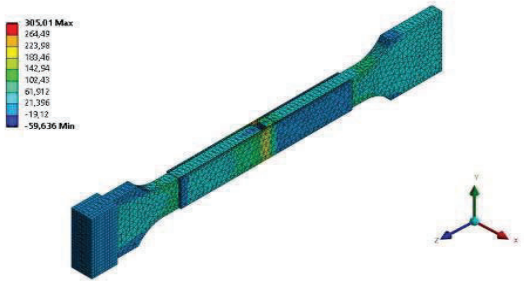

Figure 10: *Maximum principal stresses (MPa) of the entire component H33*

Figure 11 shows the maximum principal stresses of the wood components, which are analysed separately as the weakest part of the composite. Due to the lack of damage in the model, the tensile stresses in the model are compared with the maximum tensile strength or yield point.

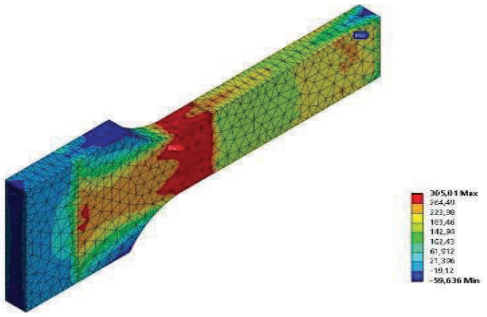

Figure 11*: Maximum principal stresses (MPa) of the timber member H33*

In the positive Z-direction, the maximum stresses over the entire cross-section develop into two stress peaks, which are illustrated in Figure 12. The crack of test specimen 02 of the test specimen series H33 is shown. It is located exactly where the curve of the shoulder stick shape begins and coincides with the edge of the red area of the stress distribution. The maximum tensile stress within the wood component is 66.4 MPa, which exceeds the material's specified yield strength of 66 MPa, causing the wood component to fail.

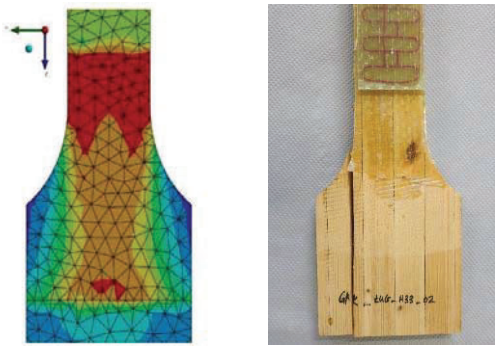

Figure 12: *(left) Stress distribution of the wood on the shoulder stick shape H33, (right) Fracture of the wooden body of the test specimen H33*

Figure 13 (left) shows the stresses curve in the horizontal direction, while Figure 13 (right) shows it in the vertical direction, with the cutting plane at the level of the maximum value. The greatest tensile stress was found to be within the steel component at the edge of the lamination layer.
However, the theory of maximum principal stress only applies to brittle materials and the steel component is the only component exhibiting ductile material behaviour. Therefore, the values of the maximum tensile stresses on the steel component must be interpreted with caution. Furthermore, the stress must be treated with care due to the high stress gradient in the direction of the negative X-axis.

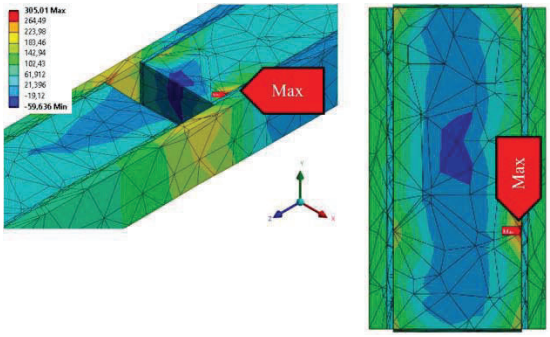

Figure 13: *(left) Stresses in the horizontal section plane H33, (right) Stresses in the vertical section plane H33*

Comparing the stress distribution of the maximum tensile stresses in the wood component and the adjacent slats provides insight into an optimal GRP slat length. The lamellas in the three models show the highest tensile stresses, with decreasing lamella length resulting in an increase in stress despite lower maximum loads. The stress distribution in the wooden component is similar in all models, with stresses increasing from the middle of the test specimen to the end of the GRP lamella.

5 Model of the Demonstrator

The demonstrator will consist of circular-shaped wood profiles and fibre-reinforced plastic node elements. The purpose of this modelling is to evaluate the performance

https://doi.org/10.52202/069179-0405

of the fibre-reinforced load-bearing systems made of wood.

The purpose of the demonstrator is to showcase the aesthetics and performance of moulded wood profiles reinforced with fibre-reinforced plastic node elements, while also serving a practical function. As a result, the building must meet certain construction requirements. To meet these requirements, a pavilion was built with a high enough roof to allow for space underneath and with solar modules as the roof to allow for the generation of solar energy. This energy could then be used to power a charging station for electric bicycles or scooters while also protecting them from the weather.

The pavilion was designed with a bar structure supported by two moulded wood supports that are 3 meters apart, with the node profiles fixed symmetrically to the supports for both sides. The roof was initially planned as an inward sloping barrel roof with innovative curved solar modules, but due to issues with module procurement and unpredictability, the roof shape was changed to a straight through roof. The roof has a surface area of 4.95 meters in length and 3 meters in width, with a one-sided inclination of 3° to ensure water drainage. The solar modules are attached to the edge and centre rails using different aluminium profiles, which are then connected to the moulded wood profiles via steel plates negligible.

The moulded wood supports have a circular ring cross-section with an outer diameter of 23 cm and a wood thickness of 2 cm. The branches connected to the supports have the same dimensions for both supports, with the lower branch connecting to the support at an angle of 55° and a maximum length of 2.022 meters. The upper branch is at an angle of 65° to the support and is 1.788 meters long. The node elements are identical for both columns, with a height of 37.2 cm and a gap between the elements.

The materials used in the model include moulded wood profiles for the supports and branches, fibre-reinforced plastic for the node elements, steel for the edge and centre supports and aluminium for the edge and middle rail. Glass was used for the roof construction, with a high modulus of elasticity of 70,000 MPa and a density of 29.85 kg/m³. The load-bearing behaviour of the wood profiles would be improved with lamination for protection against the weather, but this was not modelled. The calculation model developed for the demonstrator is based on the reliable orthotropic material properties of the wood determined by compression tests on moulded wood pipes. The model assumes an ideal bond between the wood and fibre-reinforced plastic.

The models were based on six possible wind load positions and their respective load combinations. Due to the large number of models and the similarity in the truss structure's behaviour under load, not all models are described. It was observed that a two-sided wind load, regardless of the direction of action, had a more favourable effect on the entire supporting structure than a one-sided load. Due to the loading on both sides, the deformations in the upper and lower branches of the columns were of the same magnitude on both sides. The composite roof had a stiffening effect that prevented major deformations on both sides. The deformations were specified separately for each direction of the coordinate system and Figure 14 provided an overview of the order of magnitude of the total deformation of the demonstrator, showing that the greatest deformations were in the centre of the roof area. The low deflection when the load was introduced at a point indicated that the roof construction was very stiff and could be neglected for the evaluation.

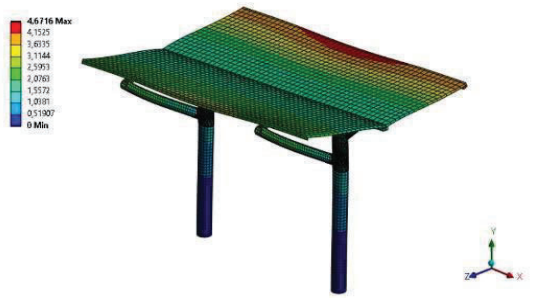

Figure 14: *Total displacement of the model with the load position bilateral wind pressure*

The deformation behaviour of the construction differs between wind pressure and wind suction. Under two-way wind suction and load combination 1, which results in a total uplift load, the structure is displaced in the negative X-direction, while under two-way wind suction the displacement takes place in the positive X-direction. This deformation behaviour can be explained by the longitudinal roof pitch. The normal vector of the wind load points in the same direction as the resulting displacement. Under wind suction, the upper and lower branches deform in the Z-direction in the same amount. Both are pulled upwards as a result of the suction. Under wind pressure, the lower branch deforms more than the upper branch due to its greater length.

The serviceability limit state was checked using the displacements. In order to be able to assess the ultimate limit state, a stress evaluation is required. In the models with wind pressure loading, the largest tensile and compressive stresses occur at the same location. Both maximum values are reached on the inside in the rear upper node element (Figure 15).

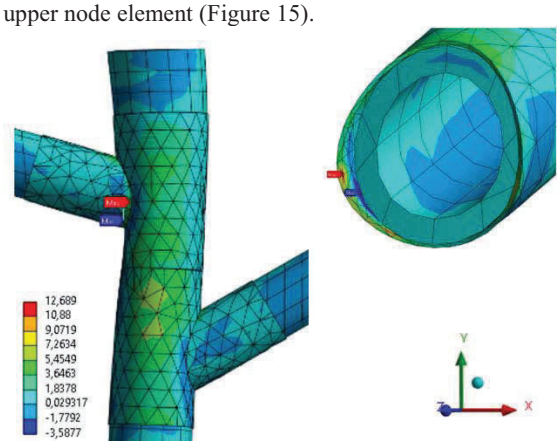

Figure 15: *Maximum principal stresses in model 1 (values in MPa)*

All tensile and compressive stresses that occur in the models are significantly lower than the maximum strengths of the individual materials of the components. The demonstrator model results show that the truss structure is stable enough to withstand maximum external loads.
The deformation behaviour of the bar structure is accurately represented and the maximum displacement values are within permissible limits. The stress evaluation of the supporting structure is consistent with the expected stress distribution and heavily stressed areas. Stress levels in the model are relatively low, but the roof structure has a significant impact on the load-bearing behaviour of the truss structure.

6 CONCLUSIONS

In this paper, the importance of advancing innovative constructions in timber technology was emphasized. While wood has clear advantages in construction, it also has technical limitations that must be addressed. The development of moulded wood profiles has demonstrated great potential for use in architecture, construction, lightweight construction and plant construction, as it improves weak points in technical applications of wood. Additionally, the use of technical fibres and textiles has increased efficiency and lowered material costs in timber construction. The combined use of moulded wood and fibre-reinforced plastics is developed coherent and modular construction solutions that meet a variety of architectural and structural requirements and enable a broad range of applications.
Test programme and the numerical models are being used in an attempt to provide sound knowledge for moulded wood tubes connecting with fibre-plastic composite node elements. The lightweight wood construction system developed features a high degree of prefabrication, extremely low dead weight with high load-bearing capacity, material efficiency and durability. Based on the moulded wood technology, a technology demonstrator in the form of a solar roof will be built.
In summary, the models used in this study were found to reliably represent tests to failure, despite simplifications and idealizations. Results of tensile tests showed that mechanical properties of wood components can be improved in combination with fibre-reinforced plastics, particularly in terms of optimal lamella length. The joining technology of shaped wood profiles and node elements using adhesive technology was found to offer an optimally adaptable force transmission surface, which is an advantage over mechanical connection means. Further testing is needed to ensure functionality under fluctuating mechanical loads and climatic conditions.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the funding provided by the ZIM via Federal Ministry for Economic Affairs and Climate Action of Germany. The authors also thank the project partners Institute of Textile Machinery and High Performance Material Technology of TU Dresden, Korropol GmbH and Niemeier Fahrzeugwerke GmbH for their collaboration.

MECHANICAL BEHAVIOUR OF NOTCH CONNECTION FOR MARITIME PINE CLT-CONCRETE COMPOSITE

Carlos Albino[1], Carlos Martins[2], Cláudio Ferreira[3], Renato Augusto[4], Alfredo Dias[5]

ABSTRACT: Cross Laminated Timber (CLT) is one of the most representative Engineered Wood Products, especially for low- and mid-rise timber buildings. Although in the 2000s, its use in Europe increased significantly, Portugal is still at a starting point and Spain needs a boost for its dissemination. Aiming promotion and dissemination of this type of buildings in SUDOE region, Eguralt project promotes research and innovation capacity for its sustainable growth. As a partner, one of SerQ's objectives is to promote the production of CLT solutions with wood from local species. The advantages of CLT are well known. However, the use of CLT in composite solutions requires the study of the overall performance, namely: stiffness; strength; dynamics and acoustic performance. Continuing recent studies in these areas, this paper presents an experimental campaign on the assessment of CLT-concrete connections and its comparison with the design models available.

CLT was produced at SerQ's facilities with local maritime pine (*Pinus pinaster* Ait.) wood. In situ concrete casting and precast concrete processes were a study variable. Notch shear connectors with different geometries and screws or U-shape rebar cages to prevent uplift, gives the system its composite behaviour. The load capacity of the connectors was theoretically predicted and validated with shear tests, and the experimental results were then compared with those. The results of the specimens cast in situ were satisfactory, while the results of the precast specimens were below expectations.

KEYWORDS: CLT-concrete composite, composite floor, connection, experimental testing, maritime pine, shear test.

1 INTRODUCTION

Both Glued Laminated Timber (glulam) and CLT are the most common used Engineered Wood Products (EWPs) for timber construction (rehabilitation and new buildings) all over the world [1,2]. They are mainly produced by softwoods, namely Spruce (*Picea abies* L.) and Scots pine (*Pinus sylvestris* L.) [3,4]. The current challenge of using timber structures in construction, is due to their positive environmental impact since they have significantly less embodied energy, and associated carbon emissions than equivalent steel and concrete structural systems [5].

The increasing demand for EWPs requires the study of alternative species, also facing some issues related to the environmental and economic impacts due to long-distance transport. Iberian Peninsula has a small number of CLT producers whose focus is the use of local species, namely Radiata pine (*Pinus radiata* D. Don) and Maritime pine (*Pinus pinaster* Ait.). Bonding and mechanical performance of both species, both for glulam and CLT, have already been validated for different adhesives [6,7].

The performance of CLT buildings by itself is recognized. However, adding a layer of concrete on the floor elements significantly increases their ultimate and serviceability performance throughout the increase of stiffness, load carrying capacity, vibration frequencies, and acoustics [8,9]. The key factor for an effective behaviour of both materials is the connection. Within the scope of Eguralt project, an experimental campaign intends to characterize the mechanical performance of CLT-concrete notched connections aiming to obtain an effective solution for medium/long spans (second phase of the study). In addition, focused on sustainability, the main goal is to develop prefabricated solutions that allow easy decoupling. The results are then compared with design methods namely those specified in the Eurocode 5 [10] and in the Technical Specification CEN/TS 19103 [11].

2 MATERIALS AND METHODS

The specimens were prepared in two different stages: S1 (May 2022) and S2 (January 2023). CLT specimens using three layers of maritime pine were produced at SerQ's facilities. In stage S1 the timber was selected according to density, ensuring the class was higher than C18. After planning, the boards had a final thickness of 30 mm and 100 mm wide. In stage S2 the timber was selected according to the dynamic modulus of elasticity, ensuring

[5] Alfredo Dias, University of Coimbra, ISISE, Department of Civil Engineering, Coimbra, Portugal, alfgdias@dec.uc.pt

https://doi.org/10.52202/069179-0406

the class was equal to or higher than C24, and the boards had a final thickness of 30 mm and a width of 200 mm. A layer of concrete (maximum aggregate dimension of 14 mm) with 60 mm thickness was considered and reinforced with an electro-welded steel mesh (AQ50; 100 mm by 100 mm) placed at mid depth of concrete to prevent cracking. Table 1 shows the material properties in each stage, where *MC* is the moisture content, ρ is the density and E_{dyn} is the dynamic modulus of elasticity of the timber; f_{cm} is the concrete mean value of the compressive strength. The timber properties shown in this table are related to the lamellae at the interface with the concrete layer.

Table 1: *Material properties.*

Stage	Timber			Concrete	
	MC [%]	ρ [kg/m³]	E_{dyn} [MPa]	f_{cm} [MPa]	Class
S1	14 ± 2	580 ± 80	12000 ± 4800	46.8	C35/45
S2	16 ± 2	620 ± 60	15500 ± 1500		

Nine connection configurations are considered (see Table 2) based on the concept of a perpendicular/inclined notch and with/without screw to resist uplift stresses. Research on inclined notches is not recent [12]. However, the used shape follows the pattern referred to in Ouch *et al*. (2021) [13]. For those connections with a screw, SPAX 8x120 mm full threaded and washer head screw is installed in the centre of the notch. The connector design using these screws is covered by the European Technical Assessment ETA-12/0114 [14].

Table 2: *Notch configurations.*

Specimen ID	Notch [mm]			Stage	
	Top Length	Bottom Length	Depth	Timber	Concrete
MrP20	150	150	20	S1	S1
MiP20	90	90	20	S1	S1

MrpI20	150	174	20	S2	S1
MpP20	90	90	20	S2	S1
MpI20	90	114	20	S2	S1

Meaning of the specimen ID:
M – wood species: maritime pine.
r – reference (150 mm notch top length); i – in situ concreting; p – prefabricated concrete.
P – perpendicular notch; I – inclined notch.
20 and 45 – notch depths in mm.

Three groups of two specimens 500 mm long, 200 mm wide and 90 mm thick were fabricated for each configuration. To comply with the symmetrical system indicated by Annex C of the Technical Specification CEN/TS 19103 [11], each specimen is composed of two CLT panels glued to each other and placed between two reinforced concrete (RC) slabs (see Figure 1). The assembly of each individual layer of RC with the respective specimen of CLT is previously performed. On reference specimens (MrP_) and in situ specimens with perpendicular notch (MiP_), a screw is installed in the centre of the notch – see Figure 2 (a). A U-shape rebar cage is installed on specimens with an inclined notch (MiI_) – see Figure 2 (b).

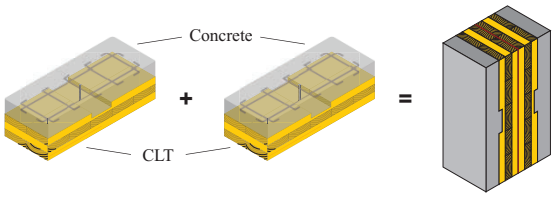

Figure 1: *Specimens bonding.*

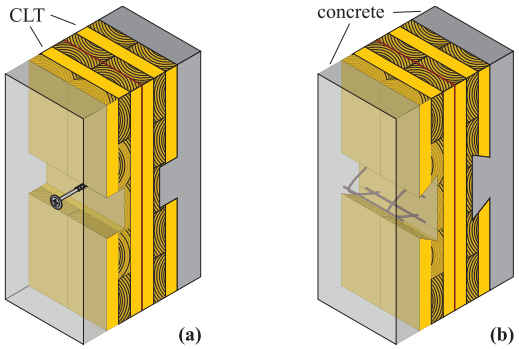

Figure 2: *Notch configurations: (a) perpendicular and (b) inclined notch.*

Precast reinforced concrete panels (Mrp_ and Mp_) are manufactured with a 90 mm square hole in the centre. The assembly is carried out by filling the notch with grout SikaGrout®-218 [15]. In specimens with perpendicular notch (MrpP20 and MpP20), the connection is reinforced with a screw to prevent uplift, while in inclined notch specimens (MrpI20 and MpI20), no steel connector is installed (see Figure 3).

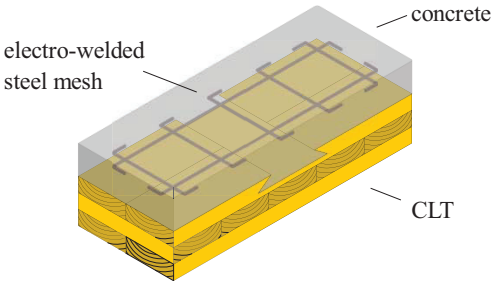

Figure 3: *Inclined notch without steel connector.*

3 EXPERIMENTAL APPROACH

For the CLT-concrete composite connections characterization, the push-out test is used. The test setup is made conform to the push-out test given in EN 26891 [16] – see Figure 4– where the dashed line represents a simulation as the graph behaviour depends on the specimen being tested. To design the loading procedure, the maximum loading must be known or estimated. Table 3 shows the estimated load-carrying capacity for some of

the specimens by Clause 10.3.4.3 of the Technical Specification CEN/TS 19103 [11]. The estimate was made considering timber strength class C24 and concrete strength class C35/40.

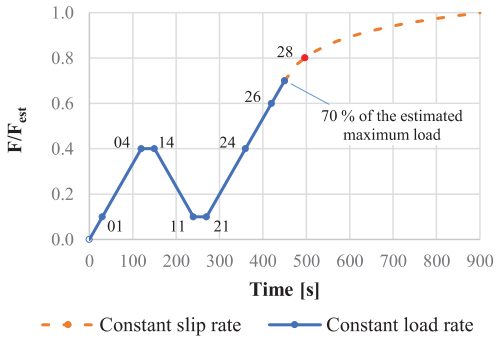

Figure 4: *Loading procedure given in EN 26891* [16].

Table 3: *Estimated maximum load for each stage S1 notch configuration based on characteristic values.*

Specimen ID	Load-carrying capacity $F_{Rd,shear\ plan}$ [kN]	Slip modulus k_{ser} [kN/mm]	Failure mode
MrP20	52	200	Crushing of timber
MiP20	52	200	Crushing of timber
MiI20	52	200	Crushing of timber
MiP45	107	300	Shear of concrete
MiI45	116	300	Crushing of timber

Test setup consisted of a force jack with a capacity of 500 kN that applied a uniform vertical load on the top surface of the CLT block through a steel plate that distribute the load across the timber, a symmetrical specimen of CLT-concrete connection, and two reaction steel plates (high enough to allow the timber section to move freely vertically within the limits of the standard: at least 15 mm) to support the reinforced concrete plates. To avoid a dangerous collapse of the specimen, it is restrained at the top and bottom without prestressing, as shown in Figure 5 (a).

To measure relative displacement (slip) between the CLT and concrete panels four LVDTs are placed, at half height, two for each shear plan – see Figure 5 (b).

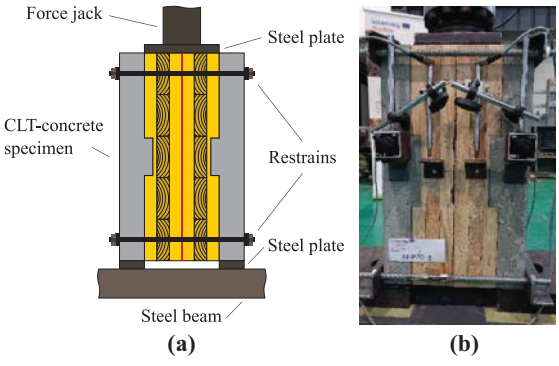

Figure 5: *(a) test setup and (b) LVDT positions.*

Load and slips were recorded at 0.1 s and all tests were filmed by two cameras, one positioned at the front and other at the back and photographed from all sides for later evaluation and clarification of doubts related to failure modes.

4 RESULTS AND DISCUSSION

4.1 RESULTS

Figure 6 shows the load (F_{appl}) *versus* joint slip of the representative shear planes of each perpendicular notch configuration, and Figure 7, of the inclined notches. Generally, the specimen reaches its maximum load-carrying capacity (collapse of the first shear plane) before a differential displacement between the CLT and the reinforced concrete of 2 mm in the notch area. After that, most specimens reach about half their maximum load-carrying capacity (collapse of the second shear plane) for slips greater than 5 mm. The specimens with notches 150 mm long, cast in situ, (reference specimens) have the highest load-carrying capacity and a ductile behaviour was observed. Specimens with a 90 mm long notch have an intermediate load-carrying capacity and prefabricated specimens have a lower load-carrying capacity.

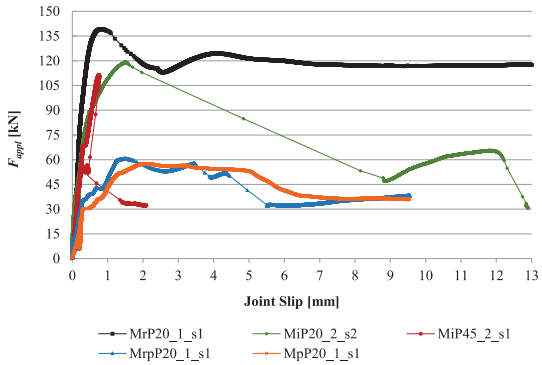

Figure 6: *Force per shear plane versus joint slip (perpendicular notch).*

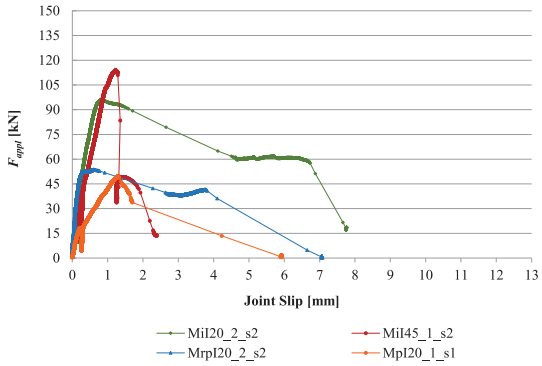

Figure 7: *Force per shear plane versus joint slip (inclined notch).*

To complement the above, see Table 4 that shows the load-carrying capacity (F_{max}), and the stiffness of the connections in the service limit state quantified by the slip

https://doi.org/10.52202/069179-0406

modulus (K_s). These values are provided by the average (μ), standard deviation (σ) and coefficient of variation (relative standard deviation, *RSD*).

Table 4: *Mean values of shear strength and slip modulus per shear plane.*

Specimen	F_{max} [kN]			K_s [kN/mm]		
	μ	σ [-]	*RSD* [%]	μ	σ [-]	*RSD* [%]
MrP20	140.6	6.9	4.9%	376.0	111.0	29.5%
MiP20	117.3	4.7	4.0%	302.4	78.0	25.8%
MiI20	100.7	5.3	5.3%	206.8	66.7	32.2%
MiP45	109.0	5.2	4.8%	251.1	76.0	30.3%
MiI45	109.6	10.1	9.2%	177.7	37.4	21.1%
MrpP20	57.3	5.4	9.4%	162.3	37.7	23.2%
MrpI20	52.9	6.4	12.2%	194.4	62.6	32.2%
MpP20	61.0	6.1	10.1%	228.4	147.9	64.7%
MpI20	49.8	4.8	9.7%	252.4	188.5	74.7%

Table 5 shows the maximum mean slips at maximum load (δ_{Fmax}) and just before collapse ($\delta_{Collapse}$). Generally, the reference specimens (MrP20) show a greater slip at maximum load. Higher values were only observed at similar configuration, for pre-cast connection (3.7 mm at maximum load). This happened very close to the collapse which occurred on average at 51 kN per shear plane.

Table 5: *Mean slip values on connections.*

Specimen	δ_{Fmax} [mm]			$\delta_{Collapse}$ [mm]		
	μ	σ [-]	*RSD* [%]	μ	σ [-]	*RSD* [%]
MrP20	1.50	0.38	25.41%	2.59	1.08	41.66%
MiP20	1.09	0.32	29.46%	1.25	0.39	30.85%
MiI20	1.46	0.66	44.88%	1.87	0.76	40.76%
MiP45	0.63	0.22	34.98%	0.71	0.32	45.58%

MrpP20	3.69	4.14	112.39%	5.11	4.14	80.98%
MrpI20	0.61	0.28	46.67%	2.24	1.91	84.93%
MpP20	1.44	0.44	30.27%	6.10	1.56	25.61%
MpI20	1.14	0.26	23.08%	1.63	0.96	59.04%

Prefabricated specimens all collapsed due to shear of grout at the interface between the concrete and CLT plates. Precast reinforced concrete panels were manufactured with a 90 mm square hole in the centre. Despite the specimens' preparation having been carried out to ensure good adhesion between grout and concrete, in some areas it was found the grout had detached from the concrete. Figure 8 shows a shear plane after the failure. It can be seen areas where the grout was properly connected to the concrete and areas where grout has detached the concrete.

4.2 DISCUSSION

The specimens with a reference notch equally presented two collapse failure modes: shear and crushing of timber. In these specimens, the collapse has a ductile behaviour. It is possible to see shear of concrete, which may have been limited by the electro-welded steel mesh. Two of the reference specimens presented both failure modes in the same shear plane (see Figure 9).

Figure 10 shows the top of MrP20_1 CLT specimen where the growth rings of the two lamellae are shown and identified. It can be seen the lamellae with wider growth rings collapsed by crushing parallel to grain and lamellae with more compact growth rings collapsed by shear parallel to grain.

In the remaining configurations, the collapse was due to shear of concrete. Collapse was governed by a brittle behaviour instantly decreasing the load-carrying capacity of the connection.

Figure 8: *Shear of grout in MrpI20_2 specimen.*

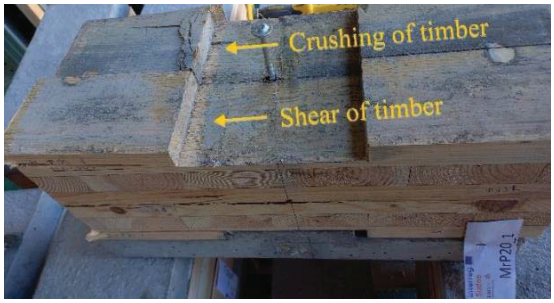

Figure 9: *MrP20_1 specimen with shear and crushing of timber in the same shear plane.*

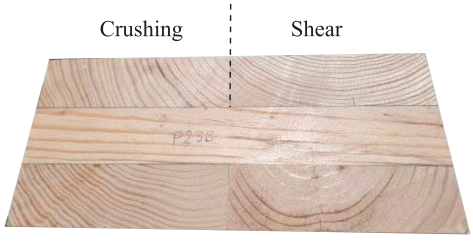

Figure 10: *MrP20_1 specimen with shear and crushing of timber in the same shear plane.*

Regarding the prediction of the connections load-carrying capacity, results given by the Technical Specification are lower than the experimental results. Nevertheless, connections with a 45 mm deep notch showed similar results. Technical Specification assumes slip modulus increase with the depth of the notch. On the opposite, tests revealed a decrease, comparing the 20 mm and 45 mm deep notches. Technical specification predictions related to failure modes only matched in specimens MrP20 (even with maximum load carrying capacity underestimated) and MiP45.

To evaluate the results of the prefabricated specimens, half of their width (100 mm) was considered to disregard some areas where the grout detached from the concrete. Table 6 presents the average load-carrying capacity and connection stiffness values, per millimetre, of the specimens cast in situ, considering a total width of 200 mm. The values for the prefabricated specimens are also presented, per millimetre, considering the width of 100 mm.

Table 6: *Load-carrying capacity and connection stiffness values per millimetre.*

Specimen	F_{max} [kN/mm]	K_s [kN/mm/mm]
MrP20	1.41	1.88
MiP20	1.17	1.51
MiI20	1.01	1.03
MrpP20	1.15	1.62
MrpI20	1.06	1.94
MpP20	1.22	2.28
MpI20	1.00	2.52

Figure 11 shows the notch length influence on results. MrP20 and MiP20 specimens were compared. Additionally, results of configurations A1 and A2 by Yeoh *et al.* (2008) [17] were also compared. In this analysis, MrP20 and A1, by Yeoh *et al.* (2008), specimens were taken as reference. The longer the notch, the higher the load-carrying capacity, slip modulus, and slip at the maximum load capacity value.

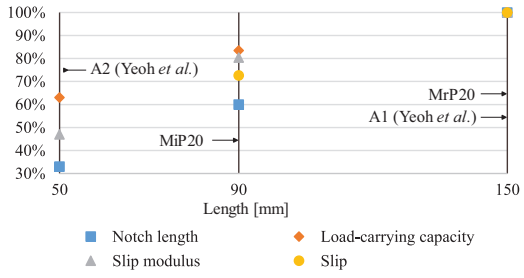

Figure 11: *Influence of notch length on results.*

Figure 12 shows the perpendicular notch depth influence on results. MiP20 and MiP45 specimens were compared. Additionally, results of configurations A1 and A3 by Yeoh *et al.* (2008) [16] were also compared. In this analysis, MiP20 and A1, by Yeoh *et al.* (2008), specimens were taken as reference. In the MiP_ specimens, it was found that increasing the notch depth by 125 %, decreased both the load-carrying capacity and slip modulus by 20 %. The slip at the maximum load capacity value decreased about 40 %. In Yeoh *et al.* (2008) study, with a 50% decrease in the notch depth, slip modulus increased by 40 %, and load-carrying capacity was kept similar.

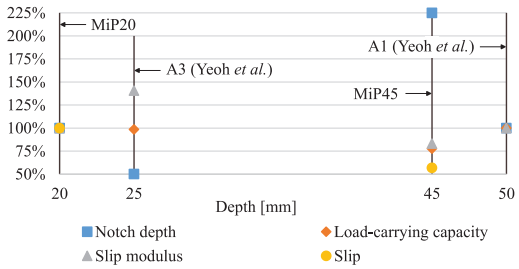

Figure 12: *Influence of perpendicular notch depth on results.*

Figure 13 shows the inclined notch depth influence on results. MiI20 and MiI45 specimens were compared. Comparison with results from literature references was not possible. MiI20 specimen was taken as reference. It was found that increasing the notch depth (125 %), decrease both the slip (20 %) and slip modulus (15 %). The load-carrying capacity increased around 10 %.

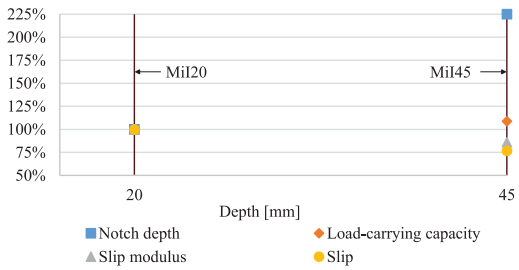

Figure 13: *Influence of inclined notch depth on results.*

Figure 14 shows the inclined notch influence on results. MiI20/MiP20 (20 mm deep) and MiI45/MiP45 (45 mm deep) specimens were compared. MiP20 and MiP45 specimens were taken as reference. Inclination in the 20 mm deep notches resulted in 15 % loss of load-carrying capacity and 30 % of stiffness (slip modulus) of the connection. In the 45 mm deep notches, there was a loss of connection stiffness similar to that of the 20 mm notches, nevertheless, the inclination had no effect on the load-carrying capacity.

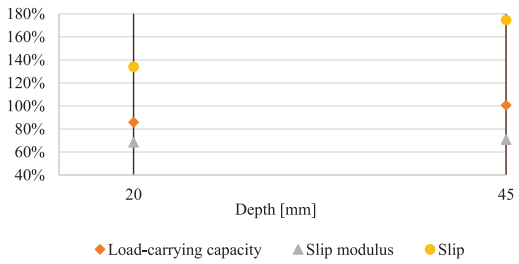

Figure 14: *Influence of inclined notch on results.*

https://doi.org/10.52202/069179-0406

The 150 mm long prefabricated specimens lose load-carrying capacity (about 20 %) compared to those cast in situ. When the notch is inclined the loss is higher (20 %). In the 90 mm long notches, the prefabricated specimens with perpendicular notches have a higher load-carrying capacity compared to inclined notches. The specimens with inclined notch maintain similar load-carrying capacity despite the length of the notch. The reference notch has less connection stiffness on the prefabricated specimens.

5 CONCLUSIONS

Connections between CLT produced with local maritime pine wood and reinforced concrete (cast in-situ and precast) were tested to study the composite system behaviour. The experimental results and the design results provided by the standards were compared.

The load-carrying capacity of the cast-in-situ concrete connection is greater than that of precast concrete, nevertheless, generally, the slip modulus is lower. The notch depth has no significant influence on results. The notch length is the most important factor affecting the connection performance both at mechanical properties and ductile behaviour. More tests must be carried out to increase the reliability of results.

EXPERIMENTAL INVESTIGATION OF AN INNOVATIVE BEAM-TO-COLUMN CONNECTION UNDER CYCLIC LOADING.

Ahmed Mowafy[1], Ali Imanpour[2], Ying Hei Chui[3], Hossein Daneshvar [4]

ABSTRACT: The mechanical behaviour of steel is crucial in hybrid steel-timber systems, especially in areas prone to seismic activity. This paper presents a study of a novel semi-rigid connection that employs U-shaped steel plates as seismic fuses in a beam-to-column connection. The connection aims to introduce self-centring steel braced frames as lateral systems, combined with mass timber structures as a gravity load-resisting system, to enhance their structural performance against earthquakes. The fuses are designed to yield in axial compression or tension, with a bending combination that enables the connection to produce yielding at a specific moment level. The study focuses on the results obtained from cyclic fuse testing, connection testing, and comparing the connections to existing solutions to demonstrate their potential as a reliable and resilient option for mass timber buildings in seismic areas. The findings indicate that the developed connections provide reliable ductile behaviour, and timber elements can be protected from damage through the capacity protection provided by the fuses and their yielding mechanism.
KEYWORDS: Hybrid Structures, Mass Timber buildings, U-shaped plates, Semi-Rigid Connections, Seismic fuses, lateral load resisting systems (LLRS).

1 INTRODUCTION

Timber mass buildings face a unique design challenge due to the need for high-performance connections. In recent years, researchers have focused on improving the behaviour of these connections to enhance the seismic resilience of timber structures. One solution to this issue is to use a pure hinge connection for timber structures that can accommodate drift during seismic events, and steel frames can provide ductility to dissipate seismic energy [1]. Alternatively, the connection itself could dissipate the energy by introducing a steel component with reasonable ductile behaviour. Various types of connections that can dissipate seismic energy have been proposed, such as perforated plates [2], top and seat angle connections[3], wooden elements connected to steel stubs [4], Glulam post-to-beam connections reinforced by dowel-type fasteners [5], connections with three separate steel box sections [6], and prestressed timber beam-column connections[7]. Despite these solutions, the ideal type of connection for timber mass buildings would have replaceable sacrificial elements to reduce downtime and rehabilitation costs, as a lesson learned from the 2010-2011 Christchurch earthquake series [8]. One example is the proposed hybrid moment resisting frame connection with replaceable steel links [9]; however, there are few examples of these advanced replaceable-fuse connections.

This paper presents an innovative beam-to-column connection that uses replaceable U-shaped plates as a source of ductility during an earthquake. U-shaped plates were first introduced by Kelly et al. to provide energy dissipation between structural walls [10]. Incorporating U-shaped plates into the developed connection offers several advantages, including cost-effective fabrication, simple installation and replacement, as well as exceptional inelastic characteristics such as high energy dissipation capacity and fatigue performance [10,11]. The developed connection, shown in Figure 1, consists of two main parts: a pin mechanism located at the centre and replaceable U-shaped fuses situated above and below it.

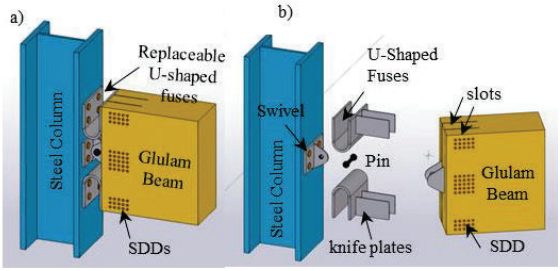

Figure 1: *Developed Beam-to-column Connection: a) Assembled connection b) Disassembled connection.*

All components are connected to the timber beam using two knife steel plates embedded in the timber and attached using self-drilling dowels (SDDs), which are widely used in these forms of connections due to their mechanical properties, including high tensile and shear strength, excellent corrosion resistance, and ductility, as well as their architecturally pleasing appearance. Then the components are connected to the steel column using regular high-strength bolts with ASTM A490 grade [13].

https://doi.org/10.52202/069179-0407

The research aims to test the seismic performance of this innovative connection and compare it with other existing solutions to demonstrate its potential as a reliable and resilient option for timber mass buildings in seismic areas.

2 EXPERIMENTAL PROGRAM

Two testing programs, the Fuse-Testing (FT) and Connection Testing (CT) have been developed. The FT program (Figure 2) assesses the inelastic properties of the seismic fuses used in the connection, while the CT program (Figure 3) tests the capacity-protected items in the connection and determines the overall hysteresis response of the connection under cyclic loading. The testing setups, loading procedures, and specimens used for both programs are discussed in this section.

2.1 Fuse Test setup

The FT setup shown in Figure 2 examines two symmetric specimens to avoid introducing eccentric loading to testing machine. The setup includes two identical testing fixtures connected to the uniaxial machine via its grips. Two back-to-back angles are welded to an intermediate plate that is attached to the machine arm for each fixture. The load from the machine is distributed evenly to the fuse legs by distributing plates. The specimens are connected to the distribution plate and ultimately to the horizontal leg angle by four pre-tensioned high-strength steel bolts. Scissor Displacement, which is the relative vertical displacement between the two fuse legs, was measured using four Linear Variable Differential Transformers (LVDTs). The front face and the outside curved surface of the left specimen were monitored through non-contact strain field measurements utilizing Digital Image Correlation (DIC).

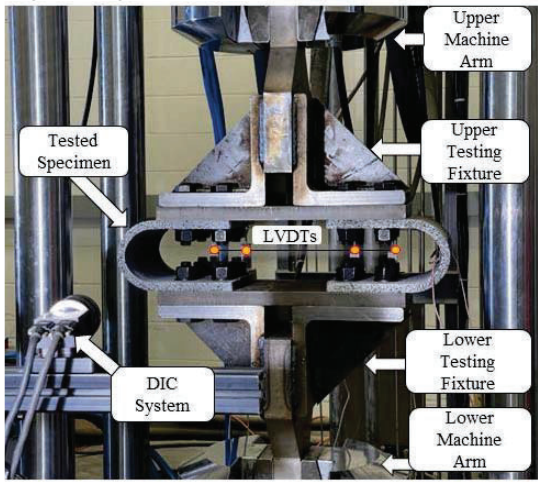

Figure 2: *Fuse-Testing Setup*

2.2 Connection Test setup

The connection testing was carried out at C-FER Technologies, Alberta, Canada, using a reaction wall made of reinforced concrete and a hydraulic actuator with a 300 kN maximum load capacity. A steel beam fastened to a reinforced concrete floor with steel anchors served as a representation of the column component. A load cell in the actuator was used to measure the load, and inclinometers, LVDTs, and potentiometers were installed to quantify connection, rotation, displacement, and lateral movement. DIC technology was used to assess the non-contact strain field.

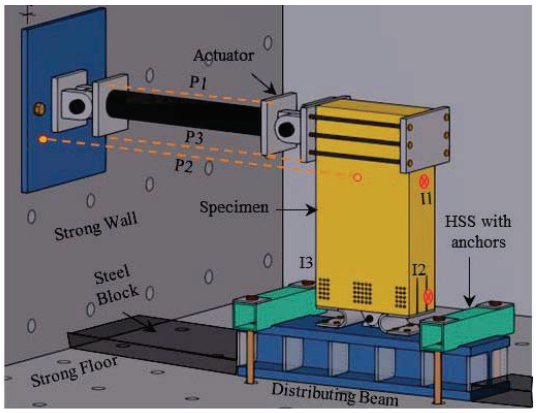

Figure 3: *Proposed Connection-Testing Setup*

2.3 Loading Procedure

Both sets of specimens were tested using the displacement control protocol recommended in FEMA 461 [14] as shown in Figure 4. This involved 26, where each pair of consecutive cycles shares the same amplitude, followed by a gradual increase in amplitude. This protocol was used to induce a 3% storey drift in a hybrid steel-timber structure. For the fuse testing, the cyclic displacement history consisted of 26 cycles to achieve a maximum displacement of 6 mm between the legs, followed by ten additional cycles to reach 20 mm. The maximum scissor displacement was limited to 20 mm to avoid bolt contact. Similarly, cyclic loading protocols were employed for connection testing, consisting of 26 cycles up to 54 mm displacement and ten additional cycles up to 140 mm or until failure. The maximum beam displacement was limited to 144 mm to avoid bolt contact and a 150 mm actuator stroke limit.

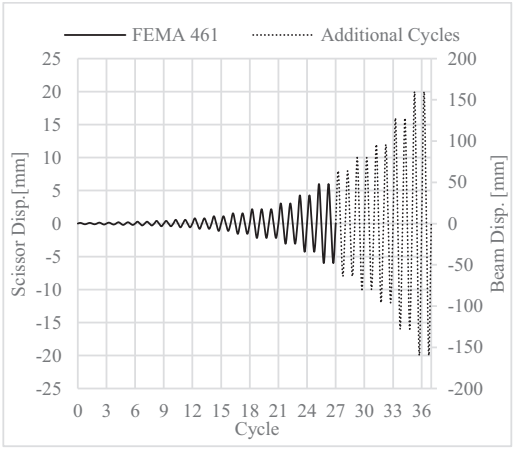

Figure 4: *Loading Protocol*

https://doi.org/10.52202/069179-0407

2.4 Specimens

The U-shaped plates used as the test specimens for fuses were made of CSA G40.21 300W steel and came in four different thicknesses: 13 mm, 16 mm, 19 mm, and 22 mm for Specimens FT-S1, FT-S2, FT-S3, and FT-S4, respectively. The plates were shaped using a bespoke bender without any heat treatment. For the connection testing, four identical glulam beams with dimensions of 265x608x1150 mm were produced, each to be utilized for a different fuse thickness, as shown in Table 1. The only aspect of the beams that varied was the quantity of Self Drilling Dowels (SDD) employed at the top and bottom portions of each specimen. The predicted maximum shear force during cyclic loading was intended to be supported by the intermediate pin SDDs, with a total number of 25.

Table 1. *Connection Testing (CT) Specimens*

Specimen	Fuse thickness	SDD number per top or lower part
CT-S1	13 mm	20
CT-S2	16 mm	28
CT-S3	19 mm	40
CT-S4	22 mm	50

3 INSIGHT FOR THE TESTING PROGRAM RESULTS

This section describes the results of experimental testing and analysis of timber connections and fuses for seismic-resistant structures. The testing involved the use of fuse and connection specimens, and the results were analyzed based on deformation hysteresis curves, Von Misses strain measurements, and moment-rotation hysteresis responses. This section also includes a discussion of the behaviour of the fuses and connections in tension and compression and a comparison between the behaviour of the fuses in connection testing and fuse testing.

3.1 Fuse Testing

Figure 5 illustrates a deformation hysteresis curve for a chosen fuse specimen 3 (a 19-mm fuse). The fuses exhibited high ductility, enabling them to effectively dissipate seismic energy. Furthermore, the fuses were able to compress up to the expected yielding strength, and all specimens could move their scissor legs up to a maximum distance of 20 mm without fracture. However, the behaviour of the fuses in compression was not identical to that in tension due to the varying boundary conditions. Under tension, the fuse reached a maximum force of 250 kN, while under compression, it reached an even higher maximum force of 340 kN.

Figure 6 illustrates the Von Misses strain measurements at the front face of the fuse at maximum tension (Point a) and maximum compression (Point b). The scale range was set to show the strain values that go beyond yielding, enabling the detection of the plastic zones. During testing, a gap in tension was observed between the fuse leg that ends at the outer bolt edge and the horizontal plate of the testing fixture that applies the loads [Figure 6. a]. On the other hand, complete contact between the plate and the fuse leg occurred during compression [Figure 6. b]. The unloaded fuse seemed to yield at the same load level until full contact was achieved. At this point, the fuse started to accommodate more stiffness until the yielding zone occurred near the full contact edge. Overall, the results suggest that the behaviour of the fuses in compression was not the same as in tension due to various boundary conditions that affected the fuses in each situation. The findings have implications for understanding the behaviour of the fuses and their potential use in seismic-resistant structures.

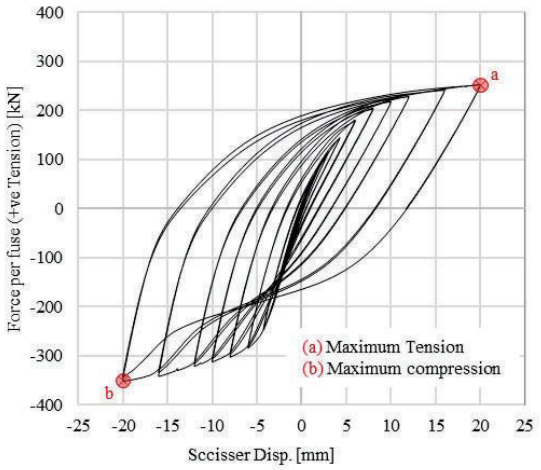

Figure 5: *Fuse Testing - Sample hysteresis response: FT- S3*

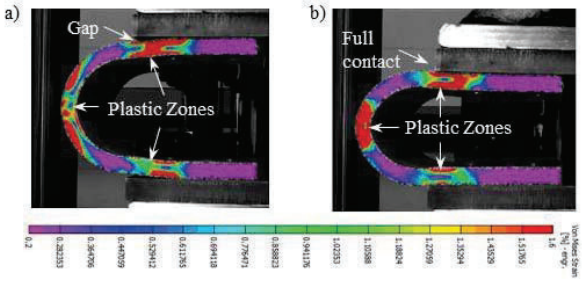

Figure 6: *Fuse Testing – Von Misses Strain measures for Specimen FT-S3: a) Maximum Tension (Point a); b) Maximum Compression (Point b).*

3.2 Connection Testing

In Figure 7, the moment-rotation hysteresis response of the CT-S3 specimen is shown, demonstrating high ductility, good energy dissipation, and no strength degradation in the connections. The overall connection stiffness did not reduce nor exhibit pinching, which suggests that even better ductility could have been achieved if the beam had undergone higher displacement during testing. All specimens followed a consistent pattern and were able to reach the maximum rotation level

https://doi.org/10.52202/069179-0407

without global failure. No significant out-of-plane deformations were captured. The ultimate moment for CT-S1, CT-S2, CT-S3, and CT-S4 specimens as 32, 48, 72, and 92 kN, respectively.

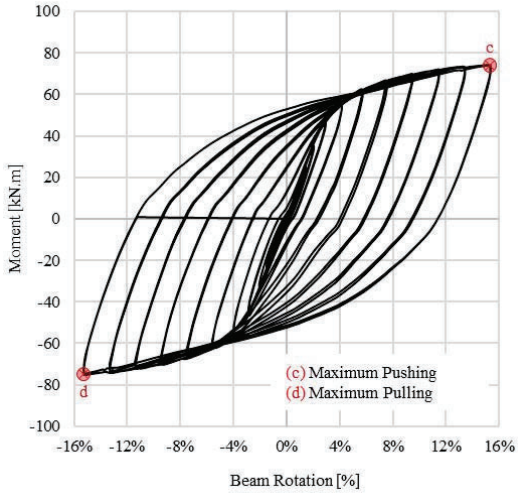

Figure 7: *Connection Testing – Sample hysteresis response: CT- S3*

Figure 8.and Figure 8.b showcase the CT-S3 specimen at maximum pushing (Point c) and pulling (Point d) during testing, respectively. As demonstrated, no splitting cracks emerged in the glulam beam specimens during testing. In Figure 9, the DIC strain measurements at the front view of both fuses in tension and compression utilized in the connection at maximum pushing (Point c) are presented. The plastic zones, in this case, were more concentrated at the mid-bent of the fuse rather than the legs.

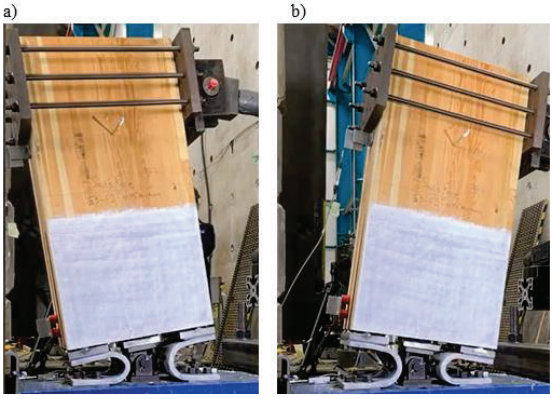

Figure 8: *Connection Testing – Specimen CT-S3 deformations: a) maximum rotation at pushing (Point c); b) maximum rotation at pulling (Point d).*

3.3 Comparison between Fuse behaviour in Fuse testing and connection testing

On analyzing the behaviour of fuses in connection testing (Figure 10.a) and fuse testing (Figure 10.b) under compression, a significant difference was observed. In connection testing, the fuse leg is allowed to rotate, while in fuse testing, it is fixed. Consequently, the plastic zones in connection testing (Figure 10.c) are more prominently concentrated at the mid-bent of the fuse than at the contact points of the fuse leg end. On the other hand, in fuse testing (Figure 6), the legs are more actively engaged due to the testing fixture forcing the legs to remain straight.

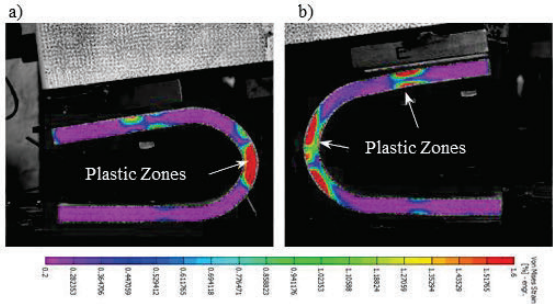

Figure 9: *DIC Von Misses Strain measures at maximum pushing (point c): a) Compressive Fuse; b) Tensile Fuse.*

This difference arises because the connection rotation matches the deformed shape of the fuse if it is compressed freely in the perpendicular direction to its legs. However, in fuse testing, the legs are constrained, and thus the deformation pattern is different. Moreover, the gap that was observed during tension in the connection testing fuses did not completely close during compression due to the residual deformations introduced in the fuse leg during tension. Therefore, the inelastic properties of the tensile fuse dominate the overall hysteresis performance of the connection, and a symmetric hysteresis response can be easily developed, which is not the case in fuse testing.

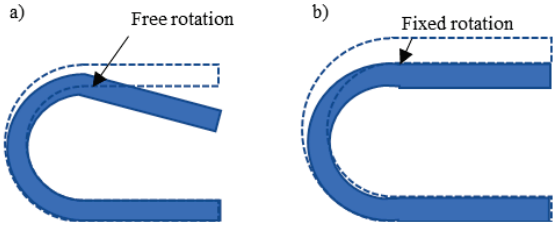

Figure 10: *Deformed shapes of fuses: a) Connection Testing; b) Fuse Testing.*

In conclusion, the testing results demonstrate the importance of considering the effects of connection rotation and leg deformation when evaluating timber connection performance. The observed ability of the fuse leg to rotate freely during connection testing resulted in a distinct deformation pattern and a concentrated plastic zone at the mid-bend of the fuse. This, combined with the inelastic properties of the tensile fuse, facilitated the development of a symmetric hysteresis response. However, using the results of fuse testing to ensure the capacity design of the connection remains valid is a more conservative approach. These findings have significant implications for the design and evaluation of timber connections, potentially leading to the development of more efficient and reliable structural systems.

4 Connection Evaluation

The connection evaluation is done by comparing its characteristics to some of the existing solutions. These characteristics include ductility factor, μ, ultimate moment, M_u and failure mode. Table 2 shows the tests used in this comparison along with the beam cross-section and the failure mode shown in each one.

Table 2. *Comparison test results with previous connection tests*

Connection	Beam Cross Section	Failure mode
Developed connection (2023)	608×265	Ductile U-shape yielding
Dong et al (2021) [15]	450×315	Ductile Dowel Yielding
Karagiannis et al.(2017) [16]	280×140	a bolt-row shear failure
He et al.(2017) [17]	260×130	Wood Splitting
He and Liu(2015) [5]	300×200	Ductile rod yielding
Lam et al.(2010) [18]	304×130	Splitting

Figure 11 provides a visual representation of the relationship between two critical factors in connection design. The chart is divided into several zones, each representing a different type of connection performance based on the compromise between ductility and ultimate moment. The horizontal axis represents ductility, a measure of how much a material can deform before fracturing. The vertical axis represents the strength ratio, which is the ultimate moment divided by the yielding moment of a connection used to measure the connections' ability to resist external loads and stresses without failing. The chart is divided into several regions or zones, each representing a different type of connection performance. The zone in the upper right corner represents the ideal connection design, characterized by high ductility and high ultimate moment. Other zones represent various levels of compromise between ductility and strength ratio, such as connections with lower ductility but a higher strength ratio or vice versa. The chart provides a valuable tool for engineers and designers to optimize connection design based on their specific needs and constraints.

The ductility factor(μ) plays a crucial role in determining the behaviour of a structural element under seismic loading conditions. As per the EN12512 [19] guidelines, μ is calculated using Equation (1):

$$\boldsymbol{\mu = \theta_u / \theta_y} \quad (1)$$

Where θ_u represents the rotation at ultimate moment capacity, and θ_y is the rotation at yielding. Based on the value of μ, the structural element is categorized as brittle (μ ≤ 2), low ductility (2 < μ ≤ 4), moderate ductility (4 < μ ≤ 6), or high ductility (μ > 6), according to Smith et al.'s categorization of Timber connections [20]. This classification helps in selecting the appropriate connection design for seismic-resistant structures based on the desired ductility and ultimate moment capacity. the ductility factor is calculated based on the average of tested specimens. In cases where there are multiple groups, the average of the strongest group is considered. For determining the ultimate moment capacity, the average value of tested specimen is used, except for the cases with no replicates, where the most robust specimen represents each study, as is the case for our developed connection.

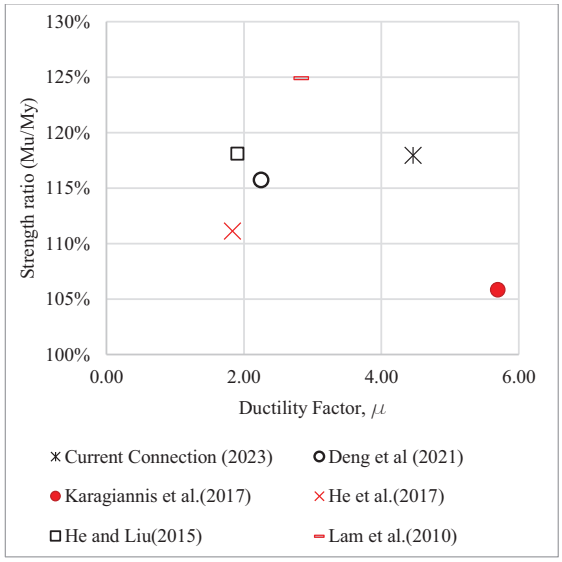

Figure 11: *Optimization chart used in the comparison between the developed connection and samples from existing solutions.*

The chart (Figure 11) clearly indicates that the developed connection is located in a favourable position. It exhibits higher ductility than the connection with the highest strength ratio presented by Lam et al. (2010) [18] and a higher strength ratio than the connection with the highest ductility factor introduced by Karagiannis et al. (2017) [16]. It is noteworthy that all the connections with a red colour legend in the chart have a brittle failure mode, such as plug shear, splitting, or bolt-row shear failure. Thus, by excluding these connections that failed in a brittle manner from the chart, the developed connection would be an ideal solution. Moreover, the developed connection offers a unique advantage in that it is the only one among the represented solutions that feature easy-to-replace fuses. This feature sets it apart from other connections and makes it a superior choice for multiple applications.

5 SUMMARY AND CONCLUSIONS

This study describes the experimental program developed to evaluate the cyclic response of a steel timber beam-to-column connection for seismic-resistant design. The testing program includes fuse testing and connection testing, which are used to determine the inelastic

https://doi.org/10.52202/069179-0407

mechanisms of seismic fuses and the connection. The results of the experimental testing are presented, including overall connection response, von Misses strain demands, and moment-rotation hysteresis responses. The fuses demonstrated a high capacity for dissipating seismic energy, and the connections were capable of resisting significant cyclic demands (in the order of 8% drift ratio) without brittle failure. The proposed connections demonstrated a comparative performance in terms of overstrength and deformation capacities in comparison with similar timber connections developed in the past. Overall, the experimental program provides valuable insight into the cyclic behaviour of U-shaped fuses implemented into beam to column connections of timber structures in tension and compression and provides a basis for future research in this field.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the generous support provided by the Natural Sciences and Engineering Research Council of Canada, Advanced Research in Timber Systems (ARTS), and the Canadian Institute of Steel Construction Centre for Steel Structures Education and Research at the University of Alberta, whose financial assistance was instrumental in enabling this research. In addition, we extend our heartfelt appreciation to PAALID ENG, Western Archrib, Alberta Innovates, the I.F. Marison Lab, and C-FER Technologies for their invaluable contributions to this study. Their provision of materials, preparation of specimens, testing operations, and hosting of the test operation were integral to our research efforts. Special thanks are due to C-FER Technologies for their partnership and commitment to advancing our understanding of this field.

AN EXPERIMENTAL STUDY ON THE SAFETY PERFORMANCE OF A WOOD MASONRY STRUCTURE

Daiki Iwamoto[1], Joichi Nakakuki[2], Waikong Lam[3], Hiro Kawahara[4], Masamichi Sasatani[5]

ABSTRACT: This paper presents the experimental results conducted to evaluate the mechanical properties and safety of a wood masonry structure called "Mirika no Ki" (Mirika) used in a complex cultural facility in Japan. Mirika is designed to prioritize the use of locally sourced wood and emphasizes its potential reusability during disasters or emergencies. The wood is stacked in 36 layers with a section size of 105 mm x 170 mm, and full-threaded screws are utilized for joints. The study evaluates the horizontal resistance of Mirika through an in-plane horizontal loading test on a wood masonry wall. Additionally, two further experiments were conducted to verify the structural integrity and functionality of the joints. The objective of this study is to provide fundamental data for designing wood masonry structures to promote the recycling of wood materials.

KEYWORDS: Wood masonry structure, Screw joint, Pull-out resistance of screws, In-plane shear test, Out-of-plane shear test

1 INTRODUCTION

Forests have multiple functions such as preserving national land and supplying forest products, so proper maintenance and preservation are necessary. In Japan, there is a movement to promote wood recycling through the establishment of laws related to the promotion of wood utilization. As part of the active use of wood, the renovation plan of a complex cultural facility in Nakagawa City, Fukuoka Prefecture, utilized a locally manufactured wood masonry structure "Mirika no Ki" (Mirika) with the concept of emphasizing space and gathering people under the tree (Figure 1).

The design of Mirika prioritizes the use of raw wood harvested in Nakagawa City to emphasize its importance and provide the ability to reuse it in case of disaster or emergency. The lumber used to construct Mirika has a section size of 105 mm x 170 mm and is stacked in 36 layers by varying the length of the members. The joints between each piece of lumber are made from the top layer using full-threaded screws (Figure 2), which have high reproducibility, are easy to construct, and allow for freedom in shaping. Therefore, the development of Mirika is expected to greatly contribute to the promotion of wood material recycling. However, there are few similar structures, so data to design from is limited. Therefore, in this research, experiments are conducted to obtain basic data to design wood masonry structures. The forces acting on the joints are thought to arise in the screw in tension and shear directions and the wood in compression direction and are carried by the tension of the screw and the compression of the wood in the bending direction. This study aimed to evaluate the safety and mechanical properties of Mirika, a material used in wood masonry structures. In-plane wall experiments were conducted as well as joint pull-out and joint bending tests to validate the structural integrity and functionality of the joints. The

results of these experiments provided fundamental data for the design of Mirika.

2 SHEAR WALL TEST

2.1 SPECIMENS AND SETUP

In Japan, elastic design is usually performed with a base shear coefficient of 0.2 to 0.3. However, since Mirika is thought to be unstable due to its high center of gravity, the base shear coefficient was set to 0.5. Therefore, Mirika's self-weight 0.5 times (15kN) was set as the target for horizontal resistance, and an in-plane horizontal loading test was conducted on a wood masonry wall. An experiment was conducted on the application of horizontal forces within the wall of the wooden assembly structure. The shape and dimensions of the test body in the wall test and the position of the displacement meter are shown in Figure 3.

The test body cuts out 1/6 of Mirika from the top and uses up to the 19th step, which is the height of the opening. Two test bodies were joined back-to-back, with the top of the two bodies were constrained by steel.

This is to consider the impact of stress on the surface and stabilize the test body shape and reproduce the resistance mechanism under the same condition where force is applied in the direction of the opening as Mirika. The sections of 105 mm x 170 mm cedar lumber were stacked vertically, and full-threaded screws 8Φ200 mm were used with 3 screws at each joint for the lower 5th step and 2 screws at each joint for the 6th step and above.

The loading schedule was implemented according to the literature and the apparent shear deformation angle was

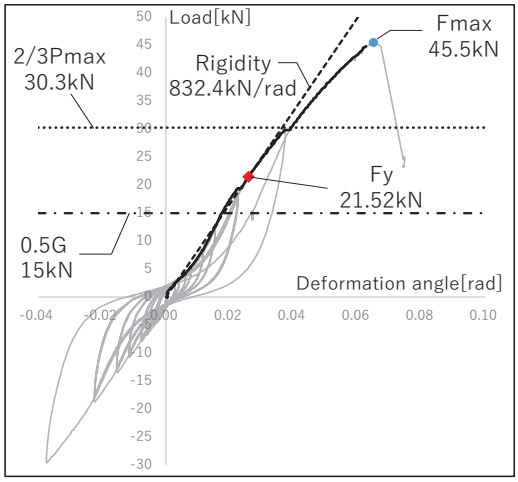

Figure 4(a): *Load deformation angle curve*

tested 3 times at various radian values (1/450, 1/300, 1/200, 1/150, 1/100, 1/75, and 1/50) in positive and negative alternation, with a single repetition at 1/30 rad. The loading was increased to reach the maximum load and then continued until it decreased to 80% of the maximum load.

2.2 RESULTS

Load deformation angle curve and final failure condition in Figure 4. The graph uses a true shear deformation angle. The horizontal displacement of the beam material was measured using a 500 mm displacement transducer

https://doi.org/10.52202/069179-0408

Figure 4(b): *Ultimate Fracture Properties (Left), pulling out of screws (Right)*

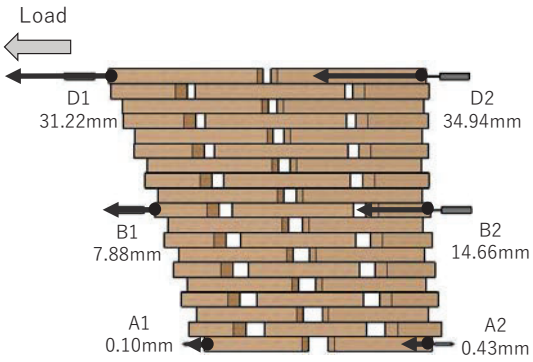

Figure 5: *Awall horizontal displacement*

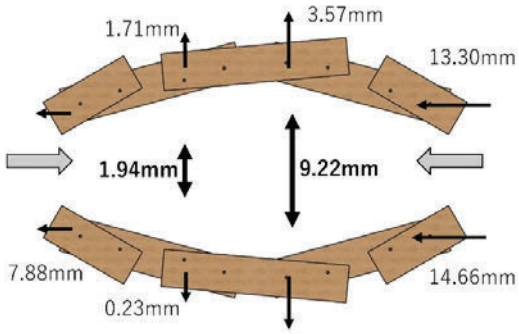

Figure 6: *10th step horizontal displacement*

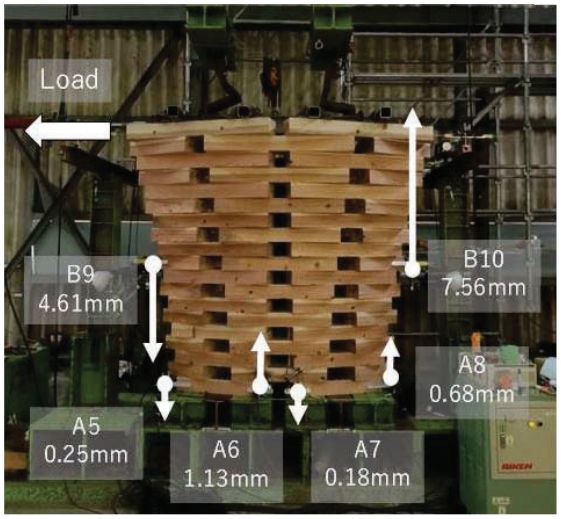

Figure 7: *Awall Vertical displacement*

attached to the shaft of the 19th step. For the horizontal displacement of the foundation, the average value of the horizontal displacement meters A1 to A4 of the 1st step is used.

For the vertical displacement of the column foot, the average value of the vertical displacement meters A5 and A9 of the first section and the average value of A8 and A12 are used to calculate. The characteristic value was calculated based on reference 4). The final fracture behavior was the pullout of screws at the 5th and 6th steps when the horizontal displacement of the 19th step was 140 mm and the maximum bearing capacity was 45.45kN, and the maximum pullout of about 70 mm was observed after the fracture. Figure 5 shows the horizontal deformation of Awall at 0.5G, and Figure 6 shows the horizontal displacement at the 10th step, which is the middle of the w all. The deformation on the right side is larger than that on the left side at the 10th step. Also, at the 10th step, both the deformation in the direction outside the surface and the deformation in the direction inside the surface are larger on the right side compared to the left side. Therefore, while the 10th step undergoes shear deformation in the direction of the applied force, it collapses in the direction inside the surface and deforms in the direction outside the surface. Figure 7 shows the vertical displacement at 0.5G (15kN). On the tenth floor, the deformation on the left side of Awall is 4.61mm vertically downwards and on the right side it is 7.56mm vertically upwards, which means it is rocking in the left direction. The safety of the wall as Mirika has been confirmed from the results exceeding the target of this structure's 0.5G in terms of buckling strength and 2/3Pmax.

https://doi.org/10.52202/069179-0408

3 PULL-OUT TESTS

3.1 SPECIMENS AND SETUP

A pull-out test was conducted to confirm the characteristics of the joint part when subjected to tension force in this structure. The test body consisted of cedar wood (density: 411.7kg/m3 (avg.), moisture content: 14.7% (avg.)) with dimensions of 105 mm x 170 mm × 250 mm and was fastened using 8φ200 mm full-threaded screws (Figure 8). The number of full-threaded screws was varied in two ways, 1 screws (S1) and 2screws (S2), with each variation resulting in 6 test bodies for a total of 12 test bodies. The load was applied at a uniform speed of 1mm/min using a universal testing machine (2000kN). The measurement item was the average value obtained from two displacement gauges, which were placed on the wood in the vertical direction and measured the bolt pull-out amount δ. The load was increased until the maximum strength was exceeded by 0.8Pmax or the wood was cracked, ending the experiment.

3.2 RESULTS

The load-deformation curve of the pull-out test is shown in Figure 9. The calculation of characteristic values was based on the manual for designing wooden joints 1). The final failure mode of the S1 test specimen was screw head embedment for 1 of the 6 specimens, and destruction by pulling out the tip of the screw for 5 specimens (Figure 10). The average ultimate strength of S1 was 6.16kN, which was 37% higher than the calculated value assuming a wooden screw in the "Standard for structural design of timber structures" (AIJ standard[1]). The final endurance was over the calculated value for 5 out of 6 bodies and had a higher distribution than the calculated value overall. Defects may have affected it, as there were knots and cracks of around 4d size in the vicinity of the screw within 7d from the screw location of the used lumber. The large variation in test results may be due to the high-density variability (CV) of 12% in the lumber and instability in the shape of the test body. The final destructive properties of the S2 test bodies were that 1 out of 6 bodies had the tip of the screw pulled out and 5 bodies were broken by cracking along the fibers of the wood (Figure 11). The test bodies that were broken by cracking had almost linear stiffness increases until the yielding and cracking of the wood occurred around 0.8mm and the load dropped once. The average final resistance per screw in S2 was 6.38kN, which was 42% higher than the calculated value assuming

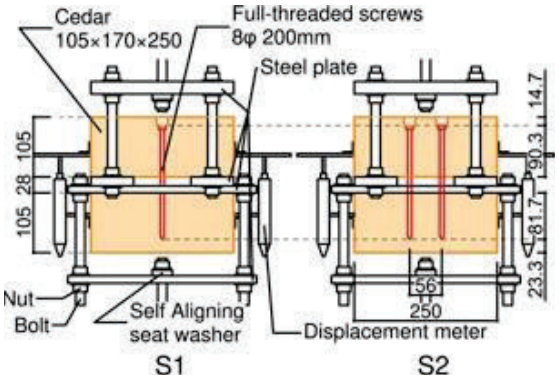

***Figure 8(a)**: Specimen configuration and set-up*

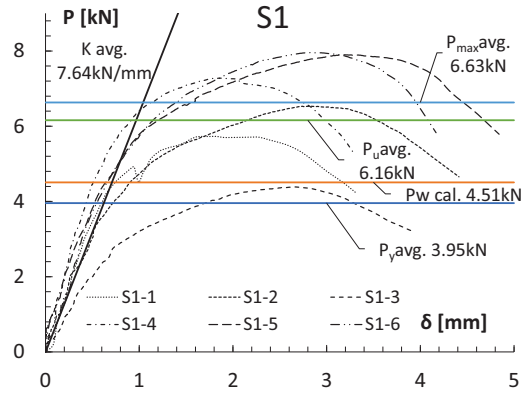

***Figure 9(a)**: S1 load-deformation curve*

wood screws using AIJ standards. When compared with the yielding resistance of S1, S2 demonstrated more than 2 times the yielding resistance. From this, it can be said that there is no reduction in withdrawal resistance due to multiple screws in the joint.

4 JOINT TEST

4.1 SPECIMENS AND SETUP

The experiment outline and test body dimensions are shown in Figure 12. The purpose of the bending experiment of the joint is to understand the mechanical characteristics when the locking deformation by the horizontal force causes the overturning moment in Mirika. The test body was shaped to reproduce the shape of the joint's 1st-2nd steps, which was considered to generate the most bending stress in Mirika.

The test body was made by layering two Sugi timber materials with main timber dimensions of 105 mm x 170 mm × 710 mm and side timber with the same cross-sectional length of 720 mm in the fiber direction parallel (BP) or rotated 15 degrees in the plane (BA), and with a water content of 16.3% (avg.), the density of 412kg/m3 (avg.), and Young's modulus of 6892.2N/mm2 (avg.). Three full-threaded screws 8Φ 200 mm were driven vertically.

The shape of the test body was layered symmetrically left and right to consider stability during loading. The rotation angle of BA is the same as that of Mirika. The screw insertion position was determined by the edge distance and spacing based on the AIJ standard for lag screw joints. Both BP and BA were arranged similarly to the first and second sections of Mirika. The number of test bodies was 6 for BP and 7 for BA. The measurement items were vertical displacement δ1 [mm] at the applied force point, compression amount t [mm] at the main member mouth position, and vertical displacement δ2 [mm] at the side member end.

The test body was placed on a counterforce base, plates for preventing compressive strain, and cylindrical fixtures were installed at both applied force points, and a uniaxial compression test machine with 2000kN was used to apply vertical force through an applied force beam. The applied force schedule was to reach the maximum strength in about 10 minutes, and the force was applied

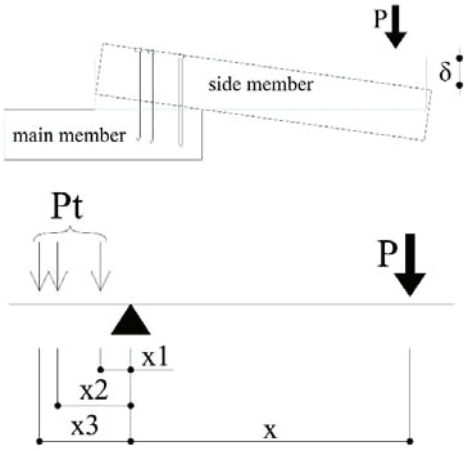

***Figure 13**: Joint dynamics model*

$$P = P_t \cdot \frac{x_1 + x_2 + x_3}{x} \qquad (1)$$

P: Estimated Bending Strength P_t: Screw Pull-out Strength
x: Distance from the bottom of the timber to the point of application
x_1, x_2, x_3: Distance from timber edge to screw core

until it reached 0.8Pmax after reaching the maximum strength. The estimated maximum strength was calculated by assuming the wood to be a rigid body and using the balance Equation of the pulling strength of the screw and the moment depending on the insertion position based on Equation (1) (Figure 13)

4.2 RESULTS

The load-deformation curve is shown in Figure 14, the experimental conditions are shown in Figure 15, and the characteristic values are shown in Table 1. The vertical axis of Figure 14 is the load on the side that broke among the left and right of 1 test body, and the horizontal axis is the vertical displacement of the point where the load was applied on the side that broke. The calculation of the characteristic values is the same as for the pull-out test.

The final fracture behaviour is dominated by the pull-out of the screws in both BP and BA, and the fracture is accompanied by wood compressive displacement. Brittle fractures were not observed in all test specimens, and the load gradually decreased after the maximum strength. In BA, rotational deformation in the direction of twisting of

Table 1: *Joint test characteristic value*

		Initial stiffness K [kN/mm]	Yield strength Py [kN]	Maximum capacity Pmax [kN]	Ultimate strength Pu [kN]
BP	Average	0.92	5.40	8.09	7.45
	Lower limit	0.88	2.84	5.49	5.16
	Equation (1)	—	6.37	—	—
	Equation (2)	—	2.84	—	—
BA	Average	0.83	4.23	6.90	6.35
	Lower limit	0.81	3.16	5.37	4.75
	Equation (1)	—	6.02	—	—
	Equation (2)	—	3.02	—	—

the side member also occurred due to the angle of the material. The average yield strength obtained from the experiment was lower than the predicted strength calculated by equation (1), with 85% for BP and 70% for BA. This is the effect of the moisture content of the wood used and the compression between the woods. The average moisture content of the wood used in both series was about 22%, exceeding the recommended value of the AIJ standard, so there is a possibility of a decrease in screw withdrawal resistance and an increase in compression amount. And the compression between the wood pieces resulted in a triangular compression that maximizes the end of the main member. This causes the rotation center of the main member during the bending deformation of the joint to move from the end of the main member to the center of gravity of the triangular compression, resulting in experimental values lower than

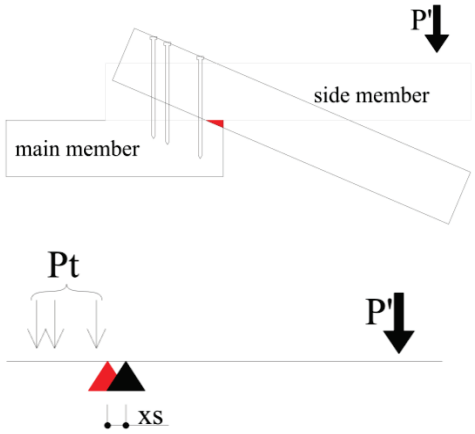

Figure 16: *Joint dynamics model considered compression*

$$P' = P_t \cdot \frac{x_1 + x_2 + x_3 - 3x_s}{x + x_s} \qquad (2)$$

P': Estimated Bending Strength $x_s : x_p/3$
x_p : Main material compression length

the bending resistance assumed in Equation (1) when the wood is assumed to be a rigid body.
Therefore, there is a possibility that the estimated value will be closer to the experimental value by modelling the support point that considers the compression of the wood. Considering the above factors, the lower limit of the bending-yield capacity of this joint was calculated using Equation (2) (Figure16), which was developed from

https://doi.org/10.52202/069179-0408

Equation (1) using the wood-screw pullout capacity equation in the AIJ Standard and the penetration equation in the Design Manual for Wood Structural Joints. Here, it is assumed that the dominant area of wood compression is near the edge of the main member, based on the extra-length condition and the experimental results. The bending capacity was estimated by applying the fulcrum reaction force of Figure 16 to ΣN in the denting equation to obtain x_p and using the moment balancing equation if the center of rotation moves to one-third of that value. Comparing the estimated values calculated above with the experimental values, the BP series and BA series are -0.3% and -4.3%, respectively, and the bending-yield capacity of the joints in this test specimen shape can be estimated on the safe side using Equation (2).

5 CONCLUSION

The mechanical properties of wooden composite structures were verified through experiments. The following are the results obtained from this study.

1. The mechanical properties of the joints in Mirika were experimentally understood.
2. In the pull-out experiment, the average ultimate strength of the S2 series was 2.07 times that of the S1 series, and it is considered that there was no reduction in initial rigidity in the wooden joint shape in the scope of this experiment.
3. When considering the rotation of the joint, there is compression between the wooden materials, and it is necessary to consider the movement of the rotation center in estimating the strength.
4. In the wall inside the surface experiment, the yielding strength was 21.5kN and 2/3Pmax was 30.3kN, and the safety as a structural body of the wall was confirmed as the result exceeded the target weight of the bookshelf (15kN).

ACKNOWLEDGEMENT

We thank Mr. Furumori Koichi (Furumori Koichi architectural design studio), Mr. Sugioka Toshikuni (Sugioka Sawmill), Mr. Ikeo Taku (Sumai koubou), and Mr. Kenzo Nagasako, Mr. Masaya Funakoshi (undergraduate students in Tokyo Denki University) for their cooperation in conducting this research. We gratefully acknowledge their support.

STRUCTURAL PERFORMANCE OF REINFORCED GLULAM BEAMS

Laith I. Gharaibeh[1], Ghasan Doudak[2]

ABSTRACT: The performance of wood glulam beams is generally characterized by brittle behaviour with little to no post-peak strength. Attempts to enhance the post-peak behaviour of glulam beams have included principles of reinforcing the tension face, while promoting more ductile compression-side failure. In the current study, Near-Surface Mounted (NSM) rebars are utilized to reinforce glulam beams in order to enhance their performance when subjected to static and dynamic loading. The reinforcement rebars are installed inside grooves at the tension face of the beam, using epoxy adhesive. The reinforced glulam beams were tested statically in four-point bending and with simply supported boundary conditions. Another set of reinforced glulam beams was tested under simulated blast loads using a shock-tube device. Similar loading and boundary conditions were also applied during the dynamic tests. An analytical approach was developed, verified, and used to investigate glulam beams reinforced with steel, GFRP, and CFRP rebars. The result of this comparison indicated a significant enhancement in the maximum peak strength and stiffness of the reinforced beams using steel and CFRP rebars, while beams reinforced with GFRP rebar exhibited lower increases in strength and stiffness.

KEYWORDS: Reinforced Glulam, Steel reinforcement, NSM, Blast load, Shock-tube device.

1. INTRODUCTION

Glued laminated timber (Glulam) has been successfully used for decades in heavy timber construction, with recent examples including the Brock Commons building in B.C. Canada and the headquarters of the Swiss media corporation in Zurich, Switzerland. The behaviour of glulam in flexure is generally characterized as linear-elastic brittle, under both static and dynamic loading [1]. The ultimate flexural failure typically occurs on the tension face at a defect (e.g. knots) or in some instances at finger joints [2]. Several research studies have been conducted to enhance the post-peak performance of timber beams in order to produce a more ductile failure mode. Examples of these attempts include reinforcing the tension face of the beam in order to delay the development of cracks at the tension side. This also helped initiate crushing failure mode at the compression face which in turn facilitated the increase in the overall energy-dissipation capabilities of the beam elements. Lacroix and Doudak [3] reinforced glulam beams using fiber-reinforced polymers (FRP) and reported an increase of 20% to 40% in the moment capacity depending on the reinforcement configuration. Yang et al, [4] reinforced a series of glulam beam specimens by applying steel reinforcing rebars at the beam tension face using reinforcement ratios of 0.5%, 1%, and 1.7%. The study reported increases in the range of 32% to 45% in moment capacity. Kliger et al. [5] investigated a wide range of reinforcement ratios of steel and carbon fiber plates. The study found that a maximum reinforcement ratio of 2% was appropriate to avoid shear failure before the ultimate flexural capacity of the beam was reached. The study also reported an increase in moment capacity in the range of 57% to 96%, when compared to the reference unreinforced beam. The behaviour of structural elements under blast loading is also greatly affected by high strain rates, resulting from the short duration of the loading. Research in the field of blast effects on timber elements has generally focussed on individual components with idealized simply supported boundary conditions, including light-frame stud walls [6,7], glulam beams and columns [1], as well as cross-laminated timber (CLT) elements [8]. Although some attempts have been made to address timber-composite assemblies, these studies have been limited to FRP sheets [3], steel straps [9], and corrugated steel panels [10]. Different types of reinforcing materials can be used to strengthen glulam beams using rebars, such as steel, glass fiber-reinforced polymer (GFRP), and carbon fiber-reinforced polymer (CFRP). In addition to providing sufficient strength and stiffness, steel can also add a significant amount of ductility, which in turn enhances the structural response of the glulam elements under blast loading. In the current study, epoxy is used as a bonding agent as well as a coating material to protect the steel. One of the disadvantages of GFRP is its low stiffness, which reduces its efficiency as a reinforcement material. CFRP material has high stiffness,

[2] Ghasan Doudak, University of Ottawa, Canada, gdoudak@uottawa.ca

https://doi.org/10.52202/069179-0409

but it is also associated with a high cost. The current study aims to investigate possible retrofit techniques to reinforce glulam beams using the near-surface-mounting (NSM) method. The structural behaviour of reinforced glulam beams using steel, GFRP and CFRP rebars will also be examined analytically.

2. EXPERIMENTAL PROGRAM

2.1 METHODOLOGY

The overarching goal of the experimental program is to validate analytical approaches that would facilitate the analysis of composite timber-reinforcement elements using the NSM reinforcement method. The experimental program includes subjecting full-scale beam specimens to static and blast-simulated dynamic testing under similar loading configurations and boundary conditions. The NSM method involves hollowing out grooves in the perimeter of the beam, placing the reinforcements inside the grooves, and then applying the epoxy over the reinforcement and initiating the curing process. The installation process of the NSM rebar method is illustrated in Figure 1.

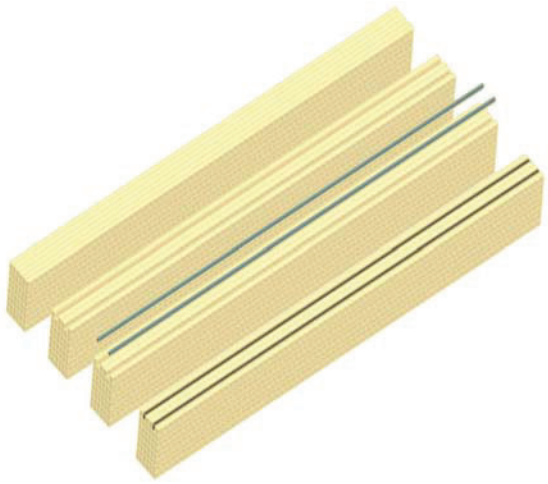

Figure 1: *NSM installation process*

The fact that the reinforcement is embedded inside the wood and surrounded by epoxy increases the contact surface area, unlike external reinforcement. Moreover, the reinforcement can be easily applied at the bottom or the side of the beam, unlike the external fabric reinforcements that have to be applied at both the bottom and side faces of the beam to provide suitable confinement and avoid debonding. The aesthetic appearance of the reinforcement could also be enhanced by adding a thin strip of wood to cover the groves after applying the reinforcement with the epoxy materials.

2.2 SPECIMENS AND TEST SETUP

Glulam beams with NSM reinforcement were tested statically and dynamically under a four-point bending. The procedure and configuration for the static and dynamic tests are presented in the following sections.

2.2.1 Static test

A set of glulam beams reinforced with 10M, 15M, and 20M steel rebars were tested statically. The beams consisted of a cross-sectional dimension of 137 mm x 191 mm and a length of 2.5 m. The beam grade was 24F-ES/NPG, produced by Nordic Structures. Wire gauge sensors were used to measure the displacement at the middle and one-third points of the beam span length. Strain gauges were also attached at the perimeter of the wood glulam section as well as along the steel reinforcements to measure the strain distributions. Furthermore, lateral supports were used at both ends of the beams to prevent out-of-plane buckling. The loads were applied to the beam specimens using a hydraulic jack, through an I-steel section. Load cells were placed at the supports to measure the reaction forces, as shown in Figures 2 and 3.

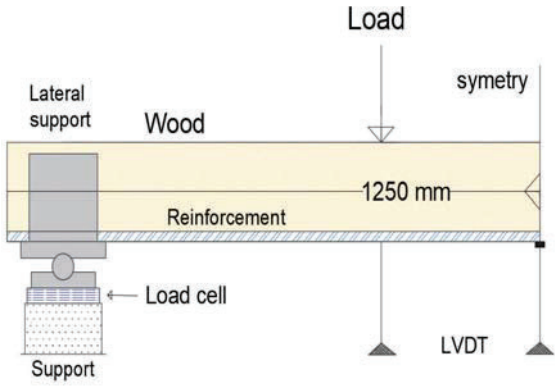

Figure 2: *Half-beam view for the static test.*

Figure 3: *Static test for glulam beam*

2.2.2 Dynamic test

A matched set of reinforced beams was tested under simulated blast loading using the shock-tube apparatus located at the University of Ottawa. Similar loading and boundary conditions to those described in the static loading tests were employed for the simulated blast tests, with the exception that the beam specimens were placed vertically, and the loads were applied horizontally. The shock-tube apparatus uses air pressure to create different

combinations of pressure and impulse to simulate the effect of far-field explosions. The device consists of three components: the driver, spool, and expansion sections. The driver section length can range from 305 mm to 5185 mm. Different combinations of pressures and impulses can be generated by changing the driver length. The shock-tube device is capable of generating a maximum pressure of 100 kPa and impulse of up to 2200 kPa-ms, as well as a positive phase duration of up to 70 ms. Aluminium foil layers are placed at the front and back of the spool, and when the desired air pressure in the spool is reached, the air pressure in the driver is drained, rupturing the aluminium foils and allowing the compressed air to propagate along the expansion section and interact with the test specimen. A load transfer device (LTD) mounted at the end-frame was used to collect the pressure and transfer it to the mounted specimen. The main components of the shock-tube device are shown in Figure 4.

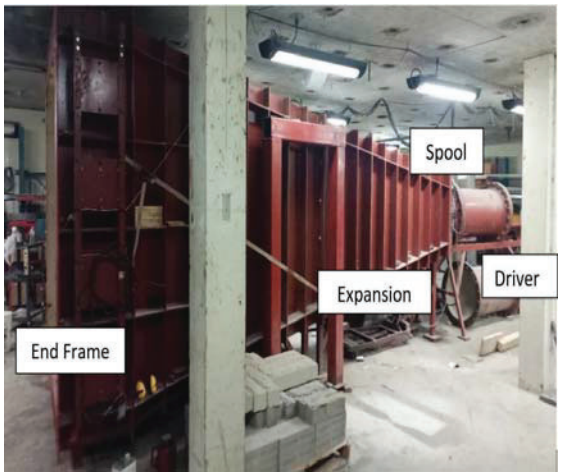

Figure 4: *Shock-tube device*

The displacement of the beam at mid-span was measured using linear variable displacement transducers (LVDTs) with the high-speed capability to capture the dynamic blast load. Dynamic load cells were used to measure the force reactions at the ends of the beams. The measurements were recorded using a data acquisition system (DAS) having a sampling rate of 10,000 samples per second. Furthermore, a high-speed camera having a recording rate of 2000 frames per second was used to capture the behaviour of the specimen and detect the failure mode during the test.

3. RESULTS AND DISCUSSION

3.1.1 Experimental Results

An example of the experiment results from the static test is presented in this section. The force-displacement curves for both the unreinforced and reinforced beams with 10M steel rebars are shown in Figure 5.

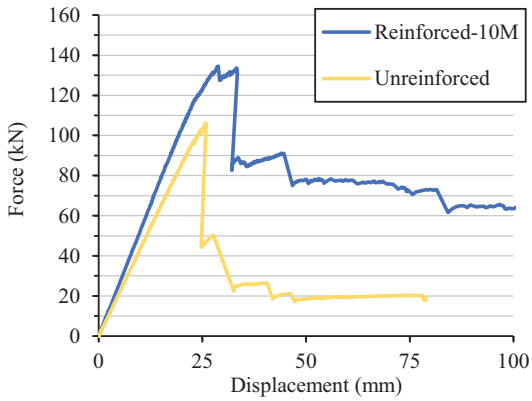

Figure 5: *Force-displacement curve*

From Figure 5 it can be observed that the strength and stiffness of the reinforced beam are significantly increased by the addition of the two steel reinforcement rebars. For this example, the strength and stiffness of the beam were increased by 34% and 23%, respectively, when compared to the unreinforced specimen. More importantly, it can be noted that the post-peak behaviour of the reinforced beam is greatly enhanced. A post-peak load carrying capacity in the range of 47% of the peak load is maintained until displacement levels are in excess of 100 mm.

Figure 6: *Damaged reinforced beam*

As shown in figure 7, cracks were developed and propagated at the tension face of the beam, and the epoxy material was fractured. The wood fibers at top of the beam were crushed due to compression stress. This type of failure mode is preferable since it enhances both the maximum peak strength as well as the post-peak behaviour of the glulam beam.

3.1.2 Analytical Results

The analysis approach used to predict the behaviour of the composite beam is the fiber section method. The analysis is conducted by setting an initial strain value at the top of the beam and selecting an initial position for the neutral axis depth (Z). Then, the strain profile along the depth of the beam is distributed linearly based on the Euler-Bernoulli beam theory by assuming that plane sections remain plane. The strain and stress are calculated at each

https://doi.org/10.52202/069179-0409

fiber based on the material model proposed by Buchanan [11], as shown in Figure 8.

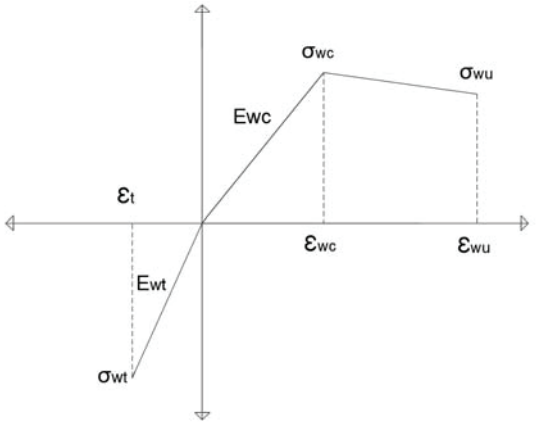

Figure 7: *Material wood model*

The model has been successfully used to simulate wood material behaviour in several previous studies [e.g., 1, 2]. In this model, σ_{wc} and σ_{wu} represents the maximum and ultimate stress in compression, respectively, and σ_{wt} is the maximum tensile stress. E_{wt} and E_{wc} are the modulus of elasticity for wood in tension and compression, respectively. ε_{wc} and ε_{wu} represent the strains at the maximum and ultimate stress in compression, respectively, while ε_{wt} is the failure strain at σ_{wt}. Following the calculation of the stresses at each fiber layer, the tension or compression force is calculated by taking the average stress at that fiber and multiplying it by the area of the fiber. The summation of the tension and compression forces from all fibers must satisfy equilibrium. If the equilibrium is not reached, a new value for depth Z is generated, and the entire procedure is repeated until the equilibrium is satisfied. The fiber moment is obtained by multiplying the force in the fiber by the distance to the neutral axis. The procedure is repeated for a new value of strain increment until the moment-curvature relationship for the beam section is achieved.

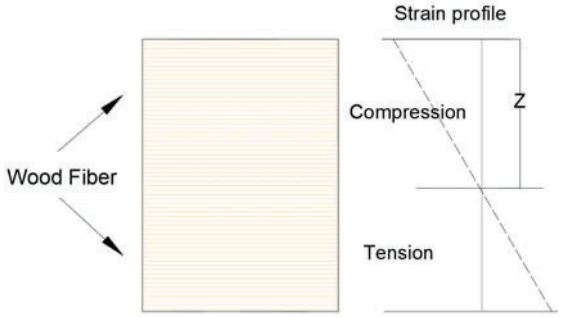

Figure 8: *Fiber section for glulam beam*

A VBA Excel-based code was developed and used to conduct the fiber section analysis and establish the stress-strain relationship along the depth of the beam. The effect of groove size was also considered in the analysis. Finally, the curvature is integrated twice to determine the displacement along the entire beam. The force-displacement curve obtained from this analytical procedure is compared with the experimentally obtained curve, as shown in Figure 10. The figure shows that the theoretical model provided a very good agreement with the experimental result in terms of force and displacement. Work is currently underway to extend the modeling capabilities beyond the peak load and to account for the behaviour of the reinforced beams.

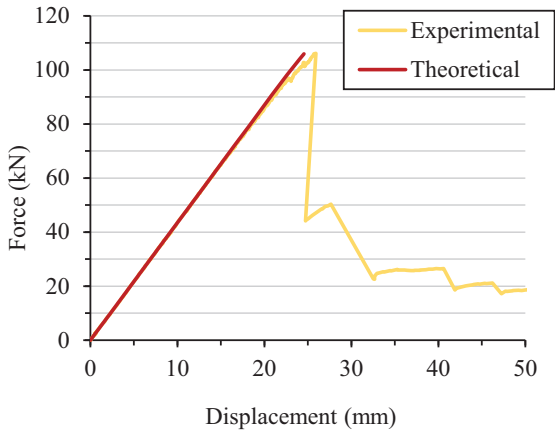

Figure 9: *Static test for glulam beam*

3.1.3 Reinforced beam

The analytical procedure presented in the previous section was used to compare the behaviour of glulam beams reinforced with steel, GFRP and CFRP rebars. For the steel rebar, an elastoplastic material model was used, as shown in Figure 11, where F_y represents the yield stress, E_s is the modulus of elasticity, and ε_y is the yielding strain. For the GFRP and CFRP materials, the stress-strain relationship is assumed to be linear, with E_g and E_c representing the modulus of elasticity, while F_g and F_c are the associated stresses, respectively. ε_c and ε_g are the failure strains for CFRP and GFRP materials, respectively, as shown in Figure 12.

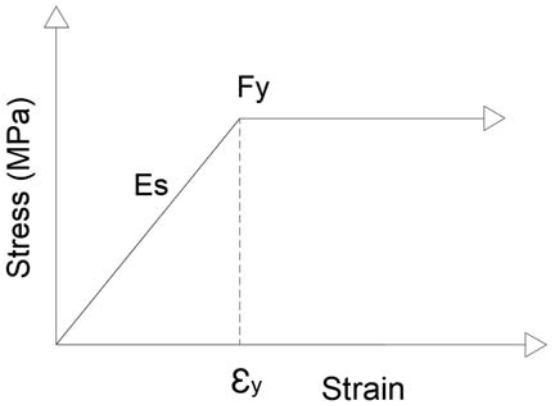

Figure 10: *Steel elastoplastic model*

https://doi.org/10.52202/069179-0409

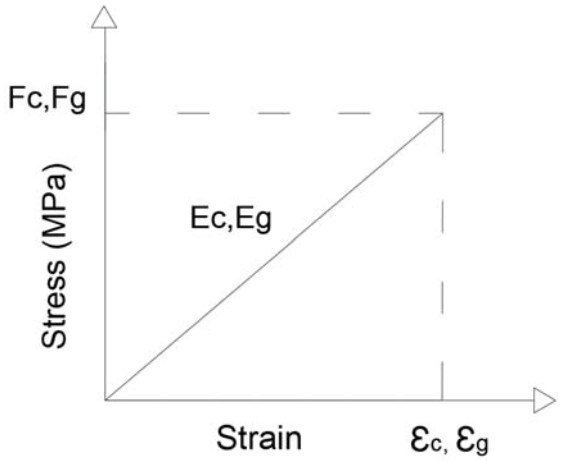

Figure 11: *GFRP and CFRP linear models*

For the reinforced beams, the forces at the reinforcements have to be included in the summation of the forces to satisfy the equilibrium along the cross-section. The reinforcements were assumed as concentrated elements since their cross-sectional area is very small compared to the glulam member. The analytical model was modified to accommodate the effect of the reinforcements in the sectional analysis. Figure 13 shows the wood fiber cross-section for the reinforced glulam beams, including the GRFP, CFRP, or steel rebar reinforcements.

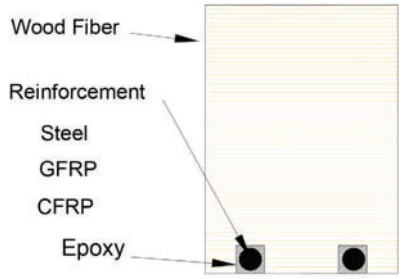

Figure 12: *Fiber-reinforced beam section*

For the purpose of the analytical comparison, US rebar sizes #4, #5 and #6 were used due to their availability in steel, GFRP and CFRP rebar sizes. The material property for the steel rebars was assumed to be according to ASTM 615 [12] with 420 MPa tensile strength and 200 GPa modulus of elasticity. The GFRP rebars were assumed to be consistent with those produced by MST Rebar Inc. in Canada [13], with 60 GPa in modulus of elasticity and 1,000 MPa minimum tensile strength, while the CFRP rebars were assumed to have 124 GPa modulus of elasticity and 2,000 MPa minimum tensile strength, similar to those produced by Hughes manufacturer in US, [14]. An example of a moment-curvature distribution along half the beam length is shown in Figure 14, for reinforced beams with #6 steel reinforcement rebars.

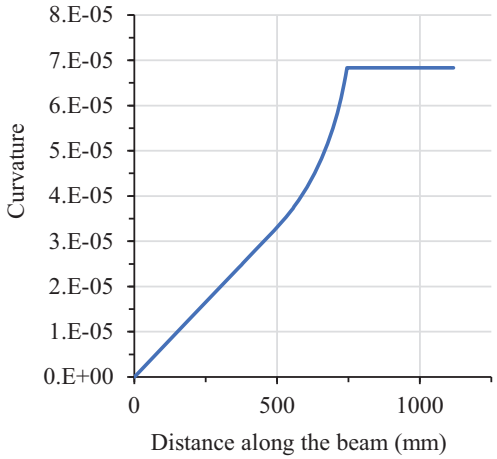

Figure 13: *Moment-curvature distribution*

Using the analytical model, the force-displacement curves obtained for the glulam beams reinforced with steel rebar sizes #4, #5 and #6 are compared, as shown in Figure 15.

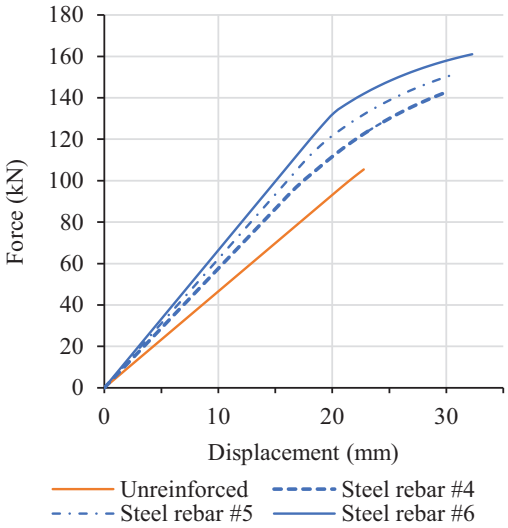

Figure 14: *Reinforced beam with steel rebar*

From this comparison, it can be observed that the strength of the reinforced glulam beams was increased by 35%, 45% and 53% when using rebar sizes #4, #5 and #6, respectively, compared to the unreinforced beam. The corresponding increases in stiffness was 24%, 34% and 53%, respectively. The curves using the GFRP reinforcement rebars are shown in Figure 16. It can be observed that the increase in strength is less than that observed in the beams analyzed with steel reinforcements, while for stiffness, only a minor increase is observed. The non-linear behaviour observed near the peak load in specimens with steel rebars is much less pronounced in GFRP rebars.

https://doi.org/10.52202/069179-0409

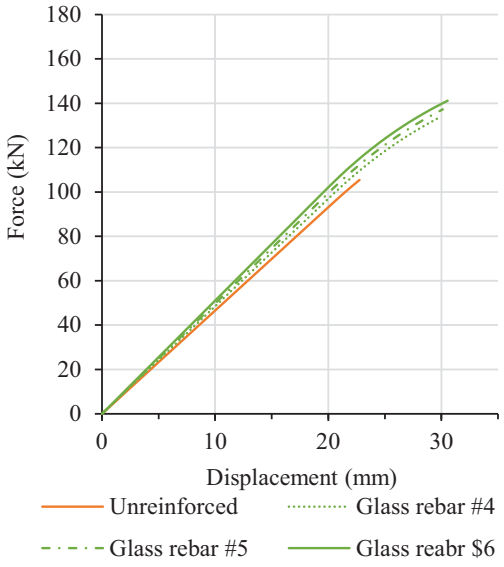

Figure 15: *Reinforced beam with GFRP*

Figure 17 presents the results for the beams with the CFRP reinforcement rebars, and shows increases in strength of 40%, 49% and 56%, using rebar sizes #4, #5 and #6, respectively, while the corresponding stiffness increases were 14%, 20% and 27%. The results show that the general increase magnitude is comparable to the steel rebars when it comes to the beam strength, however, the increase associated with stiffness is less, which can be attributed to the higher modulus of elasticity of the steel rebars.

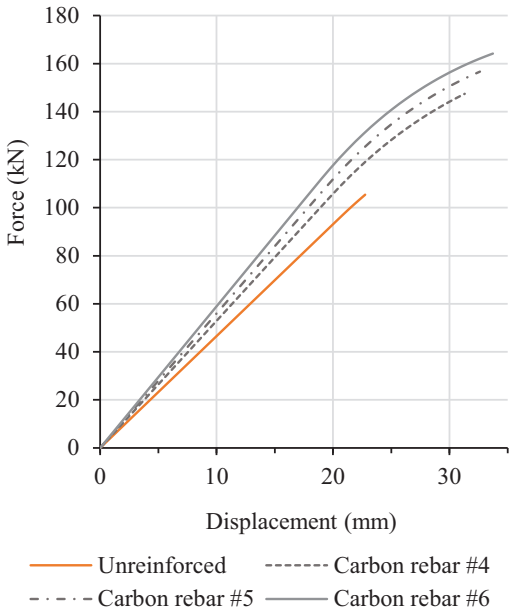

Figure 16: *Reinforced beam with CFRP*

A direct comparison between the three retrofitting options, illustrating the benefit of utilizing steel rebars, is shown in Figure 18 for the same rebar size (i.e., #6).

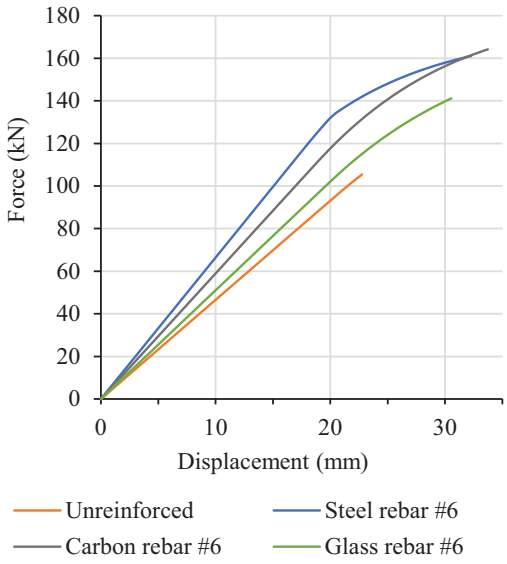

Figure 17: *Glulam beams with reinforcements*

4. CONCLUSIONS

Near-surface mounted rebars were used to enhance the performance of glulam beams, especially in the post-peak region. Reinforcements were embedded inside the beam at the tension face and adhered to the beam using epoxy. The behaviour of the reinforced beams was investigated experimentally, and results showed a significant enhancement in the strength, stiffness as well as post-peak behaviour. An analytical approach, developed based on the fiber method and using available wood constitutive models, was validated using the experimental results. The models were then used to compare the impact of using steel, GFRP and CFRP reinforcement rebars. The result of this comparison showed a significant enhancement in the maximum peak strength when using steel and CFRP rebars, while better enhancement in stiffness was obtained from the steel rebars. For beams reinforced with GFRP rebars, the increase in strength and stiffness was modest.

BENDING TESTS ON TIMBER CONCRETE COMPOSITES WITH PERFOBOND CONNECTIONS

Elif Appavuravther[1], Bram Vandoren[1], José Henriques[1]

ABSTRACT: Long spans in timber concrete composites (TCC) is the next step of improvement that is ambitioned by the industry and designers for more efficient structures. With Perfobond connections, which are originally developed for steel-concrete composites (SCC) constructions, targeting longer spans in TCC is feasible. In this paper, full scale TCC beams are experimentally investigated under four point bending with the use of Perfobond connections. Two sets of experiments are performed with a variation of the concrete type (normal weight concrete vs lightweight concrete). The results indicate that the use of Perfobond connections lead to a linear behaviour until initial local damage. In specimens with lightweight concrete, failure in the most loaded connections is observed, however it did not lead to strength degradation. For specimens with normal weight concrete however, maximum load is obtained with the connection failure which led to significant cracking of timber under bending (tension side) and subsequently, the collapse of the TCC beam. As a result of this experimental campaign, a performant behaviour of the TCC beam implementing the Perfobond connections is observed and therefore, longer spans may be envisaged.

KEYWORDS: Perfobond connector, adhesively bonded connection, timber concrete composite, bending test

1 INTRODUCTION

The use of timber is re-gaining popularity in the construction sector. To comply with the neutral emission regulations in Europe by 2050, the use of timber is one of the solutions that can help since the carbon emission of the wood is much lower when compared to the traditional, commonly used construction materials, such as concrete. To overcome the weaknesses of the structural properties of using bare timber, such as vibration and deflection, the combination of concrete with timber is an innovative solution which is becoming more and more implemented by the construction sector. Besides its reliable structural behaviour, using a concrete slab and timber beam allows a prefabricated solution where the on-site application time can be limited, the quality of the materials and assembly can be controlled due to limited execution on site. Concrete can also be used to rehabilitate and reinforce the existing timber structures. Timber-concrete composite solutions are relatively new and the experimental work on bending behaviour of the beams is limited in the current literature [1, 2].

In a TCC beam, the target is that the concrete slab resists the compression stresses and the timber beam resists the tensile stresses. This optimal case can be obtained once the beam is in a high composite action. Such high composite action is obtained with connections with high stiffness. Traditional connections used in TCC, such as dowel connections, are limited in strength and stiffness [3, 4]. Notch connections lead to a high strength and stiffness, however they do not prevent an uplift (and therefore use of a screw is required) and have a very brittle behaviour [5, 6]. Bonded-in connection is another solution to overcome the limitations on strength and stiffness exhibited by common dowel connections [7]. Even though these connections have been investigated for decades, only recently researchers are coming to an agreement to have requirements in the design codes, such as a sub-section dedicated to bonded-in rods in the version under preparation of the prEN 1995-1-1 [8]. This is an important step to support designers using bonded-in solutions however, it only covers steel rods, and an extension to steel plate connectors is still to be done since they are being experimentally investigated in TCC for the past few decades [9-15].

Once the connection behaviour is determined, it is important to examine the behaviour of the connection in full scale composite beams under bending loading. The bending tests helps to determine how the composite action is achieved, how efficient it is, the distribution of stresses, the impact of the connection behaviour on the mechanical performance of the beam and therefore the capacity to distribute load.

In this work, Perfobond connections commonly used in SCC are adopted into TCC beams. Perfobond is a steel plate connector, originally developed for SCC beams. The steel plate, welded to the steel beam, is embedded in the concrete slab where mechanical interlock is mobilised at

the tip of the plate and through a concrete dowel action, obtained through predrilled holes in the plate [16], simultaneously, shear-slip and uplift resistance are mobilised.
In this experimental work, two different configurations are tested, one series with normal weight concrete and one with lightweight concrete. Failure loads and failure modes are compared for the two cases. The results indicate that, with the use different concrete types and strengths, similar behaviour and load capacity are obtained. Then, given the high strength and stiffness of this connection, leading to increased spacing between connectors, the suitability of the Gamma method to predict bending stiffness and load capacity is assessed. Moreover, experimental results are compared with more common solutions, such as rod connections from the literature, to further evaluate on the performance of TCC beams using Perfobond connections. The results show potential for the development of long spans beams.

2 MATERIALS AND METHODS

2.1 TEST SPECIMENS AND DESIGN

In this study, full scale bending tests are performed on 5.2 m long TCC beams. Three replicas of each series are tested. The difference between the two series is the concrete type. The concrete slab cross section was 600 x 70 mm and timber with a cross section of 90 x 270 mm (see Figure 1 (a)). In the timber beams, ten grooves with the dimensions of 110 mm x 55 mm x 10 mm are opened. For each beam, a total of ten connections are used, with spacing of 500 mm. The locations of the connections are presented in Figure 1 (b). The spacing is determined using the Gamma method for residential building and complying to ultimate limit state and service limit state [17].
The timber beam is covered by an adhesive tape to avoid moisture flow from the concrete to the timber and to avoid the friction between the two materials. The adhesive, with approximately 2mm thickness, is applied and dried in an indoor environment and following the recommendations given in the product Technical Documentation [18].
Additionally, a bare timber beam with the same cross-section as those used in the composite solution was tested for sake of comparison.

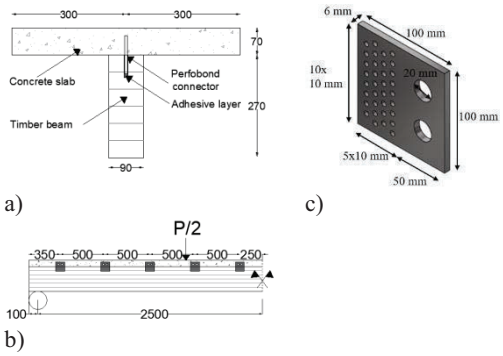

Figure 1 *Test specimens (a) cross section of the TCC beam (b) elevation view of test specimens (c) Perfobond connector dimensions*

2.2 MATERIALS

In the specimens denoted with P-NWC, normal weight concrete with a 28- day cubic compression strength of 41 MPa and density of 2200 kg/m^3 is used. In the series denoted by P-LWC, lightweight concrete with a 28- day cubic strength of 25 MPa and density of 1600 kg/m^3 is used. Minimum reinforcement is used to avoid concrete tension cracks [19]. Glulam timber of strength class 24h (Picea Abies specie) is used. Perfobond connectors with steel grade S355 are used, with cross section dimensions given in Figure 1 (c). The Perfobond is designed using the design model given in the literature [16]. For the bonding between the Perfobond connector and the timber beam, Sika Anchorfix-3030 epoxy-acrylate is used [20].

2.3 TEST SET-UP, MONITORING AND TEST PROCEDURE

The experimental set-up consists of a meccano system (the experimental frame), a hydraulic jack, load cells, supports and LVDTs (Linear Variable Differential Trasformer), as illustrated in Figure 2 (a). In total, eight LVDTs are installed on each beam, seven in the horizontal direction and one in the vertical direction at the midspan. The horizontal ones correspond to either connection location or placed under the loading. The LVDT locations are given in Figure 2 (b).
Each specimen was centred both in longitudinal and transversal direction to avoid eccentricity due to loading. The loading protocol given in EN 26891 is followed [21].

Figure 2 *(a) Test set-up (b) LVDT Locations*

3 RESULTS AND DISCUSSION

3.1 TEST RESULTS

In Figure 3, the force-midspan deflection behaviour of all three replicas of each series and of the bare timber beam under four point bending is given. In Table 1, mean loads, at two different load levels, are given, i) at the initial failure, F_1, where the first failure is observed (during the experiments with the change in the slope of the force-slip behaviour) and ii) the maximum load where sudden loss of resistance is observed, F_{max}.

For the P-NWC series, no initial failure load is recorded as the first peak in the load lead to sudden load decrease.

A steep linear behaviour is obtained until F_{max} and the recorded force is 67.6 kN on average. At this point, the failure is due to the connection failure. In Figure 4 (a), the slip increase at F_{max} can be observed for specimen P-NWC-A (for force-slip behaviour of the beams, only the results of one series is presented for sake of clarity and as other specimens followed a similar trend). The major slip increase occurred at the LH1 and LH2 followed by LH3. The LVDT LH2 is located approximately under the third connection (see Figure 1 (b)), which justifies the connections 1, 2 and 3 failing, causing the significant slip measured at LH1 and LH2. Because of the brittleness of the connection in this case (with this type of concrete, NWC), the redistribution of force does not occur smoothly. The load was distributed among the connections as there are a few spikes of increase in load after a drop, as the slip increases, until the load could no longer be bore by the timber beam. A picture of the failed beam can be found in Figure 5 (a) where the timber failure is clear. Minor cracks at the concrete were observed however, failure of the connections was not extended to a visible form in the concrete and timber.

For the P-LWC series, a very steep behaviour is observed until on average 55.8 kN. At this point, a reduction in the slope of the force-deflection is observed without loss of the load capacity. At this load level, F_1, cracks around the connections are observed. The slip recordings from LH 1 and 2 given in Figure 4 (b), show the first three failed connections. A significant slip increase is recorded on LH 3 and 5 where the 4th connection is located showing that also failure on those connections occurred. The load is distributed among the remaining connections until the load capacity increased on average of 66.2 kN and at this load level, timber cracked, as given in Figure 5 (b), setting to the maximum capacity of these specimens. At the maximum load, the cracks around the connections became more visible and cone shaped failures are observed as the connection rotated with the increased load (see Figure 5 (b & c)). And this behaviour is different from the previous, here, connection failed in a less brittle mode which is seen by the fact that load is still increasing in a smooth way up to maximum load. It should also be noted that no uplifting occurred between the concrete and the timber layer.

One timber beam (90 x 270 mm) is tested under the same conditions to observe the difference with the TCC beams. A linear but rather more flexible behaviour is observed. The beam failed due to bending strength (tension) at 44.8 kN. This force-deflection curve clearly shows how the use of concrete improves the strength and stiffness of a timber beam.

3.2 DISCUSSION

With the change in the type and the strength of the concrete, a few observations can be made;

- The stiffness the TCC beam (Figure 3) is not significantly affected. The use of normal weight concrete lead only to a slightly stiffer behaviour. This increase is due to higher young modulus of this concrete type and of corresponding connection stiffness [22].
- The concrete type had an impact on the pre-peak behaviour due to the different behaviour of the connection with each type. In NWC the connection is stronger but more brittle not allowing a smooth distribution of forces through the connections distributed along the beam.
- As concrete did not govern maximum load capacity, the two series presented similar load capacity governed by the cracking of the timber beam. However, the concrete type played a role in the pre-peak behaviour due the impact of the concrete type at the shear connection level [22].
- The use of concrete and shear connections lead to 24% and 50% increase on load capacity with lightweight concrete and normal weight concrete, respectively.
- The curve (Figure 3) shows a significant difference in the bending stiffness between the composite beams and the bare timber. The bending stiffness increased 3.2 and 2.6 times when normal weight concrete and lightweight concrete and connections are added to the bare timber, respectively.

4 APPLICATION OF THE GAMMA METHOD TO A DISCRETE CONNECTION

Currently, the Gamma method is the analytical approach used for design since it is in the design code prEN 1995-1-1 [17]. Even though the limited range of application can lead to deviations on the prediction of the bending stiffness of the composite beam, and the corresponding stress distribution [23], the method is commonly used due to the simplicity and suitability for the current practical applications of TCC beams. Some of the causes of such deviations is in the fact that the model is developed for sinusoidal loading and the load distribution among connections is assumed to be equal. This assumption is accurate if the connection spacing is small [1]. In this work, however, with four-point bending and connection spacing of 500 mm, this is not the case. The connections outside in the loading zones does have same shear flow, however, the slip is higher further away from the midspan. The slip results showed that not all connections failed at the same load level (specially the series P-NWC – the decrease and increase in the force-deflection curve shows the connections failed gradually).

In Table 2, the comparison of experimental results with the Gamma method are given for the bending stiffness (EI), maximum load (F_{max}) and failure modes. In addition to experiments from this paper, an example from the literature with rod connections are used [23].

The expected failure mode by the Gamma method was the connection failure for the Perfobond connections, and combined bending and axial forces for the rod connections [23], which are in agreement with the experimental results reported. The connection forces are calculated using prEN 1995-1-1 Annex B [17].

The results show in terms of maximum load prediction, 33% and 62% underestimation is recorded for normal weight and lightweight concrete, respectively. The force limit for connections is introduced from the shear test results [22]. In shear tests, for the series with the use of lightweight concrete, failure at the connection level is recorded at less than half in comparison to the series with

https://doi.org/10.52202/069179-0410

the normal weight concrete. This justifies the 100% difference in the expected failure loads. This results clearly show that in the Gamma method, the connection forces are underestimated under bending behaviour. And 21% of underestimation is recorded from the rod connection Again, this underestimation is due to the fact that with the Gamma method, linear force distribution among all connections is assumed, whereas, in this study and the literature [23], it is shown that it does not represent the reality and the underestimation of connection forces. The spacing of connections is however, is expected to cause more deviation, which is also shown in this comparison.

With the Perfobond connections the overestimation of bending stiffness is approximately 5%, however for rod connection this is limited to 13%. The limited deviation for these experiments shows a good accuracy however, overestimation can cause problems in design applications. With bending stiffness, the results are in better agreement with the Gamma method as it is directly dependent on the mechanical and geometric properties of the composite beams.

Table 2 *Bending stiffness comparison between experimental results and Gamma method using Annex B of EN 1995-1-1 [17]*

	EI (kNm²)	**F_{max} (kN)**	**F_{max} mode**
P-NWC	8285.7	67.6	Connection failure
P-NWC_ Gamma method	8703.0	45.3	Connection failure
Difference (%)	-5.0	33.0	
P-LWC	7161.7	55.8	Connection failure
P-LWC_ Gamma method	7613.5	21.5	Connection failure
Difference (%)	-6.3	61.5	
Sebastian et al. [23]	1889.8	40.0	Combined bending and axial force
Sebastian et al._Gamma method	1638.2	31.6	Combined bending and axial force
Difference (%)	13.3	21.0	-

5 CONCLUSIONS

The objective of this work is to investigate the bending behaviour of TCC beams incorporating Perfobond shear connections. As a result of this experimental work, it can be concluded that Perfobond connections lead to a strong behaviour under bending loading. In both series, where the difference was the strength and the type of the concrete, the initial failure was a connection failure, followed by a bending strength (timber tension) failure.

The results indicate that the concrete type and strength had an effect on the load-deflection behaviour of the beam as it impacted the connection behaviour, however, maximum load capacity was not very different since the failure was due to the timber.

When the force midspan deflection of the TCC beam is compared with a (non-composite) timber beam, an increase of 24% and 50% on load capacity with lightweight concrete and normal weight concrete, respectively was recorded.

With the use of the Gamma method from prEN 1995-1-1, the bending stiffness, expected failure load and failure mode are compared. The results show that even though the failure mode was in agreement, Gamma method underestimates the maximum load and overestimates the bending stiffness. The deviation in bending stiffness can be explained with the deviation in the material properties. The deviation in the maximum load capacity depends on a few factors such as loading type, connection spacing and underestimation of the connection forces under bending loads.

This work shows that, with the given parameters, high composite action can be obtained with connection failure, which is targeted in TCC. Especially when lightweight concrete is used, controlled ductile failure is recorded.

ACKNOWLEDGEMENT

The authors would like to acknowledge Sika Belgium and LTS for contribution of materials and technical support. The support of master's students Thomas Sutens, Frédérique Claes and Joris Swinnen from 2020 – 2021 academic year are appreciated.

DESIGN OF ASYMMETRIC FRICTION CONNECTION FOR SESIMIC RETROFITTING OF RC FRAMES WITH CROSS-LAMINATED TIMBER PANELS

Angelo Aloisio[1,2], Francesco Boggian[1], Roberto Tomasi[2]

ABSTRACT: This paper proposes a probabilistic model for predicting the friction coefficient of asymmetric friction connections to be used for the seismic retrofitting of reinforced concrete buildings using Cross-Laminated Timber (CLT) panels. The model has been calibrated on the experimental force-displacement curves of the AFC samples, tested at the Norwegian University of Life Sciences (Norway), within the e-SAFE research project.

KEYWORDS: Cross-Laminated Timber; Passive Dampers; Friction dampers; Seismic retrofitting; Probabilistic models.

1 INTRODUCTION

Among hysteretic devices, friction dampers have been gaining more attention in the last few years. These dampers dissipate seismic energy by mechanical damping through sliding friction with the primary braking rather than breaking principle [1]. There is a wide range of applications of friction dampers, from civil to mechanical and avionic engineering [2]. However, there are still a few attempts to use friction dampers for seismic retrofitting civil structures. Venuti 1976 [3] and Pall et al. in 1980 [4] were the first to add friction devices as additional damping sources in civil structures. The Limited Slip Bolt (LSB), evolved to the Pall Frictional Damper (PFD), exhibited stable, almost rectangular hysteresis cycles [5], [6]. PFD is conceived for X- and K-bracings. Its worldwide success has confirmed the merits of the PFD. Multiple applications and research papers are proving the value and efficiency of the PFD [7]–[10]. The main drawbacks of PFD are the relatively low capacity (less than 10 kips), the need for high precision work for its manufacture, and specialized training for the installation process [11], [12].
In 1989 Fitzgerald et al. [13] devised a friction connection called the Slotted Bolted Connection (SBC), characterized by a more straightforward design than the PFD. The proposed SBC worked by sliding channel bracing plate over a gusset plate interconnected by high strength bolts with washers (Belleville spring) for adjusting the bolt tension.
There are two main classes of SBC: the Symmetric and Asymmetric friction connection [14], [15]. Symmetric Friction Connection (SFC) is a type of SBC that consists of the main plate (with slotted holes), two brass shims, two outer plates, and high strength bolts.
Initially proposed by Clifton [16], Asymmetric Friction Connection (AFC) is another type of SBC [17], [18]. AFCs consist of steel plates and shim layers clamped by the pre-tensioned bolts.
AFC is a crucial component of Sliding Hinge Joints (a low damage beam-to-column connection for the Moment Resisting Frame). AFCs installed in SHJ consist of shims, cleat, cap plate, high strength bolts, and bottom flange of the beam. The friction originates from the sliding between (i) beam bottom flange and upper shim and (ii) cleat and lower shim [16]. Initial developments of AFC were based on brass shims [19]. Subsequent studies by Mackinven [20] extended the application to mild steel and aluminium shims. The AFC is simple to build, cost-effective, and capable of dissipating energy under seismic excitation.
However, the AFC hysteretic stability highly depends on the mutual hardness between the steel and shim layers. In addition, the stability of the hysteretic performance is affected by the interaction between abrasive and adhesive wear and friction phenomena. There are several examples of application of AFC connections in real buildings, see [21], [22]. A few scholars [23]–[27] attempted to verify the consequences of wear and friction on AFC in the past years. They found that a stable cyclic behaviour can be achieved if there is a significant difference in the mutual hardness of the siding surfaces, i.e. shim layer and steel plates. The similarity in sliding surfaces' hardness causes a significant instability of the hysteresis loop mainly due to the large amount of work-hardened wear particles produced during the sliding mechanism. These particles abrade the sliding surfaces in an irregular pattern, thus exhibiting a wear abrasive mechanism defined by Grigorian and Popov [19] and Khoo et al. [18]. The stability of the hysteresis curve, in the case of non-lubricated sliding surfaces, depends on the initial wear of the shim or steel plates. For instance, in the case of the shim layer being less hard than the plates, the initial wear increases the roughness of the shim layer. The wear particles generated in this process create lubrication that

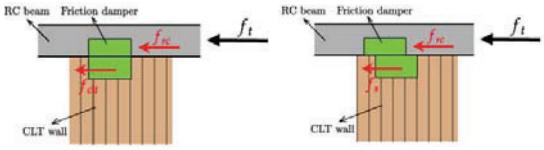
[1] University of L'Aquila, Italy
[2] Faculty of Science and Technology, Norwegian University of Life Sciences, Oslo, Norway

https://doi.org/10.52202/069179-0411

stabilizes the friction coefficient. Therefore, the wear particles generated in the initial phase are crucial to achieving a stable performance of the AFC.
Aluminium shims are among the materials that exhibit the best performance, with the lowest and more stable friction coefficient. Currently the shims to be used in AFC are recommended to be abrasion-resistant, like (high hardness) steel [21]. Nonetheless, AFCs with high hardness cleat and high hardness shims do not provide specific benefit on the seismic performance [28].
There are different typologies of AFCs. The most used and studied is the Sliding Hinge Joint (SHJ). The SHJ is a flexural connection designed to use at the beams' ends in steel moment-resisting frames. It is an AFC where energy is dissipated through sliding in slotted bolted connections in the beam bottom flange [29]. The initial application of friction connections to low-damage moment-resisting joints has been recently extended to pinching-free connections for timber structures [30]. Pinching represents one of the significant weaknesses in timber structures since it is associated with considerable degradation after repeated cycles [31], [32]. Loo et al. [33] investigated the possibility of using SFC instead of hold-down for restraining timber shear walls against uplift, to cap the force transmitted to the wall, and reduce inelastic damage. The subsequent experimental campaigns presented in [15] established the effectiveness of SFC on reducing the degradation and pinching phenomena typical of timber connections. The following studies presented in [34] pointed to a displacement-based design method for multistorey CLT buildings with friction connections. Next to the findings by Loo et al., [35] studied the response of SFC connected to a CLT panel. Zamani and Quenneville proposed a resilient slip friction connection (RSF) as a hold-down connector for CLT panels [36]. So far, no AFC was used as a connection system for CLT panels except for the attempts by Boggian et al. [37]–[39]. Boggian et al. tested AFCs for a hybrid structural system, the e-CLT technology.

2 MECHANICAL RESPONSE OF THE E-CLT

Fig.1 shows the representation of the e-CLT system applied to a building. CLT panels are attached to the beams of each floor with a couple of friction connections (AFC), which can act as rigid connections or slide according to the entity of the horizontal force acting on the building. The basic functioning principle of the AFC is illustrated in Fig.2. When the applied force is below a certain threshold the AFC doesn't activate and stays in the *stick phase*, thus the total resisting force at the i-th story (f_t) is the summation of the resisting forces of the CLT panel (f_{clt}) and the RC frame (f_{rc}). If the reaction of the CLT panel exceeds the slip force (f_s), the AFC activates and transitions to the *slip phase*, and thus the total resisting force is the summation of the resisting force of the RC frame and the slip force of the AFC.



(a) (b)

***Figure 1**: Illustration of the contributions of forces: (a) before the AFC activation and (b) after the AFC activation.*

The e-CLT unit behaves like a parallel system, whose governing equations are:

$$f_t = f_{\mathrm{rc}} + f_{\mathrm{clt}} \quad \text{if} \quad |f_{\mathrm{clt}}| \le |f_s| \tag{1}$$

$$f_t = f_{\mathrm{rc}} + f_s \quad \text{if} \quad |f_{\mathrm{clt}}| > |f_s| \tag{2}$$

The conditional statement on the exceedance of the slip force drives the transition between the two stick and slip phases of the response.

3 EXPERIMENTAL TESTS

The data used in this paper descend from an experimental campaign on AFC specimen at component level. The full campaign is described in [40], and this section will give a synthetic overview of the activity. The specimen, called HYB, is shown in Fig.2, and is composed by an anchor profile (fixed rigidly to the beam of each floor/testing machine during the experiments) and a free profile, which is connected both to the CLT panel, with a screw connection, and to the anchor profile, with two preloaded bolts which allow for sliding in an elongated hole. Both profiles are made of cold bent steel and are 8mm thick. The friction connection is completed by a cap plate and 2 aluminium shim layers to improve the stability of the friction behaviour, which are 2mm thick.

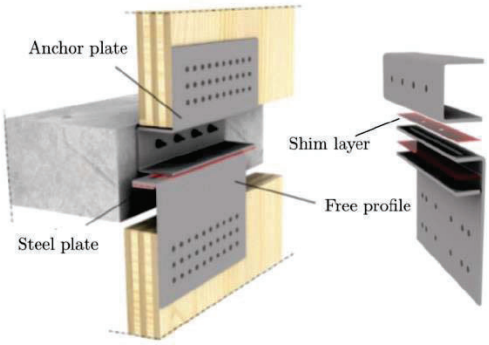


***Figure 2**: Illustration of the tested specimen.*

3.1 OVERVIEW OF THE TESTS

A total of 20 tests was carried out, on 5 different specimens. Every specimen was tested more times and in some cases with different preload forces. The main setup is shown in Fig. 3. The anchor plate is attached to the cross head of the testing machine, which moves up and down, simulating the horizontal movement of a beam subjected to seismic forces. The free profile is connected to a 100mm thick CLT panel with 33 10x80 screws, and to the anchor profile with 2 M16 bolts. The tests were carried out in displacement control method, with a speed of

https://doi.org/10.52202/069179-0411

2mm/s and the following cyclic protocol: 1x5-10mm+3x20-40-60-80-100mm. Fig.3 shows a picture of the main setup and a scheme with the indication of the various sensors acquiring data. The thermocouple was placed directly on the steel plate where friction was occurring.

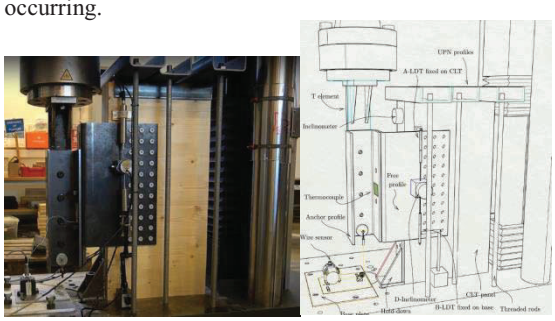

***Figure 3**: Main setup for the testing activity.*

3.2 RESULTS

An extract of the results is shown in Fig.4 for specimen HYB-3. The load displacement graph shows shape that resembles a rectangle, which would be the ideal shape for friction connections hysteresis loops. In this case the shape is not a pure rectangle because it represents the hysteresis of the whole system, which included the deformability of the steel plates and the screw connection. The S-like shape at the branches where the load changes direction is due to the pinching of the timber connection. Full detailed results are presented in [40].

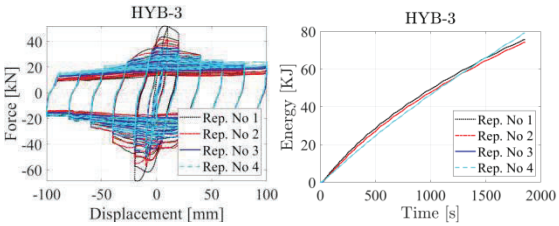

***Figure 4**: Results for specimen HYB-3.*

3.3 ESTIMATE OF THE FRICTION COEFFICIENT

The estimate of the slip force, and thus the friction coefficient, from experimental data is not direct and requires the definition of an approach. This is because the force changes during the tests and the sign changes. The definition of slip force is based on the cumulated dissipated energy, which is a strictly increasing function, as seen in Fig.5. The dissipated hysteretic energy can be defined as follows:

$$E = \sum_{i=0}^{n} E_i = \sum_{i=0}^{n} \left| \frac{F_{i+1}+F_i}{2} \cdot (\delta_{i+1} - \delta_i) \right| \quad (3)$$

where E is the dissipated energy, E_i the dissipated energy at the $i-$th time step, F_i and δ_i are the force and displacement at the same time step, respectively.

The cumulative distance of travel D is the sum of the displacement time steps:

$$D = \sum_{i=0}^{n} |\delta_{i+1} - \delta_i| \quad (4)$$

The slip force is defined as the work per unit of length:

$$F_{\text{slip}} = \frac{E}{D} \quad (5)$$

The experimental friction coefficient μ is finally calculated as

$$\mu = \frac{F_{\text{slip}}}{n_s n_b F_P} \quad (6)$$

where F_{slip} is the slip force calculated in Eq.(5), n_s is the number of shear surfaces equal to 2, n_b is the number of the preloaded bolts equal to 2, and F_P is the preload force. It must be remarked that the above definition of the friction coefficient cannot be entirely interpreted and understood in light of the Amontons laws. Friction in AFC is not just the product of friction between plates mutually sliding. Therefore, the estimated friction coefficient must be considered a system friction coefficient, representing the entire structural performance.

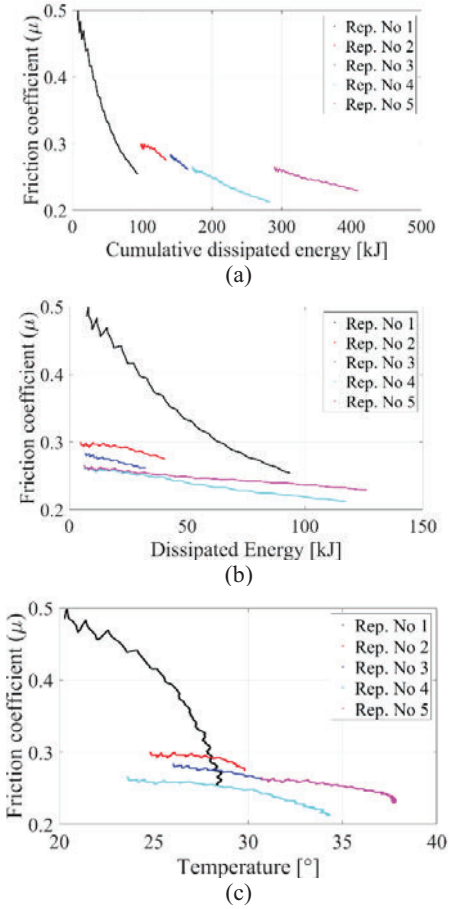

***Figure 5**: Illustration of the contributions of forces: (a) before the AFC activation and (b) after the AFC activation.*

4 PROBABILISTIC FRICTION MODEL

The formulation to predict the friction coefficient can be decoupled into two models. The first model defines the dependence between the value of the friction coefficient estimated at the beginning of each cyclic response μ_0 and its value estimated at the beginning of the first cyclic response from the time of the AFC installation $\hat{\mu}_0$. The second model predicts the value of the friction coefficient μ during each cyclic response starting from the value of

the friction coefficient estimated at the beginning of the response μ_0. The two models will describe two aspects of the friction coefficient evolution. The first will express the dependence of μ on the deformation history. The second will define its evolution during each cyclic response.

Following [40], the model that relates μ_0 to $\hat{\mu}_0$ is formulated as

$$\log(\mu_0) = \log(\hat{\mu}_0) + \gamma_1(\epsilon_p) + \sigma_1\varepsilon \quad (7)$$

where ϵ_p is the dissipated energy accumulated from the past loading tests of the specimen up to the beginning of the cyclic response to be simulated and $\sigma_1\varepsilon$ is the model error, with σ_1 model standard deviation and ε normally distributed random variable. The logarithm is used as variance stabilizing transformation.

The correction term $\gamma_1(\hat{\epsilon}_p)$ is constructed as a polynomial function of ϵ_p. The relevant terms in the polynomial function are selected using the procedure followed in [40]. The selection process (i.e., the removal of explanatory functions from the initial model) stops after a cumulative increase of the model standard deviation greater than 5% that would lead to an excessive loss of accuracy. Although the number of terms in a probabilistic model is often selected in order to balance accuracy and ease of use, in this case, given the limited amount of data available for the calibration, the number of terms is limited to avoid possible over-fitting of the data.The model for μ is formally similar and can be written as

$$\log(\mu) = \log(\mu_0) + \gamma_2(\epsilon_p, \epsilon_d, \hat{\mu}_0) + \sigma_2\varepsilon \quad (8)$$

with ϵ_d dissipated energy estimated from the beginning of the current load test, without the contributions related to the past deformation history. Among the explanatory functions considered for γ_2 there are $\hat{\mu}_0$ and powers of e_p and e_d up to the fourth order. Increasing the order of the powers of e_p and e_d above the fourth is avoided because it would lead to a limited increase in accuracy but would also result in an impractical and less manageable model. The models resulting from the selection processes read

$$\log(\mu_0) = \log(\hat{\mu}_0) + \theta_1{\epsilon_p}^{\frac{1}{2}} + \sigma_1\varepsilon \quad (9)$$

and

$$\log(\mu) = \log(\mu_0) + \theta_2 + \theta_3\hat{\mu}_0 + \theta_4{\epsilon_p}^{\frac{1}{2}} + \theta_5{\epsilon_d}^2 + \theta_6{\epsilon_d}^3 + \sigma_2\varepsilon \quad (10)$$

Both models are calibrated with a Bayesian approach. For all models, the calibration is performed at each stage of the model selection process with the STAN package of the R software that uses a gradient descend method.

Ref provides the statistics of the unknown parameters $\boldsymbol{\Theta} = \{\boldsymbol{\theta}, \boldsymbol{\Sigma}\}$, with $\{\boldsymbol{\theta} = \{\theta_1 \dots \theta_5\}$ and $\boldsymbol{\Sigma} = \{\sigma_1, \sigma_2\}$. The Adjusted R-squared for the two models are Adj-R^2=0.8287 for the model of $\log(\mu_0)$ and Adj-R^2=0.7217 for the model of $\log(\mu)$.

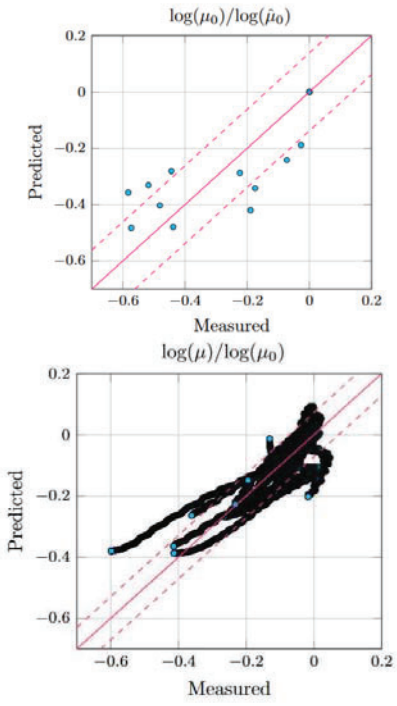

Figure 6: *: Predicted capacity versus measured values of the*

Fig.6 (a) and (b) show the predicted versus measured values of the ratios $\log(\mu_0)/\log(\hat{\mu}_0)$ and $\log(\mu)/\log(\mu_0)$, respectively. The closer the data points are to the 1:1 lines (i.e., the continuous lines in the figure), the more accurate are the predictions. The two figures also show the region within one standard deviation of the median value (i.e., the region between the dashed lines). From Fig. 6(b), it is possible to recognise data from different load tests. The predictions related to some of them exhibit a limited bias that may depends on features that are not captured by the explanatory functions considered in the model selection. A prediction for μ can be obtained combining Eq. (9) and Eq. (10) as

$$\mu = \hat{\mu}_0 e^{\theta_2 + \theta_3\hat{\mu}_0 + (\theta_1+\theta_4){\epsilon_p}^{\frac{1}{2}} + \theta_5{\epsilon_d}^2 + \theta_6{\epsilon_d}^3 + \sigma_t\varepsilon} \quad (11)$$

where $\sigma_t = ({\sigma_1}^2 + {\sigma_2}^2)^{1/2}$. To understand if the temperature can be used as a predictor for the values of μ, the temperature measured during the load test, T, is added into the set of the explanatory functions used to find the correction term for $\log(\mu)$, i.e., $\gamma_2 = \gamma_2(\epsilon_p, \epsilon_d, \hat{\mu}_0, T)$. In this case, the inclusion of T among the explanatory function change the selection process, and T is selected among the significant explanatory functions. The modified model for $\log(\mu)$ has the form

$$\log(\mu) = \log(\mu_0) + \theta_6 + \theta_7{\epsilon_p}^{\frac{1}{2}} + \theta_8\epsilon_p + \theta_9{\epsilon_p}^2 + \theta_{10}{\epsilon_d}^3 + \theta_{11}\epsilon_d + \theta_{12}{\epsilon_d}^4 + \theta_{13}T + \sigma_3\varepsilon \quad (12)$$

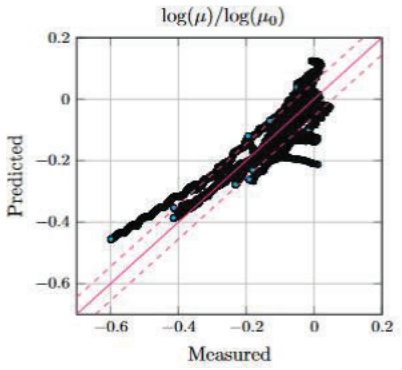

Figure 7: Predicted capacity versus measured values of the friction coefficient.

Fig.7 shows the agreement between the recorded and predicted values of μ, obtained using Eq. (12). The standard deviation of the model error is smaller compared to the model in Eq. (11) and the Adjusted R-squared higher (Adj-R^2=0.8267) . Although the probabilistic friction model dependent on the dissipated energy exhibits a satisfactory performance with an Adj-R^2=0.7217, the inclusion of the temperature as a regressor significantly increases the accuracy of the prediction, leading to an Adj-R^2=0.8267. This increased accuracy does not show the causal link between temperature increment and friction coefficient reduction. Instead, the probabilistic friction model provides evidence of the temperature role without clarifying if it is the cause or the effect of the friction coefficient variation. The experimental results and probabilistic model proved that the proposed structural system based on aluminium shims deserves further improvement to achieve a more stable and reliable hysteretic response.

5 CONCLUSIONS

This research presents the results of quasi-static cyclic tests on Asymmetric Friction Connections (AFC), serving as dissipating devices in the e-CLT system. The e-CLT, proposed under the Horizon 2020 research project e-SAFE, is a seismic retrofitting solution for RC frames based on Cross-Laminated timber (CLT) panels and AFCs. The authors carried out multiple repetitions of the same cyclic load protocol to assess the dependence of the aluminium-steel friction coefficient of the tested AFCs on the temperature, the energy dissipated during the test and that dissipated during the past deformation history of the specimen. The friction coefficient exhibited a significant dependence on both physical quantities. The friction dependence on the dissipated energy during the deformation history might originate from wear phenomena, mainly localized by the bolts, and MPV effects. The mutual sliding between aluminium and steel leads to the abrasive wear of the softer material (aluminium in the current case) and the reduction of the friction coefficient from nearly 0.5 to 0.2 during the first load protocol. Further repetitions of the load protocols on the same specimen also evidenced a dependence on the dissipated energy cumulated during each test. The physical variable possibly responsible for this phenomenon is the increasing temperature during each loading protocol. Following the standard semi-physical approach in hysteresis, the authors developed two probabilistic data-driven friction models calibrated from the experimental data using a Bayesian approach. The data-driven model simulates the evolution of friction without distinguishing between the causes of strength degradation's, like MPV interaction, changes in the properties in the sliding surfaces, and/or prying effects. The first engineering-oriented model depends on the dissipated energy, while the second includes the measured temperature as regressor. The first model exhibits a satisfactory performance with an Adj-R^2=0.7217. However, the presence of temperature as a regressor significantly increases the accuracy of the prediction, leading to an Adj-R^2=0.8267. The higher description capability of the model that includes temperature among the regressors does not show the causal dependence of the friction coefficient reduction on temperature but only the high correlation between the two. Regrettably, the authors do not have multiple tests where the initial temperature of the specimen is varied to rigorously prove the possible dependence of friction on the temperature variation. The first model can predict the friction coefficient in nonlinear analyses of the AFC using a straightforward Coulomb friction model, where the friction coefficient represents an energy-dependent parameter. The authors followed a Bayesian approach for calibrating the coefficients of the friction model, which also provides the complete distributions of the model parameters and allows the update of the model with newly available data.This model can be theoretically extended to different AFCs typologies after proper calibration based on the experimental cyclic response related to multiple load protocols repetitions. Future research efforts, possibly carried out within the Horizon 2020 research grant, will aim to rigorously assess the friction coefficient's dependence on the initial temperature of the specimens.

ACKNOWLEDGEMENT

This paper was carried out in the framework of the Energy and seismic affordable renovation solutions (e-SAFE) project, which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No.893135. SHEAR TESTS ON PERFOBOND CONNECTIONS IN TIMBER CONCRETE COMPOSITES

Elif Appavuravther[1], Bram Vandoren[1], José Henriques[1]

ABSTRACT: With an increase in trend to integrate more wood into the construction industry, timber concrete composite (TCC) solutions are an efficient manner to overcome the limitations of timber. In the current literature, there are various connections that have been investigated for TCC systems. One with sufficient performance to target massive constructions is still limited. In this paper the use of the Perfobond connector, originally developed for steel concrete composite (SCC), is explored in TCC. The connection consists of a discrete steel plate with dowel action in the concrete side. For TCC an adjustment of gluing a part of the Perfobond to the timber member is made. Experimental investigation with the variable of a few parameters such as, different types of concrete and surface roughness of the Perfobond (bonded in the timber part) is performed. As a result of this experimental work, it is possible to observe that the Perfobond connector is performant in terms of both strength and stiffness. The results of this work indicate that, by using the most optimal design of a Perfobond connector, a performant connection can be introduced to TCC which makes it possible to target longer spans.

KEYWORDS: Perfobond connector, adhesively bonded connection, timber concrete composite, shear test

1 INTRODUCTION

The use of TCC systems in construction is in an increasing trend as more environmentally friendly solutions are targeted. Therefore, performant shear connections between timber and concrete are needed. The goal is to target a high composite action, by using a stiff shear connection, which minimizes the slip between the members and ideally leading to compression stresses in the concrete and tension stresses in the timber.

In TCC literature, dowel connections, notch connections and recently bonded-in dowel are extensively studied [1]. Bonded-in dowel connections are proven to minimize the strength and the stiffness limitations, of the traditional dowel connections, and to avoid the brittle failure common in notch connections [2]. The major problem with the bonded-in dowels was to come to common design rules for researchers and designers. The use of an adhesive makes a significant difference in the behaviour of the connection [3]. In the recently consolidated version of the prEN 1995-1-1 under preparation for the 2nd generation of Eurocodes, a subsection is devoted to the bonded-in rods [4]. Even though the guidelines are limited, it will support designers. Since the early 21st century, bonded-in steel plates are an ongoing application in TCC. The first patented system is HBV developed in Germany by Bathon [5-7]. This is a continuous steel mesh adhesively bonded to timber and the remainder of the connector is embedded into the concrete. With the mesh on the steel, a bonding is formed with the adhesive in the timber part and with the concrete. The continuous steel mesh is designed to be controlled by the yielding of the steel mesh, which leads to a ductile behaviour of the connection.

Since the success of HBV, multiple researchers worked on continuous or discrete steel plate connections [3, 8-12]. In this paper, a connector commonly used in SCC, the Perfobond connector was used, which was developed to be used in long span bridge constructions [13]. This connector is welded to the steel beam, and inserted into the concrete layer of the SCC member. The part in the concrete has holes, which mobilizes dowel action between the connector and the concrete in addition to the bearing component at the tip of the connector. The application of the connector is slightly modified to be used in TCC. The part welded to the steel profile is now extended to be embedded into the timber element. An adhesive is used to bond the connector to the timber. The plate in the concrete part is designed and used as done in SCC [14].

In this work, an experimental investigation of the Perfobond connector is performed. The impact of concrete type and surface roughness of Perfobond on strength and stiffness is investigated. The results show that a Perfobond is a promising performant connector with high strength and stiffness, however, with limited ductility, which can be further improved to be used in industrial application.

2 DESIGN OF TEST SPECIMENS

The use of Perfobond connections are a common application in SCC. They have been developed to replace studs in long span construction and with the optimized design requirements in the literature, strong and stiff connections are obtained in which one Perfobond replaces a significant number of studs [13].

In this work, the connections that are embedded in the concrete part are designed using the experimental work conducted by Oguejiofor and Hosain [14]. The steel plate is designed using EN 1993-1-8 [15]. The part adhesively bonded to timber was slightly more challenging to design as there are no guidelines. Potential failure modes are identified that can occur in the timber part by using examples from the bonded-in literature [2] and application of bonded-in steel plates [3, 8-10]. The final dimensions of the Perfobond can be found in Figure 1 (a) and (b). In both of the plates, the surface of the steel plate is smooth without any treatment. To assess the bond between the steel plate and the adhesive, two different configurations are tested; i) a smooth Perfobond in which the bond with adhesive is directly through the surface of the plate (Figure 1 (a)) and ii) perforations formed in the part embedded in the timber to increase the surface area of the adhesive and with the adhesive filled through the perforations, a mechanical interlock is targeted (Figure 1 (b)).

In this experimental work, two different parameters are investigated; i) the effect of perforations on the connector and ii) the type of the concrete.

3 MATERIALS AND METHODS

3.1 TEST SPECIMENS

Symmetrical shear push-out type tests were conducted with a central timber and concrete layer on both sides. The timber is predrilled with groove dimensions of 110x10x55 mm, and the sides that were in contact with concrete are taped to avoid moisture entering the timber and to avoid the friction between the two materials. The 2/3 of the groove is filled with an epoxy acrylate-based anchoring adhesive, Sika Anchorfix-3030 [16], and the Perfobond is inseerted as soon as the adhesive is applied. The specimens are prepared in an indoor lab environment and were left a minimum of 24h for the adhesive to dry as recommended by the manufacturer [16]. The concrete is casted approximately after 7-days the adhesive was applied. Minimum reinforcement is used to avoid concrete tension failure [17]. Detailed dimensions of the specimens are given in Figure 1 (c) [18].

3.2 MATERIALS

The timber used in this work is GL 24h with a moisture content of 12.34% (Hydromete or oven dry method) and average density of 483 kg/m^3.

The Perfobond connector is steel grade S355 without any surface treatment.

For the concrete, two different concrete types are used: normal weight and lightweight concrete. Physical and mechanical properties of the concrete, determined according to the EN 12390-3 [19], can be found in Table 1 along with the other testing variable, the use or not of perforation in the perforbond connector (Figure 1 a) and b)).

Each specimen is named by the connection name initial (P) – presence of perforations in the bonded part (Y if available, N if not) and by the concrete type used (NWC for normal weight concrete and LWC for lightweight concrete).

Table 1 *Test specimen properties*

Experimental ID	Concrete type & Density (kg/m^3)	Concrete mean cube strength (MPa)	Perforation
P-Y-NWC	NWC 2400	78	Yes
P-N-NWC			No
P-Y-LWC	LWC 1600	25	Yes
P-N-LWC			No

3.3 TEST SET-UP, MONITORING AND TEST PROCEDURE

The experimental set-up (Figure 2), including monitoring system, consists of a test frame, a hydraulic jack, a load cell and LVDTs (Linear Variable Differential Transformer). The specimens are equipped with seven LVDTs, two horizontal and five vertical ones. The horizontal ones are placed at the top and bottom of the specimens to record timber-concrete separation. Four of the vertical ones are placed at the connection level, on both sides of the specimens as recommended by EN 26891 [20], to measure relative slip between materials. The remaining vertical LVDT is placed at the level of the load cell.

The loading procedure from EN 26891 is followed [20].

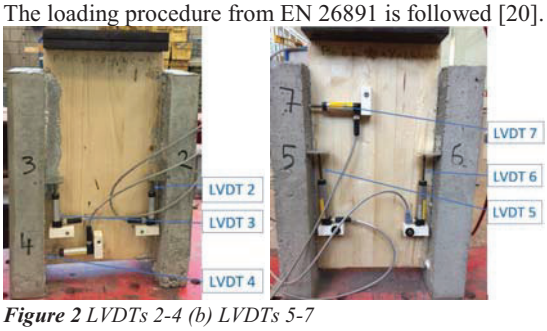

Figure 2 *LVDTs 2-4 (b) LVDTs 5-7*

https://doi.org/10.52202/069179-0412

4 RESULTS AND DISCUSSION

4.1 TEST RESULTS

In Table 2, mean value and coefficient of variation (COV) of the initial damage load (F_1), maximum load capacity (F_{max}) and stiffness (K_{ser}) are given for all four series. Initial damage load is determined by the reduction on the slope of the force-slip curve. The maximum load capacity is determined by the maximum capacity a connection could bear and the stiffness of the connection is determined as recommended in EN 26891 [20] and corresponding to the load-slip curve slope at 10% and 40% of F_{max}. In Figure 3, the load-slip curve for the series with and without perforations are presented. In both figures, F_1 is marked to clearly illustrate the initial damage load.

In series P-Y-NWC and P-Y-LWC, given in Figure 3 (a), the initial reduction in stiffness is caused by the damage between the bondline to the timber at 94.4 kN and 44.4 kN, respectively. With the loss of adhesion, load is transferred through bearing to the timber. Because the concrete was strong enough, crushing of timber started in the specimens with the use of normal weight concrete and governed the load capacity. When the bonding was totally lost, the connection reached its maximum capacity of 117.4 kN. For the specimens with lightweight concrete, with bondline failure, the load is transferred to the concrete through bearing between timber and perfobond connector and due to the lower strength of the concrete, concrete dowel failure is observed at 60.8 kN.

For the series P-N-NWC and P-N-LWC, given in Figure 3 (b), initial damage is due to the bondline failure of the bond to Perfobond connector at 76.7 kN and 38 kN, respectively. After the initial damage, the failure patterns are very similar to cases with the presence of surface roughness.

In all series, a very high stiffness is recorded, ranging between 297 to 442 kN/mm. It should also be noted that the COV is high for this parameter as a small deviations or inaccuracies in measurments as low as 0.1 mm have a significant impact.

Table 2 *Test results*

Specimen ID		F_1 (kN)	F_{max} (kN)	K_{ser} (kN/mm)
P-Y-NWC	Overall mean	94.4	117.4	441.9
	COV (%)	9.7	18.1	24.0
P-N-NWC	Overall mean	76.7	87.5	419.7
	COV (%)	27.0	17.5	41.3
P-Y-LWC	Overall mean	44.4	60.8	403.4
	COV (%)	16.6	6.5	39.3
P-N-LWC	Overall mean	38.0	48.3	296.9
	COV (%)	20.1	14.7	44.3

4.2 DISCUSSION OF TESTING PARAMETERS

In this experimental work, the effect of concrete type and the connector perforations in the timber part are investigated. In Figure 3, the effect of the concrete type can be clearly observed. In both figures, the series with the use of normal weight concrete have a very stiff behaviour until (almost) the maximum load carrying capacity, after this point, with brittle failure at the bondline, a sudden decrease in the load capacity (30 – 50%) is observed. In the series with the use of lightweight concrete, the behaviour is linear until F_1, with much flexible behaviour due to participation of the concrete. After this load level, the force-slip behaviour shows a nonlinear response until the maximum load capacity is reached. Unlike the series with normal weight concrete, the drop in load capacity is smaller, as the use of lightweight concrete lead to a more ductile behaviour since the participation of the concrete was higher. In terms of maximum load capacity, the use of normal concrete

https://doi.org/10.52202/069179-0412

lead to double capacity in comparison to the lightweight concrete (Table 2).
The use of perforated connections leads to a difference in the mechanics of the connector as the bond between the connector and the timber is efficient. The use of perforations leads to an increased load capacity and stiffness behaviour.

5 COMPARISON WITH THE LITERATURE

In order to contextualize the mechanical performance of the Perfobond connector for TCC, the different types of connections available for use in composite beam floor solutions, and covering different target applications, are here discussed. In Table 3, various connections used in TCC and Perfobond connections used in steel-concrete composites (SCC) are summarized in terms of strength (F_{max}), stiffness (K_{ser}) and ultimate slip (v_u). The ultimate slip is determined by EN 12512 [21], which is the slip value corresponding to the 80% of the force after the maximum load capacity is reached.
Four groups of connections are identified: i) dowel type connections; ii) notch connections; iii) steel plate connections in TCC; iv) Perfobond connections in SCC. The results of the referred mechanical properties are given per connection per shear plane. Details of the experiments can be found in the given references. In Figure 4 the chart provides a comparative overview of the different types of shear connections collected. For each mechanical property (F_{max}, K_{ser} and v_u), values are normalized to the respective maximum reported value, namely: strength and stiffness connection 11 [22] and ultimate slip connection 12 [23]. Then, the mean values of test specimens (normalized) P-Y-NWC and P-Y-LWC are also included (represented by the dots). Only these two type of specimens have been used because, as discussed previously, the use of perforations can delay the failure of the bondline zone and consequently, the connection can perform better.
Though, a quantitative comparison may not be entirely realistic, given the geometrical and material differences between the collected test specimens, however, Figure 4 provides a good perception on their relative mechanical performance. The chart shows that Perfobond in SCC is the strongest, the stiffest and the most ductile [22, 23]. Then, on the other side, screw connections present a lower load capacity and stiffness. Consequently, their application in TCC solutions targets lower load-bearing demands and is mainly due to the easiness and cost of application. Notches are as performant as the connections with steel plates, being the limited ultimate slip the main drawback. However, except for case 7, limited ultimate slip is also a problem in shear connections using plates in TCC due to the brittle behaviour of glue connections. Regarding this mechanical property, connections using Perfobond in SCC and SNP toothed metal plate (case 7) can provide the highest values, even higher than screws [22-24]. The extensive research on Perfobond connections for SCC also demonstrates that, if optimally designed, this type of connections can provide a balanced response, combining high stiffness and load bearing capacity with interesting plastic deformation on the Perfobond connector.
The comparison of the tested connection with the collected connections shows that it is as performant as the connections with bonded-in plates (cases 7 – 10). Case 9 is the case most similar to the configuration investigated in this paper, with a steel plate glued to the timber using an epoxy based adhesive [24]. In the reference (case 9), normal weight concrete is used. The strength of the series P-Y-NWC is in perfect agreement. In terms of stiffness, P-Y-NWC behaves slightly better (due to surface roughness). In terms of slip capacity however, a small reduction is observed. However, given the fact that the connection was design to avoid plastic deformations in the Perfobond connector, there is potential to increase plastic deformations, as it is the case of the Perfobond in SCC.

6 CONCLUSIONS

As a result of this experimental work, it can be concluded that Perfobond connection are strong and very stiff therefore a high composite action can be achieved. The concrete type and strength had a significant effect on the load capacity of the connections. Adding surface roughness through the inclusion of perforations had a positive impact on the performance of the connection as the bond between the connector and the timber improved. Moreover, a comparison with commonly used TCC connections has been made and showed that the solution is as performant as notch connections and as similar connections using steel plates. The tested Perfobond connections present high strength and stiffness with relatively low ultimate slip, however, the latter was somehow expected, as the focus was on the performance of the connection depending mainly on the adhesive part. Ductility should be sought with the plastic deformations of the connector and / or by adding a rebar through the holes on the concrete side of the connection, which was not covered in the present study.

ACKNOWLEDGEMENT

The authors would like to acknowledge Sika Belgium and LTS Belgium for their material contribution and Philippe Courtoy (LTS Belgium) for his technical contribution. Hasselt University Master's students from the 2019 – 2020 academic year, Mathias Hendrikx and Stijn Gielis, are gratefully acknowledged for their help and experimental work.

DELTABEAM® WITH TIMBER FLOOR JOINTS – LOAD BEARING CAPACITY AT AMBIENT TEMPERATURE AND IN FIRE SITUATION

Salla-Mari West[1], Elena Camnasio[2], Simo Peltonen[3]

ABSTRACT: DELTABEAM® Composite Beam represents an excellent solution for creating a slim floor structure with timber slabs. Hybrid structures are nowadays increasingly popular as the combination of steel, concrete and timber enables the optimization of the design by taking advantage of the strong points of each material. However, the combination of different materials and the use of innovative design details set the challenge for assessing the safety and reliability of the solution. Therefore, Peikko investigated the load bearing capacity of the joints between DELTABEAM® and cross-laminated timber slabs both at ambient temperature and in fire situation. Load transfer tests, a charring test and a loaded fire test were carried out in order to prove the effectiveness of the transverse reinforcement, which ties the beam and slab together and secures the load transfer. As far as DELTABEAM®, the fire resistance is ensured by inner rebars so that no additional fireproofing is needed. In particular, the full-scale loaded fire test confirmed the satisfactory performance of both edge and intermediate DELTABEAM®s with cross-laminated timber slabs. The results allowed for developing test-based design recommendations and showed how the typical timber slab details can be used in a new and more efficient way with DELTABEAM® slim floor solution.

KEYWORDS: composite beam, slim floor, hybrid structure, timber slab, fire performance, full-scale tests

1 INTRODUCTION

Innovative construction solutions are nowadays needed to meet a wide range of design requirements, like complex architectural shapes, optimized use of the materials, demanding load conditions, sustainability aspects, and even cost-efficiency, among others. In this regard, DELTABEAM® hybrid timber structures represent a perfect way to tackle these aspects simultaneously [1]. DELTABEAM® slim floor structures [2] have been widely approved and successfully used in projects over the years. Recently, the solution has been adopted in combination with timber slabs as well [3]. Compared to traditional timber structures, the use of a steel and concrete composite beam integrated into the floor allows to achieve longer spans and to avoid load-bearing walls (Figure 1). This gives more architectural freedom, enables smooth ceilings, reduces the volume of the materials, and eases the construction process.

One of the main benefits of DELTABEAM® solution is that additional fireproofing of the beam is not needed. This is particularly convenient for timber structures, where fire design might be critical. DELTABEAM® fire rebars that are embedded in the concrete inside the steel profile guarantee the resistance of the main structural load bearing element in the event of a fire. Such reinforcement is designed depending on project fire rating requirement according to Eurocodes [4] and [5] and its performance has been extensively proved by testing in the past [6].

Figure 1: *DELTABEAM® slim floor structure with mass timber slab.*

However, additional testing is needed for hybrid constructions to give evidence that timber, concrete and steel can satisfy the design demands in overall, as their combination is not yet comprehensively standardized. In order to fill the lack of regulations and give reliable proof at the same time, Peikko conducted a wide research program on DELTABEAM® hybrid timber structures, which took into account not only its behaviour in fire situation but also other design issues, such as the vibration performance [7] and the way how to connect other timber elements and how to ensure the timber-concrete composite action [8].

The part of the research on the load carrying capacity of DELTABEAM® timber floor joints both at ambient temperature and in fire situation is herein presented.

2 DELTABEAM® TIMBER FLOOR JOINTS

Joints and their design usually have a major impact on a structure's properties. In fact, the joints affect its load-bearing capacity, stability and fire performance, thus even influencing the type of failure that can occur. This can be even more critical for timber structures that have many different joints and connecting details [9].
Beam-floor joints have to be designed to prevent the separation between the parts and to transfer the forces from the slab to the supporting structural elements depending on different design conditions. In case of hybrid timber structures, the interaction between concrete and timber at the interface between the composite beam and the floor panel should be considered as well. Moreover, when accounting for the fire situation, beam-floor joints need generally to be protected by concealed connections, fire-rated gypsum boards and/or intumescent paints or seals in order to get the required fire resistance [10].
The above-mentioned design challenges can be effectively solved by using DELTABEAM® with timber slabs. The load bearing capacity at DELTABEAM® floor joint is ensured by a strut-and-tie mechanism that relies on DELTABEAM® inclined web. In fact, in the final composite stage, the loads are transferred to DELTABEAM® through a compression arch against the inclined web (Figure 2). Such mechanism is valid both at ambient temperature and in fire situation.

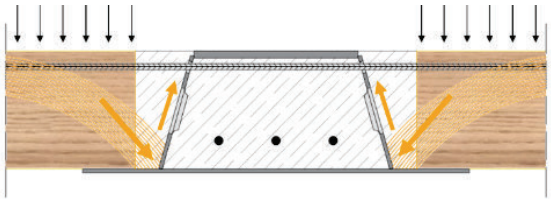

Figure 2: *Load transfer mechanism of DELTABEAM® hybrid timber structure at final stage.*

Compression forces are taken by the concrete surrounding DELTABEAM® steel profile while transverse rebars carry tension forces [3]. This means that the load is supported directly by the steel ledge only at installation stage and not after concrete hardening. During construction, the presence of the ledge allows for fast and easy positioning of the floor elements on the bottom flange of DELTABEAM® and it is suitable for different slab types, such as mass timber slabs, composite timber slabs and beam decks.
The transverse reinforcement is essential in securing the load transfer mechanism at DELTABEAM® floor joint (Figure 3). Rebars are usually placed through DELTABEAM® airholes, web holes, and additional web holes or within the concrete topping in case of composite slabs. In case of solid timber slabs, grooves are cut in the panels for rebar installation. More information about the detailing of DELTABEAM® timber floor joint can be found in [3].

3 RESEARCH PROGRAM

As joints are generally the weakest part of a timber structure, especially when exposed to fire, the main scope of the investigation regarded the fire performance of DELTABEAM® floor joints. However, the load carrying capacity of the joint has been first studied by finite elements and then verified by load transfer tests at ambient temperature. Such investigation is important to validate the assumed load transfer mechanism and useful to understand how the fire exposure possibly affects the behaviour.
A charring test and a loaded 90-minute fire test were then carried out on DELTABEAM® and timber slabs as continuation of the load transfer tests at ambient temperature. Cross-laminated timber (CLT) floor panels were used for all the tests, as being one of the main representatives of mass timber products [11].

3.1 LOAD TRANSFER TESTS

Load transfer tests were carried out on full-scale specimens of both timber and composite timber slabs supported by DELTABEAM® Composite Beam. Aim of the test was to prove that the failure would eventually take place in the slab, either in timber or in concrete, but not at DELTABEAM® support with load level well above the practical loads in projects. In the purpose of investigating the load capacity of the floor joint only, the beam behaviour was excluded by supporting the central part of DELTABEAM® bottom flange along its length. Thus, only the steel ledge was left unsupported and free to deform under the load.
The specimens were grouped by type as shown in Figure 4. The depth of DELTABEAM® standard profile was selected to match the thickness of the slab, which was built with 5-layer assembly CLT panels. In particular, composite timber slabs had a concrete topping thickness equal to 1/3 of the total thickness, as it occurs in most of the real cases. The shear connection between the timber

https://doi.org/10.52202/069179-0413

panel and the concrete topping was a notched one with large head screws inside the notches [12].
Each specimen had a different detailing of the interface between the timber panels and the outer concrete of DELTABEAM® to cover possible cases that are used in projects. The end face of the timber panel was cut either vertical or inclined so to be parallel to the web of the beam. In case of the inclined end cut, additional details that consisted in pockets or chamfers along the end face were introduced to check the improvement of the resistance of the joint given by such tailored geometry (Figure 4). More information can be found in [1] and [13].
A preliminary check of the load transfer capacity of the joint in a simulated fire situation was performed during this phase of the research program by removing the supporting ledge in three of the specimens with the inclined end cut. This represents the worst-case scenario by assuming the complete loss of stiffness and resistance of the ledge, which in reality occurs progressively when exposed to fire. Similar simulated fire situation was even previously tested by removing artificially the bottom part of a CLT panel and performing bending tests on a simply supported single span timber slab with edge DELTABEAM® [3].

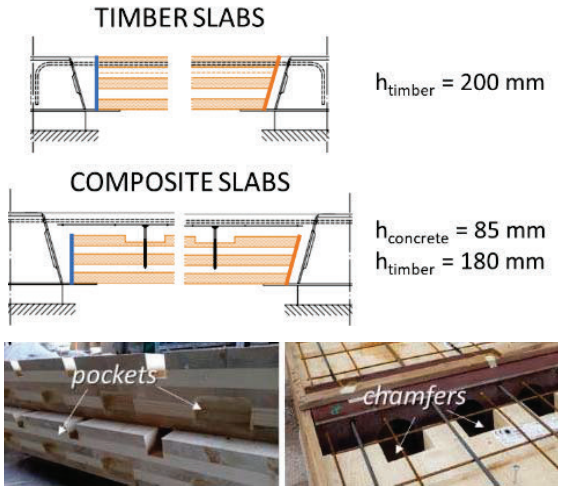

Figure 4: *Types of the tested specimens and close up-view of the panel end faces with tailored geometry.*

The test setup consisted of two symmetric 3-meter long CLT spans supported by one intermediate DELTABEAM® and by roller supports at the ends (Figure 5). The slabs were loaded with a line load and slab deflections were measured below, at a distance from the centre line of DELTABEAM® that equals three times the thickness of the slab. Compared to distributed load in normal design conditions, this is an unfavourable condition, which maximizes the shear and forces the failure in the area close to the beam. Test results can be then assumed on the safe side with respect to standard design loads.

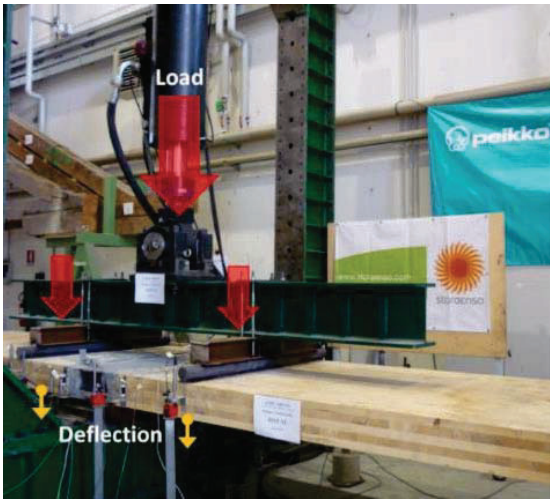

Figure 5: *Test setup of the load transfer tests.*

3.1.1 Timber slabs

Specimens with timber slabs exhibited a rolling shear failure in the slab area between the applied load and the support, as expected (Figure 6). In fact, timber exhibits limited resistance to shear forces that act orthogonal to grain direction, which determines the low rolling shear capacity of the CLT panels and may trigger the failure in circumstances such as concentrated loads and short spans like the ones in the tests.
Despite the severe test conditions that induced high shear stresses in the panel area close to DELTABEAM®, the load bearing capacity of the support was kept until the end of the tests, although the steel ledge deflected up to 20 mm, which was due to a significant rotation of the slab end.

Figure 6: *Rolling shear failure and ledge deflection in timber specimens.*

The satisfactory performance of the joint was observed even in the specimens without the supporting ledge. This proves that the ledge does not support the load directly and that the assumed load transfer mechanism is actually established. However, the presence of the ledge is favourable for the confinement of the bottom part of the slab, thus preventing the tensile failure due to the stresses orthogonal to the fibres of the longitudinal bottom layer.
On the contrary, such failure type occurred in the two specimens representing the simulated fire condition (Figure 7) even though it did not hinder a satisfactory load carrying capacity. These specimens had both the inclined end cut of the panel and one of these had the pockets along

https://doi.org/10.52202/069179-0413

the end face. In this case, the joint was stiffer, and the bearing resistance was even higher thanks to the concrete parts inside the pockets that can offer back-up support to the slab. Such detail is useful to improve the performance of the joint especially when the edge of the timber panel is cut vertically.

Figure 7: *Timber panel failure in specimens without DELTABEAM® ledge.*

Figure 8 shows the load-deflection curves of the timber slab specimens. The load represents the support reaction on both DELTABEAM® sides, which was about 80% of the total load applied on the slabs in all cases. This is due to the test setup with concentrated load close to the beam support, but it also shows that DELTABEAM® floor joint can provide a higher degree of fixity to the slab end compared to the simply supported condition that is usually assumed for timber slabs.

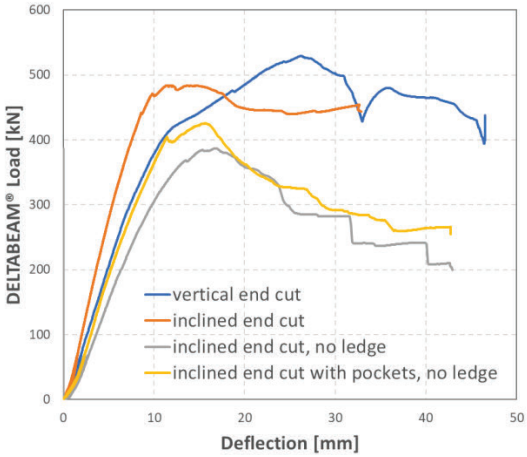

Figure 8: *Load-deflection curves of timber slab specimens.*

The peak loads were significantly high. Even in the simulated fire condition that showed the lowest load carrying capacity, the applied force corresponded to a load of about 130 kN/m on one side of the beam. This is far beyond standard design loads. Moreover, the results showed that the load carrying capacity of the support was maintained even for a slab deflection up to about 40 mm for all cases, which is above usual design deflection limits.

3.1.2 Composite slabs

The failure type of the composite timber slabs was mainly the cracking of the topping, which started from the separation between timber and concrete in the area close to the beam that had no connectors to take the tensile forces. The crack pattern clearly indicated the direction of tensile stresses, which were orthogonal to the orientation of compression forces pointing from the applied load to the notches (Figure 9).

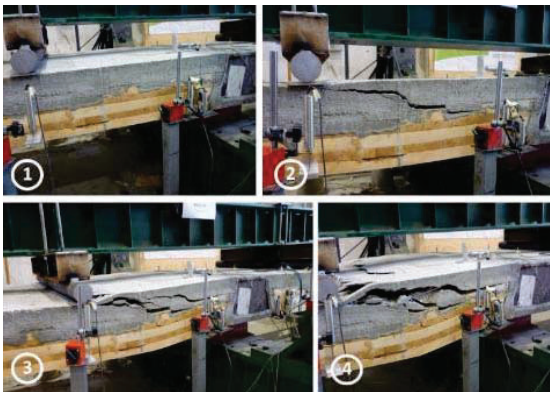

Figure 9: *Concrete topping crack pattern development in composite timber slabs.*

Rolling shear in timber and/or bending failure of the slab occurred as well. The latter one usually develops in CLT panels when the composite action between concrete and timber is lost. Slight pull-out failure of the large head screws was also observed, as the actual failure load exceeded the expected one (Figure 10). In fact, such failure modes occurred at load levels that were far higher than the standard design ones. The simulated fire condition, i.e. DELTABEAM® with no ledge, was tested in case of composite slab as well. Similarly to what observed with solid timber slabs, the bottom layers of the timber panel failed due to tension orthogonal to the grain. The support was anyhow able to carry the load without failing.

Figure 10: *Failure modes in composite timber specimens: bending, rolling shear, screw pull-out and tension orthogonal to the grain (clockwise).*

Figure 11 shows the load-deflection curves of the composite timber slab specimens. The load carried by DELTABEAM® was about 74% of the total load applied

on the slabs in all cases. Composite timber slabs are generally stiffer and more resistant than timber slabs of equal height, when concrete is properly connected to the timber panel. That is why the composite specimens showed greater stiffness and higher peak load values than the solid timber ones.
In particular, the specimen with inclined end cut of the timber panel and chamfers cut along the edge reached the maximum load capacity of the actuator (100 tons) without failing. The failure occurred then by keeping the load constant for few minutes. The improvement of the bearing capacity, which is due to the development of concrete struts close to DELTABEAM® web holes, shows the effectiveness of the tailored geometry and supports the assumptions of the model of the load transfer mechanism.

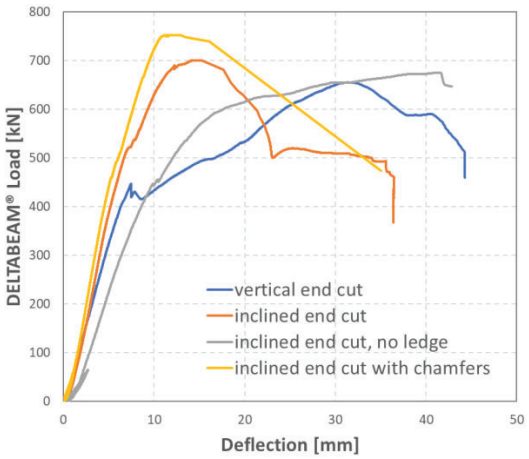

Figure 11: *Load-deflection curves of composite timber slab specimens.*

3.2 FIRE TESTS

The charring test and the 90-minute loaded fire test concerned DELTABEAM® Composite Beam with solid timber slabs without any top concrete. Composite timber slabs are usually stiffer and performed better in load transfer tests in ambient temperature. Because of this, solid timber slab structure was selected for the two fire tests to test the most unfavourable situation.

3.2.1 Charring test

Due to the fall of charred layers, the carbonization of the CLT board is not linear and progresses at several carbonization rates [14]. To design CLT slabs against fire, it is recommended to use the reduced cross-section method described in EN 1995-1-2 [15]. In the reduced cross-section method, the parts of the cross-section with assumed zero strength and stiffness are removed and no longer contribute to the resistance of the cross-section. The charring depth is the distance between the bottom surface of the original member and the position of the char-line and should be calculated from the time of fire exposure and the relevant charring rate. The position of the char-line should be taken as the position of the 300-degree isotherm [15].
The two-hour charring test concerned DELTABEAM® with commonly used timber slab details adapted for a slim floor structure. Based on the load transfer tests in ambient temperature, experience and performed fire design calculations, the most suitable joint details were selected for the test. The specimen for the charring test had seven different details, which were equipped with thermocouples. DELTABEAM® Composite Beam was not fireproofed in any of the seven cross-sections. CLT 200 L5s and CLT 280 L7s timber slabs were placed on the DELTABEAM® Composite Beam ledges or downstands. The DELTABEAM® and the CLT 200 L5s slabs had equal depth. In Figure 12 the finished specimen for the charring test is presented. The temperature data from the charring test proved that the charring depth is smaller in the joint area between DELTABEAM® Composite Beam and CLT slab than in the middle of the CLT slab area, without any additional fireproofing.

Figure 12: *Specimen for the two-hour charring test without loading.*

There are different options for the edge geometry of the timber slab, like vertical or inclined end cut shown in Figure 4. The geometry of the CLT slab end does not affect the load-bearing capacity of the structure or joint. Figure 13 shows the temperatures in the joint area between DELTABEAM® and CLT slabs without any additional fireproofing under the beam or under the CLT slabs. The charring rate with the vertical end cut is higher in the beginning, but in the end, the effective charring depth is about the same for both end cuts. At a distance of 100 mm from the CLT soffit the temperature has settled to 100 degrees for both end cuts.
Before the charring test, the effective charring depth was calculated for the CLT slab without any additional fireproofing. The effective charring depth would be 108 mm according to [15] and the CLT product charring rate [16]. After the test, the effective charring depth was calculated according to [15] and the temperature data. Figure 13 shows that the 300-degree char-line at 120 min is between 60 mm and 80 mm. To be on the safe side, 80 mm will be selected. By adding the thickness of material close to the char line with zero strength and

https://doi.org/10.52202/069179-0413

stiffness according to [15], the effective charring depth for both end cuts is then 87 mm. With both CLT end cuts, the effective charring depth proves to be less in the joint area between DELTABEAM® and CLT slab than the calculated effective charring depth at the midspan of the CLT using CLT product charring rate.

In conclusion, both vertical and inclined end cuts are safe to be used in CLT slabs in fire situation. Moreover, based on the extensive measurement data from the various details, it could be clearly seen that DELTABEAM® Composite Beam had no negative impact on the charring rate of the CLT panel in any of the investigated details.

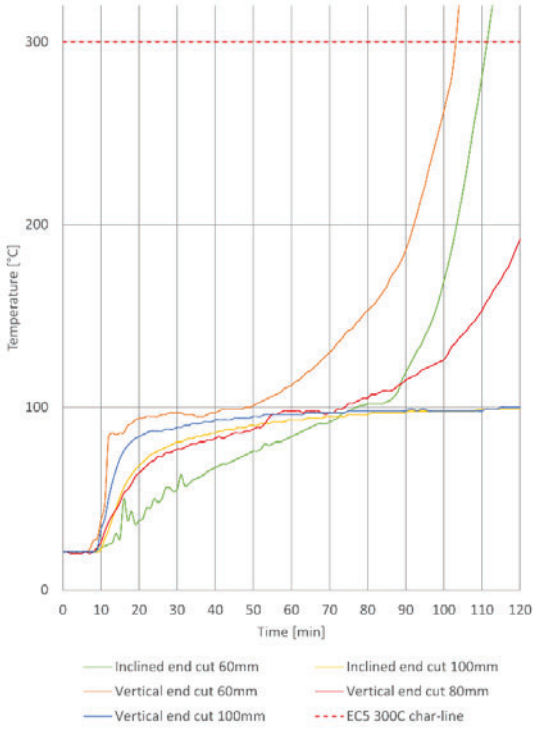

Figure 13: *Temperature in the CLT slab in the joint area, 60-100 mm from the CLT soffit.*

3.3 90-MINUTE LOADED FIRE TEST

In the REI90 fire test, CLT 200 L5s timber slabs were placed on the DELTABEAM® Composite Beam ledges. The specimen consisted of DELTABEAM®s and CLT slabs which all had an equal depth of 200 mm. No additional fireproofing was used in DELTABEAM®s or in CLT slabs. In Figure 14 the finished specimen for the 90-minute fire test is presented.

The load was constant during the entire 90-minute fire test. The load arrangement simulated DELTABEAM® and CLT slab structure with 8 m CLT span, 1.7 kN/m^2 permanent load and 5 kN/m^2 live load (ψ_1=0.7). Therefore, the support reaction in the joint area between DELTABEAM® Composite Beam and CLT slab was equal to 20.8 kN/m on each side. This corresponds to only the 16% of the maximum support reaction measured in the simulated fire condition (Paragraph 3.1.1). This shows that standard design conditions are well on the safe side when compared to the maximum load carrying capacity of the joint, that was evaluated at ambient temperature with no ledge.

Figure 14: *Specimen for the 90-minute loaded fire test consisting of two edge beams, an intermediate beam and two CLT panels.*

Rebars with 12 mm diameter and 600 mm spacing were used in DELTABEAM®s. At the intermediate beam, the transverse reinforcement passes through the air holes at the top end of DELTABEAM® web plates. At the edge beams the transverse reinforcement passes through the web holes (Figure 15).

Figure 15: *Reinforcement in edge beam situation.*

The 90-minute loaded fire test proved that the interface between DELTABEAM® Composite Beam and timber floor can sufficiently transfer loads from the floor to the beam in both edge and intermediate beams during a fire situation. Due to the protecting effect of the DELTABEAM® ledge the charring depth in the joint area was not as deep as in the middle of the CLT span. After the 90-minute loaded fire test, the specimen was demolished to investigate the charring of the structure. Figure 16 shows that the charred timber above the DELTABEAM® ledge stays in place. This is due to the presence of the steel ledge, which prevents the spalling of the charred parts and the possible tensile failure orthogonal to the remaining timber fibres (Paragraph

https://doi.org/10.52202/069179-0413

3.1.1), despite having completely lost its strength and stiffness after 90-minute exposure. In addition, this charred timber keeps protecting the joint area after the bottom lamella of the CLT slab has fallen along the span.

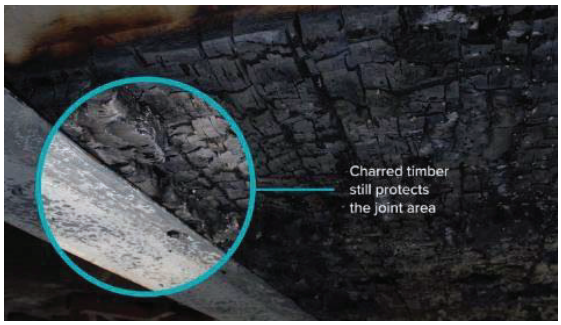

Figure 16: *Specimen from below after 90-minute loaded fire test.*

3.3.1 Load bearing capacity, integrity, and insulation

In the case of fire, structures shall be designed and constructed in such a way that they can maintain their load-bearing capacity during the relevant fire exposure. Where fire compartmentation is required, the elements forming the boundaries of the fire compartment, including joints, shall be designed and constructed in such a way that they maintain their separating function during the relevant fire exposure. The criteria for integrity and insulation must be fulfilled when relevant [15]. In the 90-minute fire test with loading, all REI90 requirements for load-bearing capacity, integrity and insulation were met.

Deflections were measured in the middle of the CLT elements, in the middle of the intermediate DELTABEAM® and in the middle of the edge DELTABEAM®s. The deflections at 90-minute were between 40 mm and 50 mm for DELTABEAM®s and CLT slabs, which are less than $L^2/400d$ mm = 136 mm (depth of the specimen d is 200 mm, and the span L is 3300 mm). The deflection rate was less than $L^2/9000d$ mm/min = 6.05 mm/min. Therefore, the criteria of the load-bearing capacity R were met.

The average temperature rise for the whole structure at 90 min was 62 degrees. This value is smaller than the value of 140 degrees, which is the limit temperature of the insulation criterion. The highest temperature rise was equal to 92 degrees at 90 min. The highest temperature rise was less than 180 degrees, which fulfils the insulation criteria at any point of the specimen. Based on the high number of measured temperature values in the joint area between DELTABEAM® Composite Beam and CLT slabs, the insulation I criteria for average and the highest temperature rise were met.

There were no flames on the unexposed surface and no gaps in the specimen. Based on the visual observations, the integrity E criteria were met.

3.3.2 Load transfer

Figure 17 shows how the loads are transferred to DELTABEAM® through a compression arch against an inclined web in a fire situation. The angle of inclination of the compression arch slightly changes during fire exposure and the support shifts to the bottom corner of DELTABEAM® profile. As a result of the compressive stresses path, the charred timber part remains in the confined space between the beam ledge, the concrete grout and the uncharred timber slab. This provides an insulation to the joint area during fire and slows down the charring of the portion of the timber panel above the ledge.

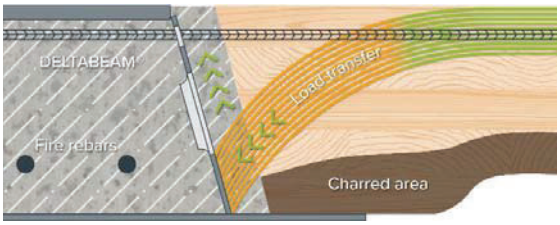

Figure 17: *Load transfer in a fire situation.*

Based on visual observations of the REI90 fire test, the charring happens only at the bottom of the timber slab, as expected. The joint concrete is clean without any damage. The fire has not burned through the joint. After the fire test, when the specimen had cooled down, the specimen was cut into three pieces at mid-spans of the CLT parallel to the beam. Finally, a section of the CLT slab next to the edge and intermediate DELTABEAM® was removed to investigate the charring in the joint area.

Figure 18 and Figure 19 present that there is about half of the second lamella remaining in the joint area, while in the middle of the CLT span the second lamella is already fully charred. The depth of the uncharred timber in the middle of the CLT span was between 120 mm and 135 mm, meaning that about 70 mm of the CLT slab depth was charred. On the contrary, about 50 mm of the CLT slab depth was charred in intermediate and edge beam cases at the joint area. The specimen continued to burn during disassembling the load arrangement and lifting the specimen. Due to this, the measured remaining timber slab depth is on the safe side. The charring depths measured during demolition support the temperature data measurements and prove that the calculated effective charring depth is conservative.

All displacement transducers were set on DELTABEAM® as a reference. The relative displacement between the top end corner of CLT slab and the top plate corner of DELTABEAM® was measured in vertical and horizontal direction (Figure 20). The measured relative displacement values show that the joint area performs well during a fire situation, as no major slip was observed. The results prove that the transverse reinforcement effectively ties DELTABEAM® Composite Beam and CLT slab together, thus securing the load transfer.

3.3.3 Normal stresses in transverse reinforcement

In Figure 21 the normal stresses in the transverse rebars in edge and intermediate beam situations during the 90-minute loaded fire test can be seen. The normal stresses were highest in an edge beam situation due to the unsymmetric load. Based on the stress-strain curves of the transverse rebars, the normal stress increases linearly and then decreases linearly following the same path. This shows that the transverse rebars do not yield since there are no permanent deformations according to the stress-strain curves.

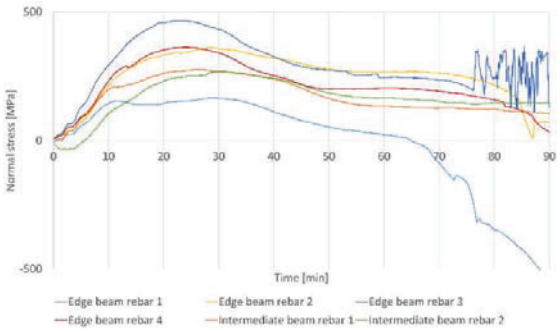

Figure 21: *Normal stresses vs time in the transverse rebars.*

In Figure 22 the changes of the bending stiffness of DELTABEAM® Composite Beam during the 90-minute loaded fire test are presented. The highest reduction of the bending stiffness can be observed during the first 30 minutes. At the same time, the normal stresses in the transverse rebars increase the most.

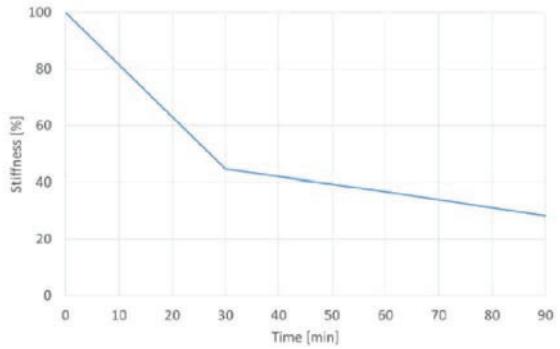

Figure 22: *Bending stiffness of DELTABEAM® Composite Beam vs time during the 90-minute loaded fire test.*

4 TIMBER FLOOR JOINTS DESIGN RECOMMENDATIONS

Relevant design recommendations for DELTABEAM® timber floor joints can be drawn based on test evidence. The load transfer mechanism is safely established regardless the shape of the end face of the timber panel. In fact, the results showed that both the vertical and inclined end cut of the timber panel give adequate resistance to the joint. However, the inclined end cut can provide higher peak values of the load capacity, as friction reaction forces that develop between the outer concrete of DELTABEAM® and the inclined side of the panel are in favour of the strut-and-tie mechanism. The additional details such as pockets and chamfers proved to be effective as well and are therefore recommended. In any case, proper concrete filling of the gap between the beam and the timber panel should be ensured.

https://doi.org/10.52202/069179-0413

The use of transverse reinforcement is essential to carry the tensile forces that develop through the joint. The effectiveness of the tying system was proved by the performance of the specimens at ambient temperature, where any rebar failure such as pull-out or blow-out failure occurred despite the high load level and severe test condition.
The results of the load transfer tests also confirmed that joints of the composite slabs are stiffer and more resistant compared to timber ones with same thickness. Moreover, the reinforced concrete topping provides continuity between adjacent slabs, is favourable to reduce floor vibrations and allows for easy installation of the transverse rebars through or above DELTABEAM® steel profile.
On the contrary, grooves need to be cut in solid timber slabs for the installation of the transverse reinforcement. The required length of the grooves depends on the needed amount of notches to secure the load transfer from timber slabs to DELTABEAM®. In fact, grooves are filled in with concrete so that compressive stresses between concrete and timber develop at the locations of the notches (Figure 23). The distance between the notches has to be designed in a way that it will not fail in shear. In order to transfer the total force properly, the tie rebar shall also extend beyond the last notch up to the end of the groove. Therefore, the rebar length depends on either the required length of the grooves or the required anchorage length according to [4], whichever the maximum. For example, for the REI90 fire test specimen, the anchorage length of the rebars was determined by the design of the grooves. The minimum concrete cover according to [4] should be also guaranteed.

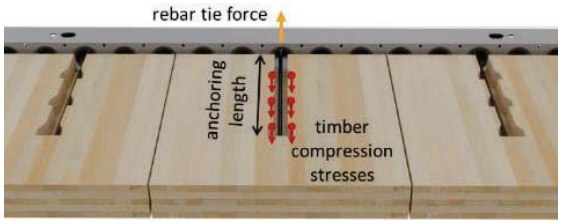

Figure 23: *Force in transverse rebar creates pressure in the notches.*

It is important to have wide enough grooves especially when the transverse rebar is not only securing the load transfer but also carrying an unsymmetric load, for example. In fact, having a wide enough concrete block, along with a sufficient amount of reinforcement, prevents the concrete from cracking, which might occur when tensile stresses get higher. For example, the grooves in the fire test specimen for the edge beam situation were two times wider than in the intermediate beam. Moreover, the load eccentricity causes compressive stresses to the topmost part of the timber panel (Figure 24). Such compression must not exceed the design compressive strength of timber along the grain.

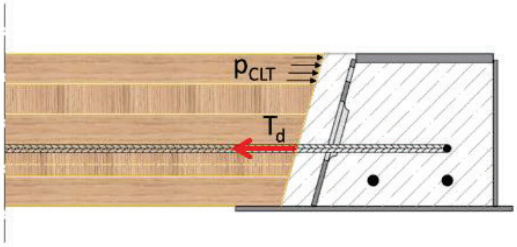

Figure 24: *Unsymmetric load in the edge beam situation.*

In case of unsymmetric load, which occurs in the edge beams, the transverse rebars should be located as low as possible in order to maximize the lever arm between tension and compression resultants. Deeper grooves are then needed and rebars are generally placed through the web holes or through additional lower holes depending on the project. However, the progression of the charring in the timber panels and the temperature increase in the slab at fire exposure have to be considered. In fact, transverse rebars should be placed satisfactorily above the area affected by the major temperature increase so as to limit the steel strength reduction that shall be accounted for according to [5].
After the timber under the groove has charred away, the concrete would heat up following the standard fire exposure. According to the measurement data at 90-minute fire exposure, this design assumption is on the safe side. In fact, the temperature on the bottom of the groove was 100 degrees, while the temperature in the transverse rebar was 114 degrees in the joint area. According to [5], rebar steel strength reduction is 80% at 200 degrees. This proves that the mechanical properties of the transverse rebars were reasonably not affected by the temperature increase during the entire test, which confirms the satisfactory performance of DELTABEAM® timber floor joints in fire situation.

5 CONCLUSIONS

The extensive research program, which included load transfer tests at ambient temperature, a charring test and a 90-minute fire test with loading, assessed that timber floor joints equipped with proper transverse reinforcement can safely transfer the load from the slab to DELTABEAM® Composite Beam. In particular, it has been proved that the assumed strut-and-tie design model is established and effective in fire situation too without any additional fireproofing under the beam or the timber slab, so to achieve a slim floor structure that can be left exposed and used together with various common timber floor details used in real-life projects.
Peikko is nowadays continuing the research on DELTABEAM® hybrid timber structures in order to optimize the solution even more, provide reliable design information and give engineering support to customers. Future investigations will concern shear connection tests and beam tests, among others.

MECHANICAL BEHAVIOUR OF TIMBER-STEEL COMPOSITE CONNECTION SYSTEMS

Alireza Shahin[1], Craig J.L. Cowled[2], Henri Bailleres[3], Sabrina Fawzia[4]

ABSTRACT: Although timber is an ideal building material offering significant structural, environmental, and economic advantages, restrictions on the supply of high-quality timber is a limiting factor for the construction industry. To manage this problem, this study investigated an innovative approach to develop a sustainable and economical composite section with improved structural performance by combining low-grade timber and steel using advanced manufacturing technologies. In this paper, 20 specimens with 2 different configurations of this novel adhesive-free Timber-Steel Composite (TSC) connection system were designed, manufactured, and tested. By conducting standard pull-out tests on these new types of composite systems, the influences of factors such as type, pattern and spacing of the fasteners on the shear performance of these systems were evaluated and discussed. Test results demonstrated a significant difference between failure mode and nonlinear behaviour of nailed and screwed TSC connections. Screwed TSC connections showed on average 40% more shear capacity but 12% less stiffness compared to nailed TSC connections. A FE model of this composite system was developed and verified against test results. The FE model could accurately predict the nonlinear load-slip behaviour of this composite system. This model will be used in further work to develop an optimised full-scale TSC beam.

KEYWORDS: Timber-Steel Composite (TSC) connection system; Shear connectors; Static pull-out tests; Load-slip curves; Finite element modeling

1 INTRODUCTION

Timber is a strong, safe, and sustainable building material that offers significant structural, environmental, and economic advantages compared to other traditional building materials like concrete [1-3]. However, two significant reasons that are endangering the growing interest in timber construction are the high costs of manufacturing existing engineered mass timber products and limitations on the supply of high-quality timber [4]. One practical solution to address this problem is to combine low-grade timber with another building material like steel and manufacture a cost-efficient and sustainable composite section that would benefit from the structural advantages of both materials. Prior studies focused mostly on the potential for combining wood with other materials such as hot-rolled steel or concrete to create composite sections with better structural performance [5-8]. A literature review showed that even though the performance of some of these composite sections showed considerable improvement, the majority of them failed commercially because they used expensive materials or required a labour-intensive, and complex manufacturing methods [9, 10]. Therefore, the primary objective of this study is to develop a sustainable and economical composite connection system using low-grade timber and sheet steel and evaluate the performance of these novel adhesive-free components by conducting experimental studies and numerical modeling.

2 EXPERIMENTAL STUDY

2.1 MATERIALS AND METHODS

Timber material was provided from the Southern Queensland pine resource, which includes *pinus elliottii* var. *elliottii* (a.k.a. slash pine), *pinus caribaea* var. *hondurensis*, and a hybrid of the two species with F5 stress grade in accordance with AS 2858 [11]. F5 is the lowest grade of timber used in structural components with a nominal average modulus of elasticity of 6.9 GPa. All timber boards used for building TSC samples were cut with the same cross-section dimensions of (35 × 90) mm and length of 460 mm. Grade 250 structural steel plates with 1.6 mm thickness were utilised for manufacturing the composite specimens. All steel plates used for manufacturing specimens were cut with similar cross-

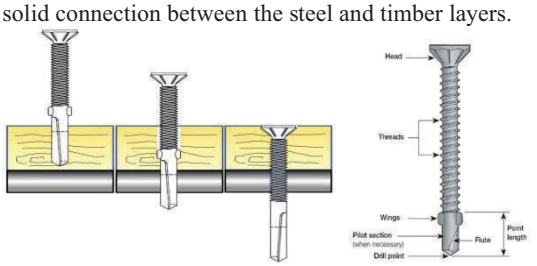
section dimensions of (1.6 × 90) mm and length of 340 mm. To fabricate each TSC specimen, a steel plate was placed in between two (2) F5 timber pieces in a symmetrical arrangement and all three layers were connected using mechanical fasteners. While smooth shank D-head nails with 2.87 mm diameter and 65 mm length were used for manufacturing of nailed TSC configurations, fully threaded self-drilling screws with 4.8 mm diameter and 70 mm length were used to fabricate screwed TSC configurations. The main advantage of using gun-driven D-head nails and self-drilling screws was increasing the speed of fabrication by elimination of pre-drilling timber and steel components.

Figure 1 shows the function and details of the self-drilling screws used for fabrication of TSC specimens of this study. The twist shaped point of this type of screw acts as a drill and eliminates the necessity of pre-boring timber and steel elements. To prevent threads from engaging the upper timber piece, wings of this type of screw help by making a clearance hole through the timber that is wider than the threads. At final stage, the wings hit the steel and break off and threads then begin to engage. In this way, application of this type of self-drilling screw creates a solid connection between the steel and timber layers.

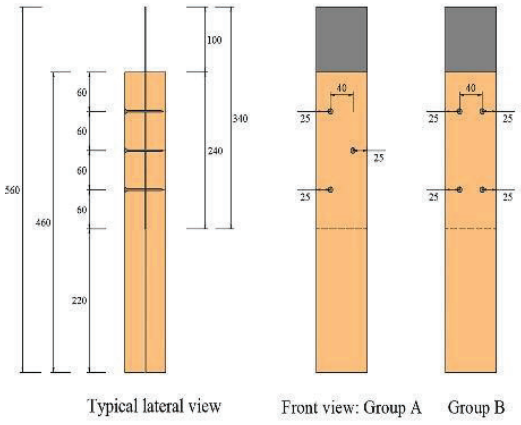


(a): Function *(b): Details*

Figure 1: *Self-drilling screws for developing TSC specimens*

Besides using simple, fast, and cost-effective fabrication method for developing these novel TSC connection systems, a unique testing setup and arrangement were fabricated to carry out the standard pull-out experiments of this study (Figure 2(a)). The pull-out tests were conducted on 20 TSC specimens with two (2) different configurations (Figure 2(b)) based on testing procedure provided by BS EN 26891 [12] standard to evaluate the effects of key parameters such as connector type, number, and patterns on the shear performance of these systems. The lower part of each specimen was held with three (3) bolts and the upper part was gripped in the jaws of the machine. As shown in Figure 2(b), specimens of group A were manufactured with three (3) fasteners with staggered pattern, while group B samples were built with four (4) fasteners with linear pattern. To evaluate the performance and effects of using different types of fasteners, all samples of each different group were fabricated using both D-head nails and self-drilling screws.

(a): Test setup



(b): Different TSC configurations

Figure 2: *Pull-out test on TSC connection systems*

2.2 CONFIGURATIONS, LOADING PATTERN AND INSTRUMENTATION

To make a direct comparison between different TSC configurations with various fasteners' pattern and spacing, the connectors end, and edge distances of all specimens were considered the same. Table 1 shows details of each TSC configuration of this study.

Table 1: *TSC configuration details and characteristic*

Group name	Config. ID	Type and size of connector	Spacing (mm)	Number of specimens
Group A	TSCA1	D-head Nail (Ø = 2.87, L= 65)	60	5
	TSCA2	Self-drilling Screw (Ø = 4.8, L= 70)	60	5
Group B	TSCB1	D-head Nail (Ø = 2.87, L= 65)	120	5
	TSCB2	Self-drilling Screw (Ø = 4.8, L= 70)	120	5

All specimens were loaded parallel to the grain direction until total failure. The pull-out loading protocol was based on a modified approach presented by the BS EN 26891 [12] standard with initial loading and unloading to remove any internal looseness between timber and steel elements. The load-slip curve of each specimen was obtained using two laser extensometers placed at both side of each sample.

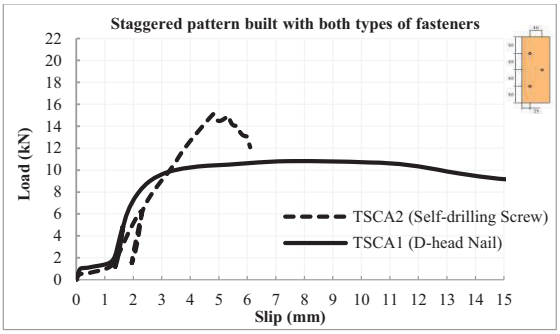
3 TEST RESULTS AND DISCUSSION

To compare the performance of various TSC configurations, the average nonlinear load-slip curves of all tested specimens of each configuration were plotted.

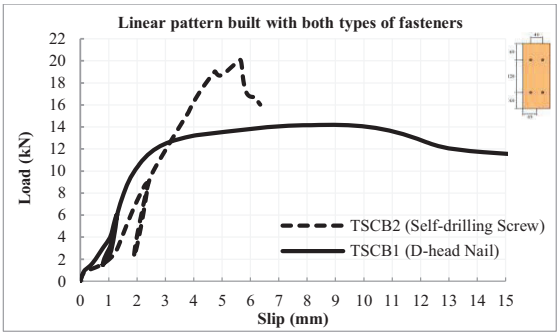
To evaluate the effects of different types of connectors on the shear performance of TSC connection systems, Figure 3 illustrates the average load-slip curves of TSC connections with staggered and linear connectors' patterns each of them built with both self-drilling screws and D-head nails.

As the load-slip curves clearly show, the major difference between nailed and screwed TSC connections is their failure modes and nonlinear behaviour of the connections after reaching their yield load. While nailed TSC connections experienced ductile behaviour with gradual failure, screwed TSC connections showed brittle behaviour with sudden failure. After reaching their ultimate load, nailed connections still had remarkable residual capacity left and this trend continued until total failure of the system, while the screwed connections suddenly failed with no residual capacity left in the system.

According to the test results and obtained nonlinear load-slip curves of all tested specimens, self-drilling screws showed greater load-carrying capacity in comparison to D-head nails used in TSC connections with both staggered and linear fasteners patterns. Using self-drilling screw instead of D-head nail for manufacturing TSC connections improved the yield, ultimate, and maximum load-carrying capacity of TSC configurations with staggered fasteners' pattern on average by 60%, 40%, and 40%, respectively. In contrast, due to this replacement the stiffness of the TSC connection reduced on average by 12%. Similarly, screwed TSC connections with linear connectors' pattern showed on average 40% more load-carrying capacity and 17% less stiffness compared to nailed ones with the same fasteners' pattern.

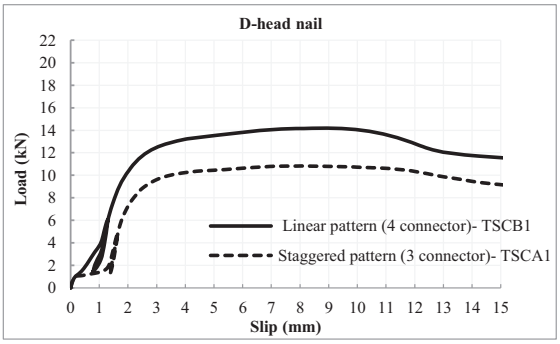


(a): Staggered pattern

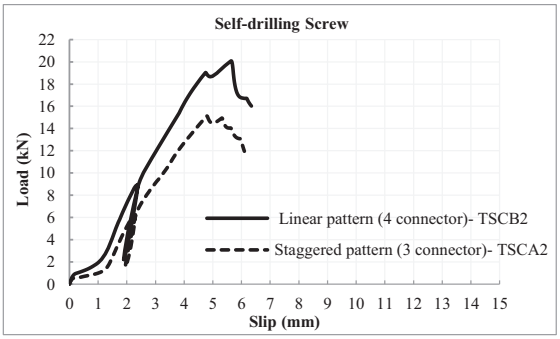


(b): Linear pattern

Figure 3: *Average load-slip curves of TSC connections with various connectors' patterns built with both types of fasteners*



(a): D-head nail



(b): Self-drilling Screw

Figure 4: *Average load-slip curves of nailed (top) and screwed (bottom) TSC connections with staggered and linear patterns*

https://doi.org/10.52202/069179-0414

Figure 4 shows the influences of number and patterns of the fasteners on shear performance of the TSC connection systems.

According to the test results, the shear capacity and stiffness of both nailed and screwed TSC connections significantly improved by one fastener addition. We expect to see an improvement of 33% with the addition of an extra connector.

For nailed TSC connections, the shear capacity and stiffness of the specimens with linear pattern improved on average by 31% and 36%, respectively compared to nailed samples with staggered pattern. This aligns with expectations.

For screwed TSC connections, the shear capacity and stiffness of the specimens with linear pattern increased on average by 33% and 28%, respectively compared to in comparison with screwed specimens with staggered pattern. This aligns with expectations.

4 NUMERICAL MODELING

A nonlinear 3D finite element (FE) model of nailed TSC connection with linear connectors' pattern was developed and analysed using CSI SAP [13] structural analysis software (Figure 5). The result of the nonlinear load-slip of the numerical FE model was compared and validated with experimental results.

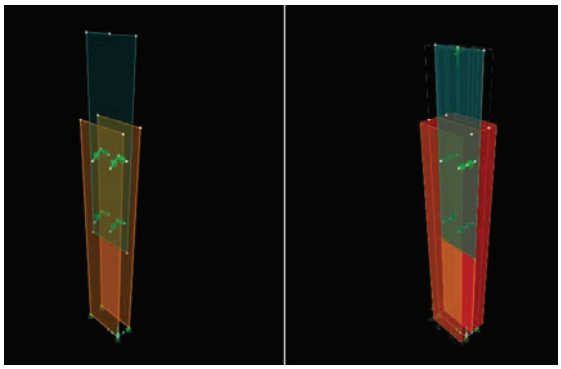


Figure 5: *FE model of nailed TSC connection in SAP program*

4.1 MATERIAL MODELLING

Timber was modelled as a nonlinear orthotropic material. To define the behaviour of F5 timber in the elastic zone, the material properties were obtained by conducting standard tests according to AS/NZS 4063.1:2010 [14] as presented in Table 2.

To define the nonlinear behaviour of timber under loading in plastic zone, the stress-strain curves of timber obtained by conducting standard compression and tension material tests on F5 timber specimens were used as shown in Figure 6.

Grade 250 structural steel was modelled as a nonlinear isotropic material with modulus of elasticity and Poisson's ratio equal to 200100 MPa and 0.3, respectively. Thanks to information obtained from the manufacturing company, the stress-strain curve of G250 steel plate was defined, as shown in Figure 7, to consider the actual behaviour of steel plate under loading.

Table 2: *Elastic Material properties and parameters for developing numerical models of F5 timber*

Description	Value
Longitudinal modulus of elasticity	6447 MPa
Tangential modulus of elasticity	290 MPa
Radial modulus of elasticity	477 MPa
Poisson's ratio for deformation along the tangential axis	0.444
Poisson's ratio for deformation along the radial axis	0.392
Poisson's ratio for deformation along the tangential axis	0.447
The modulus of rigidity based on shear strain in the LT plane	341.7 MPa
The modulus of rigidity based on shear strain in the LR plane	354.6 MPa
The modulus of rigidity based on shear strain in the RT plane	64.5 MPa

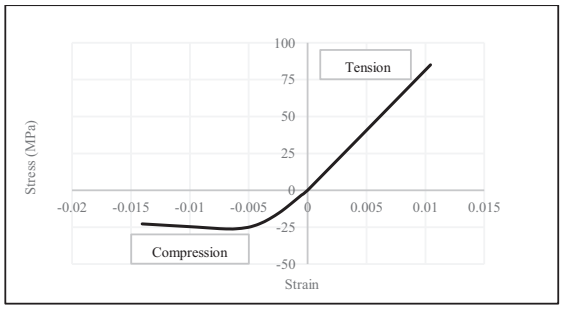

Figure 6: *Nonlinear stress-strain curve of F5 timber material in compression and tension zone*

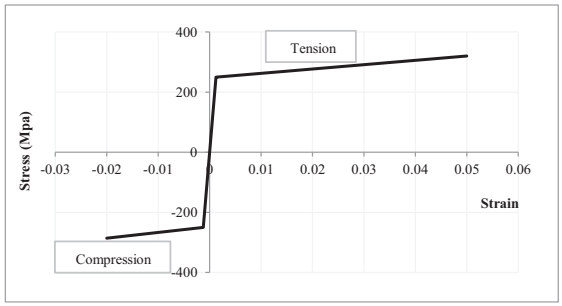

Figure 7: *Bilinear stress-strain curve of Grade 250 structural steel in compression and tension zone*

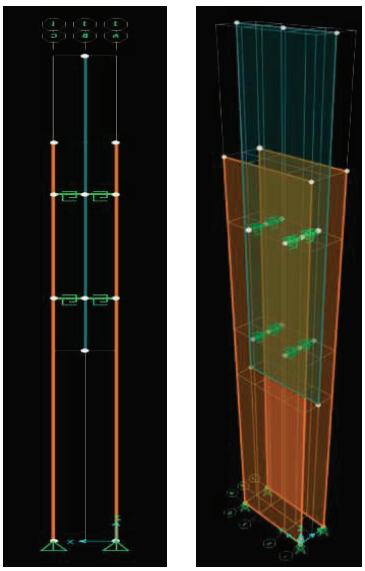
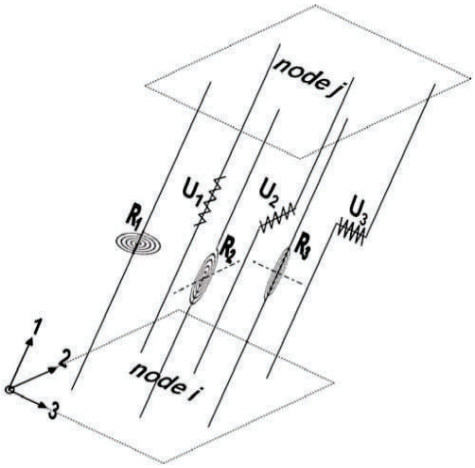
4.2 SHEAR CONNECTORS MODELLING

Fasteners can be modelled in CSI SAP software [13] using nonlinear two-joint link elements to connect timber and steel components as illustrated in Figure 8. This element has six controllable degrees of freedom (DOF) including three translational springs (U1, U2, and U3) and three rotational springs (R1, R2, and R3). U1 is an axial spring, U2 and U3 are shear springs, R1 is a torsional spring, and R2 and R3 are pure bending springs.

https://doi.org/10.52202/069179-0414



(a): Developed FE model in SAP



(b): Six DOF of link element

Figure 8: *Nonlinear two-joint link element used for modeling fasteners in CSI SAP software*

In actual testing condition, the compression of the fasteners is negligible. Therefore, to avoid the link elements being compressed or elongated during analysis, the U1 axial spring was fixed. The pure bending springs R2 and R3 were also fixed to avoid any relative rotation of the steel plates and timber boards during analysis. Torsional spring R1 represents the actual spinning of the nail inside the wood components. To consider this behaviour a stiffness of zero was assigned to this spring to enable the free torsional rotation of the link elements. The accurate nonlinear behaviour of the connectors was considered in the FE model by defining and assigning the nonlinear load-slip curve obtained by conducting pull-out tests on TSC connections to U2 and U3 shear spring as shown in Figure 9. Since the responses of the link elements in the U2 and U3 DOF are independent, they were defined uncoupled.

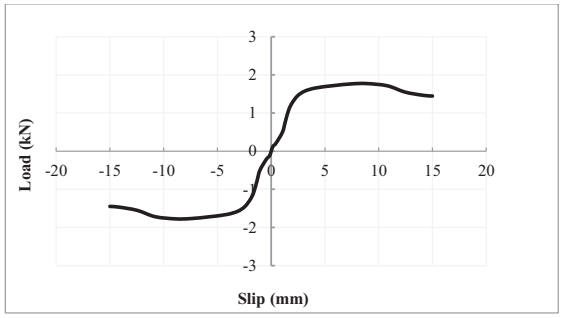


Figure 9: *Nonlinear load-slip response of each link element*

SAP software offers several options to define the nonlinear features of the link element among which the multi-linear Takeda plasticity property was chosen since it allowed the precise definition of the load-slip data even with this capability to consider stiffness degradation under cyclic loading condition.

Each connector was modelled by two link elements at each side of the steel plate so that the sum of the forces of two link elements were equal to the force of each fastener.

4.3 FE MODELLING PROCEDURE

Both timber boards as well as steel plate were modelled by Thick Shell Element. By assigning the nonlinear material properties that were defined in section 4.1 to these elements, the actual nonlinear behaviour of these elements was considered.

Eight points were defined on the middle steel plate and four points were defined on each timber board at the exact location of the fasteners to assign the nonlinear two-joint link element at these places for connecting timber and steel plates. All points on each shell element were constraints as a full body to move and rotate as a uniform element. To model restraint effects of steel brackets in actual testing condition, the end of each timber board was restrained as a pinned support to prevent translation in three (3) directions.

Unit loads at locations of loading points were assigned to the steel plate. This load was incrementally increased and pulled the steel plate upward until the control point at the top of the steel plate reach the target displacement. Nonlinear displacement controlled static pull-out analysis were then performed by considering P-Delta effects to fully monitor large displacement due to nonlinear behaviour of the connectors.

4.4 ANALYSIS RESULTS

Figure 10 shows the comparison between the average experimental load-slip curve obtained by conducting pull-out tests on nailed TSC connections (grey line) with linear connectors' pattern and the simulated load-slip curve obtained from the developed FE model of this TSC configuration in CSI SAP software (black line). Clearly, the FE model closely simulates the load-slip response of the connection system. The model could precisely predict the behaviour and stiffness of the connection in the elastic zone and closely determine the yield point and maximum

https://doi.org/10.52202/069179-0414

load-carrying capacity of the system (Table 3). More importantly, the developed FE model could accurately reflect the real nonlinear behaviour of the connection system by simulating the strength reduction and stiffness degradation after reaching its peak shear capacity. It should be noted that since the FE model was analysed under uniform loading condition, it did not reflect the initial slip of the system that was monitored in the actual tests due to applying ISO loading pattern with initial loading and unloading steps.

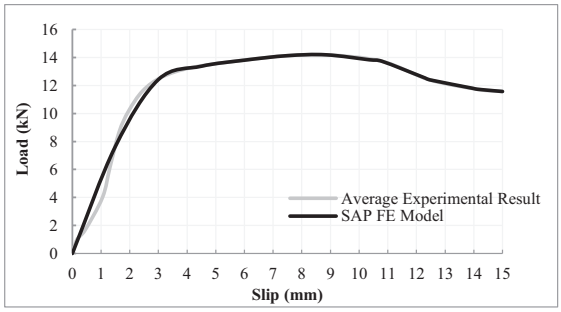

Figure 10: *Comparison between experimental and numerical load-slip curves of nailed TSC connection*

Table 3: *Comparison of experimental and FE results*

Config. ID	F_{Exp} (kN)	F_{FE} (kN)	V_{Exp} (mm)	V_{FE} (mm)	$\frac{F_{Exp}}{F_{FE}}$	$\frac{V_{Exp}}{V_{FE}}$
TSCB1	14.19	14.18	8.85	8.86	1.0007	0.9988
Standard Deviation	1.17	-	1.21	-	-	-

Note: F denotes maximum load and V is the joint slip corresponding to the maximum load.

5 CONCLUSION

Several pull-out tests on different configurations of a novel TSC connection system were conducted to monitor the shear performance and capacity of the specimens and evaluate the impacts of key variables such as various type, pattern and spacing of the fasteners. In addition, FE model of this composite system was developed in CSI SAP software and the analysis result of the model was compared and verified against experimental load-slip curve.

The test results showed critical difference between failure mode and nonlinear behaviour of nailed and screwed TSC connections under loading condition. While nailed TSC connections showed ductile behaviour with gradual failure, screwed TSC connections experienced brittle behaviour with sudden failure. Self-drilling screws showed 40% more shear capacity compared to D-head nails used in TSC connections. However, screwed TSC connections had on average 12% less stiffness compared to nailed ones. TSC connections with linear pattern of fasteners showed on average 30% more load-carrying capacity compared to the TSC configurations with staggered pattern.

The developed FE model could simulate the nonlinear load-slip response of the nailed TSC connection with great accuracy. This modeling approach offers a simple means to investigate the influences of key variables such as a greater number of fasteners or different thickness of steel and timber elements on shear capacity of the TSC connection system. The calibrated FE model will be refined with additional test results of various configurations and used to develop optimised full-scale TSC beams. Furthermore, to further investigate the effects of various variables, a comprehensive parametric study will be conducted in future research.

ACKNOWLEDGEMENT

The work presented here was supported by an Australian Government Research Training Program Scholarship and a top-up scholarship provided by Craig Cowled and the School of Civil and Environmental Engineering at Queensland University of Technology to AS.

Materials were kindly provided by Hyne Timber and QUT.

We also wish to thank QUT technical staff who assisted with preparation of the specimens and experimental testing. Frank De Bruyne, Barry Hume, Benjamin Brownlee and Zeph Kadel have all made this project possible and their contribution is highly valued.

FINITE ELEMENT MODELLING OF HYBRID WOOD/ALUMINIUM ASSEMBLY WITH WOOD-FILLED ALUMINIUM AND STEEL DOWELS

Gotre Bi Djeli Bienvenu. BOLI [1, 2], Marc. Oudjene [2], Daniel. Coutellier [3], Hakim. Naceur [4]

ABSTRACT: This paper presents a Finite Element modelling procedure for hybrid structures made of confined wood within a thin aluminium envelope using the explicit dynamic analysis through the use of LS-DYNA® software. The primary use of hybrid structures will be for highway bridge safety barriers in order to assess the energy absorption capabilities during an impact due to a car accident. The mechanical behaviour of the wood was modelled using the built-in material model MAT-143 in LS-DYNA. The comparison of the numerically predicted failure behaviour and the global response expressed as force-displacement responses of the studied hybrid structures to those reported in the literature, has shown the ability of the model to simulate the failure behaviour of such hybrid structures.

KEYWORDS: Wood, Aluminium, Finite Element, Hybrid structures, wood-filled aluminium composites.

1 INTRODUCTION

Timber is known as one of the oldest and longest standing building materials in existence, with evidence showing homes built over 10,000 years ago used wood as a primary source for construction materials [1]. In the last two decades, the used of wood in the construction sector has increased due to the development of engineered wood products (EWPs) such as cross-laminated timber (CLT), laminated veneer lumber (LVL) and glued laminated timber (glulam), which offer improved and homogenous mechanical properties for their use as structural materials. Massive timber construction requires suitable connections in order to join the different elements of the building. The most common connection in contemporary timber structures are manufactured using steel plates and laterally loaded metal dowel-type fasteners (Figure 1). The benefits of these types of connections are the ease of manufacturing, design, and assembly, in addition to their high load carrying capacity and ductility. However, the use of metallic connections in timber structures can reduce the fire resistance of the structure as metallic components increase the heat transfer in the connection [2]. In addition, the weight of the steel elements (plate, dowels, bolts) in the connection can be regarded as drawbacks during the operating phase. In fact, the high stiffness of steel in comparison to wood can increase the stress in the wood, thus increasing the probability of brittle failure in the timber members, which is undesirable in timber construction. In this respect, the use of lightweight et competitive connection systems by reducing the amount of metal used within the timber structure would be most advantageous in terms of the improvement of the fire resistance, the corrosion resistance and the reduction of the weight of the connection.

Figure 1: *Metal fasteners in timber construction [3]*

Glued connection is also used in the category of non-metallic connection in timber structures. However, the use of adhesives has some drawbacks as they can produce volatile organic compounds (VOCs) and reduce the recyclability of the wood products. In this context, a

research program called: "Towards Adhesive-Free Timber Buildings (AFTB)" and funded by the North-West-European Interreg program was born. The aim was to develop ''green" and adhesive free EWPs and connection systems using compressed wood dowels as a joining fastener to substitute the traditional adhesives (or metallic fasteners) [4]. In the same context, El-Houjeyri et al. [4] have designed some novel adhesive free engineered Wood Products by using compressed wood dowels (CWD) as a joint element to connect timber laminates and members. The strength and stiffness properties of the CWD were characterized based on three-point bending tests and compared to the values obtained from uncompressed wood specimens. The CWD were used as connection elements in timber-to-timber connections in double shear push-out tests and the results were compared to those of a timber-to-timber connection with a steel dowel. The authors [4] have found that, in terms of load-carrying capacity, the joints assembled using compressed wood dowels compared well to their counterparts assembled using a steel dowel, but have a strength and stiffness characteristic values lower than to the joints assembled using a steel dowel. In this respect, an optimization of the CWD could be achieved for better structural performance.

As some countries in Europe, some countries in North America like Canada have shown also interest in using those EWPs and lightweight materials in the construction sector. For example, the government of Quebec published in 2013 the Wood Charter [5] and in 2015 the Quebec Aluminium Development Strategy (SQDA) [6], which aim to promote the use of EWPs and aluminium in the construction sector. In fact, these two materials (wood and aluminium) have low environmental impact in comparison to steel et concrete, are recyclable, sustainable and are locally produced in Québec. In this context, Rollo et al. [7] have investigated a solution of a hybrid dowel by confining a CWD in an aluminium tube in order to improve the mechanical characteristics of the CWD developed by El-Houjeyri et al. [4]. Following the work of El-Houjeyri et al. [4] and Rollo et al. [7], Tétreault et al. [8] have proposed a novel hybrid timber-to-aluminium connection by using hybrid wood-filled aluminium dowels and steel dowels. However, due to the novelty of these hybrid structures using wood and aluminium, they are not yet considered in calculation standards like the CSA-O86 (National Standards of Canada: Engineering design in wood). Thus, to obtained reliable and safe application of these products, experimental tests are needed and the tests need to cover as many scenarios as possible. In contrast, the use of numerical simulation means of the finite element (FE) method appears to be a good alternative in order to reduce the number of experimental tests. In this study, it is proposed to investigate and evaluate a numerical procedure for the design and the analysis of hybrid structures with confined wood. We investigate the capability of the wood material formulation (*MAT_143/*MAT_WOOD) available in LS-DYNA for simulating the mechanical behaviour and the failure response of hybrid assembly (Wood/Aluminium) using either wood-filled aluminium hybrid dowels or steel dowels.

2 FINITE ELEMENT MODELLING

Different hybrid wood/aluminium structures including confined wood available in the literature were selected to evaluate the performance of the built-in material model **MAT_143/*MAT_WOOD*. Three-Point Bending test on densified wood dowel and on hybrid wood-filled aluminium dowel (Figure 2) were carried out by Rollo et al. [7]. Double shear tests on hybrid systems (timber-to-aluminium connections) assembled using wood-filled aluminium hollow tube dowel and steel dowel were carried out and analysed experimentally by Tétreault et al. [8]. This section presents the different material models used in the FE model, the FE modelling techniques used to simulate the different loading and geometric conditions.

2.1 MATEIRAL MODELLING

2.1.1 Wood material model: MAT-143

At macroscopic scale, wood material is commonly assumed to be orthotropic as its properties vary in the three directions: longitudinal (L or 1), radial (R or 2) and tangential (T or 3). Wood material model MAT-143 [9] in LS-DYNA considers the wood as a transversely isotropic. Parallel direction represents longitudinal (L) axis and perpendicular direction refers to radial (R) or tangential (T) axis of timber. The strength criteria are defined using Hashin's formulation with different analytical forms for the parallel $f_{||}$ and perpendicular $f_{\perp}$ criteria according to equations (1) and (2) respectively:

$$f_{||} = \frac{{\sigma_{11}}^2}{X^2} + \frac{({\sigma_{12}}^2 + {\sigma_{13}}^2)}{{S_{||}}^2} - 1 \qquad (1)$$

$$f_{\perp} = \frac{(\sigma_{22} + \sigma_{33})^2}{Y^2} + \frac{{\sigma_{23}}^2 - \sigma_{22}\sigma_{33}}{{S_{\perp}}^2} - 1 \qquad (2)$$

where σ_{11}, σ_{22}, σ_{33}, σ_{12}, σ_{13}, σ_{23} are the stress components; X and Y are the tensile or compressive strength in parallel and perpendicular to the grain direction respectively. $S_{||}$ and $S_{\perp}$ are the shear strength in parallel and perpendicular to the grain direction respectively. Failure occurs in parallel to the grain direction when $f_{||} > 0$ and in perpendicular to the grain direction when $f_{\perp} > 0$.

The evolution of the damage parameter *d* follows separate rules for parallel and perpendicular to the grain directions. In parallel direction, failure is often considered to be catastrophic and failure in this direction renders the wood useless. When failure occurs in parallel direction, all six stress components are degraded uniformly and wood cannot carry any load after failure. However, if failure occurs in perpendicular to the grain direction, only the perpendicular stress components are degraded. The two expressions of the damage are given by equations (3) and (4) for parallel and perpendicular modes respectively:

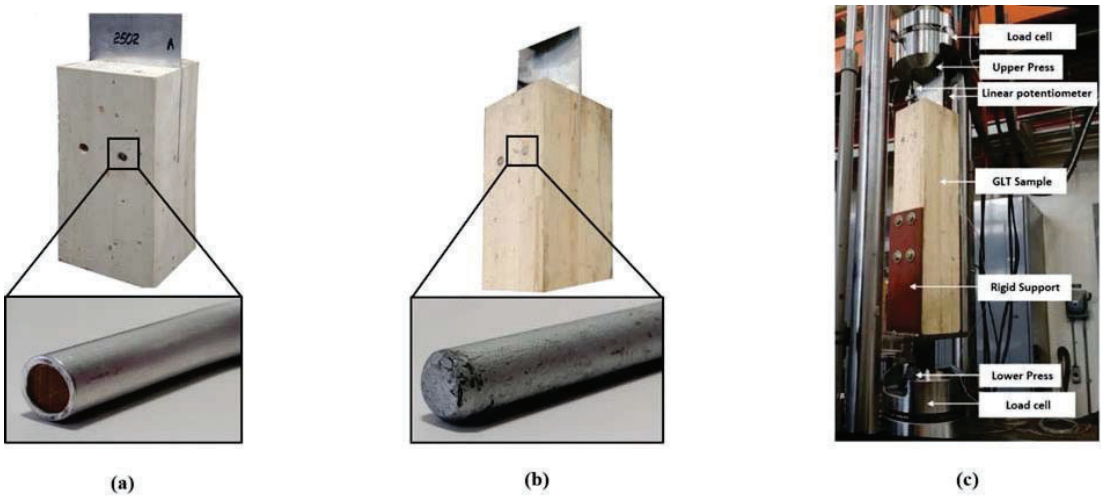
(a) (b) (c)

Figure 2: *Different parts of the hybrid wood-filled aluminium dowel: (a) compressed wood dowel; (b) aluminium tube; (c) hybrid wood-filled aluminium dowel [7]*



(a) (b) (c)

Figure 3: *Hybrid wood/aluminium system: (a) assembled with hybrid wood-filled aluminium dowel; (b) assembled with galvanized steel dowel; (c) experimental setup [8]*

$$d(\tau_{\parallel}) = \frac{d_{max\parallel}}{B}\left[\frac{1+B}{1+Be^{-A(\tau_{\parallel}-\tau_{0\parallel})}} - 1\right] \quad (3)$$

$$d(\tau_{\perp}) = \frac{d_{max\perp}}{D}\left[\frac{1+D}{1+De^{-C(\tau_{\perp}-\tau_{0\perp})}} - 1\right] \quad (4)$$

where B and D are the softening parameters obtained from experimental data. A and C are internally calculated based on the value of fracture energy G_f according to equations (5) and (6):

$$A = \tau_{0\parallel} L\left(\frac{1+B}{BG_{f\parallel}}\right) log(1+B) \quad (5)$$

$$C = \tau_{0\perp} L\left(\frac{1+D}{BG_{f\perp}}\right) log(1+D) \quad (6)$$

The laminated stock used during the experimental test for the Glued Laminated Timber (GLT) were made of Spruce-Pine-Fir. The wood dowel used for the manufacturing of the hybrid wood-filled aluminium dowel were made of French spruce. The material properties as applied for MAT-143 in this study are summarized in Table 1. The mechanical parameters are either identified based on the mean experimental values or by means of the well-known inverse approach.

2.1.2 Material model for the aluminium: MAT-024

The mechanical behaviour of aluminium was modelled with MAT-024 material model in LS-DYNA. MAT-024 describes an elastic-plastic material with an arbitrary stress versus strain response and arbitrary strain rate dependency can be defined. Strain rate may be accounted for using the Cowper and Symonds model. The stress-strain curve of the aluminium is given using the Ramberg-Osgood law using equation (7):

$$\varepsilon = \frac{\sigma}{E} + K\left(\frac{\sigma}{E}\right)^{n} \quad (7)$$

where $\boldsymbol{E}$ is the Young's modulus and K and n the hardening parameters. Equation (7) represents the evolution of the engineered strain as a function of the engineered stress. Material model MAT-024 requires the true stress as a function of the true strain. The curve of the engineered stress as a function of the engineered strain is transformed into a curve representing the true stress as a function of the true strain and is given through the material model MAT-024. The material properties used in the FE were defined as:

- Density: 2700 kg/m^3
- Young's modulus: 70 000 MPa
- Poisson's ratio: 0,33
- Yield stress: 210 MPa
- Hardening parameters for aluminium A6061-T6: n = 45 for an ultimate strain of 8% as prescribed by Eurocode 9.

2.1.3 Material model for the steel dowel: MAT-003-Plastic Kinematic

The material behaviour of the steel dowel was modelled with the material model MAT-003 representing an elastic-plastic isotropic material behaviour with the option of including rate effects by using the Cowper and Symonds model. The material properties used in the FE were defined as:

- Density: 7877 kg/m^3
- Young's modulus: 210 000 MPa
- Poisson's ratio: 0,33
- Yield stress: 450 MPa

2.2 FE MODELLING OF THE THREE-POINT BENDING TEST ON HYBRID WOOD-FILLED ALUMINIUM DOWEL

The FE model of the Three-point bending test was done first for the compressed wood dowel and then for the hybrid wood-filled aluminium dowel. Figure 4.b shows the FE model of the three-point bending test and Figure 4.a shows the experimental set up used by Rollo et al. [7]. Constant stress eight-node solid elements (LS-DYNA ELFORM 1) and fully integrated shell elements (LS-DYNA ELFORM 16) are applied to represent the geometrical setup of the test. The wood dowel is meshed using solid elements and the loading cylinder and support are meshed using shell elements. The material behaviour of the loading cylinder and the supports is modelled with the rigid material model MAT-020 with a Young's modulus $E = 207\,000\ MPa$ and a Poisson's ratio of $\nu = 0{,}3$. All nodes of the supports are fully clamped and a velocity control was applied to the rigid loading cylinder using an explicit time integration. A rate of $5mm/min$ was used during the experimental tests, which is like a quasi-static test.

The FE model of the hybrid wood-filled aluminium dowel was done by inserting under compression the wood dowel inside the aluminium tube. Constant stress eight-node solid elements are used to mesh the aluminium tube. The boundary conditions used for the hybrid wood-filled aluminium dowel are the same as those used for the compressed wood dowel. The contact between the wood dowel and the aluminium tube was defined using the AUTOMATIC_SURFACE_TO_SURFACE contact with a friction coefficient of 0,3. Figure 5 shows the FE model of the Three-Point Bending test on the hybrid wood-filled aluminium dowel.

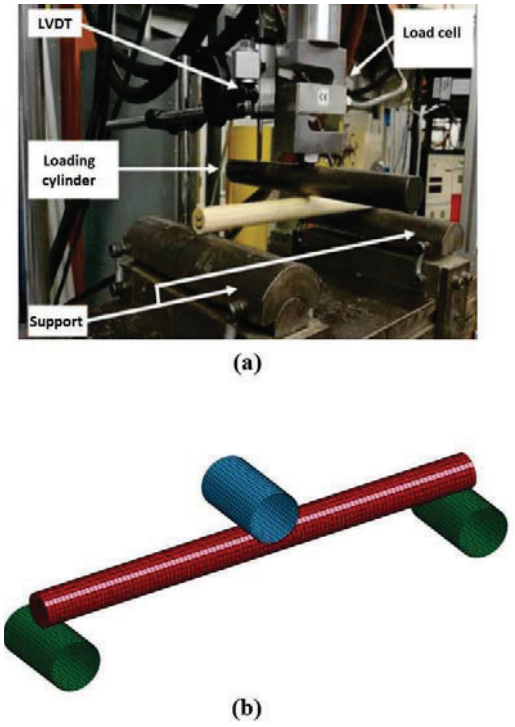

Figure 4: *Three-Point Bending test on compressed wood dowel: (a) experimental setup [7]; (b) FE model*

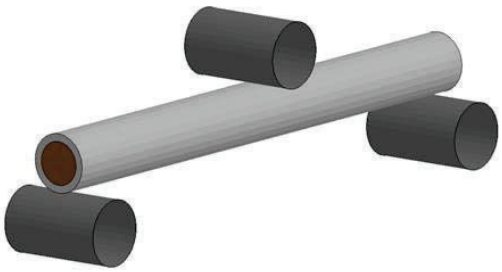

Figure 5: *FE model geometry for the Three-Point Bending test on hybrid wood-filled aluminium dowel*

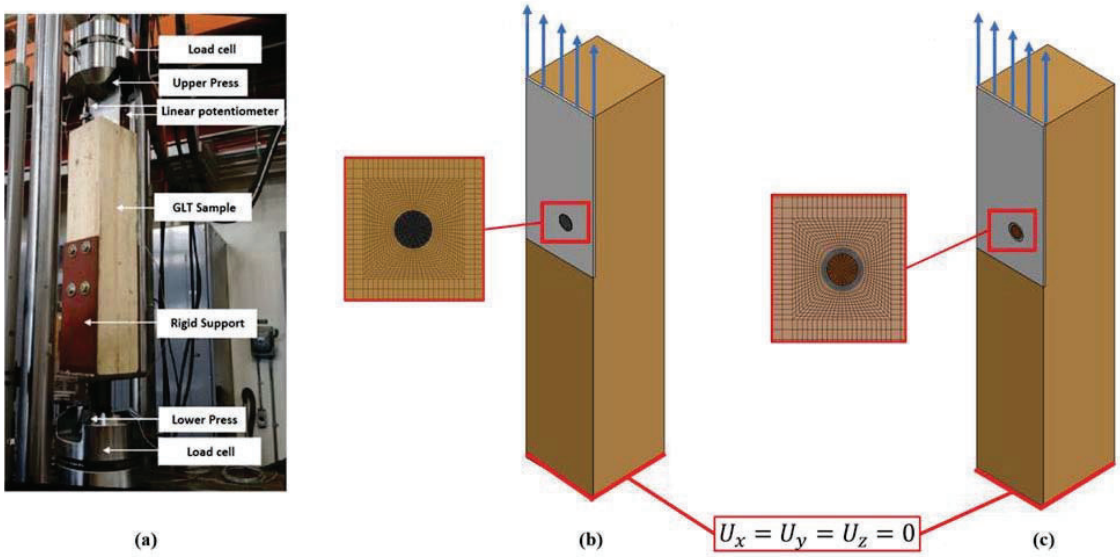

Figure 6: *Double shear tensile test on hybrid wood/aluminium assembly: (a) Experimental setup [8]; (b) FE model of the assembly with galvanised steel dowel; (c) FE of the assembly with hybrid wood-filled aluminium dowel*

2.3 FE MODELLING OF THE DOUBLE SHEAR TESTS ON HYBRID SYSTEMS (TIMBER-TO-ALUMINIUM CONNECTIONS)

Two series of experimental tests were conducted on structural timber-to-aluminium assemblies. The first series of tests were carried out on hybrid timber-to-aluminium assemblies connected with galvanised steel dowels (Figure 3.b). The second series of tests were done on hybrid timber-to-aluminium assemblies connected with wood-filled aluminium dowel (Figure 3.a). For the two series of tests, the hybrid assembly is made of Glued Laminated Timber with a groove in which an aluminium plate is inserted and hold with the dowels. The assembly is hold on the bottom with screws on a rigid support and the aluminium plate is given a displacement at a rate of $2mm/min$.

The FE model of the two types of assemblies was done using eight-node constant stress solid elements (LS-DYNA ELFORM 1) with hourglass control type 6 (which use the Belytschko-Bindemann approach) for the Glued Laminated Timber, the aluminium plate, the galvanised steel dowel, as well as for the wood-filled aluminium dowel. The presence of two symmetry planes allows to modelled only one-quarter of the model by applying symmetry boundary conditions in the two symmetry planes. The mesh was refined in the vicinity of the dowel's holes in the Glued Laminated Timber (Figure 6.b and 6.c). In the FE model, only the part of the assembly above the rigid support is modelled by assuming that the dowels used to assembly to the rigid support stay undeformed during the test and so no failure happens in the part of the Glued Laminated Timber in contact with the rigid support.
The nodes on the bottom surface of the Glued Laminated Timber are all constrained ($U_x = U_y = U_z = 0$) and a velocity control is applied on the top nodes of the aluminium plate (Figure 6.b and 6.c) using an explicit time integration.
All contacts in the FE model, either existing at the beginning or developing during the simulation are set to be automatically detected by the software by using the AUTOMATIC_SURFACE_TO_SURFACE contact algorithm.

3 RESULTS

3.1 THREE-POINT BENDING TEST ON WOOD FILLED ALUMINIUM DOWEL

The results of the Three-Point Bending test on the wood-filled aluminium dowel were analysed in terms of the global response expressed as force-displacement curves and the failure predictions. Figure 8 compares the numerically obtained Force-Displacement curve (red dashed curve line) to those reported experimentally (black curves) in literature by Rollo et al [7]. All experimental responses showed a first drop of load, which corresponds to the failure of the confined wood into the aluminium tube. The load is then carried by the aluminium tube until the occurrence of the final failure in the aluminium tube. These results show the ability of the aluminium tube in reducing the brittle failure of the wood material by improving the ductility of the entire hybrid wood-filled aluminium structure. The experimental curves showed also some variations in the peak force as well as in the failure of the confined wood which results from the natural bio-composite characteristic of the wood material. However, with the calibrated material parameters, it can be seen through Figure 8 that the FE model was able to predict the mean value of the experimental responses. Figure 7.a shows the fracture pattern of the FE model which is in good agreement with the experimental observations. The failure occurred in tension on the bottom side of the hybrid dowel and propagated through it.

Figure 7: *Failure modes during the Three-Point Bending test on hybrid wood-filled aluminium dowel: (a) Numerical; (b) Experimental*

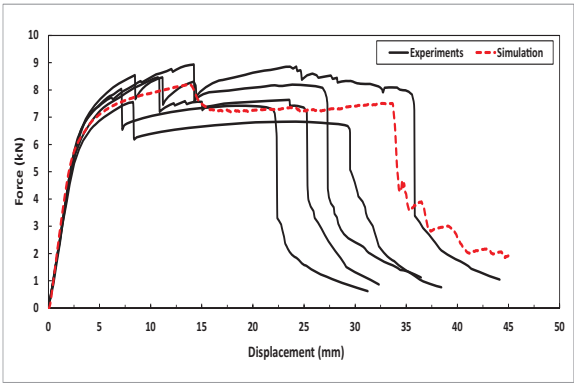

Figure 8: *Force-Displacement curves on the Three-Point Bending test on hybrid wood-filled aluminium dowel*

3.2 DOUBLE SHEAR TEST ON HYBRID WOOD/ALUMINIUM ASSEMBLY

The failure modes observed during the first series of experimental tests on the hybrid assembly connected with galvanised steel dowel was observed in the Glued Laminated Timber. Figure 9.a depicts the experimentally observed failure. The cracks observed along the grain direction in the Glued Laminated Timber members are probably caused by tension load perpendicular to the grain direction resulting from the displacement of the dowels. The predicted failure modes and cracks propagation with the FE analysis are presented in Figure 9.b. A good correlation can be seen between the predicted failure modes and the crack growth and the experimental inspection. The failure starts in the vicinity of the dowels and propagates in the Glued Laminated Timber in transverse tension. A comparison of the load-deflection curves between the numerical prediction and experiments is displayed in Figure 10, in which a good agreement can be seen for the global linear and non-linear behaviour and for the peak load at failure.

The failure behaviour during the second series of the experimental tests with the hybrid wood/aluminium assembly connected with the hybrid wood-filled aluminium dowel is displayed in Figure 11.a. The failure happens in the Glued Laminated Timber in the location of the aluminium plate, resulting from the deformation of the hybrid wood-filled aluminium dowel which fits into the groove of the Glued Laminated Timber due to the displacement of the aluminium plate. It can be seen on Figure 11.b that the predicted failure mode is in good agreement with the experimental observations. The comparison of the numerically obtained Force-Displacement curves to the experiments as presented in Figure 12 shows a good agreement in the non-linear behaviour as well as the load-carrying capacity and the failure. It is worth noting that the failure in perpendicular tension along the grain direction in the Glued-Laminated Timber as observed during the first series of test with the galvanised steel dowels initiates also in the Glued Laminated Timber during the second series of the test with the hybrid wood-filled aluminium dowels, but this failure modes do not propagate because of the premature failure of the hybrid dowel. Thus, an optimization of the hybrid wood-filled aluminium dowel is necessary in order to reach the performance of the galvanised steel dowel.

4 CONCLUSION

In this study, the ability to predict the mechanical behaviour of wood and confined wood by using the FE method and the built-in LS-DYNA material model MAT-143 was investigated. This material model performs well in simulating the global mechanical behaviour of the confined wood under quasi-static loading condition and the initiation and propagation of the fracture in timber. Though the numerical results are in good agreement with the experimental ones, works are needed in order to asses results of the numerical model, to become a real alternative for predicting the failure of safety barriers for highway bridges.

EXPERIMENT ON AXIAL CAPACTY-BENDING CAPACITY RELATIONSHIP OF STEEL BAR-TIMBER COMPOSITE COLUMN

Keisuke Hayata[1], Motohiro Mukai[2], Shinich Shioya[3]

ABSTRACT: In light of the current climate crisis, there has been much recent interest in using timber structural members in large buildings, because timber is as renewable natural resource, and moreover, in severe earthquake prone, such as Japan, they are more desired on the grounds of light weight of timber members. We are developing a frame system formed by timber members reinforced by deformed steel bars, i.e., rebars using epoxy resin adhesive and have already developed a technique for the connection between column of ground floor and reinforced concrete foundation. Performance of the column was reported in the previous WCTE2021. We have planned an experiment to investigate bending characteristic of the other portion except hinge of the column bottom. This paper reports the experiment, its results, and comparison of experiment result and calculation on bending moment capacity.

KEYWORDS: Composite timber, Column, Deformed steel bar, Bending moment capacity, Yield moment

1 INTRODUCTION

S.Shioya, (author [3]), has proposed a structural system for building construction, adopting Hybrid Glulam Timber members using Steel bars (HGTSB, nicknamed "Samurai" in Japan) and has developed the structural design methodology [1]. Our team is now developing more refined and more competitive and commercial structural system for buildings adopting HGTSB and its structural design methodology.

2 BACKGROUND AND TARGET

S.Shioya has already developed a technique for rigid connection of rebars inside the composite timber, using carbon fiber plastic sleeve (CFS) and epoxy resin adhesive with works similarly to work process of the glued-in-rod, and reported performance of the column adopted the technique [1]. And then his group testified the application of the technique to the connection between column of ground floor and reinforced concrete foundation, by loading test of column specimens [1,2].

Figure 1(a)-(b) illustrate cross-section and side view of one specimen of an experiment [2], which is modelled for mid-rise buildings with a half-sized scale. Figure 1(c) and (d) show horizontal force-deformation angle relationship of a specimen and bending moment-rotation relationship of its footing's hinge. Yellow line relationship indicates one calculated for a conventional glulam timber column with no rebar, same cross-section, and rigid-fixed end. Light black line indicates experimental loops. The connection is found to produce high bending capacity and abundant-energy dissipation up to large deformation. Red line indicates skeleton curve calculated by the method mentioned in the previous literature [2]. The method has accurately estimated yielding moment and bending capacity of bending hinge of HGTSB column. On the other hand, the method for estimating those moment and capacity for the portion except the hinge in column, also is required. The aim of this study is to develop the method for estimating bending characteristic of the portion and the column of story above second story in building.

3 COMPRESSION TEST

3.1 SPECIMEN

Figure 2 illustrates cross-section and side views of specimen. The scale was 1/4. Area ratio of rebars/ 8-D13 to column's gross-area/150mm x 150mm was 4.5%.
The number of specimens was to be 5 for conventional glulam timber column and 5 for the composite column. Glulam timber was prepared according to Japanese Ceder, E65-F225, in Japanese Agriculture Standard (JAS); its laminas had no joint such as finger joint. Table 1 lists mechanical properties of lamina by tests; bending strength of the lamina was 49.0N/mm^2. Rebar grade was SD345; tensile yielding strength was 384N/mm^2; ultimate tensile strength was 553N/mm^2. The adhesive for the rebar was epoxy resin adhesive with allowable upper temperature of 110℃. The process of embedding rebars adhered to the same way as Literature [3].

3.2 LOADING AND MEASUREMANT

Figure 4 illustrates set-up for loading and measurement. Monotonic compression was loaded using Amsler compression testing machine (Capacity=2MN). Axial compression force, axial deformation of overall of specimen, and axial strain of timber surface were measured.

3.3 RESULTS

Table 3 lists experimental and calculated results.

3.3.1 **Failure**

Figure 5 illustrates final failures; Figures 5(a)-(c) are WO specimens and Figures 5(d)-(f) are HW specimens.

i) Glued laminated timber specimen (WO)

In WO-4 in Fig. 5(b), vertical cracks appeared in wood at an axial force of 570 kN and after then the cracks developed along the wood grain. Eventually, the wood grain was crushed in middle region of specimen height, resulting in grain bending. In WO-5 in Fig. 5(c), portion of fracture was at the top, but the fracture was similar to that of WO-4.

ii) Composite timber specimen (HW)

The fracture condition of HW-3 is shown in Figure 5(e). Vertical crack occurred at axial force of 959 kN and then the crack developed along the rebar as the force increased. Portion of fracture was at the top. The fracture of HW-5 is shown in Fig. 5(f). Fracture was at the bottom. It can be seemed that location of local defects due to wood heterogeneity would be starting point of the fracture.

https://doi.org/10.52202/069179-0416

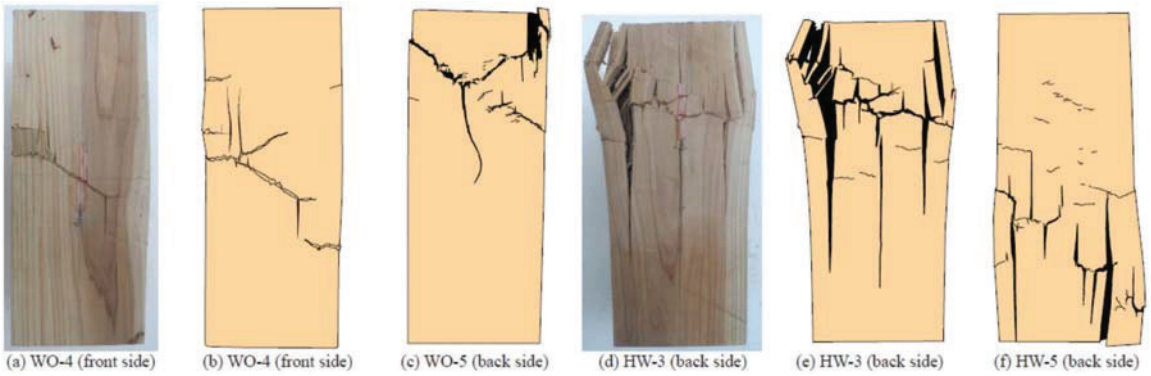

Figure 5: *Final failures*

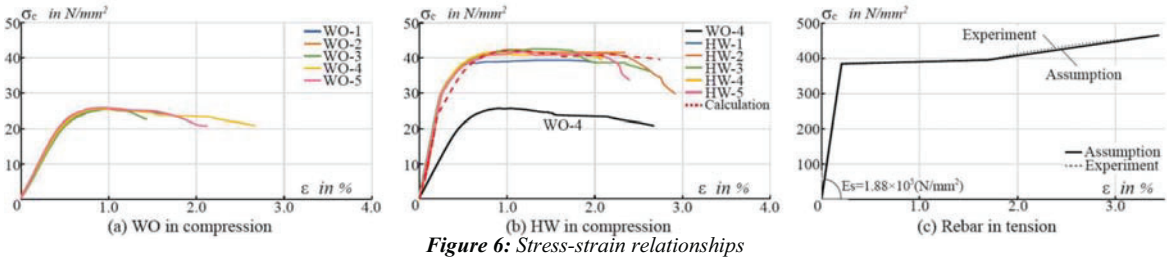

Figure 6: *Stress-strain relationships*

3.3.2 Compression stress-strain curve

The stress-strain relationship is shown in Figure 6. Vertical axis is taken as the compressive force divided by gross area of column (150x150mm), while horizontal axis is taken as the average deformation of the displacement transducers divided by height of column (385mm).

i) Glulam timber specimen (WO)

Figure 6(a) shows compressive stress-strain relationship of WO specimen is shown; those of the five specimens was similar stress-strain relationship.

ii) Composite timber specimen (HW)

Figure 6(b) shows compressive stress-strain relationships of HW specimen in comparison with that of WO-4, where the HW specimen had significantly increased elastic stiffness, compressive strength, and limit strain at which the compressive strength can be maintained (hereafter referred to as limit strain) in comparison with those of WO-4. Compressive strength increased by a factor of nearly 1.7 and was maintained up to a range of 2.0-3.0% in compressive.

3.4 ESTIMATION of COMPRESSIVE STRESS-STRAIN RELATIONSHIP

In Figure 6(b), a red dash line indicates a stress-strain relationship calculated, by assuming stress-strain curve for wood being the same as that of WO-4 and that for rebar as a curve shown in Figure 6(c) based on the results of Table 2 and Figure 3. The calculated stress-strain relationship is seen to estimate initial stiffness and compressive strength of experimental result. The point at which experimental capacity start to decrease against calculated one might be thought to be that at which buckling of rebars within column occurred. It might be thought that axial force of rebar increased as the capacity of the timber decreased, causing the rebar to buckle. The amount of decrease in the capacity of timber is thought to be a key to identifying the point at which buckling of the rebar occurs.

4 BENDING TEST

4.1 SPECIMEN

Figure 7 illustrates configuration of specimen. Scale, cross-section, and material were the same as the compression test mentioned above. Direction of bending was selected to be parallel to gluing layer of lamina, i.e.,

Table 4: *List of specimens*

η : Ratio of axial force N : Axial force

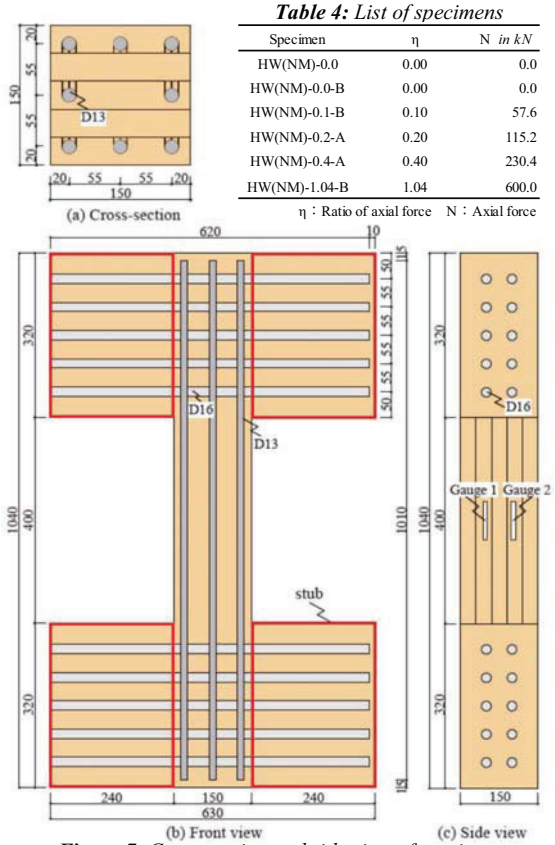

Figure 7: *Cross-section and side view of specimen*

https://doi.org/10.52202/069179-0416

weak-axis direction. Upper and lower portions of the specimen were bound to four timber stubs, with a connection using Glued-in-rod. The section between the upper and lower stubs was tested.

Table 4 lists specimen names, ratios of axial force to compressive capacity assumed, and axial forces acted. The specimen was one type of steel bar-timber composite column and the number of it was 6. Variable of specimen was magnitude of axial force, i.e., vertical force. The name of specimen was HW(NM), charged with a numerical value 'η' representing axial force ratio.

As described in later Section 4.4.1, consideration of failure of the first specimen led to adhesion of steel plate A or steel plate B to both sides of the stubs. The same adhesive as that used for the rebar was also used for these plates. Names of specimen to which the steel plates were bonded were additionally marked with the symbol 'A' or 'B' for the steel plate.

The axial force ratio was assumed to be ratio of the constant vertical load divided by average compressive capacity of the composite specimens of the compression test mentioned above. The specimens were manufactured at the same time as the specimens of the compression test.

4.2 LOADING AND MEASUREMANT

Figure 8 and Photo 2 illustrate set-up for loading of combing compression with bending. The stub was fixed with high-tension PC bar, to upper or lower H-shaped steel beam. The apparatus including a specimen was placed into other Amsler compression testing machine (Capacity=2MN) for long column. The loading was conducted to be exert a specified constant compression and to exert bending moment on it by both oil jacks up to ultimate capacity while maintaining the magnitude of the axial force. One-way pin was connected to connections between testing machine and the upper and lower H-shaped beams. Lateral braces were connected between upper stub and lower stub to prevent specimen from being out of plane. Figure 9 illustrates positions of foil strain gauges and measuring sections of deformation by displacement transducers. Foil strain gauges (measuring length: 60 mm) were adhered to surface of the wood. Two strain gauges were adhered to both surface in tensile and compressive surface; one strain gauge was adhered to side surfaces. The position of displacement transducers was changed between the upper and lower stubs in relation to

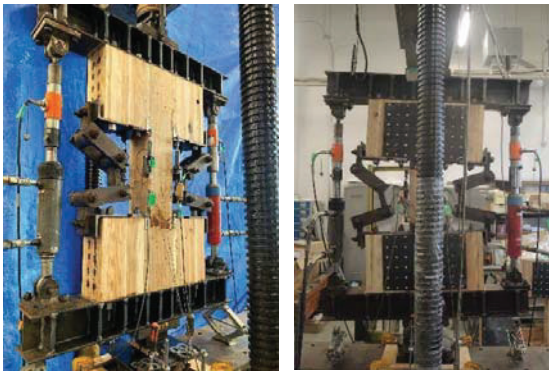

Photo2: *Set-up for loading*

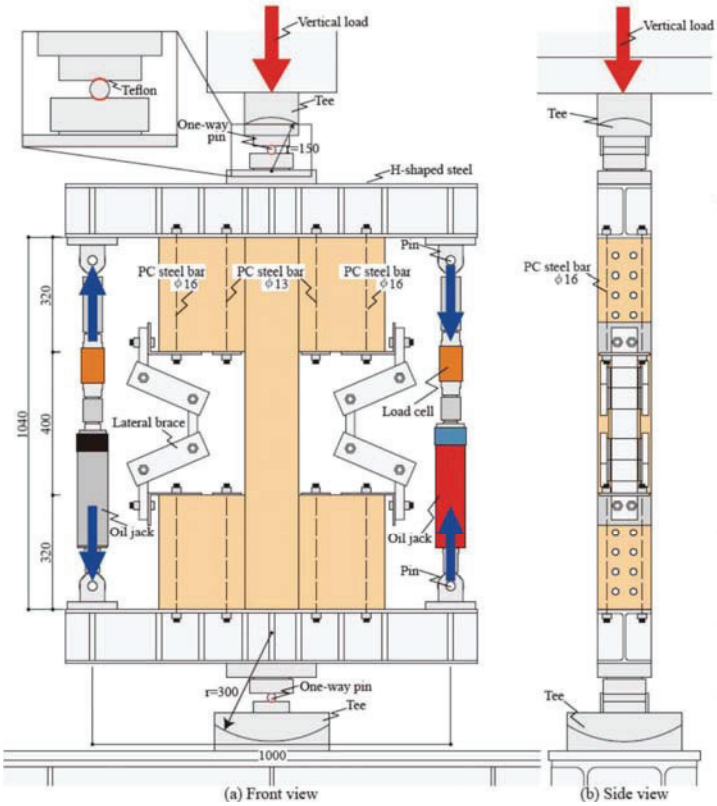

Figure 8: *set-up for loading*

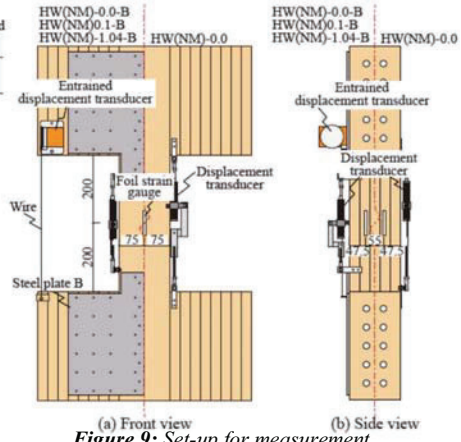

Figure 9: *Set-up for measurement*

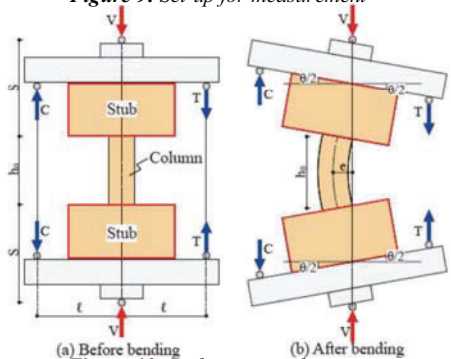

Figure 10: *Deformation of specimen under bending force*

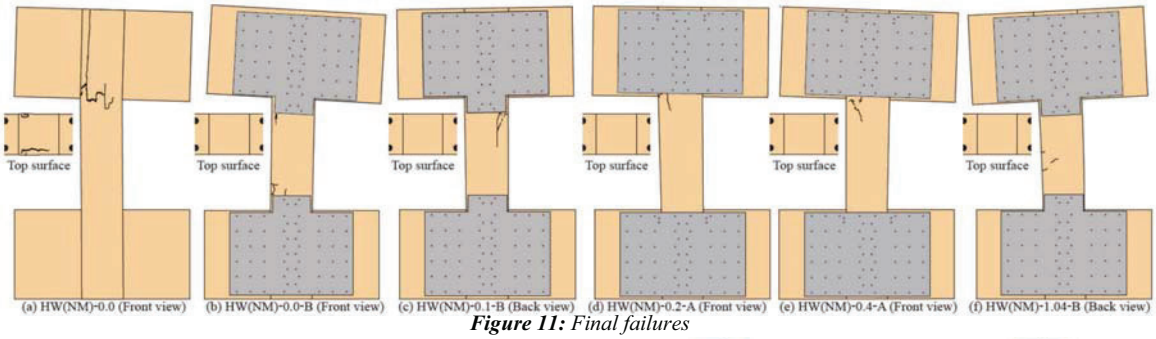

Figure 11: *Final failures*

the steel plates reinforcing the stubs. For the specimens adopting steel plate B, which will be described in Section 4.4.3, in addition to the displacement transducers, two entraining-displacement transducers were installed at both ends of the stub so that deformation due to cracks by bending could also be measured to be included.

4.3 BENDING MOMENT OF COLUMN

Figure 10 illustrates deformation of specimen under bending force. When moment is exerted on the section between the pins, cross-section at the middle height of column moves horizontally from its initial position. The horizontal distance is designated as eccentricity distance/e. An additional moment/ V・e also acts on the section due to the vertical force/V. The maximum moment/M_u is expressed as Equation (1), and the additional moment increases as the vertical force/V is increased.

$$M_u=C\cdot(\ell-e)+T\cdot(\ell+e)+V\cdot e \quad (1)$$

where C: compressive force of the oil jack for bending force, T: tensile force of the oil jack for bending force, ℓ : horizontal distance from the one-way pin to the oil jack, e: horizontal distance from line of action of the vertical load to centroid of cross-section at the middle height of the column, V: vertical force.

As the eccentricity distance/e was not measured in this experiment, it was calculated from the curvature by strain of wood or the angle of rotation between the upper and lower stubs. The curvature was taken as value by the foil strain gauge on wood and the angle of rotation was taken as value from the displacement transducer. Section/S in Figure 10(a) from center of rotation of the one-way pin to the border of column was assumed to be as rigid. Because the column is under bending and axial force, the eccentricity distance/e is expressed in Equation (2) using curvature/ϕ and in equation (3) using rotation angle/θ, on the basis of deformation of specimen.

$$e_s=S\cdot\phi\cdot h_o/2+(\phi\cdot h_o/2)\cdot(h_o/4) \quad (2)$$

$$e_d=S\cdot\theta/2+(\theta/2)\cdot(h_o/4) \quad (3)$$

4.4 RESULTS

4.4.1 Failure and strengthening of stub

Figure 11(a) illustrates failure of specimen HW(NM)-0.0 with zero axial force. This is the first specimen which was tested. Vertical cracks progressed along tensile rebars

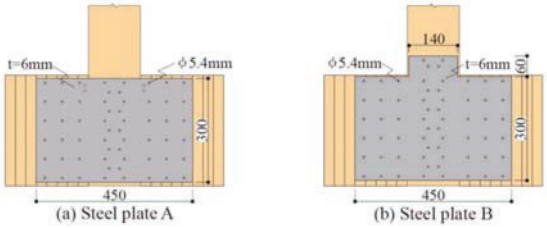

Figure 12: *Shape and dimensions of steel plate*

within the stub at near maximum load capacity; finally, anchorage failure of rebar occurred. Split cracks were observed on top surface of column after having removed the specimen from the apparatus, as shown in Figure 11(a). In buildings, the anchorage length of rebar is significantly ensured because columns are continuous in several stories. Because purpose of this study is to estimate bending capacity, steel plate A shown in Figure 12 (a) was bonded to side surface of the stubs in order to prevent the crack along rebar. It was employed for specimens with axial force ratios of 0.20 and 0.40. These specimens were named as HW(NM)-0.2-A and HW(NM)-0.4-A. Figures 11(d) and 11(e) illustrate final failures of specimens/HW (NM)-0.2-A and HW(NM)-0.4-A. The cracks along rebar occurred slightly and no cracks were observed at the top and bottom surface of column. Considering of these failures, the shape of steel plate was further modified as shown in Figure 12(b). These three specimens were HW(NM)-0.0-B, HW(NM)-0.1-B, and HW(NM)-1.04-B with axial force ratios of 0.00, 0.10 and 1.04, respectively. Figure 11(b) illustrates failure of specimen HW(NM)-0.0-B bonded with steel plate B. Cracks by bending occurred and reached maximum capacity of higher amount. Figure 11(f) illustrates failure of HW(NM)-1.04-B, in which the axial force was increased up to an axial force ratio of 1.04. No crack was observed in tensile surface, and a slight swelling was observed in wood portion in compression.

4.4.2 Moment-curvature relationship

Figure 13 shows moment-curvature relationship. The moments according to Equation (1) and (3) are shown as a solid line, and the case where the eccentricity distance 'e' is set to zero is shown as a dotted line. The assumption of e=0, after reaching the maximum bending moment, was selected on the ground of those failures which were concentrated near the borders between the stub and the column section. The moment of the solid curve increases as the axial force increases, against the dotted curve. It can be confirmed that the additional moment due to the vertical force should be taken into account in the moment of action.

η:Ratio of axial force, N:Axial force, E:Young's modulus, $_eM_y$:Yeilding moment, $_eM_m$:Bending capacity

Hereafter, the moments are described in terms of the additional moment.

The curvature was calculated from strain in the gauges on wood surface. The strain for curvature used average of the two strain gauges on a surface. The two values were in close agreement. The symbols '△',etc. indicate timings at which the strains at positions of tensile rebar, compression rebar, and middle rebar reached yielding strain of rebar, by using linear interpolation from values of the strain gauges on tensile and compressive surfaces.

The tensile rebar is indicated by symbol '○'; the compression rebar by symbol '□'; the middle rebar by symbol '△'. Tensile yield is indicated by white paint and compression yield by black paint. It was confirmed that when the axial force ratio was 0.00, yielding of tensile rebar or compressive rebar was almost simultaneous. However, as the axial force ratio increased, compressive yielding of the compression rebar preceded and yielding of the tensile rebar delayed. In the case of HW(NM)-1.04-B, of which the axial force was the highest of them, the tensile rebar did not yield and the middle rebar yielded in compression. Yielding of rebar is seen to decrease the stiffness. Bending moment at yielding decreased as the axial force increased, but the bending capacity tended to increase up to an axial force ratio of 0.2 and to decrease above that value. Table 5 lists experimental values of Young's modulus of column. The Young's modulus tended to decrease with increasing axial force. The maximum decrease is 8.9%, but it should be noted that yielding moment decreases significantly.

4.4.3 Moment-rotational angle relationship

Figure 14 shows moment-rotation angle relationship. HW(NM)-0.0, which was not reinforced with steel plates, is indicated by dotted line. HW(NM)-0.0 had the largest reduction of capacity after reaching maximum capacity because it accompanied rebar slip within the stub and wood split around rebar. HW(NM)-0.2-A and HW(NW)-0.4-A produced a less increase in rotation angle after the bending cracks. In HW(NM)-0.2-A and HW(NW)-0.4-A, the displacement transducer was fixed to the inner of the column section and deformation of bending cracks near the inner could not be included in the deformation, so the curves had less increase in the rotation angle after the bending crack. In the specimens reinforced with steel plate/B, two entrained displacement transducers (sensitivety:1 /10 mm) were installed to measure elongation and contraction between top stub and bottom stub, and the rotation angle was calculated from deformation by them.

5 BENDING TEST OF BEAM

5.1 AIM

Only material tests of the lamina were conducted in the column bending tests, and no bending tests of column of Glulam timber was conducted. Because bending strength of the Glulam timber could not be specified, experimental capacities of the column bending capacity could not be validated. Bending test by Glulam timber beams was conducted to capture relative relationship between strength of lamina and bending strength of Glulam timber in the column (cross section:150x150 mm).

5.2 CAUSE OF REDUCTION OF BENDING CAPACITY OF COLUMN SPECTIMN

As described in Section 4.4.1, failures were concentrated at the boundary between column and stub. The cause for this will be holes (diameter: 20mm) for the Glued-in-rod

to connect column to the stubs (hereinafter referred to as "insertion hole") drilled in column, and insertion holes close to the failure zone may have reduced bending capacity of Glulam timber.

5.3 SPECTIMN

Figure 15 shows shape and dimensions of beam specimen. Two types of specimens were employed: one Glulam timber beam and two Glulam beams with rebar inserted and glued at mid-span of the beam. The former was named as BWO and the latter as BWR-1 and BWR-2. The details of rebar and the insertion hole (diameter:20mm) were the same as those of the column specimen mentioned in Section 4.1. The lamina of the specimen also was the same species and grade, i.e., cedar/L50. However, the timing of fabrication of these specimens differed from that of the column specimens.

5.4 LOADING AND MEASUREMANT

Figure 16 illustrates set-up for loading and measurement. 4-point bending test was employed. Direction of bending was selected to be parallel to gluing layer of lamina as that of the column. Vertical deformation at the mid-span of beam, sinking deformations at left and right support points, and wood strain on upper and lower surfaces near the mid-span (length of inspection: 60 mm) were measured.

5.5 RESULTS

Figure 17 shows vertical force-deflection relationship at mid-span. The deflection was subtracted by deflection of both supports. The reduction in stiffness by inserted rebar is not clear, but maximum forces were reduced to 77.5% and 87.3% for BWR-1 and BWR-2 beams with rebar compared to that of Glulam timber beam (BWO). Figure 18 shows moment-curvature relationship of mid-span. The curvature was calculated from strain of foil strain gauges on upper and lower surfaces of timber. Figure 19 s hows positions of the foil strain gauges. Curvature in Figure 18(a) employed that of strain gauge away from the rebar/ (Location I). Bending stiffness of position away from the insert hole of rebar was hardly affected. The curvature in Figure 18(b) employed that of the location II close to the rebar. At the location, bending stiffness was reduced by the insert hole. Photo 4 shows final failures. Specimens with rebar had tensile cracks on at lower tensile surface as if connecting the insertion holes, whereas compressive portion by bending was never affected by the insertion holes because rebar and its adhesive produce compressive resistant. Figure 20 shows the relationship between moment and strain of foil strain gauges. Solid line indicates strain on lower tensile surface and dashed line dose strain of that on upper compression surface. In lower tensile surface, strain near the rebar was larger, while, in upper compression surface, strain was not affected by the rebar.

From these results, it can be concluded that, in compression zone by bending, bond interface between rebar and wood can resist compression, but, in tensile zone, the adhesive for rebar peels off at that of insertion hole and only wood's width excluding the sum of diameter of the hole can resist, resulting in a decrease in maximum bending capacity of Glulam timber beam.

5.6 BENDIG STRENTHS OF GLULAM TIMBER AND LAMINA

Figure 21in the next page shows resisting cross-section of beam for calculation of bending strength of timber at Location II. In BWR-1 and BWR-2, width equal to

https://doi.org/10.52202/069179-0416

diameter of the insertion hole was assumed to be unresisting over range from the neutral axis to lower tensile surface, and then the sectional modulus was calculated: the bending strength was calculated by dividing maximum moment using the modulus. Sectional modulus for BWO was calculated as a rectangular cross-section. The bending strength based on these calculations are indicated as horizontal lines in Figure 22. The bending strengths of BWO (solid line) and BWR-1 (dotted line) were almost the same, while that of BWR-2 (dashed line) was 1.11 times greater than BWO. The maximum force of BWR-1 was 0.78 times as much as that of BWO, and that of BWR-2 was 0.87 times as much as that of BWO. Therefore, it can be considered that bending strength of glulam timber can be identified more accurately by using the sectional modulus for effective cross-section in Figure 21. In the same figure, data of bending strength are plotted as symbol '△' and data of tensile strength are done as symbol '○' , by material tests of lamina. Figure 23 illustrates shapes and dimensions of the lamina testpiece. The numbers of bending and tensile specimens was 15 each. Tensile strength of BWO was 0.67 times as much as average of bending strengths and 1.20 times as much as average of tensile strengths.

It is well known that bending strength of glulam timber approaches tensile strength as its depth increases, and their magnification ratios correspond to this tendency. Figure 24 shows distribution of data of bending strength and tensile strength from material test of lamina testpieces of the column specimen described in Section 4.1.

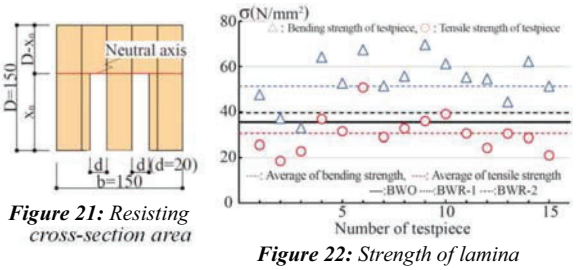

Figure 21: *Resisting cross-section area*

Figure 22: *Strength of lamina*

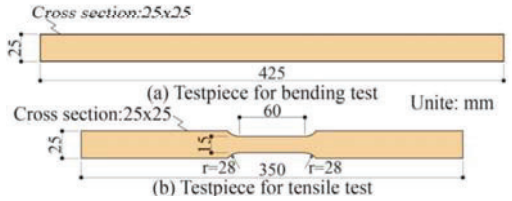

Figure 23: *Shapes and dimensions of the lamina testpiece*

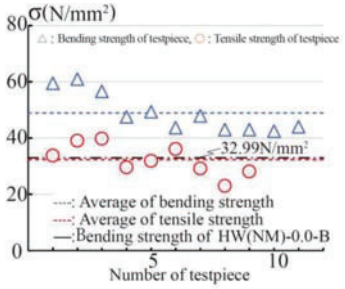

Figure 24 *Strength of column lamina by testpiece*

Similarly, comparing the mean values, tensile strength was 0.66 times as much as that of the bending strength. The bending strength of the Glulam timber calculated from HW-(NM)-0.0-B with zero axial force using the sectional modulus for Figure 21 is shown as a horizontal one dot chain line in Figure 24. In the calculation, Young's modulus of rebar was assumed to be the standard value of 2.05×10^5 N/mm^2, the yield strength of the rebar was done to be test value (384 N/mm^2), and Young's modulus of timber was done to be average/5530 N/mm^2 of Young's modulus by tensile and compression tests of lamina. Bending capacity was calculated using Equation (18) described later. In Figure 24, the horizontal one dot chain line is seen to be within range of data of tensile strength of lamina.

From above discussion, it can be concluded that it is reasonable to assume bending strength of Glulam timber to be 32.99 N/mm^2, which is the bending strength calculated from HW(NM)-0.0-B by Young's modulus of average of experimental values of the tensile testpieces and the sectional modulus for Figure 21.

6 AXIAL FORCE-BENDING CAPACITY CORRELATION CURVE

6.1 EXPERIMENTAL RESULTS

Figure 25 plots data of axial force and yielding moment with symbol '○' and data of axial force and bending capacity with symbol '●'. The experimental values for compression test of column were plotted with bending capacity being zero. Yielding moment employed bending moment at which rebar yielded on the moment-curvature relationship in Figure 13. Bending capacity employed maximum bending moment. HW(NM)-0.0 without steel plate reinforcement is indicated by symbols '△' or '▲'. The yield moment decreases linearly with increasing axial force. On the other hand, the bending capacity increases over range of axial force ratio/ η of 0.0-0.2, but rather increases and decreases when η is 0.4 or higher.

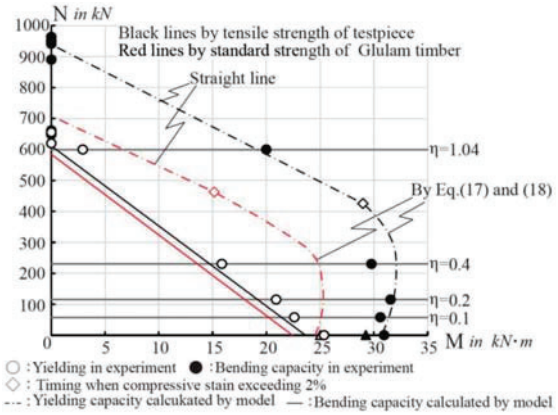

Figure 25: *Axial forth-bending capacity correlation curve*

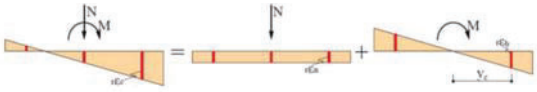

Figure 26: *Model of bending strain distribution*

https://doi.org/10.52202/069179-0416

6.2 ESTIMIATION FOR YIELD MOMENT

Figure 26 illustrates a model of bending strain distribution in a column section. Except when axial force is zero, compression rebar yields first because axial force/N and bending moment/M act simultaneously. The moment can be estimated as moment at which compression rebar yields. Even if axial force is zero, yielding moment can be estimated on the assumption that tensile yielding of tensile rebar and compressive yielding of compression rebar occur simultaneously in a symmetrical cross-section. Strain ${}_r\varepsilon_c$ of compression rebar is the sum of the strain ${}_r\varepsilon_n$ by axial force and the strain ${}_r\varepsilon_b$ by bending moment. ${}_r\varepsilon_n$ and ${}_r\varepsilon_b$ are expressed by Equations (2) and (3) .

$$ {}_r\varepsilon_c = {}_r\varepsilon_n + {}_r\varepsilon_b \quad (1) $$

$$ {}_r\varepsilon_n = N/A_e \cdot 1/E_w \quad (2) $$

$$ A_e = b \cdot D + (n-1) \cdot \Sigma a_r $$

$$ {}_r\varepsilon_b = \phi \cdot y_c $$

$$ = M/(E_w \cdot Ie) \cdot y_c \quad (3) $$

where, b: column width, D: column depth, n: Young's modulus ratio (=E_r/E_w), E_r: Young's modulus of rebar, E_w: Young's modulus of timber, a_r: area per rebar, ϕ : curvature, y_c: distance from neutral axis to compression rebar, I_e: sectional secondary moment of column including effect of rebar.

Strain ${}_r\varepsilon_y$ of rebar which reaches the yield stress/σ_y can be expressed by dividing σ_y by the Young's modulus/E_r of the rebar by using Equation (4).

$$ {}_r\varepsilon_y = \sigma_y/E_r \quad (4) $$

Substituting this ${}_r\varepsilon_y$ into ${}_r\varepsilon_c$ in Equation (1), yield moment/M_y in which stress in the rebar reaches yielding stress/σ_y is finally expressed as Equation (5).

$$ M_y = (\sigma_y/n - N/A_e) \cdot I_e/y_c \quad (5) $$

6.3 ESTIMATION FOR BENDING CAPACITY

6.3.1 Rapture strain of wood in bending capacity

Figure 27 shows bending moment-strain relationship of the column specimen. Moments were assumed to be moments taking axial force into account. The strain was taken as foil strain gauge value.

For HW(NW)-0.0 and HW(NW)-0.0-B with zero axial force, the magnitude of compressive strains on compression surface and tensile strains in tensile surface at the maximum bending moment were almost identical: the former was -0.40% and the latter was 0.55%.

For HW(NM)-1.04-B, where the axial force was the greatest of them and its wood did never fail in tension by bending, the strain at the compression surface increased up to -1.80 to -1.95%, but the strain at the tensile surface was only 0.42%. The maximum strain at the tensile of HW(NM)-0.0, where the rebar slip-failed at the stub without steel plates, was still only 0.42%.

From these results, it can be concluded that if bending capacity is determined by tensile rupture by bending, the tensile strain of wood of the tensile surface by bending can be assumed to be 0.5%.

6.3.2 Stress-strain relationship of wood

Figure 28 shows stress-strain curves for compression and tensile tests for testpiece of lamina of the column specimen. In only one testpiece of compression test, compressive strength was maintained up to approximately 2% of strain after compressive yielding. However, as seen in Figure 6, rebar boosts the strain up to approximately 2%. Roughly, the relationship can be assumed to be fully elastoplastic. In tensile test, wood ruptures immediately when the tensile strength is reached.

On the basis of these results, stress-strain relationship of wood in compression and tension, adopted as a model for estimation of bending capacity, are shown in Figure 29(a).

6.3.3 Equation for estimation of bending capacity

Figure 29(b) illustrates an assumed stress distribution of column at bending capacity. Timing when strain of tensile surface by bending reaches 0.5% is assumed to be timing of bending capacity. The distance/x_n from the compression surface to neutral axis is expressed in Equation (6).

$$ x_n = -\varepsilon_c/(\varepsilon_t - \varepsilon_c) \cdot D \quad (6) $$

where ε_c: strain on compression surface by bending, ε_t: strain on tensile surface, D: column depth

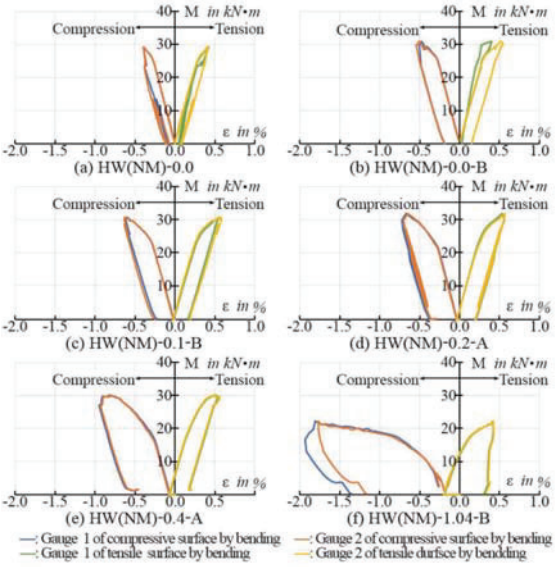

Figure 27: *Bending moment-strain relationship*

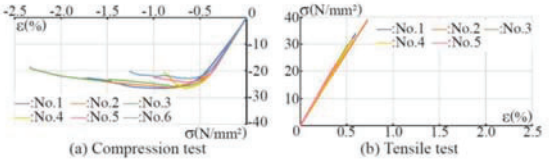

Figure 28: *Stress-strain relationships of lamina*

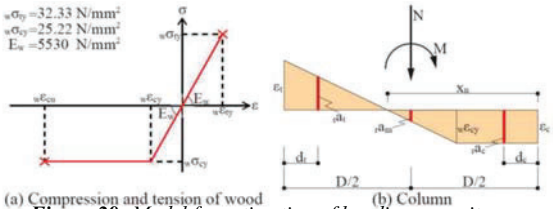

Figure 29: *Model for estimation of bending capacity*

https://doi.org/10.52202/069179-0416

Strain/$_r\varepsilon_c$ of rebar on the compression, strain/$_r\varepsilon_t$ of rebar on the tension, and strain $_r\varepsilon_m$ of middle rebar at column depth are expressed by Equations (7)-(9), respectively.

$$_r\varepsilon_c=\varepsilon_c\cdot(x_n-d_c)/x_n \quad (7)$$

$$_r\varepsilon_t=\varepsilon_t\cdot(D-x_n-d_t)/(D-x_n) \quad (8)$$

$$_r\varepsilon_m=\varepsilon_c\cdot(x_n-0.5\cdot D)/x_n \quad (9)$$

where d_c: distance from compression surface to its near rebar, d_t: distance from tensile surface to its near rebar.

Resultant force/$_rT$ of rebars in tension, resultant force/$_rC$ of rebars in compression, and resultant forcer/$_rC_m$ of rebars in the middle at column depth are expressed by equations (10)-(12), respectively.

$$_rT=E_r\cdot{}_r\varepsilon_t\cdot{}_ra_t \quad (10)$$

$$_rC=E_r\cdot{}_r\varepsilon_c\cdot{}_ra_c \quad (11)$$

$$_rC_m=E_r\cdot{}_r\varepsilon_m\cdot{}_ra_m \quad (12)$$

where $_ra_t$: cross-sectional area of tensile rebar
$_ra_c$: cross-sectional area of compression rebar
$_ra_m$: cross-sectional area of middle rebar

Resultant force/$_wT$ of wood in tension and resultant force/$_wC$ of wood in compression are expressed by Equations (13) and (14).
The compression range can be divided into a constant section and the other section like a triangle because there is a section where stress level is constant within assumed stress-strain relationship of wood.

$$_wT=0.5\cdot{}_w\sigma_{ty}\cdot b\cdot(D-x_n) \quad (13)$$

$$_wC={}_wC_1+{}_wC_2 \quad (14)$$

$$_wC_1=0.5\cdot{}_w\sigma_{cy}\cdot b\cdot{}_w\varepsilon_{cy}/\varepsilon_c\cdot x_n \quad (15)$$

$$_wC_2={}_w\sigma_{cy}\cdot b\cdot(\varepsilon_c-{}_w\varepsilon_{cy})/\varepsilon_c\cdot x_n \quad (16)$$

where $_w\sigma_{ty}$: tensile strength of wood, $_w\sigma_{cy}$: compressive strength of wood, $_w\varepsilon_{cy}$: strain of wood at its compressive strength

Axial force balance is given by Equation (17), and bending capacity/M_u is given by Equation (18).

$$N+{}_rT+{}_wT={}_rC_m+{}_rC+{}_wC \quad (17)$$

$$\begin{aligned}Mu={}&{}_rT\cdot(0.5\cdot D-d_t)+{}_wT\cdot(0.5\cdot D-1/3\cdot(D-x_n))\\&+{}_rC\cdot(0.5\cdot D-d_c)+{}_wC_1\cdot(0.5\cdot D-(1/3\cdot x_n\\&\cdot{}_w\varepsilon_{cy}/\varepsilon_c+x_n\cdot(\varepsilon_c-{}_w\varepsilon_{cy})/\varepsilon_c))\\&+{}_wC_2\cdot(0.5\cdot D-0.5\cdot x_n\cdot(\varepsilon_c-{}_w\varepsilon_{cy})/\varepsilon_c)\end{aligned} \quad (18)$$

6.4 COMPARISON OF CALCULATION AND EXPERIMENTAL VALUES

In Figure 25, correlation curves of axial force-yield moment by solid line and axial force-bending capacity by single-dotted curve are shown. The black curves were calculated on the basis of strength and resisting cross-section mentioned in Section 5.6. However, as the axial force increases, the strain of the compression surface exceeds the limit of strain (2.0%). For higher axial forces, the curve was assumed to be approximated by a straight line connecting the point and the point of uniaxial compression capacity with bending being zero. Yield moment tends to decrease linearly as axial force increases, and bending capacity curve has a maximum value at an axial force ratio/ η of approximately 0.3, which is consistent with experimental trend. Calculated curves are generally in agreement with experimental values. Red curves using standard values for rebar (SD345) and cedar laminated wood (E65-F225) are evaluated on the safe side. For wood, compressive strength on compressive zone was assumed as compressive strength, whereas tensile strength on tensile zone was assumed as bending strength.

7 SUMMARY

In order to develop estimation method of yield moment and bending capacity for the steel bar-timber composite column subjected to axial compression and bending moment for column of story above second story in building, compression test and bend test of column, and bend loading test of Glulam timber beam were conducted by specimens scaled as 25%. The results are summarized as followings:

i) Compression capacity and stiffness of column increase as the amount of rebar increases. Also, ductility of compression increases slightly and become stable.
ii) Yield bending moment decreases linearly as axial force increases whereas bending capacity varies as a curve with a peak at axil force ratio being approximately 0.3.
iii) Bending capacity of column was estimated more accurately when duct of wood in column due to joint rebar for connection stub to column was taken account. This suggests that column-beam connection in building should also take account for the duct by bolts or glued-in rod used in the connection.
iv) Formula for estimation of bending yield moment and bending capacity of column with increasing axial force were proposed, and the correlation curve by using the formulas and tensile properties of lamina estimated accurately experimental data. By using standard values of Glulam timber, the curve estimated the experimental data on the safe side.
v) The ratios of tensile strength, compressive strength of lamina, and bending strength of glulam timber were identified. Tensile strength of timber by bending of glulam timber can be estimated to be close to the tensile strength of lamina and the compressive strength of the wood in the compression zone by bending can be done to be close to the compressive strength of lamina.

FINITE ELEMENT ANALYSIS OF BUCKLING BEHAVIOR OF TIMBER ENCASED STEEL COMPOSITE COLUMNS SUBJECTED TO AXIAL LOAD

Ying Gao[1], Feiyang Xu[2], Minghao Geng[3], Qibin Hu[4], Xinmiao Meng[5]

ABSTRACT: Timber encased steel composite (TESC) columns provide a feasible application to large-scale and high-rise structures. This paper investigates the axial load distribution and buckling behavior of TESC columns with embedded H-section steel through finite element (FE) analysis combined with parametric studies. The numerical results revealed that increasing the slenderness ratio could enhance the confinement effect of the timber in improving the maximum load. A larger proportion of timber area provided a more significant confinement effect in enhancing the ductility of the steel, and then a minimum area ratio for TESC columns considering the confinement effect of timber was determined.

KEYWORDS: Finite element analysis, Steel-timber composite column, Load distribution, Parametric study

1 INTRODUCTION

The use of wood for construction purposes has increasingly been the subject of investigations in past decades due to its significant sustainability superiorities such as carbon sequestration and low environmental impact [1]. Timber-steel composite structures have been demonstrated as effective structural solutions for modern timber structures. Benefiting from the composite systems with reasonable design, the disadvantages of wood can be minimized to some extent, while the advantages of steel and timber can be fully utilized.

Timber encased steel composite (TESC) column is a steel-timber composite member with remarkable potential for multi-story timber buildings that have been increasingly needed in recent years. Typically, the steel is fully embedded in the glulam and connected through adhesives, [2]. The use of steel, on the one hand, can effectively improve the stiffness and strength of the column without increasing or not significantly increasing the column size, which is beneficial to structural design such as indoor space utilization. On the other hand, it alleviates the issue of the shortage of wood resources in China and is conducive to the promotion and application of timber in construction. Meanwhile, the outer timber not only provides lateral confinement on the inner steel to enhance the strength but also offers anti-corrosion and fire-retardant coating for the inner steel. The TESC column has been applied as fire-resistant structural columns in timber structures such as the Wood Square Building [3]. TESC columns could be prefabricated in the factory, ensuring product quality and on-site assembly efficiency. Although the cost of the TESC column will increase compared with the glulam column, it is expected that the improvement of the structural performance of TESC columns can offset this increase.

Several experimental studies have been conducted to investigate the mechanical behavior of TESC columns with different configurations. [2, 4-7] Significant improvements in the stiffness and load-carrying capacity of TESC columns were observed. However, the application of TESC columns is inhibited to some extent due to the lack of design methods. A choice should be made between the steel and the timber design methods or made based on both methods. The root of the choice lies in an insightful evaluation concerning the load distribution of each component in the composite column and the interaction at the interface, which is critical for structural design. In this regard, more efforts are needed to gain insight into the structural responses and establish relevant design methods. Nonetheless, the load distribution and interaction are difficult to monitor during the tests. Thus, performing numerical studies to fill the gaps is an available and significant approach to structural analysis [8].

In this paper, a numerical investigation on the axial load distribution and buckling behavior of TESC columns with embedded H-section steel is described. The proposed FE models are built via ABAQUS and validated through experimental results from previous studies [2]. Parametric studies are then performed to evaluate the effects of variations in geometric parameters and material strengths on the compressive behavior of the encased steel column by analyzing the axial load distribution on steel and timber of TESC columns.

2 AXIAL COMPRESSION TESTS OF TYPICAL TESC COLUMNS

Axial compression tests of TESC columns were performed by Hu et al. [2]. The glulam of the column was made of first-grade Douglas-fir. The moisture content of the tested samples was approximately 12%. The mean density was 480 kg/m^3. The inner steel was wide flange hot-rolled H-section steel (Q235B class) with sectional dimensions of 125 × 125 × 6.5 × 9 mm. The resorcinol adhesive was used to produce the glulam and the two-component epoxy adhesive was applied to connect the glulam and steel. The width (D) of the square TESC column was 226 mm. The manufacturing process of the TESC column is shown in Figure 1(a). A total of 6 TESC specimens were tested with lengths of 1100 mm, 1700 mm and 2300 mm. The loading protocol was according to standard GB/T 50329–2012 [9], and the test setup is displayed in Figure 1(b). The axial compression tests were conducted with the same moisture content. The support conditions of the specimen were fixed at the bottom and hinged at the top. Strength failure of 1100 mm long specimens and global buckling of 1700 and 2300 mm specimens was observed. as shown in Figures. 1(c). The load–axial displacement curves are shown in Figure 1(d) The load-axial strain behavior, initial stiffness, load-carrying capacity and ductility were determined (see Hu et al. [2]). The previous test results provide a basis for the calibration of the FE models.

3 FINITE ELEMENT ANALYSIS

3.1 MATERIALS

The elasto-plastic constitutive law was adopted for timber [10]. The elastic behavior of timber was defined as orthotropic through the Engineering Constants in ABAQUS, and the properties are listed in Table 1. The compressive MOE E_L and strength f_{ct} parallel to the grain of timber were determined by axial compression tests on two short full-scale glulam columns. The plastic behavior was characterized by the Hill yield criterion for anisotropic materials [11].

Table 1: *Material properties of timber*

Property		Timber	CoV (%)
Elastic Modulus (MPa)	E_L	13600	3.12
	E_R [7]	577.9	16.70
	E_T [7]	424.2	9.01
Poisson's Ratio [13]	u_{LR}	0.292	
	u_{LT}	0.449	
	u_{RT}	0.390	
Shear Modulus (MPa) [13]	G_{LR}	870.4	
	G_{LT}	1060.8	
	G_{RT}	95.2	
Compressive strength (MPa)	Parallel	26.32	7.45

Note: L, R and T represent the axial, radial and tangential directions of timber, respectively.

The material properties of the steel were obtained through tensile tests. The average MOE E_s and yield strength f_y were taken as 206 GPa and 280 MPa, respectively. The elastic-plastic isotropic behavior was considered and a multilinear stress-strain relationship was adopted in FE models. The Poisson's ratio was set to 0.3.

3.2 MODELING

The FE models were built using the software ABAQUS. The 8-node linear brick element with reduced integration (C3D8R) was selected to simulate the steel and timber. For simplicity, the following steps were adopted: the arc at the flange-web junction of the H-section steel was taken as the right angle due to the negligible effect on the simulation results. However, the six pre-drilled holes (diameter = 20 mm) for threading through the strain gauges in actual TESC columns were considered, given that it significantly affected the failure modes of the specimens [7]; each glulam was regarded as an entirety without glue delamination [14]; the tie constraint was set to simulate the contact between steel and timber due to a near full composite action before reaching the maximum load observed in the tests [2, 5, 7].

The boundary conditions and meshing are shown in Figure 2. A reference point coupled with the top surface of the column was established for applying the load and boundary conditions. The top and bottom surface of the specimen was constrained as a hinge end and a fixed end, respectively.

A mesh convergence test was carried out by element refinement. The global size of the characteristic element varied from 20, 15 and 10 mm. Considering the computational accuracy and efficiency, the global size of the characteristic element was set as 15 mm. The FE models were loaded using a displacement-control procedure in a quasi-static state. The displacement was directly applied to the reference point at the top surface.

The first buckling mode obtained from the eigenvalue buckling prediction was adopted as the initial geometric imperfection distribution, and its magnitude was taken as 1/1000 of the column length.

https://doi.org/10.52202/069179-0417

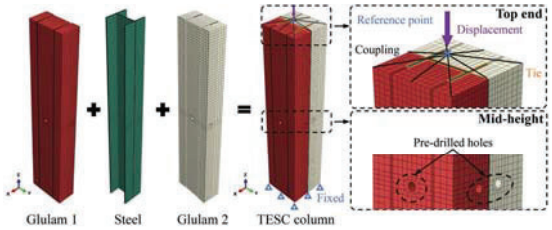

Figure 2: *Geometric modeling of the TESC column*

3.3 SIMULATION VALIDATION

The numerical results were compared and discussed with the experimental results. The numerical failure modes exhibited good agreement with the test observations, as shown in Figure 3. The local damage caused by the pre-drilled holes at the mid-height of the column was well simulated by FE models. It should be noted that the pre-drilled holes increase the influence of the geometry of the TESC column on its buckling performance, thus weakening the ability of FE models to verify the correctness of the material properties of timber to a certain extent. Nevertheless, the built FE models remain reliable since the pre-drilled holes affect the buckling capacity of the TESC column to the same extent. If the strength of the timber is too large or too small, it will lead to significant errors. In addition, the FE model could not predict the cracking at the post-peak stage since the adhesive layers were neglected. The numerical load-axial displacement curves displayed a relatively good trend with test results, as displayed in Figures 4(a) to (c). Nevertheless, the initial slope of numerical curves in the elastic stage was slightly higher, which was commonly observed [15, 16]. The initial differences between FE models and physical specimens, as well as the relatively large deformation at the specimen end, may cause the higher axial displacement recorded from the LVDTs, thus exhibiting a lower initial stiffness in the experimental curves. The load-axial strain relationships of timber were further used to validate the FE modeling methods, especially the elastic behavior, as shown in Figures 8(b) to (f). It was found that the numerical results showed excellent consistency with the experimental results.

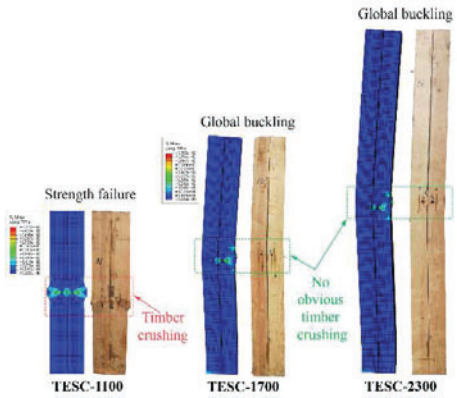

Figure 3: *Comparison of deformation and damage of TESC specimens observed in experiments and FE models.*

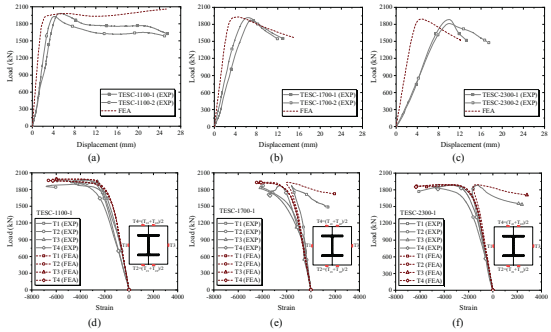

Figure 4: *Comparison between numerical and experimental results: (a), (b) and (c) load-axial displacement curves; (d), (e) and (f) load-axial strain curves of timber*

The authors also performed a finite element analysis on the axial compressive behavior of 16 L-shaped TESC columns with the same materials in this paper but a different cross-sectional shape [7]. The differences between numerical results and experimental results are basically within 10% and the reliability of FE models was validated. Although the section of the simulated TESC column is different, the same modeling methods were adopted. Therefore, it can be further proved that The proposed modeling approaches show to be sufficiently accurate in predicting the axial compressive behavior of the TESC columns.

3.4 LOAD DISTRIBUTION

The validated FE models were used to analyze the load distribution on individual components of the TESC column. The load on each component was extracted through the function of "Free body cut" in ABAQUS. Figure 5 shows the load-axial displacement curves of TESC columns and components. 'IS' and 'OT' respectively represent the inner steel and outer timber in the TESC column, and 'TESC' represents the composite column. The yield point was determined by the farthest-pointing method [17].

The failure sequence of steel and timber was shown from the analysis of load distribution on components. The steel yielding occurred earlier than the timber and TESC column, with a load level of approximately 40% of the load-carrying capacity. It results from the relatively small steel ratio (5.77%) of the TESC column, even though the steel yield strength is much larger than the timber compressive strength. The specimen TESC-1100 entered the yield stage almost synchronously with the timber. In contrast, the yield displacement of specimen TESC-2300 was closer to that of the steel. It implies that with an increasing slenderness ratio, the crucial component that determines the yield of the TESC column changes from timber to steel. It is worth noting that both the timber and steel components almost simultaneously reached their maximum load with the TESC column, indicating a

https://doi.org/10.52202/069179-0417

perfect composite effect with the full utilization of different materials being achieved. The residual load-carrying capacity of steel in the specimen TESC-1100 was kept stable due to the sufficient lateral restraint provided by the timber. However, the load allocated on components in specimens TESC-1700 and TESC-2300 gradually decreased after reaching the maximum load due to the global buckling.

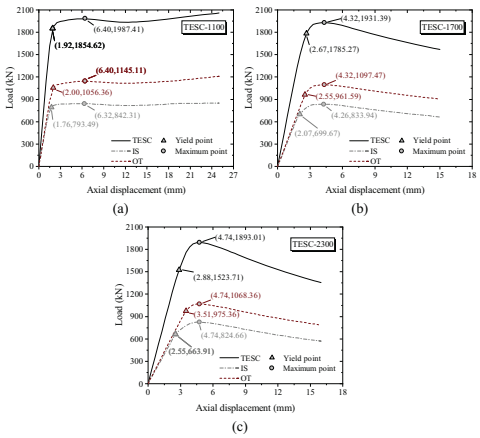

Figure 5: *Load distribution on components of specimens: (a) TESC-1100, (b) TESC-1700 and (c) TESC-2300*

To assess the confinement effect provided by the timber on steel, the load-axial displacement curves of each component in the TESC column and the bare parts were compared, as shown in Figure 6. “S” and “T” represent the bare steel column and bare timber column, respectively. Take specimens with a length of 2300 mm as an example. It was found that the confinement effect provided by the timber on steel was primarily reflected in enhancing the load-carrying capacity and ductility. The confinement effect was activated after the yielding of the steel component, allowing the steel component in the TESC column to exhibit a smoother yielding stage and a higher maximum load than the bare steel column. The bare steel column reached the maximum load of approximately 713 kN at 3.20 mm, while the steel component reached the maximum load of approximately 825 kN at 4.80 mm. Furthermore, the outer timber suppressed the post-buckling behavior of the inner steel, thus leading to a substantially higher residual load-carrying capacity than that of the bare steel column. However, the load-carrying capacity of the timber component was lower than the bare timber column. The bare timber column reached the maximum load of approximately 1195 kN at 5.80 mm, while the timber component of the TESC column reached the maximum load of approximately 1068 kN at 4.80 mm. It is because the timber component is in the field of axial compression and lateral pressure, which weakened the load-carrying capacity of the timber.

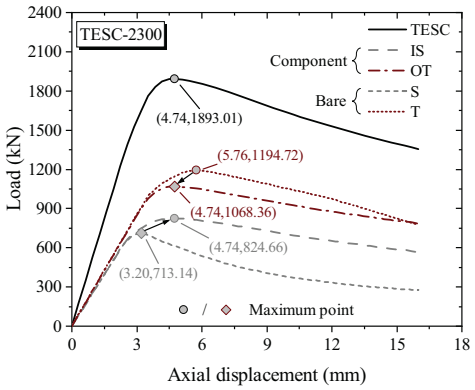

Figure 6: *Comparison of load on components and individual loaded parts*

4 PARAMETRIC STUDY

Based on the validated FE modeling, a parametric study was conducted to evaluate the influence of geometric and material parameters on the compressive behavior of TESC columns and the load distribution on components. The parameters were categorized into two groups. The first group A focused on the strength-related parameters, including the steel yield strength and the compressive strength parallel to the grain of timber. The second group B regarding the geometric-related variables, including the steel area, timber area and slenderness ratio.

The details of the parameters are listed in Table 2. The steel yield strengths changed from 235, 345, 460, and 960 MPa. According to [13], three commonly used wood species of Engelmann Spruce (*Picea engelmannii*), Red Pine (*Pinus resinosa*) and Western Larch (*Larix occidentalis*) were selected. The average compressive strengths parallel to the grain are 30.9 MPa, 41.9 MPa and 52.5 MPa, respectively. Five types of H-section steel with different steel areas were chosen from the standard GB/T 11263—2017 [18]. The steel ratio (A_s/A_{TESC}) by the steel sectional area A_s and the TESC column sectional area A_{TESC} was used to describe the specimen with the same composite area but different steel areas. The area ratio (A_{TESC}/A_s) was used to describe the specimen with different timber areas but the same steel area. The value of A_{TESC}/A_s was determined by the cross-section width D (ranging from 125 mm to 260 mm) of the TESC column or the width t (ranging from 0 mm to 50 mm) of the encased timber between the H-section steel shown in Figure 10(b). The slenderness ratio λ changed from approximately 5 to 200. The corresponding column lengths L were taken as 500, 1100, 1700, 2300, 2900, …, and 16300 mm. The increment of the length was 600 mm. The λ was calculated as follows.

$$\lambda = \frac{KL}{i} \tag{1}$$

$$i = \sqrt{\frac{I_t + I_s E_s / E_t}{A_t + A_s f_y / f_{ct}}} \quad (2)$$

where K represents the effective length factor. Since the top end of the TESC column was hinged and the bottom end was fixed, the value of K was set to 0.7. The radius of gyration of the cross-section i was calculated by Eq. (2) according to [19], where I_s and I_t were the moments of inertia of the steel and timber components around the minor-axis of H-section steel, respectively. The column TESC-2300 was selected as the control specimen of the parametric study considering that the column length of 2300 mm was common in practical applications. A total of 140 FE models, including the corresponding bare steel columns and timber columns, were built and analyzed. It should be noted that the predrilled holes at the mid-height specially designed for the strain measurement of the inner steel in tests, were not considered in the parametric study.

Table 2. *Investigated parameters in the parametric study*

Group	Steel yield strength f_y (GPa)	Timber strength f_{ct} (MPa)	Steel ratio (Steel sectional dimensions, $b \times d \times t_w \times t_f$, mm)	Width t/D (mm)	Area ratio A_{TESC}/A_s	Length L (mm)

			5.77% (125 × 125 × 6.5 × 9)		17.34	500, 1100, 1700, …, 16500
			7.66% (150 × 150 × 7 × 10)		13.06	500, 1100, 1700,

https://doi.org/10.52202/069179-0417

Note: The steel ratio was calculated as $A_s/A_{TESC} \times 100\%$; When the value of t/D is less than 125, it represents t, otherwise it represents D.

To evaluate the confinement effect provided by the timber on steel, the maximum load enhancement N_{ens} and the ductility enhancement μ_{ens} of the steel component were defined and calculated as follows.

$$N_{ens} = \frac{N_{IS}}{N_S} \tag{3}$$

$$\mu_{ens} = \frac{\mu_{IS}}{\mu_S} \tag{4}$$

where N_{IS} and μ_{IS} represent the maximum load and ductility of the steel component, respectively. N_S and μ_S denote the maximum load and ductility of the bare steel column under axial loading, respectively. The ductility μ was calculated as follows.

$$\mu = \frac{d_u}{d_y} \tag{5}$$

where d_y and d_u are the displacements corresponding to the yield load and ultimate load, respectively. The ultimate load of the steel was the load when the load dropped to 85% of the maximum load.

4.1 STEEL YIELD STRENGTH

The load-axial displacement curves of TESC columns and their components with different steel yield strengths are shown in Figure 7. It was assumed that the constitutive relationship of the steel was less influenced by the strength grade, so the consistent stress-strain relationship was adopted for the steel. The trends of curves shown in Figure 7(a) indicate that although steel contributed a small percentage of the total sectional area, increasing the steel yield strength could remarkably enhance the maximum load of the composite column. A significant strength enhancement of 73.07% is achieved when the steel yield strength increased from 235 MPa to 960 MPa. Moreover, it could be seen from Figures 7(b) and (c) that the load-carrying capacity of the composite column was mainly provided by the steel component when the steel yield strength was larger than 460 MPa. An interesting finding was observed in Figure 7(c) that increasing the steel yield strength led to a higher maximum load of the timber. It can be explained by the fact that the yield of the TESC column is delayed when the steel yield strength increases, thus can fully utilize the compressive strength of the timber. Nonetheless, the TESC column with a higher steel yield strength exhibited a slightly less ductile response, even though the higher residual load-carrying capacity at the end of the analysis was observed.

The enhancement of maximum load and ductility of the steel component is shown in Figure 7(d). When the steel yield strength increased from 235 MPa to 960 MPa, the value of N_{ens} and μ_{ens} decreased in general, indicating that the confinement effect is insufficient for the higher grade steel. In other words, reducing the strength differences between timber and steel can receive a better confinement effect for the steel. Furthermore, the value of μ_{ens} was much higher than that of N_{ens}, showing that the confinement effect provided by timber influences the ductility of the inner steel more than the strength.

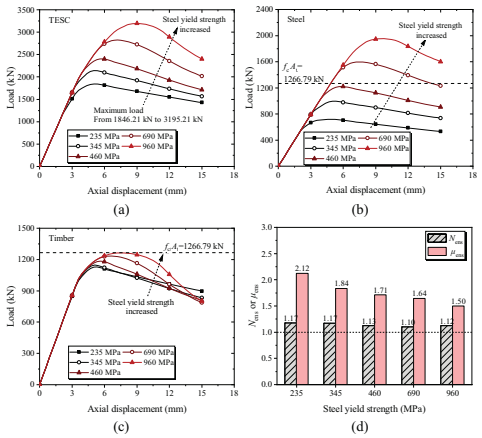

Figure 7: *Comparison of load-axial displacement relationships with different steel yield strengths: (a) TESC column, (b) steel component, (c) timber component and (d) enhancement of maximum load and ductility*

4.2 STEEL AREA

The load-axial displacement curves of TESC columns with different steel ratios are shown in Figure 8. As expected, the larger steel ratio contributed to the higher stiffness and load-carrying capacity of the TESC column, as shown in Figure 8(a). When the steel ratio increased from 4.12% to 12.15%, the initial stiffness and maximum load were enhanced by 72.01% and 56.23%, respectively. It can be seen in Figure 8(b) that such enhancement results from the contribution of the steel component. Meanwhile, Figure 8(c) shows that the stiffness and maximum load of the timber component decreased when the steel ratio increased due to the relative decrease in the timber area.

The comparison of maximum load enhancement and ductility enhancement of the steel component and the individual part is shown in Figure 8(d). With the increase of the steel ratio from 4.12% to 12.15%, the values of N_{ens} and μ_{ens} decreased, indicating that the higher steel ratio leads to the lower confinement effect provided by timber, and the steel ratio should be less than 12.15% in the proposed TESC columns. Furthermore, it can also be seen that the ductility showed higher sensitivity to the steel ratio than the maximum load.

https://doi.org/10.52202/069179-0417

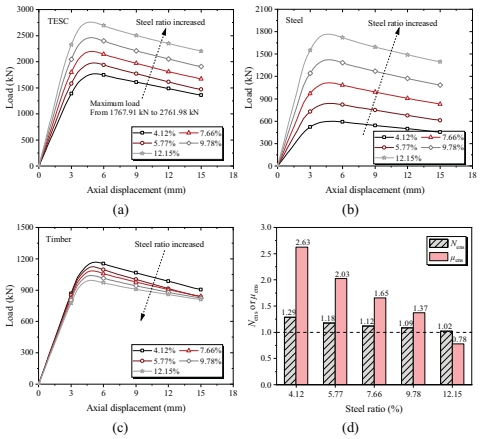

Figure 8: *Comparison of load-axial displacement relationships with different steel ratios: (a) TESC column, (b) steel component, (c) timber component and (d) enhancement of maximum load and ductility of steel*

4.3 TIMBER STRENGTH

The maximum load of TESC columns with different compressive strengths parallel to the grain of timber and steel ratios are compared in Figure 9(a). Similar to the effects of the steel yield strength, the higher value of f_{ct} also led to the higher maximum load of TESC columns. Using a higher grade of timber is an effective method to enhance the capacity of the composite column due to the much larger sectional area proportion of the timber component. For the TESC column with a larger steel ratio, however, a lower enhancement of the load-carrying capacity of the TESC column was observed. It indicates that the TESC column with high timber compressive strength and a large steel ratio may not be economic in terms of load-carrying capacity. It was also found that the effect of increasing timber compressive strength on improving the steel component capacity was not significant. Take specimens with a steel ratio of 5.77 % as an example. The load-axial displacement curves of the steel component are shown in Figure 9(b). Only less than 6% of the enhancement of maximum load was gained. It may result from the steel already reaching its yield strength. In this regard, increasing the compressive strength of timber allows the steel to experience a more pronounced yield plateau accompanied by a larger maximum displacement. In conclusion, it is reasonable to consider that the response of improving timber compressive strength on the steel component is mainly reflected in the hardening effect after the yielding of the steel.

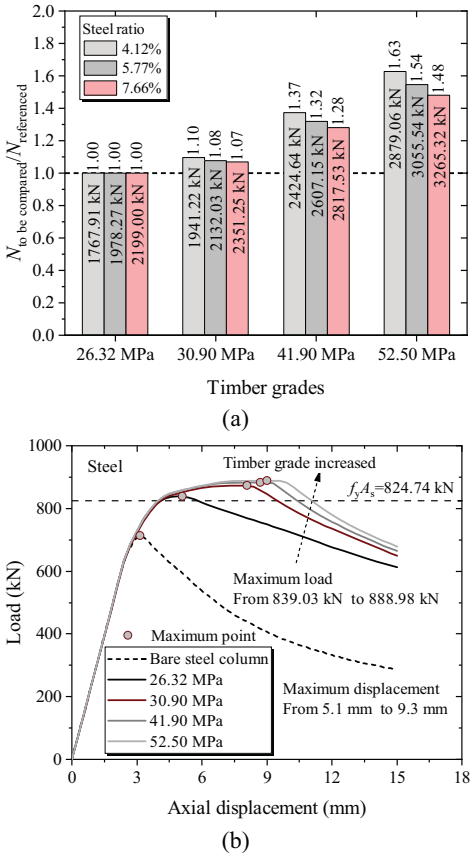

Figure 9: *The influence of timber compressive strength: (a) enhancement of maximum load of TESC columns and (b) load-axial displacement curves of the steel component in TESC columns with the steel ratio of 5.77%*

4.4 AREA RATIOS A_{TESC}/A_S

The effects of timber area on the steel component are discussed and analyzed in this section, as shown in Figure 10. It should be noted that when $A_{TESC}/A_S < 5.30$, the steel component is partially covered by timber, while the steel is fully coated by timber when $A_{TESC}/A_S > 5.30$.

Figure 10(a) shows that the influence of an increasing timber area followed a similar trend to the decrease of the steel ratio, with the enhanced maximum load and the ductile response of the steel. In the case of $A_{TESC}/A_S < 5.30$, increasing timber area slightly improved the load-carrying capacity and ductility of the steel component, as shown in Figure 10(b). It is because the buckling of the steel flanges is not well restrained since the steel is not fully covered. For $A_{TESC}/A_S > 5.30$, the mechanical performance of the steel component, especially ductility, was significantly improved. More than twice times enhancement of ductility was obtained when A_{TESC}/A_S was increased to approximately 23, whereas the value of the strength was only enhanced by approximately 20%. It is noteworthy that the steel could reach the yield strength when the value of A_{TESC}/A_S was 11.62. A slight enhancement of strength was observed when $A_{TESC}/A_S > 11.62$. The results revealed

https://doi.org/10.52202/069179-0417

that before reaching the steel yield strength, increasing the timber area greatly improves both the load-carrying capacity and the ductility of the steel component. After that, the effects of such an increase are mainly reflected in suppressing the post-buckling behavior of the steel component.

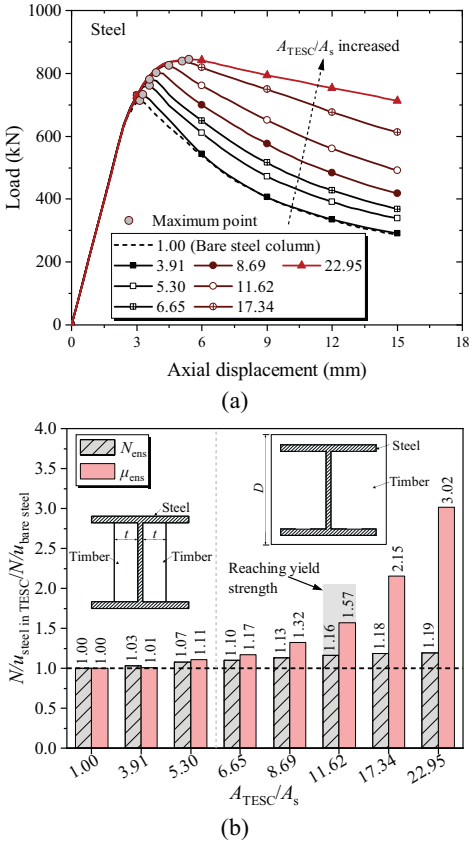

Figure 10: *Comparison of the steel component and the bare steel column: (a) load-axial displacement curves and (b) enhancement of maximum load and ductility*

The results mentioned above imply that the strength of the steel component might not be fully utilized with a relatively thin timber coating. Consequently, there is a minimum ratio of A_{TESC}/A_S (ξ_{min}) to ensure the steel component could reach the strength capacity under axial compression [20]. A parametric study was conducted to identify the value of ξ_{min}. The length-to-width ratio (L/d) of the steel component was defined, where d was the flange width of the H-section steel and was set to 125 mm (sectional dimensions of the steel: 125 × 125 × 6.5 × 9 mm) in this case. The column length L changed from 1000 mm to 3500 mm. Three steel yield strengths, namely 235, 280 and 345 MPa, were adopted. The relationship between ξ_{min} and L/d is shown in Figure 11(a). It was found that as L/d increased, a larger ξ_{min} was needed to provide enough lateral confinement. Subsequently, linear relationships are proposed to calculate the ξ_{min} as follows.

$$\xi_{min} = k\left(L/d - r_0\right) + s_0 \quad (6)$$

where k is the slope of the design curve, r_0 is the smallest L/d to ensure that the bare steel column could reach the yield strength under axial compression, and s_0 is the minimum ξ_{min} related to the sectional area of the steel component, which is taken as 5.30 in this work. The recommended values of parameters in Eq. (6) are shown in Figure 11(b). The ratios of calculation to simulation results were within the range of 0.85 to 1, indicating that the proposed design curves are safe. Meanwhile, it avoids material waste due to overly conservative calculation results.

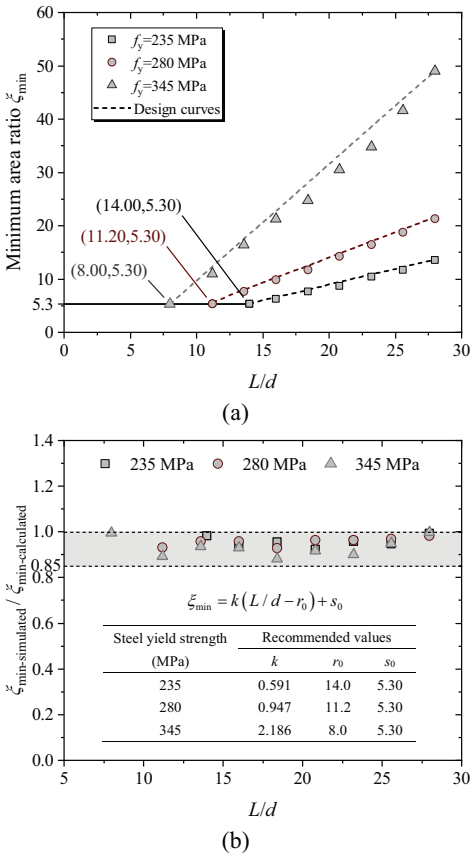

Figure 11: *Calculation results: (a) design curves and (b) comparison between calculation and numerical results*

4.5 SLENDERNESS RATIO

The influences of the slenderness ratio on the load-carrying capacity of the steel component were investigated. The TESC columns with steel ratios of 4.12%, 5.77% and 7.66% were selected in this section. The sectional dimensions of TESC columns were 226 ×

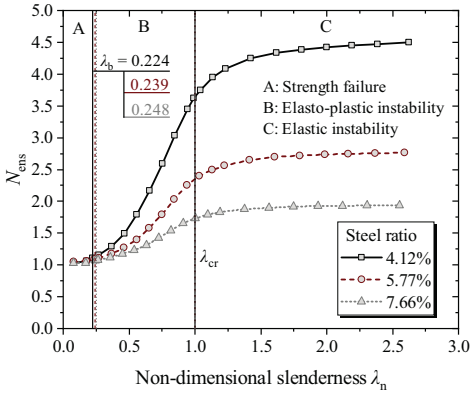
226 mm. The non-dimensional slenderness λ_n was used and calculated as follows.

$$\lambda_n = \sqrt{\frac{N_p}{N_{cr}}} = \frac{KL}{\pi}\sqrt{\frac{f_y A_s + f_{ct} A_t}{E_s I_s + E_t I_t}} = \frac{\lambda}{\pi}\sqrt{\frac{f_{ct}}{E_t}} \quad (7)$$

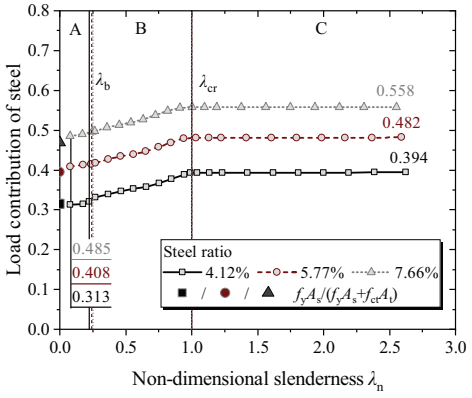
$$N_p = f_y A_s + f_{ct} A_t \quad (8)$$

$$N_{cr} = \frac{\pi^2 (E_s I_s + E_t I_t)}{(KL)^2} \quad (9)$$

Considering that the steel was converted into timber in Eq. (2), only the parameters of timber (f_{ct}/E_t) were adopted in Eq. (7). Relationships between the enhancement of the maximum load of the steel component and the non-dimensional slenderness are shown in Figure 12(a). The maximum load was nonlinearly enhanced with an increasing slenderness ratio. Three distinctive stages are observed. In stage A ($\lambda_n < \lambda_b$), the TESC column exhibited strength failure and the maximum load increased slowly. In stage B ($\lambda_b < \lambda_n < \lambda_{cr}$), the elasto-plastic instability dominated the failure mode of the composite column. A substantial amount of the load-carrying capacity recovered owing to the lateral restraint of timber, thus remarkably improving the maximum load when the slenderness ratio increased. In stage C ($\lambda_{cr} < \lambda_n$), the increase rate of the maximum load enhancement slowed down and tended to be stable since the elastic instability governed the failure mode. In addition, the smaller steel ratio of the TESC column contributed to the higher load enhancement of the steel component.



(a)



(b)

Figure 12: *Influence of slenderness ratios on the steel component: (a) enhancement of maximum load and (b) load contribution of steel*

The load contribution of the steel component when the TESC column reached the maximum load was compared, as shown in Figure 12(b). It was observed that the larger steel ratio led to the higher load contribution of the steel component. Owing to the confinement effect, the minimum load contribution ratio of the steel in the investigated slenderness ratios is slightly higher than the value of $f_yA_s/(f_yA_s+f_{ct}A_t)$. When it entered stage B, the elasto-plastic instability occurred and the curves almost linearly increased. After that, the load contribution of the steel component kept stable with a negligible improvement. It is due to the occurrence of elastic instability, the much high second-order effect results in the load-carrying capacity of the slender TESC column being independent of the material strength. In conclusion, the steel component carries an increasing percentage of the maximum load of the TESC column when the slenderness ratio increases.

5 CONCLUSIONS

The axial load distribution and buckling behavior of TESC columns with embedded H-section steel were investigated via a thorough numerical investigation in this work. The proposed FE modeling approaches of TESC columns reasonably simulated the experimental responses. The numerical results showed that the steel influenced the yield of the TESC column more than timber under a large slenderness ratio. Additionally, the increase in column length also led to a large load enhancement of the steel component compared with the bare steel column.

Parametric studies revealed that the geometry parameters exhibited more influence than the material strength on the compressive behavior of TESC columns and the encased steel. For a TESC column with a certain slenderness ratio, the maximum load of steel increased significantly with a larger area ratio when the minimum area ratio was not reached. While the ductility of the steel increased remarkably with a larger area ratio when the minimum area ratio was reached. For a TESC column with a certain

https://doi.org/10.52202/069179-0417

area ratio, either reducing the steel yield strength or enhancing the timber compressive strength could benefit the compressive performance of the steel. In addition, increasing the slenderness ratio led to a larger load contribution of the steel when the TESC column reached the maximum load.

The minimum area ratio of the TESC column was determined considering the inner steel could reach the yield strength. A thicker timber coating was required with an increase in either yield strength or length-to-width ratio of the inner steel. The proposed design curves regarding the area ratio and length-to-width ratio of the steel could be used for determining the scale of the TESC column.

EFFECTS OF ELEVATED TEMPERATURE ON BENDING CAPACITY OF STEEL BAR-TIMBER COMPOSITE BEAM

Tsukasa Ueno [1], Nao Matsuoka [2], Shinichi Shioya[3]

ABSTRACT: We have been developing a rigid frame system formed by timber members strengthened by deformed steel bars using epoxy resin adhesive. Buildings may often suffer from elevated temperature in Summer , such as 45.3℃ ever reported in Japan or approximately 65℃ in the attic space. On the other hand, when buildings suffer fire, the composite members also be required to resist against Dead load by using fireproof coating or burning marginal layer (i.e. charring layer). The resisting portion may be mainly lower than 100℃. We planned an experiment to reveal effects of those elevated temperatures on bending capacity of the composite beam. This paper reports the test, its results and discussion.

KEYWORDS: Composite timber, High temperature, Beam, Deformed steel bar, Bending capacity, Fire

1 INTRODUCTION

We have been developing a rigid frame system formed by timber members strengthened by deformed steel bars using epoxy resin adhesive [1]. Buildings may often suffer from elevated temperature in Summer, such as 45.3℃ ever reported in Japan or approximately 65℃ in the attic space. On the other hand, when buildings suffer fire, the composite members also be required to resist against Dead load by using fireproof coating or burning marginal layer (i.e. charring layer). Its portion resisting to dead load will be designed to be mainly lower than 100℃. We planned an experiment to reveal effects of those elevated temperatures on bending capacity of the composite beam. This paper reports the test, its results and discussion.

2 BACKGROUND AND AIM

Little research on heat resistance of timber mixed with different kind of materials, has been reported. Elevated temperatures in building in Japan is such as mentioned above; in an attic space, the maximum temperature may be approximately 75℃. These increase of temperature needs to be considered in design for steel bar(rebar) - timber composite member because of their deference in thermal expansion. We have already revealed creep of the composite beam under elevated temperature of 80-110℃ and reported that the rebar can reduce dramatically the creep of bending deformation of the beam and the proposed method can estimate the creep [2].

However, effects of elevated temperature on bending capacity of the beam were not revealed because of limit of loading apparatus capacity.

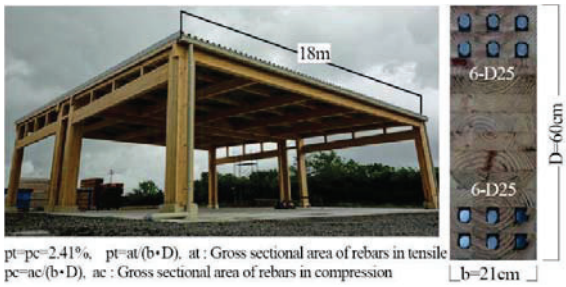

Figure 1: *Prototype building utilizing hybrid beam and column proposed in this study, designed by S. Shioya with approval from authorities and constructed in July 2014*

We planned an experiment of loading the composite beam under the elevated temperatures to reveal the capacity. This paper reports the experimental test and its results.

3 EXPERIMENTAL TEST

3.1 SPECIMEN

Figure 3 shows cross-sections of beam specimens which are conventional Glulam timber and the composite timber. Those sizes were adjusted to testing space inside electric heating furnace. Scale ratio of depth of beam was 1/5 and that of width was 1/3 to full-scale beam expected. Area ratios of upper rebar to gross area of beam was 2.54%. The ratio of lower rebar was, also, the same as the upper rebar. Glulam timber employed all low-grade laminas of L50 in Japanese Agriculture Standard to prevent excessive increase in bending capacity because upper limit of the apparatus. The laminas were bonded with resorcinol resin adhesive. Manufacturing process of specimens was the same as that in previous paper [2]. Figure 4 illustrates side views. Furthermore, finger joints were, also, made to be located at its mid-span range in order to prevent excessive increase in load. Properties of rebar, adhesive for rebar, and lamina are listed in Table 1-Table 3.

3.2 SETUP AND LOADING

Figure 4(a) illustrates setup for loading and heating in electric furnace. Photo 1(a) shows loading system against specimen when it is not yet installed within the furnace.; Photo 1(b) shows an outside view of the furnace. The loading was conducted under hanging in mid-air from reaction frame. Specimen was loaded under 4-point bending; upper H-shaped steel beam was subjected to vertical force/F at its mid-span, by oil jack as shown in Figure 4(a) and Photo 1. Shear-span and mid-span lengths were selected so that the specimen will fail in bending.

To prevent the lateral buckling of beam, four steel plates to bind specimen, were connected to the reaction frame, at both supports and near mid span.

Figure 5 shows measuring positions for deformation, strain, and temperature. The deflection at the mid-span was measured with two displacement transducers. The curvature was calculated from foil strain gauges on timber at mid-span and shear strain was done with rosette gauge on both shear spans. Temperatures were measured with thermocouples at three positions: at the top bar, at the bottom bar, and at middle of beam depth.

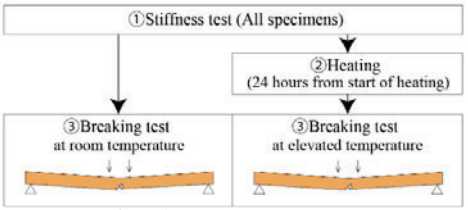

Figure 6: *Procedures for testing*

3.3 HEATING PROGRAM AND TEST PROCEDURE

Table able 4 shows the number of specimens for each target temperature. The temperature levels were assumed as following: room temperature/29.3℃-31.2℃, maximum temperature of the general floor of building/45℃, maximum temperature of the attic of building/70℃, and maximum temperature of steel bar-timber composite beam with fireproof cladding for 2-hour fire resistance/90℃. Figure 6 illustrates procedure for test. First, loading to measure stiffness of each specimen for deflection was conducted at room temperature, and then the specimens were heated up to the target temperature and then was maintained at the temperature for about 24 hours from the start of the heating, and finally, loading was conducted up to fracture under the temperature. On the other hand, unheated specimens were also prepared for loading up to fracture at room temperature. Symbols in the specimen name represents cross section, target temperature, and the order tested within specimens at each target temperature.

3.4 CALIBRATION OF VALUE OF FOIL STRAIN GAUGE

Table 5 lists types of foil strain gauges used for each material. Figure 7 shows condition of gauge attached on test piece of rebar, and Figure 8 shows conditions of foil strain gauge attached on quartz glass with thickness of 10 *mm*. In order to capture behavior of strain gauges due to elevated temperature, strain gauges were attached to quartz glass which is hardly affected by temperature change. In addition, strain change of one external rebar in Figure 7, which was not externally restrained, was prepared for comparison with that of internal rebars within specimen. Quartz glass and external rebar were placed on top of the specimen within the furnace. Only four specimens: HW45-1, HW45-2, HW70-1, and HW70-2 were measured axial strain of the internal rebar. Figure 9 shows behavior of strain gauges attached to the quartz glass as temperature change from the start of heating. The horizontal axis is amount of temperature increase at top of specimen in the furane. As the temperature elevates, the strain of the gauge progresses toward the compression side. This is a characteristic of the strain gauge's self-temperature compensation. The straight line for the data is shown by a pink one dot chain line. The strain value based on the approximate straight line was, in this paper,

Table 5: *Type and measuring length of foil starin gauge*

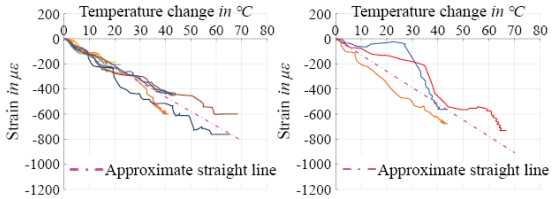

Figure 9: *Foil strain gauge behavior due to elevated temperature*

assumed to be subtracted from value direct-measured on specimen to cancel effect of the self-temperature compensation.

3.5 DIFINITION OF REDUCTION OF MECHANICAL PROPETIES AND ITS EXPRESSION

Effects of moisture content on mechanical properties of wood at elevated temperature was investigated by Kaku and Hasemi et al. by means of bending tests on small specimens of Japanese cedar and zelkova wood [3].

As well as the paper, to investigate effects of temperature rise on mechanical properties of the composite beam, Young's modulus in bending, shear modulus, and bending strength of Glulam timber beam are first expressed as E_{wt}, G_{wt}, and F_{wt}, respectively, with elevated temperature/t. When assuming t=R at room temperature, Young's modulus in bending for Glulam timber beam can be expressed as E_{wR}, E_{w45}, E_{w70}, and E_{w90} at each temperature. Furthermore, residual modulus ration is defined as an index of change in mechanical property with elevated temperature. The residual modulus ratio of Young's modulus/E_{wt} in bending of a Glulam timber beam is expressed as E_{wt}/E_{wR}. Residual modulus ratio of other properties is expressed in the same way.

As Young's modulus in bending and shear modulus can be measured by non-destructive test, E_{wt} and E_{wR}, G_{wt} and G_{wR} can be determined for one same specimen, and the residual modulus ratio can be measured for each specimen. On the other hand, for one same specimen, it is impossible to compare values of bending strength, proportional limit moment, yield moment, and bending strength at different temperatures, for example, 45℃ against room temperature at the same specimen, because the specimen will be subjected up to failure at room temperature.

Therefore, their residual ratios were calculated by dividing experimental value at each target temperature/t by average of an experimental value for specimens that were tested up to failure at room temperature.

https://doi.org/10.52202/069179-0418

Table 6: *Room temperature at starting of heating test* *in ℃*

Specimen	RT			45℃		70℃			90℃

HW	31.2	31.0	30.1	26.4	28.8	29.4	29.7	27.3	27.1	-

3.6 HISTROY OF HEATING

Table 6 lists room temperature at the time of the non-destructive stiffness test for each specimen. Figure 10 shows history of heating temperature of specimens. Figure 10(a) and Figure 10(b) are those by thermocouple at upper and lower rebar positions in specimens except HW70-1 and WO70-1; Figure 10(c) is by those of HW70-1 and WO70-1.

For the two specimens shown in Figure 10(c), fluctuating heating was used in order to investigate stress variation in wood and rebar by temperature changing. Heating system of electric furnace caused difference in temperature at upper and lower positions of beam. The temperature in test was controlled by that of thermocouple at upper rebar within specimen.

3.7 EXPERIMENTAL RESULTS

3.7.1 Mechanical properties at room temperature

Table 7 lists experimental results of each specimen by destructive test at room temperature. Figure 11(a) shows moment/M – curvature/ ϕ relationship/M- ϕ for Glulam timber specimen/WORT, Figure 11(b) shows force/F – deflection/δ relationship/F-δ, and Figure 11 (c) shows maximum shear stress/τ_{max} – shear strain/γ relationship /τ_{max} – γ. In Figure 11(a) and (c), average value of three slopes of elastic stiffness is shown by a pink dashed line. Figure 12 shows results for the composite speceimens/HWRT. https://doi.org/10.52202/069179-0418

stiffness and bending capacity of the composite specimens/HWRT were 5.28 and 3.40 times higher than those of Glulam timber specimens/WORT, —using Young's modulus of wood in bending of Glulam timber specimen and Young's modulus and yield strength of rebar are shown by a pink one dot chain line by Cal.1 and Cal.2. Calculation process was refered to previus papers[4,5]. Equation for estimation of bending capacity of the composite beam is discribed as following.

$$M_u = {}_wM_u + {}_sM_y \quad (1)$$

where ${}_wM_u$: ultimate moment capcity of timber except the rebars, *i.e.* product of the section modulus and bending strength of timber, ${}_sM_y$: yield moment capacity by only rebar within beam section.

$${}_sM_y = a_t \cdot f_y \cdot j \quad (2)$$

where a_t: gross cross-area of upper or lower rebar
f_y: yield strength of rebar, j: distance from lower the rebar to the upper rebar.

In the composite beam, it can be thought that as yielding and plastic flow occures in rebar befor the beam reaches bending capacity, internal stress due to elevated temperature will decay after its yielding. Therefore Equation (1) can estimate bending capaity of the composite beam by ignoring the internal stress and by considering only decrease of Young's modulus and bending strength of timber owing to elevated temperature. In Figure 11(b) and Figure 12(b), elastic stiffness relationship based on the beam theory (Cal. 2), which considers only flexural deformation is shown by a pink one dot chain line. The relationship (Cal. 3) calculated up to bending fracture by addition of shear deformation is shown by a pink solid line. Point at yield moment is indicated by '□' and point at bending capacity is done by '△'. For shear deformation, a shear modulus of elasticity of 729 *N/mm*^{2} was assumed to be the average of experimental values for Glulam timber specimens /WORT, and the shape factor was assumed to be 1.2 from the energy method for calculating the shear deformation. In the calculated values for the composite specimen, the stiffness of only timber within the composite specimen was assumed to be exhibited, after yielding of rebar. As seen in Figure 12(b), Cal. 3 which considers shear deformation, roughly estimates elastic stiffness, yield moment, secondary stiffness and bending capacity of the composite specimens.

3.7.2 Correction of strain by foil strain gauge

As described in Section 3.4, it is necessary to correct foil strain gauge reading. Figure 13 shows relationship between change in strain of wood and quartz of WO45-1 from heating start and heating elapsed time; Figure 13(a) shows change in measured value, and Figure 13(b) shows change in the corrected value. The time at which target temperature was reached is indicated by black vertical one dot chain line; Figure 14 shows change in strain in wood of HW70-2, and Figure 15 shows change in strain in rebar of the same specimen. Positions and number of the gauge are shown in Figure 16. The strains of wood and rebar need to be corrected on the basis of the approximate straight line shown in Section 3.4 by a pink one dot chain line.

γ: Ratios at elevated temperatures

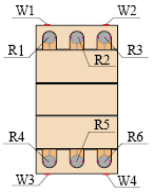

Figure 16: *Gauge's number*

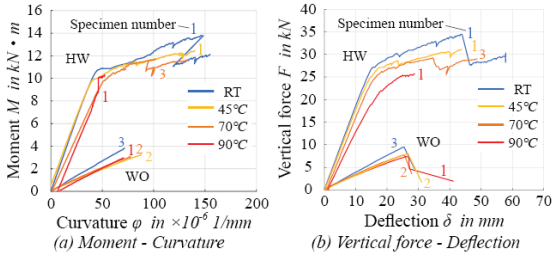
https://doi.org/10.52202/069179-0418

The quartz strain is negative and shrinking over the entire range. This means effect of the self-temperature compensation of foil strain gauge. Measured strains of wood and rebar are negative as the temperature rises, but the corrected strains of wood and rebar are positive until the target temperature was reached, which can be explained by phenomenon of thermal expansion of material. By using the corrected values of strain, discussion hereafter is done.

3.7.3 Degrade in mechanical properties with elevated temperature

Table 8 in the previous page lists mechanical properties and the residual modulus ratios from the loading tests. Figure 17 shows comparison of moment-curvature and force-deflection relationships for Glulam timber specimen and composite specimen. Numbers in the figures indicate the number of specimen name. Compared to Glulam timber specimen, the composite specimen maintained extremely high stiffness and bearing capacity even at high temperatures. Stiffness and bending capacity of both the Glulam timber specimen and the composite specimen decreased with elevated temperature, against those at room temperature.



(a) Moment - Curvature (b) Vertical force - Deflection

Figure 17: *Comparison of experimental property at each temperature*

Figure 18 shows variation of residual modulus ratio of the initial bending stiffness. Coloured symbols indicate experimental values for the composite specimen; uncoloured symbols indicate those for the Glulam timber specimen. Red solid line and blue solid line indicate average of those experimental values for each type, respectively.

The residual modulus ratio of initial stiffness in bending of Glulam timber shown in Figure 18 hardly decrease above 45°*C* and increases at 90°*C*. This tendency is also observed in the residual modulus/$\gamma_{wG(t)}$ and $\gamma_{hG(t)}$ of elasticity in shear, as seen in Table 8 (a) and (b).

It is considered that moisture in wood might have been removed as temperature rising and this phenomenon would mitigate the decrease in stiffness.

On the other hand, it should be noted that the residual modulus ratio of bending stiffness of the composite beam

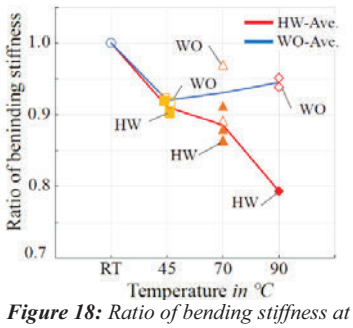


Figure 18: *Ratio of bending stiffness at elevated temperature to stiffness at room temperature*

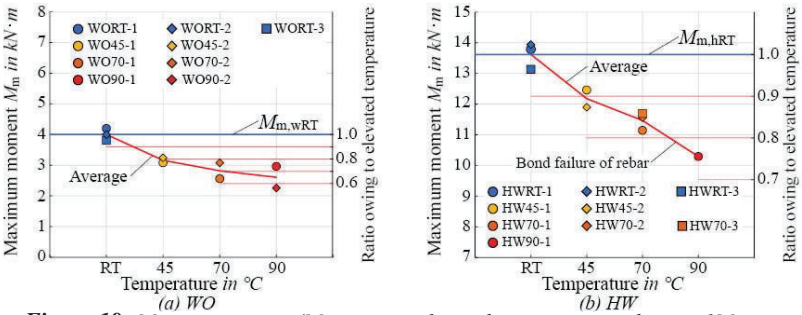
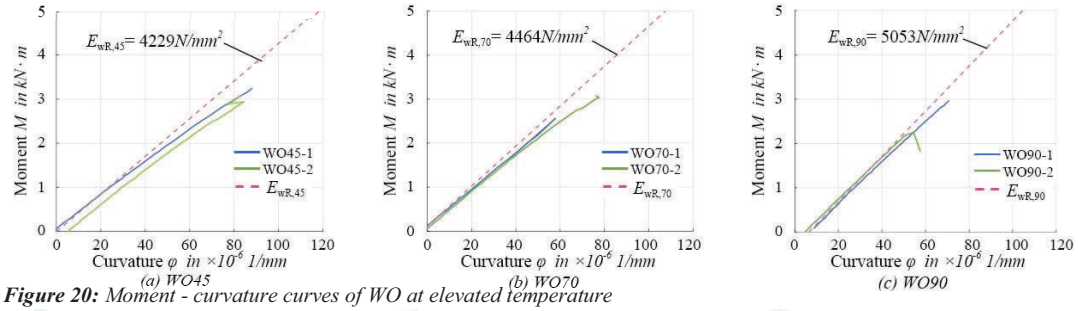


(a) WO (b) HW

Figure 19: *Maximum moment/M_m owing to elevated temperature and ratio of M_m at elevated temperature to $M_{m,RT}$ at room temperature*



(a) WO45 (b) WO70 (c) WO90

Figure 20: *Moment - curvature curves of WO at elevated temperature*

Figure 21: *Vertical force - deflection curves of WO at elevated temperature*

https://doi.org/10.52202/069179-0418

decreased as temperature rising as seen in Figure 18. In addition, the performance of rebar bonded in timber under high temperature might have decayed due to softening of the adhesive of rebar at elevated temperature.

Figure 19 shows variation of the residual ratio of bending capacity. Compared to Glulam timber specimen, the composite specimen performed a smaller percentage loss of performance. The decrease was more pronounced as temperature rising in both specimen types. It can be confirmed that the decrease in bending capacity of the composite specimens is limited to be 20% or less at temperatures below 70°C. Figure 20 shows moment-curvature relationship for Glulam timber specimen at elevated temperatures. Pink dashed line is average of bending stiffness at room temperature. Figure 21 shows force-deflection relationship of Glulam timber specimen at different temperatures. Horizontal pink dashed line is average of maximum force of the Glulam timber specimen/WORT at room temperature. Stiffness and maximum capacity of the Glulam timber specimen is seen to decrease at elevated temperatures compared to room temperature.

3.7.4 Failures after loading test

Figure 22 shows failures of specimens after destructive loading test. All specimens showed tensile fracture at lower portion of wood near mid-span. Those cracks progressed from finger joints. For the Glulam timber specimens, there was no significant difference in failure between at room temperature and at 90°C. On the other hand, for the composite specimens, bond failure around lower rebar was observed in addition to the finger joint fracture in HW90-1. The fracture is shown in Figure 22(d), (e), and Photo 2. Its Cracks were observed along the lower rebar in the axial direction of it. This failure was not observed in the other composite specimens. The upper temperature limit of the epoxy adhesive for bonding rebar is 110°C based on the results of a push-through test under elevated temperature [5]. As shown in Figure 10(a) and (b), owing to heating system of electric furnace, temperature at

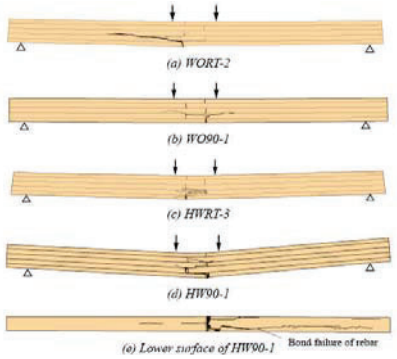

Figure 22: *Failures of specimens after loading test*

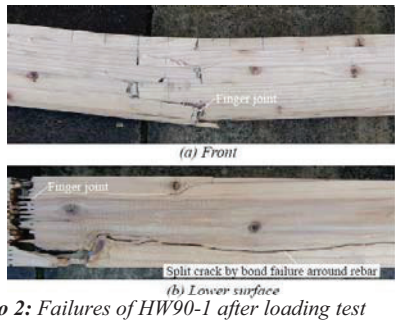

Photo 2: *Failures of HW90-1 after loading test*

position of the lower rebar exceeds 120°C when heated to 90°C at the upper rebar. The excessive temperature rising might have resulted in a decrease in rigidity of Epoxy adhesive around the lower rebar.

3.7.5 Estimation of mechanical properties of composite beam

Figure 23 and Figure 24 show moment-curvature and force-deflection relationships of the composite specimens at different temperatures, respectively.

As curvature, deflection, and strain were generated during heating, there was a residual component due to its heating at the start of loading immediately after heating program was completed.

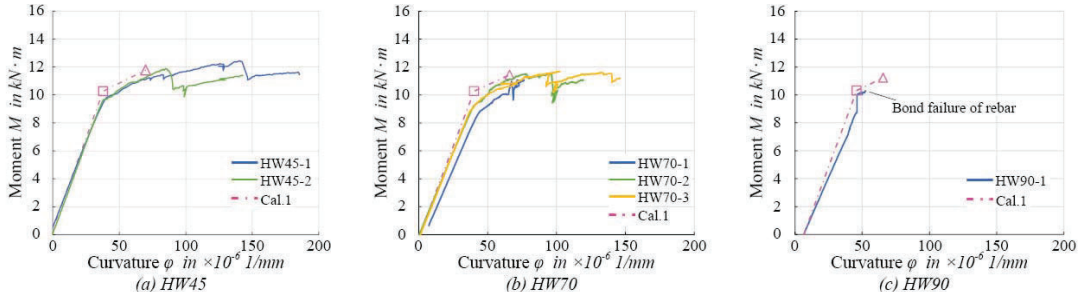

Figure 23: *Moment - curvature curves of HW at elevated temperature*

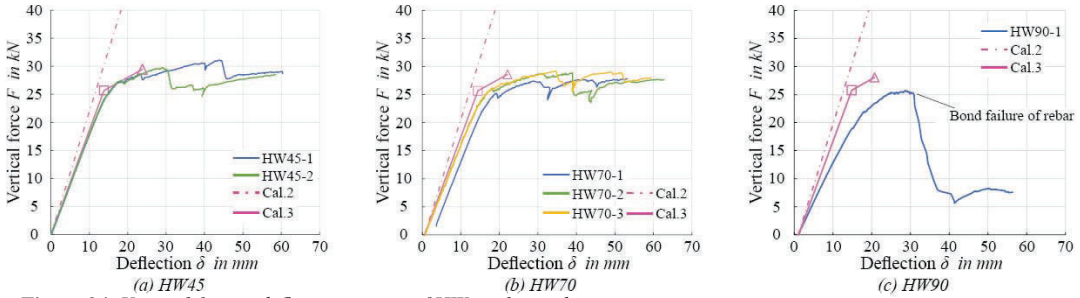

Figure 24: *Vertical force - deflection curves of HW at elevated temperature*

https://doi.org/10.52202/069179-0418

Cal.1, Cal.2 and Cal.3 in the same figure are the same as those in Section 3.7.1, but as modulus of elasticity and bending strength of timber decrease with elevated temperature, the decrease ratios were considered in the calculation. In Figure 24, except for the bending strength at 90°*C*, the bending stiffness and bending capacity are generally estimated by the calculated values.

On the other hand, the variation of temperature and moisture content might have caused internal stress and decreased the yield moment. The fact that none of the calculated values considers the amount of variation in the stress may have resulted in overestimation of yield moment. In Figure 23(c) and Figure 24(c), those of the specimen at 90°*C* have overestimated bending capacity. As mentioned above, bond stiffness around rebar is considered to have decreased with the elevated temperature. The decrease in bond stiffness is considered to have led to a decrease in bending capacity because contribution of the rebar is reduced.

Figures 25(a) and (b) show moment-strain relationships for wood and rebar of the composite specimens during stiffness tests at 45°*C*. Figures 25(c) and 25(d) and 25(e) and 25(f) show moment-strain relationships at 45°*C* and 70°*C*, respectively, during destructive loading. Solid yellow and red lines represent strain of upper and lower surface of timber and strain of rebar, respectively, calculated based on the assumption of plane of cross-section. To the increased strain by loading, the residual strain after the heating was added. In calculated values, degradation of wood's performance due to elevated temperature was considered. In the figure, '□' is experimental strain of wood and ○ is experimental strain of rebar. For 70°*C*, experimental value of wood strains on the bending-tension side were larger than the calculated values. Temperature at lower rebar position reached 90°*C* or higher when heated at 70°*C* as reason of electric furnace mentioned above. This is considered to cause a decrease in wood performance or adhesion stiffness. The horizontal pink dashed line in the figure represents calculated yield moment. This calculated value is the same as '□' symbols shown in Figures 23 and 24, which only consider the reduction in wood performance. As mentioned above, it can be seen here that the calculated values provided an overestimation of yield moment.

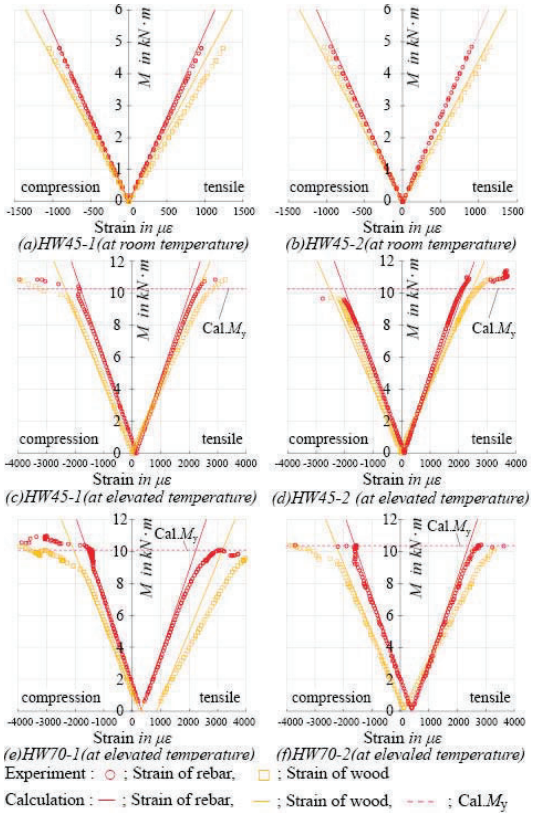

Figure 25: *Comparison of calculation to experiment of bending moment-strain curves on rebar and timber surface*

3.7.6 Strain of rebar outside and wood within specimen

Figure 26 and Figure 27 show variations of strains of external rebar and surface of timber with heating time passing. Timing at which is reached the target temperature is represented by a vertical one dot chain line. In WO45-1, the gauge at point W1 on the upper surface of beam was defective. Strain on the external rebar was almost constant after it reaching target temperature. Assuming that coefficient of thermal expansion of rebar is 10 μ/°*C*, i.e., a common value, amount of the coefficient multiplied by the amount of temperature increased from initial temperature of heating is shown by thin blue line/Cal.R.

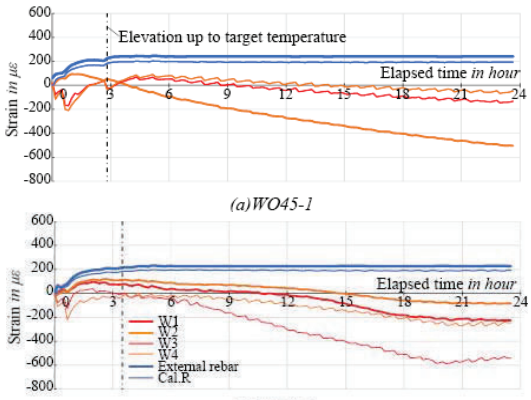

Figure 26: *Variation of axial strains of wood and external rebar in WO45-series specimen heated up to 45 °C*

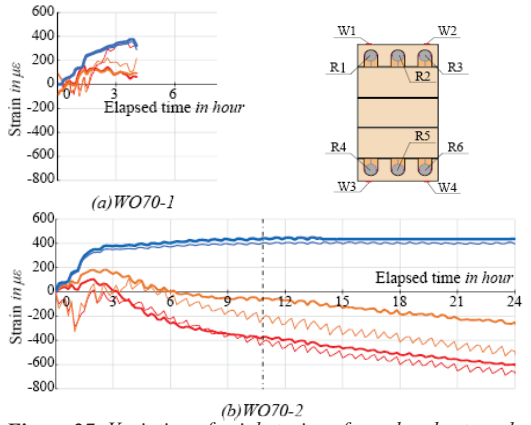

Figure 27: *Variation of axial strains of wood and external rebar in WO70-series specimen heated up to 70 °C*

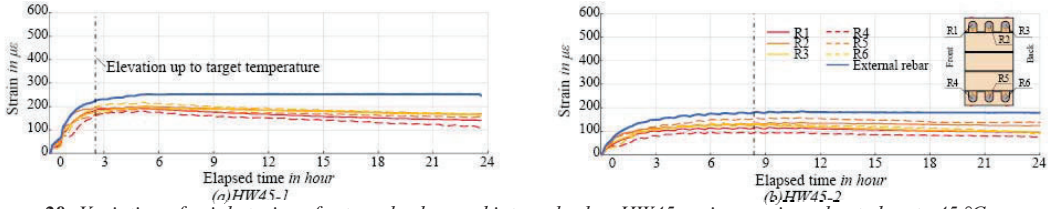

Figure 28: *Variation of axial strains of external rebar and internal rebar HW45-series specimen heated up to 45 ℃*

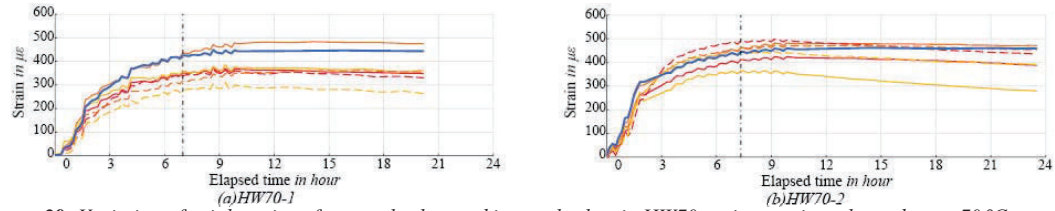

Figure 29: *Variation of axial strains of external rebar and internal rebar in HW70-series specimen heated up to 70 ℃*

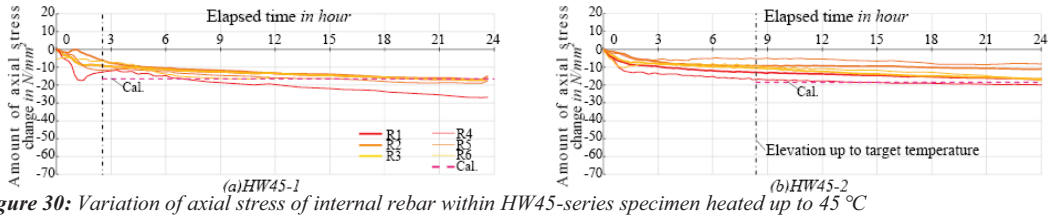

Figure 30: *Variation of axial stress of internal rebar within HW45-series specimen heated up to 45 ℃*

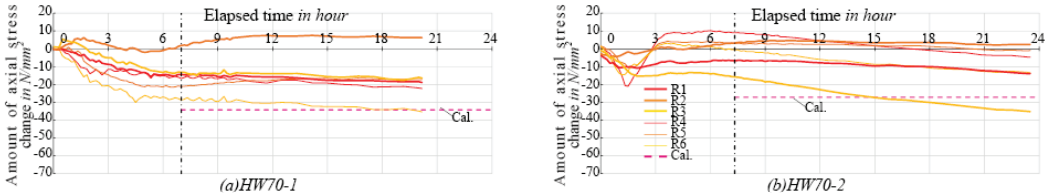

Figure 31: *Variation of axial stress of internal rebar within HW70-series specimen heated up to 70 ℃*

As the external rebar was located on the upper surface of specimen, temperature at the upper rebar was assumed to be temperature of the external rebar. For heating temperatures of 45°*C* and 70°*C*, amounts of elongation strain (thick blue line) of the external rebar generally agreed with the calculated values (thin blue line) of the elongation strain of the external rebar.

On the other hand, strain of wood in Glulam timber specimens increased positive at the beginning of heating, but began to decrease before the target temperature was reached, and then became negative and shrank after the target temperature was reached. This phenomenon is considered to be caused by dehumidification of wood during heating and shrinkage in grain direction of wood because humidity was not controlled in the electric furnace. This is more pronounced at the higher heating temperature of 70°*C*. It can be confirmed that shrinkage due to decrease in moisture content is larger than thermal expansion of wood due to elevated temperature. This suggests that internal stresses in attic of actual buildings need to be estimated taking into account both the shrinkage of wood due to decrease in moisture content and elongation of rebar due to increase in temperature, because of repeative high temperature environment in the attic.

3.7.7 Strain of rebar within specimen

Figure 28 and Figure 29 show variations of strains of the external rebar and the internal rebar. The point at which it reached the target temperature as well, is indicates by a vertical one dot chain line. For the specimens at 45°*C*, strain of the internal rebar was smaller than that of the external rebar, and strains of upper and lower bars were similar. In HW70-1 at 70°*C*, strain of internal rebar was also smaller than that of the external rebar, but in HW70-2, strains of the external and internal rebars were close. As strain of the external rebar was stable at the same level in the two specimens, it is considered that variation of wood may have some influence, but the increase in strain of internal rebar in HW70-2 cannot be explained. The reason for the smaller strain in the internal rebar relative to the external rebar is that the internal rebar is restricted by wood around itself. All strains of the internal rebar decreased as heating time passing. No such decrease occurs in the external rebar. Therefore, the decrease in strain of the internal rebar can be attributed to the shrinkage of timber due to the dehumidification of wood.

3.7.8 Stress of internal rebar based on strains of external rebar and timber

Figure 30 and Figure 31 show variation of amount of axial stress of rebars in the composite specimens during heating. The amount of stress variation is the amount of variation of the difference in strain between the external and the internal rebar in Figure 28 and Figure 29 multiplied by Young's modulus of rebar (experimental value). Equation (3) shows an equation for estimation of yield moment.

https://doi.org/10.52202/069179-0418

$$M_y = \sigma_y / n(I_e / y_s) \quad (3)$$

where y_s: distance from the neutral axis to rebar, σ_y: yield strength of rebar, n: ratio of Young's modulus of rebar to bending Young's modulus of timber, I_e: sectional secondary moment considering rebar

Equation (3), which estimates yield moment when the rebar yields, is affected by ratio/n of Young's modulus in bending between rebar and timber. As shown in Table 1, Young's modulus of timber in bending with increasing temperature was captured by force tests on Glulam timber specimens. Using Young's modulus from non-destructive test before heating and Young's modulus from loading after heating test, yield moments in each case are calculated using Equation (3), and difference between the former and latter calculated values may be regarded to be component of yield moment due to only the reduction in Young's modulus of timber.

Figure 32 shows variation of calculated yield moment with increasing temperature as indicated by pink dashed line/Cal.M_y, where Cal.M_y can be seen to estimate experimental value of HWRT at room temperature.

Average of the experimental values at room temperature is shown by a blue horizontal line/$M_{y,hRT}$.

Difference of Cal.M_y with respect to $M_{y,hRT}$ means amount due to the reduction of Young's modulus in bending of timber. Magnitude of those difference ranges only 4-8% of calculated yield moment at room temperature. The difference between Cal.M_y and experimental value indicated by red solid line means amount due to the difference in expansion and contraction between rebar and timber.

The reduction/ΔM in moment can be evaluated by replacing yield stress/σ_y in Equation (3) with amount /$\Delta\sigma_T$ of increase or decrease in axial stress of rebar, and the equation can be given as Equation (4).

$$\Delta M = \Delta\sigma_T / n(I_{eT} / y_s) \quad (4)$$

$\Delta\sigma_T$ in Equation (4) can be back-calculated by ΔM. Assuming that ΔM is equal to amount of Cal.M_y subtracted by average values of experimental yield moments at each temperature, $\Delta\sigma_T$ can be obtained by using Equation (4).

Results of $\Delta\sigma_T$ calculated are shown in Figure 30 and Figure 31 by horizontal a pink dashed line (Cal.). Cal. estimated roughly the experimental value of stress in internal rebar in HW45-1 and 2, but, in HW70-1 and 2, Cause of tend to overestimate those in compression is unknown currently.

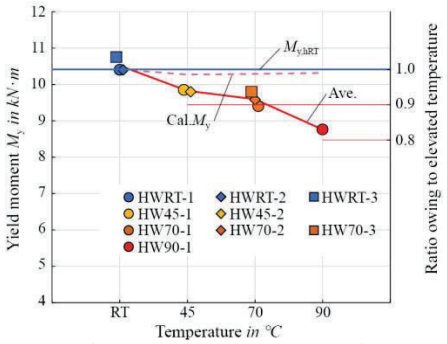

Figure 32: *Yield moment/M_y owing to elevated temperature and ratio of M_y at elevated temperature to $M_{y,RT}$ at room temperature*

On the basis of above discussion, equation for estimation of yield moment of steel bar-timber composite beam that takes temperature rise into account can be summarized as following.

$$M_y = (\sigma_y - \Delta\sigma_T) / n(I_{eT} / y_s) \quad (5)$$

where σ_y, $\Delta\sigma_T$, y_s: previous definition, n_T: ratio of Young's modulus of rebar to Young's modulus of timber in bending at elevated temperature, I_{eT}: cross-sectional secondary moment of the composite beam considering elevated temperature

In the future, it is necessary to estimate variation of the internal stress of rebar.

4 SUMMARY

Bending test of beams under high temperature with uncontrolled moisture absorption and dehumidification of wood were conducted to investigate effect of temperature rising on mechanical properties of the steel bar-timber composite beam. The results are summarized as the followings:

i) Although Young's modulus in bending, shear modulus and bending strength of timber decrease with temperature rising, the decrease is mitigated by loss of moisture in timber.

ii)Bending stiffness and bending capacity of the composite beam could be estimated from room temperature to 70°C, by the proposed estimation method considering the decrease in Young's modulus and bending strength of timber due to temperature rising, ignoring internal stress caused by the temperature.

iii) Yield moment of the composite beam should take into account effect of the internal stress in addition to decrease in mechanical performance of timber owing to temperature rising. In the future, we plan to develop a method for estimating the internal stress on safe side.

ACKNOWLEDGEMENT

This project was funded by Grant-in-Aid for Challenging Research in Japan and its experiment was conducted by all staffs of Shioya's laboratory. The authors gratefully acknowledge their work.

THE ADHESIVE SHEAR CONNECTION OF TIMBER AND CONCRETE SLABS IN HUMID ENVIRONMENT

Viktória Bajzecerová[1], Ján Kanócz[2], Viktor Karľa[3], Miroslava Javoríková[4]

ABSTRACT: The paper analyzes the influence of humidity and temperature changes on the normal and shear stresses in timber-concrete composite (TCC) panels with an adhesive shear connection. Three TCC panels were placed into an air-conditioned climate chamber and subjected to an environment typical of swimming-pool areas. Within the test, strains in two orthogonal directions were measured. A FEM model of the TCC specimens was created and validated against the measured strains. Using the FEM model, both normal and shear stresses were evaluated. The results show that the highest normal stresses occurred near the shear connection. In addition, increased timber moisture content by 2.1% caused achieving the flexural tensile strength of concrete perpendicular to the timber grain direction.

KEYWORDS: Timber-concrete composite slab, Adhesive shear connection, Hygrothermal load, shear stress

1 INTRODUCTION

Timber-concrete composites (TCC) are widely applied today as footbridge and/or bridge slabs [1,2], as well as the floor slabs of multi-story buildings [3,4]. For rapid construction, prefabricated TCC panels are especially useful, for which it is advantageous to use mass timber panels, such as vertically-laminated timber and cross-laminated timber plates [5–7]. There are numerous ways to ensure the concrete and timber layers' composite action, such as mechanical fasteners, notches, perforated steel strips, glued-in rods, and adhesives [8–11].

In comparison to mechanical fasteners, adhesive shear connections provide many advantages: rigid connection providing full interaction of timber and concrete slabs, a more uniform shear flow distribution, so no local stress concentrations occur, and a relatively simple calculation model since it is not necessary to consider the slip between timber and concrete parts of composite slab. While the glued-in rods method is well established and is becoming more common for the joining of timber structures, adhesive shear connections for TCC slabs still need to be studied in more detail from several aspects regarding its long-term behaviour, such as the creep, ageing of mechanical properties, as well as the effects of humidity, thermal changes and fire exposure [12].

The long-term bending tests of timber-concrete composite slabs with adhesive shear connection [13–15] showed that the adhesive might not be the weak link in their long-term behaviour. The composite action was unaffected by long-term loading. Results, however, indicated that the humidity and temperature conditions significantly impact the stress and deflection of the TCC over time. Furthermore, the effects of the ambient humidity and temperature changes are manifested increasingly with the growing rigidity of the shear connection between the timber and the concrete [16].

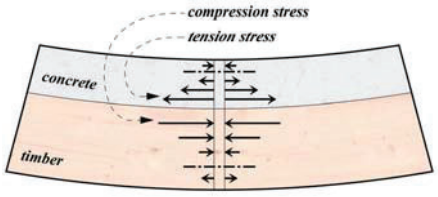

Figure 1: *The effect of restrained timber deformation in adhesively bonded TCC panel with increasing moisture content*

2 INFLUENCE OF HYGROTHERMAL LOAD

Due to uneven thermal and humidity deformations of concrete and timber in orthogonal directions, normal stress in composite members occurs, which can cause

https://doi.org/10.52202/069179-0419

defects of timber or concrete or the failure of the adhesive shear connection [17]. The effect of hygrothermal load on TCC is explained in Figure 1.

The increasing moisture content of the timber causes the elongation of the timber slab, which is limited by the adhesive concrete board and results in deflection and normal and shear stress near the glue line of TCC.

Using TCC panels as structural elements of roofs and walls of buildings with wellness, sauna or swimming pools may use the accumulation ability of the concrete and thus reduce the energy required for heating. On the other hand, the humid environment can cause unwanted deformations or possible failure of the glued joint. The presented study discusses the potential use of TCC with adhesive shear connection in such humid environmental conditions.

The research performed [19] dealt with the behaviour of TCC panels with an adhesive shear connection solely under the hygrothermal load and without other impacts, such as creep from gravity load or concrete shrinkage. The specimen loading was performed in a climate chamber. The test included temperature, moisture content, and strain measurements in two orthogonal directions. This paper presents evaluations of the measured results using the numerical FEM model. The aim was to analyse the normal and shear stresses caused by the humid environment typical of swimming-pool areas.

3 EXPERIMENTAL INVESTIGATION

3.1 SPECIMENS

Three specimens of TCC with adhesive shear connection were prepared to conduct the test (Figure 2).

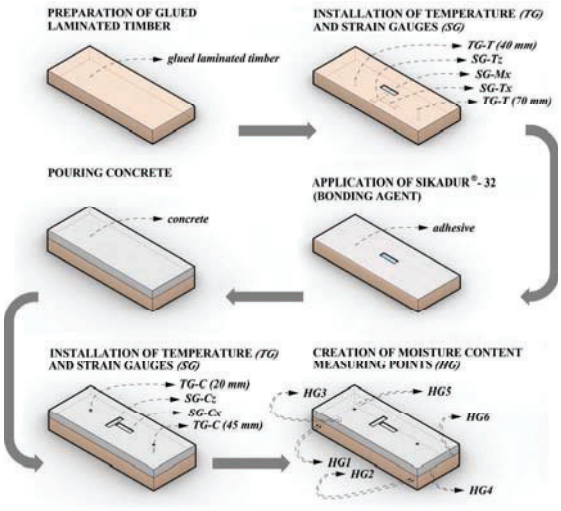

Figure 2: *Illustration of specimens' preparation*

First, strain gauges (SG) were installed on the top of the 750 mm long, 300 mm wide and 80 mm deep glued laminated timber slabs. After that, the 2-component epoxy adhesive Sikadur 32 was applied on top of the timber slabs. Subsequently, the 50 mm thick fresh concrete layer was cast on the wet adhesive on the timber slabs with no structural reinforcement. The prepared specimens were stored in lab conditions for about two years. Before the test, temperature (TG) and strain gauges (SG) were installed, as well as moisture content measure points (HG) were created. The final setup of specimens in the climate chamber is photographed in Figure 3, along with inset dimensions.

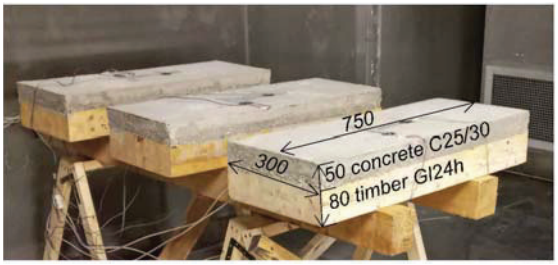

Figure 3: *Specimens in climate chamber; dimensions in mm*

3.2 MATERIAL PARAMETERS

For the test specimens, concrete C25/30 was chosen. Its real mechanical properties were defined according to EN standard 12390 [20]. Its cylinder and cube compressive strength 371 days after concreting were 55 MPa and 67 MPa, respectively. Its modulus of elasticity was determined as 26 GPa, flexural tensile strength as 8 MPa, and density as 2295 kg.m^{-3}. The mechanical parameters of the concrete are listed in Table 1.

Table 1: *Mechanical parameters of 371-day concrete*

Mechanical parameter	Value	Unit
Cylinder compressive strength	55	MPa
Cube compressive strength	67	MPa
Flexural tensile strength	8.1	MPa
Modulus of elasticity	26	GPa
Density	2295	kg.m^{-3}

The properties of glued laminated timber used for TCC panels were defined according to EN standard 408 [21]. Its modulus of elasticity parallel to the grain was determined as 13.9 GPa and bending strength as 50 MPa. The density of timber used was 425 kg.m^{-3}. The mechanical parameters of the timber are listed in Table 2.

Table 2: *Mechanical parameters of timber*

Mechanical parameter	Value	Unit
Bending strength	50.0	MPa
Modulus of elasticity parallel to the grain	13. 9	GPa
Density	425	kg/m^3

The modulus of elasticity and coefficient of thermal expansion of bonding agent Sikadur®-32, provided by the manufacturer [22], were 4.0 GPa, and 8.2x10^{-5} °C^{-1}, respectively. The shear strength of the adhesive connection with a value of 4.0 MPa was evaluated from 5 shear specimens of the same material used [7].

3.3 TES SET UP AND MEASURING METHODS

The three specimens (TC1, TC2 and TC3) were exposed to an environment with varying relative humidity and temperature by being placed in one chamber of air-conditioned climate chamber Thermotron WP-2(527)-2(THCM1-5) (Thermotron Industries, Holland, MI) (Figure 3).

Data acquisition system ALMEMO 5690-2 (Ahlborn, Holzkirchen, Germany) was used to store the data of ambient temperature, ambient relative humidity, and temperature gauges at various depths of the specimens (TG in Figure 2) at 15 min intervals.

Strain gauges with a length of 100 mm were placed in the x-direction and z-direction on top of the concrete and at the bottom of timber slabs (SG in Figure 2) to measure strains. Before concreting, another strain gauge was fixed on top of the timber slabs in the x-direction, which was 50 mm long (SG-Mx in Figure 2). Quantum MX 840 (HBM, Darmstadt, Germany) universal measurement amplifier module acquired data from strain gauges at 50 s intervals.

Moisture content in timber was monitored at six measuring points created on each specimen (HG in Figure 2) using a two-pins moisture content resistance meter WHT 770 (ELBEZ, Czech Republic).

3.4 HYGROTHERMAL LOAD

The hygrothermal load chosen for the analysis of humid conditions that are typical of that in swimming-pool areas are given in Table 3. The thermal and humidity conditions are similar to the measured data published in [18].

Table 3: *Considered environmental conditions*

Environment	T (°C)	RH (%)
0 - Initial conditions	20.0	65.0
1 – Swimming pool hall without mechanical ventilation	20.3	88.5
2 – Swimming pool hall with mechanical ventilation	34.3	51.8
3 - Shower room	34.6	71.9

T – temperature; RH – relative humidity

The initial conditions against which all further environmental changes were compared were a temperature (T) of 20°C and relative humidity (RH) of 65% (Environment 0). The initial conditions took 12 days, and the timber moisture content stabilised at 14%. The following environment settings were initiated only after stabilising the measured strains, the temperature in the whole depth of specimens and timber moisture content. Under humid Environment 1, warm and dry Environment 2, and warm Environment 3, the moisture content was stabilised at 16.1%, 11.4% and 14%, respectively.

3.5 THERMAL AND HUMIDITY EXPANSION COEFFICIENTS

Within the test, two segments of timber and concrete slab with dimensions of 300 mm × 450 mm were subjected to environmental changes. The same materials as for the TC specimen were used. Thermal and humidity expansion coefficients were calculated as the ratio of the measured strains and differences in temperature or moisture content of the timber slabs. These coefficients for concrete were calculated similarly, but the differences in relative humidity of the environment were used for the humidity expansion coefficient. More can be found in [19].

Table 4: *Thermal expansion Coefficients*

Thermal Expansion Coefficient	$\times 10^{-6}$ (1/°C)
Concrete	17.15
Timber parallel to grain	1.93
Timber perpendicular to grain	54.43

Table 5: *Humidity expansion Coefficients*

Humidity Expansion Coefficient	$\times 10^{-3}$ (-)
Concrete*	0.26
Timber parallel to grain	3.78
Timber perpendicular to grain	96.04

4 THEORETICAL INVESTIGATION

4.1 FEM MODEL GEOMETRY

The theoretical analysis of the specimens was performed by a finite element method (FEM) using ANSYS software [19]. The geometry of the model corresponded to real specimens. The depth of the adhesive layer was neglected, and the adhesive connection was defined as a bonded contact region between the timber and concrete. Regarding boundary conditions, zero displacements were set in 3 points, according to Figure 4. The mesh element size was set to 5 mm.

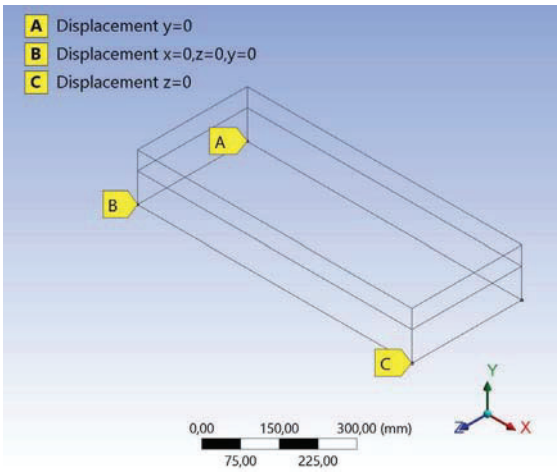

Figure 4: *FEM model – boundary conditions*

https://doi.org/10.52202/069179-0419

4.2 MATERIAL SETTINGS

The concrete was considered a linear elastic isotropic material. The mechanical parameters of the concrete were set according to Table 1. Poisson's ratio of concrete was assumed to be 0.18.
The timber was defined as linear elastic orthotropic material with the grain orientation in the x-axis, according to Figure 5.

Orthotropic Elasticity		
Young's Modulus X direction	13900	MPa
Young's Modulus Y direction	463	MPa
Young's Modulus Z direction	463	MPa
Poisson's Ratio XY	0	
Poisson's Ratio YZ	0	
Poisson's Ratio XZ	0	
Shear Modulus XY	690	MPa
Shear Modulus YZ	690	MPa
Shear Modulus XZ	69	MPa

Figure 5: *FEM model – the timber material parameters setting*

The reliable values of Poisson's ratios of timber were not possible to define due to a large discrepancy in available data [24]. Therefore, Poisson's ratios were set to zero because they were assumed to have a negligible effect on the results. A similar assumption was declared in [25].
Thermal and humidity expansion coefficients were set according to the measured values in Tables 4 and 5.

4.3 HYGROTHERMAL LOAD

In the FEM analysis, the temperature and humidity changes were modelled as a change in Thermal Conditions relative to the initial temperature.
Regarding the specimens' relatively small depth and the long duration of the hygrothermal load test step, it was assumed that the diffusion laws could be neglected. An instant adaptation of the temperature and humidity of both volumes of the FEM model was considered.

5 RESULTS

5.1 STRAINS

Strains parallel to the timber grain (x) and perpendicular to the timber grain (z) in the middle parts of the panels were analysed. The strain differences between each of the three environments (Table 3) and the initial environment were evaluated. In Figures 6 to 8, the strain differences over the cross-section of the TCC panel calculated from the measured (TC1, TC2, TC3) and calculated (FEM) data are plotted.
Although the calculation model did not consider the uneven temperature and humidity profiles in the cross-section and neglected the diffusion laws, it predicted the measured strains relatively well. Therefore, based on this comparison, the model was considered valid and suitable for the following analyses of normal and shear stresses.

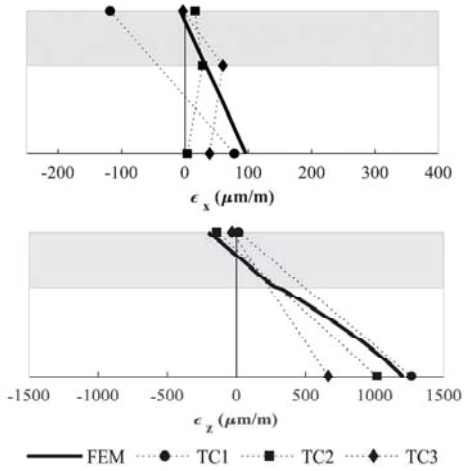

Figure 6: *Measured (TC1, TC2, TC3) and calculated (FEM) strains in x- (ε_x) and z- direction (ε_z) in Environment 1*

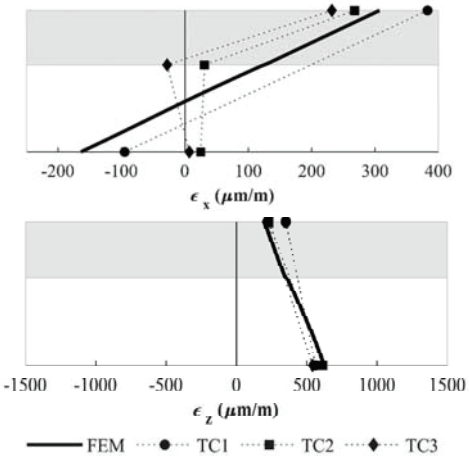

Figure 7: *Measured (TC1, TC2, TC3) and calculated (FEM) strains in x- (ε_x) and z- direction (ε_z) in Environment 2*

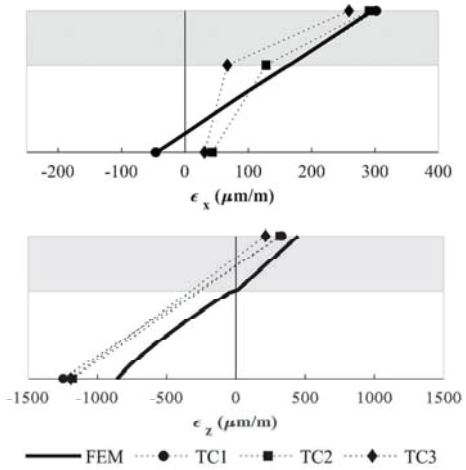

Figure 8: *Measured (TC1, TC2, TC3) and calculated (FEM) strains in x- (ε_x) and z- direction (ε_z) in Environment 3*

https://doi.org/10.52202/069179-0419

5.2 NORMAL STRESSES

Due to uneven and resisted deformation of the timber and concrete slab of the TCC panel, normal stresses occur (Figure 1). Therefore, the higher the differences in inelastic thermal and humidity strains, the higher stress can be expected. The normal stresses evaluated using FEM analysis are presented in Figures 9 to 13 and listed in Tables 6 and 7.

The tension in the concrete seems to be the weakest part of TCC slabs in humid Environment 1. The growth of the timber moisture content (MC) causes an increase in the tension stresses on the bottom surface of concrete up to +2.1 MPa in the x-direction (Figure 9), and in the z-direction increased almost to a value of the tensile strength of the concrete used with the value of +7.5 MPa (Figure 10). It should be noted that the tension strength of standard concrete is lower than that of the concrete used. The tension stresses usually bear the reinforcement in the concrete slabs, but the tension stress in the case of hygrothermal load occurs near the glued line and might cause the local failure of the adhesive connection.

The humid Environment 1 caused only a small increase in timber normal stresses with a value of less than 1 MPa.

The highest values of the normal stresses were expected in the middle part of the TCC slabs in both directions. Based on this expectation, the strain gauges were placed in the middle of the TCC slab span. However, as resulted from the FEM analysis of the warm Environment 3, the highest values of normal stresses were observed not in the middle part of the specimens, as previously expected in [19], but at the edges of specimens (Figures 13 and 14).

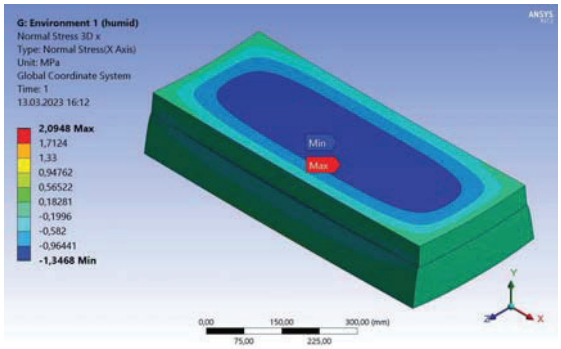

Figure 9: *Humid Environment 1 - normal stress in x direction*

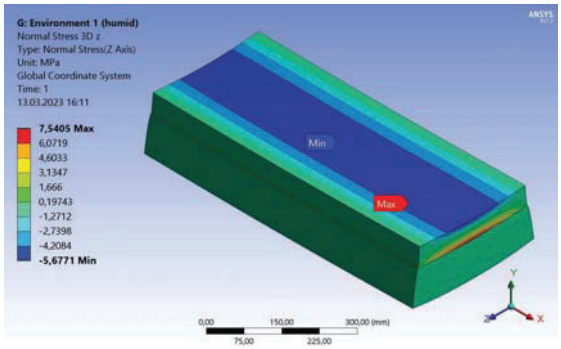

Figure 10: *Humid Environment 1 - normal stress in z direction*

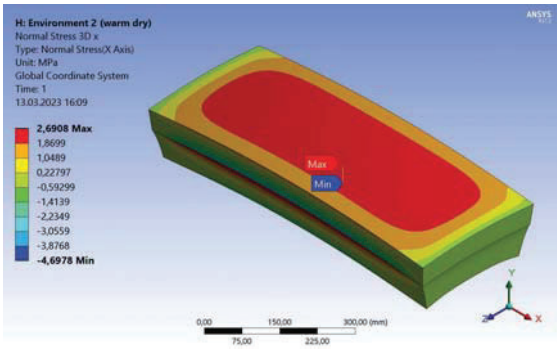

Figure 11: *Warm and dry Environment 2 - normal stress in x direction*

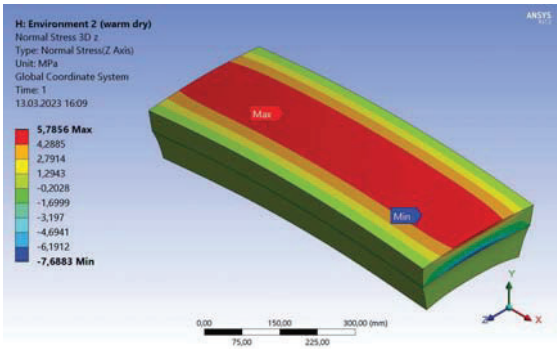

Figure 12: *Warm and dry Environment 2 - normal stress in z direction*

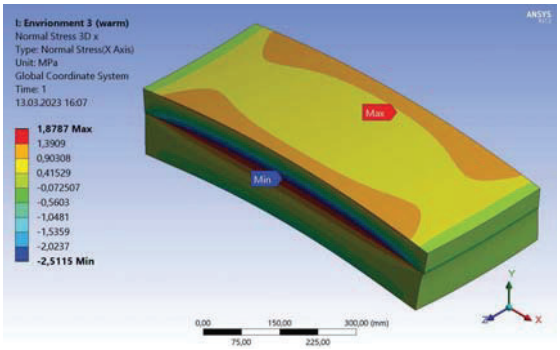

Figure 13: *Warm Environment 3 - normal stress in x direction*

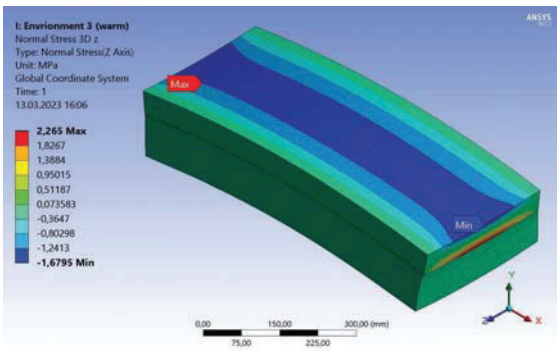

Figure 14: *Warm Environment 3 - normal stress in z direction*

https://doi.org/10.52202/069179-0419

The thermal expansion coefficient of concrete is almost 9-times higher than that of the timber parallel to the grain (in the x-direction), but on the contrary, it is 0.32-times lower than that of the timber perpendicular to the grain (in the z-direction). The orthotropic behaviour of the timber leads to a complex 2-dimensional problem of TCC slabs. From the Figure above, the highest stresses in all environments occurred solely in the concrete. Therefore, Tables 6 and 7 list the maximum stress values in timber and concrete parts separately.

Table 6: *Maximum values of normal stresses in x direction*

Env.	Concrete		Timber	
	compress. (MPa)	tension (MPa)	compress. (MPa)	tension (MPa)
1	-1.35	2.09	-0.69	0.25
2	-4.70	2.49	-1.33	2.69
3	-2.51	1.16	-1.02	1.88

Table 7: *Maximum values of normal stresses in z direction*

Env.	Concrete		Timber	
	compress. (MPa)	tension (MPa)	compress. (MPa)	tension (MPa)
1	-5.68	7.54	-0.90	0.07
2	-7.69	5.79	-0.07	0.91
3	-1.68	2.27	-0.25	0.02

In the case of the warm and dry conditions of Environment 2, the increase in temperature and the decrease in timber moisture caused an increase in compressive stresses on the bottom surface of the concrete in the z-direction, with a value of -7.7 MPa (Figure 12 and Table 7), which is about 14% of the cylinder compressive strength (Table 1).

From all considered environments, the timber slab was subjected to the highest stresses in Environment 2. On the other hand, the tension stress on the top of the timber surface and the compression stress on the bottom surface would reduce the normal stress due to possible future positive bending due to an external load.

It can be concluded that based on the FEM analysis, the normal stresses in the TCC panels caused by the chosen hygrothermal load did not exceed the strength values of the timber or concrete used. On the other hand, standard concrete with a lower value of flexural tensile strength will possibly crack near the glued line and can lead to the failure of the adhesive shear connection.

5.3 SHEAR STRESSES

Figures 15 to 17 show the shear stress diagram on the bottom surface of the concrete since higher values than on the top of the timber were observed (Table 8). According to FEM analysis, the shear stress in the glue line reached the value of the shear strength of the adhesive connection in Environment 2. This may explain the thin cracks in the glue line at the edges of the panels that were observed after the test.

Table 8: *Maximum values of shear stress*

Environment	Concrete (MPa)	Timber (MPa)
1	3.77	1.33
2	4.02	1.51
3	1.99	1.27

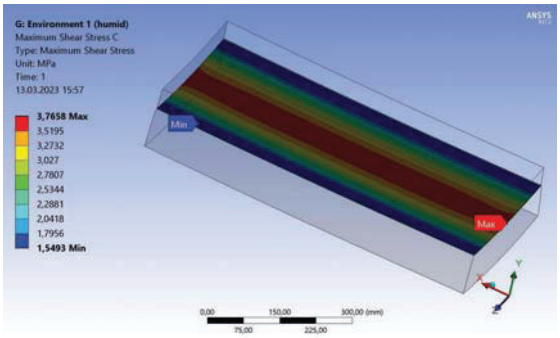

Figure 15: *Humid Environment 1 - Maximum shear stress on the bottom of the concrete*

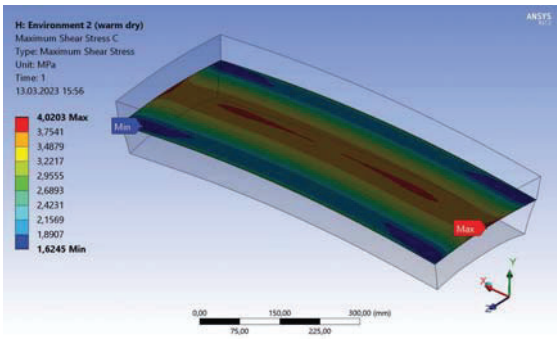

Figure 16: *Warm and dry Environment 2 - Maximum shear stress on the bottom of the concrete*

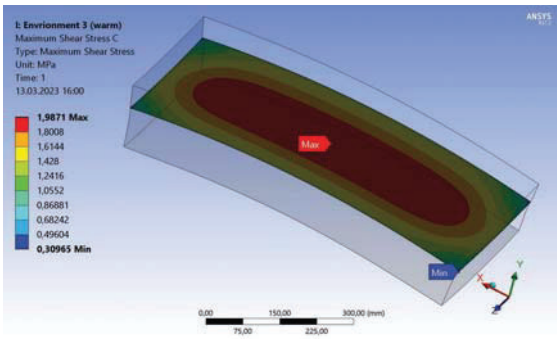

Figure 17: *Warm Environment 3 - Maximum shear stress on the bottom of the concrete*

6 CONCLUSIONS

The hydrothermal stresses near the glue line can limit the use of TCC panels with adhesive shear connections in humid environmental conditions. Therefore, in the experimental analysis, three various environments typical of swimming-pool areas were considered. Based on the measured data, a numerical FEM model was validated and used for the stress evaluation.

From the results, it can conclude that the weakest point of adhesively bonded TCC is the tension stress in the concrete layer. Concrete with a lower value of flexural tensile strength will possibly crack near the glued line and can lead to the failure of the adhesive shear connection. For a humid environment, therefore, high-strength concrete could be more suitable. The shear stress at the edges of the specimens possibly caused the thin cracks in the glued line observed after the test.

The geometrical dimensions of the specimens were relatively small; only fragments of real panels were used in the analysis. But it can assume that the hygrothermal deformations of panels with the same concrete-to-timber ratio cause the same curvature, regardless of the width and length, causing similar normal stresses. On the other hand, the shear stress at the real-size panel edges could possibly be more significant. The size effect will be studied in more depth in future.

Ongoing research focuses on the shear strength differences in the glued line of TCC panel specimens subjected to hygrothermal load over the entire contact surface of the timber and concrete parts of the panels. In addition, further research is still needed to fully comprehend the complex topic of the adhesive connection of TCC, especially in the field of ageing.

CYCLIC TESTS ON AN INNOVATIVE FRICTION DISSIPATIVE DEVICE FOR SEISMIC RETROFIT WITH CLT PANELS

Francesco Boggian[1,2*], Angelo Aloisio[1,3], Roberto Tomasi[1]

ABSTRACT: Seismic renovation is a topic of crucial importance for many countries in the southern part of Europe, where the high levels of seismic hazard, combined with the presence of old RC frame structures, poses a severe risk to the lives of many. The e-CLT system, part of the European project e-Safe, proposes a seismic retrofit system for existing RC frame buildings by attaching CLT panels to the facade and connecting them to the existing structure with innovative friction dissipative devices. The authors conducted an experimental campaign at component level for this novel connector, with two different setups, with and without a CLT panel. This paper presents the cyclic test results on these friction devices, with particular attention to the influence of the timber connection on friction behaviour.

KEYWORDS: seismic renovation, Friction connector, experimental test, energy dissipation

1 INTRODUCTION

Up to 60% of residential buildings in Italy were built between 1946 and 1990, and 25% before 1946 [1], when proper seismic building codes were not available (the first codes were presented in the 1980s), and are therefore in great need of retrofitting. Many retrofit systems are available, directed either at reinforcing the existing structure, or providing extra energy dissipation Some systems can offer both. Traditional systems include steel jacketing, FRP, but are often cumbersome and expensive. The dissipation approach uses three different types of dissipation devices: active, semi-active and passive [2]. This paper will focus on friction dampers, a particular type of passive dissipation device that is becoming more studied in recent years for application in buildings. In its simplest form, a friction device is composed of three plates clamped together by preloaded bolts [3]. The middle plate has an elongated bolt, the outer plates have round holes, so there can be relative slip between the plates when the applied force reaches the friction limit. The system proposed by the authors is called e-CLT (Fig.1)[4], [5]: CLT panels are attached from the outside of existing buildings without disturbing the users' lives during renovation work. The main novelty of the system lies in the connection between the timber panel and the existing building: a Friction Connection, capable of offering a stiff joint for low levels of horizontal actions whilst sliding and dissipating energy via friction when subjected to higher loads like earthquakes. This paper presents an experimental study on a prototype of this novel connection, following the first phase presented in [5]. In the first phase, the friction connection was tested by itself, focusing solely on the friction behaviour, while the novelty of this paper is a new testing setup that includes a CLT panel. The goal is to study the performance of the interaction between friction connection and timber connection.

2 E-CLT

The system tested in this paper is part of an ongoing European project called e-SAFE (Energy and Seismic AFfordable rEnovation solutions) [5]. The project was financed in the Horizon 2020 framework of "decarbonizing the EU building stock", and proposes a multi-faceted approach to building renovation [4]. Different disciplines are involved, with to obtain better performances both regarding energy efficiency and structural behaviour. One of the systems proposed for seismic retrofit of existing RC frame buildings with masonry infill is called e-CLT, shortly illustrated in Figure 1.

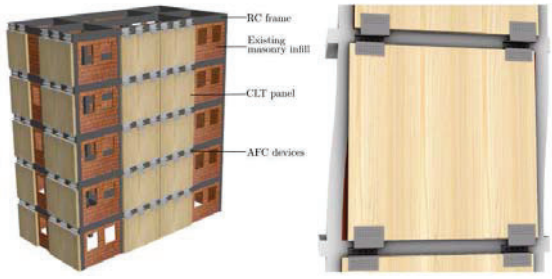

Figure 1: *e-CLT seismic retrofit system* [5].

The renovation system e-CLT entails the application of a CLT panel from the outside of a building, on the bays without any openings, thus without disturbance for the residents. The main novelty lies in the connection system between the CLT panel and the existing structures: friction connections link the CLT panel to the beams of every floor. The friction connection is composed of two steel plates: the anchor profile is rigidly connected to the RC beam of a floor and the CLT panel of the floor above, while the free profile is connected to the CLT panel of the floor below and the anchor profile via preloaded bolts that can slide in an elongated hole. In this way, by setting the desired preload in the bolts, it is possible to choose the activation force of the sliding mechanism. For lateral force levels below the activation threshold the connection will behave as stiff. In contrast, for higher load levels, such as in the event of an earthquake, the system will start to slide and dissipate energy via friction. This paper will describe of one of the prototypes of this novel friction connection and the results from some cyclic tests.

3 MATERIALS AND METHODS

3.1 SPECIMEN

Different shapes and configurations of the specimen were modelled and tested in various phases, as seen in Figure 3. In the first testing phase, presented in [5], the research focused on two main designs: STD (standard) and ALT (alternative), seen in Figures 3 and 4. STD is composed of two steel plates: the anchor profile is rigidly connected to the beam of a floor and the CLT panel above, while the free profile has an elongated hole and is connected to the anchor profile and to the CLT panel below. In this case the screw connection the CLT panel is on the front of the system, offering easy access and inspection. Initial modelling and tests highlighted weaknesses in the 3-bend shape and high eccentricity between friction bolts and free profile, as seen in Fig.4, which brought to the conceiving of the ALT profile [6]. In this case, both CLT-to-steel screw connections are moved to the back, which means simpler L shapes for the plates and reduced eccentricity. This brought better mechanical performances at the expense of reduced accessibility of the screw connection. A further elaboration of the ALT is the ALT-AS, seen in Fig.5. In this prototype the free profile is composed of two separate pieces, connected by lateral bolts in elongated holes, which offer the additional benefit of vertical adjustability in the mounting phase [6], [7]. The third phase of testing, addressed in this paper, used a design called HYB (hybrid), which attempts to keep the positive aspects of STD and ALT: front mounting possibility and more straightforward L shape [8].

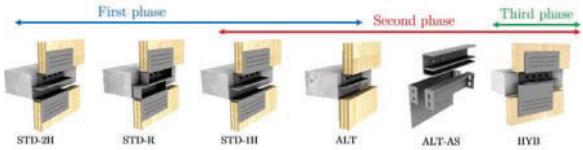

Figure 2: *Evolution of the dissipator shape.*

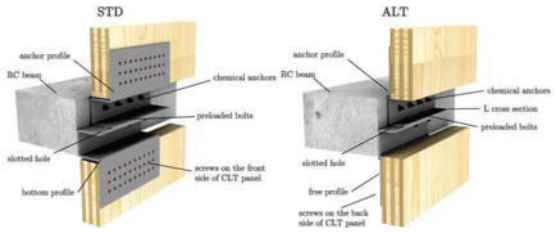

Figure 3: *Main features of the initial STD and ALT shapes* [5].

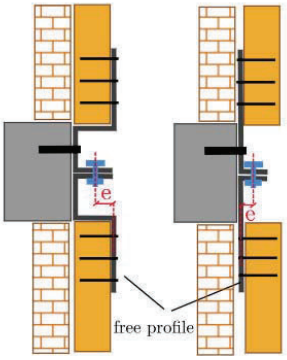

Figure 4: *Section illustration of STD and ALT shapes* [5].

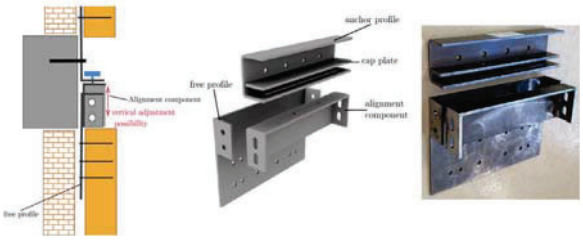

Figure 5: *Illustration of the ALT-AS shape* [7].

The HYB specimen, seen in Fig.6, is composed of two 8mm thick cold bent steel plates: the anchor profile is attached to the beam of the existing building and the CLT panel of the upper floor, while the free profile is attached to the CLT panel of the lower floor and the anchor profile with two high strength M16 bolts. The connection to the CLT panel is made with 33 10x80 screws. The free profile presents an elongated hole, which permits relative sliding, with a clearance of movement of 100mm in both directions. The friction connection is completed by a cap plate and two aluminium shim layers, which improve the friction behaviour. Four specimens were tested, as seen in Tab. 1. HYB 2 and HYB 3 were identical, HYB_e had a slightly reduced eccentricity, HYB_s was tested on a different steel setup. Multiple repetitions were performed on each specimen, with different preloads according to Tab.1.

https://doi.org/10.52202/069179-0420

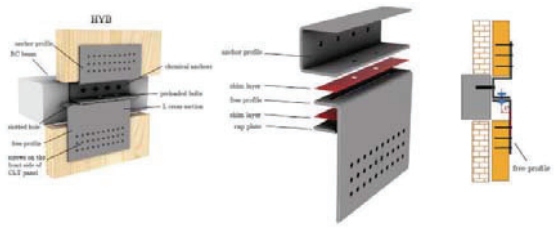

Figure 6: *Illustration of the HYB specimen* [8].

3.2 SETUP AND LOAD PROTOCOL

Two different setups were used for testing. The main setup is seen in Fig.3, where the free profile is connected with screws to a 100mm thick CLT panel. The anchor profile, simplified to a C shape for testing purposes, was connected to the actuator of the press, which simulated the movement of beam in a real building by moving up and down. One specimen was tested on a different setup, without the CLT panel, seen in Fig.8, to study the influence of the screw connection on friction behaviour. All the tests were carried out in displacement control with a speed of 2mm/s and the same cyclic protocol: 1x5-10mm+3x20-40-60-80-100mm.

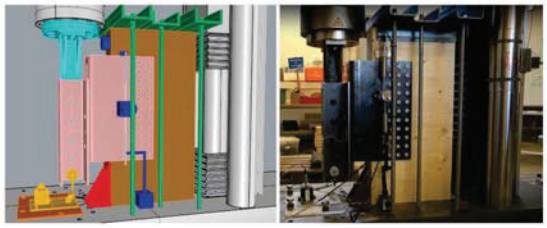

Figure 7: *Setup with CLT panel* [8].

4 RESULTS AND DISCUSSION

This section will give a brief overview of the experimental results; the complete outcome is presented in [8]. Figures 9 to 12 show results of the tests in term of force-displacement graphs. The first three pictures refer to the specimens tested on the main setup, with the CLT panel. The shape of the hysteresis loops closely resembles that of a rectangle, which is the ideal shape for a rigid-plastic system. The shape is not precisely a rectangle since the system is not a pure friction connection, but it's influenced by the deformability of the steel plates and of the timber screw connection. The influence of the screw timber connection on the friction system is primarily visible in the initial cycles and at the change of directions: the graphs present a slight S shape, typical of the pinching phenomena of timber connections, which causes a loss in energy dissipation. In all the tests, the force value reaches peaks at initial cycles and then stabilizes to lower constant values, this was also observed in the previous campaign and is due to both the static vs dynamic friction behaviour and to wear degradation phenomena of the friction surfaces.

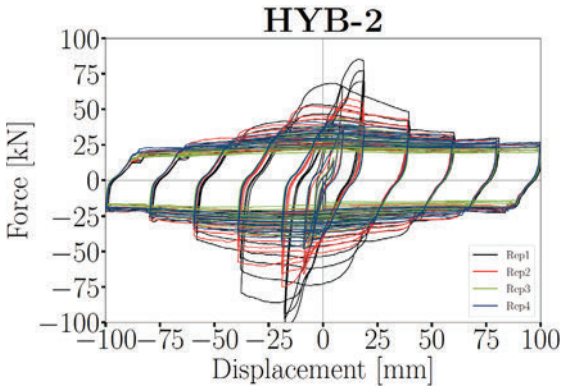

Figure 9: *Results of specimen HYB-2.*

Specimen HYB_e doesn`t present a drastically different behaviour from specimens HYB-2 and HYB-3, suggesting that the reduced eccentricity doesn`t play a key role in the stable friction behaviour. Figure 12 presents the results from the specimen that was tested on the second setup, which was made only of steel and used a bolted connection instead of a screw connection. The immediate difference in the graphs is that the shape is more

https://doi.org/10.52202/069179-0420

rectangular, and the load inversion branches are more vertical, given the higher stiffness of the bolted connection. Additionally, the steel setup offers a more stable friction behaviour, with minor fluctuations in the slip force value, suggesting that a stiffer connection system is preferable to exploit the full potential of the friction connection.

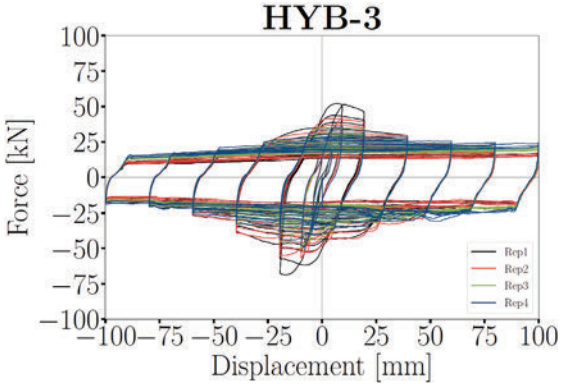

Figure 10: *Results of specimen HYB-3.*

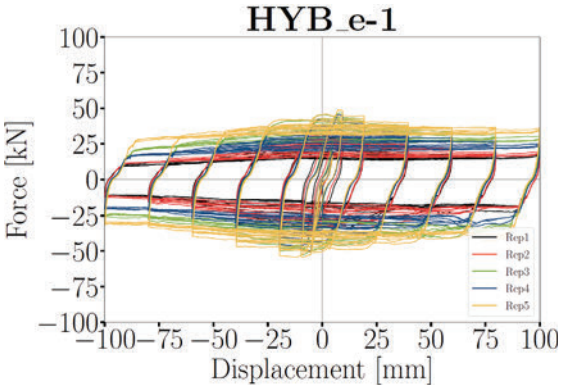

Figure 11: *Results of specimen HYB_e-1.*

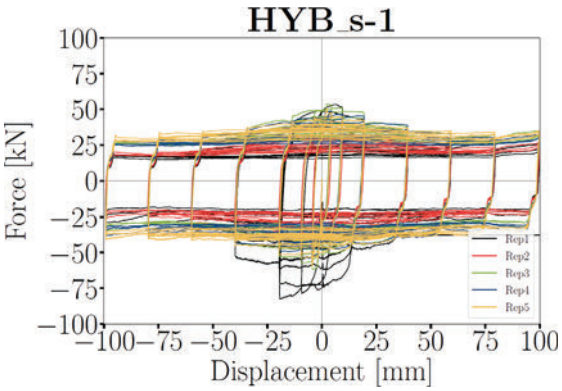

Figure 12: *Results of specimen HYB_s-1.*

Results in terms of slip force and friction coefficient are presented in Table 2. The definition of the slip force from the experimental data is not immediate, as the value fluctuates throughout the test, changes sign and is influenced by the initial phenomenon of changing from static to dynamic friction. The authors decided, therefore, to use the same approach adopted by [9]. The definition of slip force is based on the total dissipated energy and the cumulated displacements, both values are positive and strictly increasing functions. The dissipated hysteretic energy is defined by the following:

$$E = \sum_{i=0}^{n} E_i = \sum_{i=0}^{n} \left| \frac{F_{i+1}+F_i}{2} \cdot (\delta_{i+1} - \delta_i) \right| \quad (1)$$

where E is the dissipated energy, E_i the dissipated energy at the $i-$th time step, F_i and δ_i are the force and displacement at the same time step, respectively.
The cumulative distance of travel D is the sum of the displacement time steps:

$$D = \sum_{i=0}^{n} |\delta_{i+1} - \delta_i| \quad (2)$$

The slip force is thus calculated as the energy per unit of length:

$$F_{\text{slip}} = \frac{E}{D} \quad (3)$$

The experimental friction coefficient μ is calculated as

$$\mu = \frac{F_{\text{slip}}}{n_s n_b F_P} \quad (4)$$

where F_{slip} is the slip force calculated in Eq.((4)), n_s is the number of shear surfaces equal to 2, n_b is the number of the preloaded bolts equal to 2, and F_P is the preload force from Tab.1.

Tab. 2 shows the friction coefficient values as an average for the repetitions on every specimen with the same preload force. The global average of the testing campaign is 0.21, which aligns with literature values for friction coefficients of aluminium vs steel. [10]. Aluminium is also a good choice for the friction system for its ease of sourcing, manufacturing, and price, when compared to other possible materials for the shim layers of the friction connection.

Tab. 3 attempts to clarify the most critical aspect of the difference between the two setups: energy dissipation. When testing a simple friction connection, composed of a basic system of 3 plates with relative sliding, the expected mechanical behaviour is a perfectly plastic system, producing rectangular hysteresis loops, as seen in Fig.13a. The friction device tested in this campaign is more complex than a basic friction connection, it has a complex

https://doi.org/10.52202/069179-0420

shape and it`s asymmetric, thus introducing additional deformational contribution to the system. These components then reduce the energy dissipation compared to the ideal rectangular behaviour, see Fig.13b. Moreover, if a connection with screws is added to the system, then it acts as an additional deformation component, which also causes a loss of energy dissipation and a more unstable friction behaviour, see Fig.13c. This concept is summarised in Tab. 3 where some values of dissipated energy are presented. In the first part of the table, the dissipated energy is the average as the tests on the CLT setup vs the test on the steel setup for a preload of 25kN, while in the second part, the same dissipated energy value is presented but referred to the tests with 37.5kN preload. The percentage of difference in dissipated energy summarises the contribution of the screw connection to the friction system. On average it causes a 12% energy loss when compared to a system without the CLT connection.

Table 3: *Test results: dissipated energy.*

5 CONCLUSIONS

This paper presents the results of an experimental campaign on a novel friction connection for seismic retrofit purposes. The retrofit system, part of the European project e-Safe, is called e-CLT and consists of applying a CLT panel to the outside of existing RC-framed buildings by using a special connector that acts as a friction damper. The experimental campaign presented in this paper, following the first phase presented in [11], aims at studying the interaction between the friction behaviour and the presence of a screw connection between the steel plate and a CLT panel. Four different specimens were tested on two setups: one with a CLT panel and one without a CLT panel, and the main conclusions are:

- The system works and dissipates energy with a rectangular-like shaped hysteresis loop, while not being a perfect rigid-plastic system because of the many components of the system;
- Aluminium represents a good choice for the shim layers, and the friction coefficient values that were obtained are in line with literature values;
- The main effect of adding a steel-to-timber screw connection to the system is a loss of dissipation capacity due to the added deformability component: on average the system with CLT connection dissipates 12% less energy.

Following the promising results of the testing campaign at component level, a new series of tests at frame level is being planned. A 3x4 m RC frame with masonry infill will be tested with and without the e-CLT retrofit system.

FUNDING

This paper was carried out in the framework of the "Energy and seismic affordable renovation solutions" (e-SAFE) project, which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No.893135. Neither the Executive Agency for Small and Medium-sized Enterprises (EASME) nor the European Commission is in any way responsible for any use that may be made of the information it contains.

NAIL-LAMINATED TIMBER-CONCRETE COMPOSITE BEAMS WITH NOTCHED CONNECTIONS AND STEEL FIBRE REINFORCEMENT

Hamidreza Chaboki [1], Lei Zhang [2], Thomas Tannert [3], Jianhui Zhou [4]

ABSTRACT: The utilization of timber-concrete composite (TCC) floors, which involves connecting a wood beam or panel to a concrete layer via shear connectors, has experienced a surge in popularity in recent years. Although notched connections have proven to be cost-effective shear connections, without proper concrete reinforcement, cracks can develop in the notched area and ultimately lead to brittle shear failure. In this paper, we present research aimed at mitigating crack growth in concrete and preventing notch shear failure in concrete by employing steel fibre reinforcement. Eight groups of nail-laminated TCC beams with varying notch depth, location and number of notches, and thickness ratio of concrete to timber were tested under third-point bending. The results demonstrated that the number of notches and thickness ratio had the greatest impact on beam bending properties, while the influence of notch location and depth was marginal. Furthermore, the steel fibres effectively delayed crack propagation in the concrete notches, resulting in timber failure in all tested specimens. The notches cut on NLT and filled with concrete affect the modulus of elasticity of NLT and need to be considered for the calculation of composite efficiency and effective TCC beam bending stiffness.

KEYWORDS: Timber-concrete composite floor, Bending performance, Notched connection, Steel fibres

1 INTRODUCTION

1.1 Background

Timber-concrete composite (TCC) floors exhibit enhanced bending stiffness and load-carrying capacity compared to pure timber floors of the same depth, enabling longer spans. The combination of a concrete layer to resist compression and timber to resist tension results in efficient utilization of the mechanical properties of both materials. In addition, TCC floors offer superior fire resistance, vibration damping, and acoustic performance compared to bare timber floors [1-5].

Shear connections are integral to generating composite action between the materials in TCC. Various types of connections have been tested, including self-tapping screws and glued-in steel mesh plates [5]. However, these metal fasteners can be disadvantageous in terms of constructability, cost, and labour intensity. Notched connections, prefabricated using computer numerical control machines, offer a potential solution, as they allow for precise, rapid, and cost-effective production with minimal use of metal fasteners [4]. However, the reduction of the cross-sectional area due to the notches impacts the bending capacity and stiffness of the TCC floors [6]. The TCC floor bending stiffness and strength are also influenced by the number and locations of notches, as well as the presence of additional steel fasteners [7]. Up to date, the notched connections are not standardized in the TCC floor design.

Zhang et al. [7] conducted a parametric study to investigate the impact of various geometry-related factors such as depth and number of notches, timber shear length, and concrete thickness on the bending stiffness of TCC floors. Their findings suggest that optimizing the number, location, and size of notches can lead to high composite efficiency in the TCC system. Shi et al. [6] examined the shear behavior of notched connections and observed that when the length of the notch increased from 150 mm to 250 mm, the failure mode changed from shear failure of concrete in the notch to compression failure of timber in front of the notch. Zhang et al. [8] developed an analytical method involving a simple release-and-restore procedure to predict stress distribution and slip between timber and concrete while considering the discrete and semi-rigid features of the notched connections.

The high stiffness of notched connections allows the notches to be spaced along the beam at a large distance, making the concrete layer susceptible to cracking due to stress concentration at the notches. The cracking of concrete can lead to brittle failure and a reduction in beam load-carrying capacity, especially in the absence of reinforcement [9,10]. To address these issues, additional screws are often used to take the tensile forces and restrict crack opening and uplifting [11,12]. Alternatively, micro-notches with millimetre dimensions can be milled into the timber surface to improve continuous shear transfer and reduce uplifting forces [13]. Müller and Frangi [13] showed that micro-notches can achieve close-to-full

composite action and sufficient shear strength for common residential and office buildings.

In concrete structures, steel fibres are often used as reinforcement to reduce crack formation and control propagation. These fibres connect and bridge gaps in the concrete during hardening, delaying crack growth and reducing crack width [14]. It is advantageous to strength the concrete layer in TCC with steel fibres to restrict the crack opening and prevent shear failure of notched connections.

1.2 OBJECTIVES

In this study, the bending performance of nail-laminated timber-concrete composite beams with notched connections and steel fibre reinforcement was investigated. Third-point bending tests were conducted on eight groups of nails-laminated TCC beams, each featuring varying notch depth, location, and number of notches, as well as thickness ratios of concrete to timber layers, to investigate the variation of notches on the bending performance of the beams, as well as the efficacy of steel fibres in mitigating brittle failure of notched connections. The effect of notches on the modulus of elasticity of NLT for calculating the composite efficiency of TCC was also evaluated.

2 EXPERIMENTAL INVESTIGATIONS

2.1 SPECIMEN CONFIGURATIONS

A total of 24 TCC beams, divided into eight groups, with three replicates in each group, were constructed and tested. The beams had a width of 190 mm, a length of 3.06 m (span of 2.9 m), and a total thickness of 150 mm. The number, depth, and location of notches varied among the groups are shown in Table 1 and illustrated in Figure 1. The notches were symmetrically positioned about the mid-span of beams.

To prevent layer separation, three self-tapping screws with a diameter of 8 mm were inserted into each specimen at the mid-span and two ends, as illustrated in Figure 2. The screws, which had an embedment length of 50 mm in both wood and concrete, were made of carbon steel with a zinc coating. In the case of SP7, the thicker timber layer required a longer embedment length of 60 mm into the wood.

Table 1: *Specification of specimens*

Group	Concrete to timber thickness ratio	Number of notches	Notch depth (mm)
SP1	2:3	2	20
SP2	2:3	2	20
SP3	2:3	4	20
SP4	2:3	4	30
SP5	2:3	4	40
SP6	2:3	4	15-25
SP7	1:2	4	20
SP8	1:1	4	20

The reference group SP3 had a concrete thickness of 60 mm and a timber thickness of 90 mm, with four notches that were 20 mm deep and 150 mm long. To explore the impact of the number of notches on the stiffness and strength of the TCC beams, SP1 and SP2 featured only two notches that were 20 mm deep and spaced 1800 mm and 1200 mm apart, respectively. The location and length of notches in SP4 and SP5 were identical to those of the reference group, but the depths of the notches were 30 mm and 40 mm deep, respectively. In SP6, the notch depth varied along the beam length, with a depth of 25 mm near the supports and 15 mm near the mid-span. Finally, SP7 and SP8 were similar to the control group but differed in their timber-to-concrete thickness ratios. The thickness of timber and concrete in the specimens ranged from 75-100 mm and 50-75 mm, respectively.

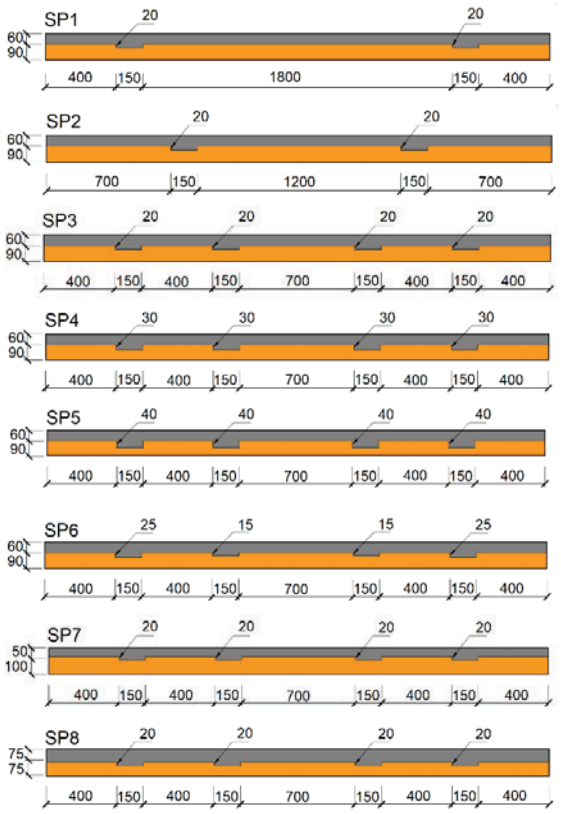

Figure 1: *Nail-laminated timber-concrete composite beam configurations (dimensions in mm)*

2.2 MATERIALS

Five 38 mm thick spruce-pine-fir (SPF) lumber planks of grade No. 2 were nailed together (6d, 3 inches long, one row @ 120 mm spacing) to fabricate the nail-laminated timber (NLT) beams. The lumber had an average density of 444 kg/m^3 and a moisture content of 13% before testing. The notches on NLT were cut using a router. The moduli of elasticity (MOE) of the NLT beams were measured before (E_t) and after ($E_{t,notched}$) cutting the notches by non-destructive centre-point bending tests.

https://doi.org/10.52202/069179-0421

The average measured MOE values of each NLT group are listed in Table 2, which indicates different levels of MOE reduction after notching (11% to 62%). SP5 with the deepest notches showed the highest drop in MOE while SP1 with the minimal number of notches showed the lowest reduction. The choice of MOE on the composite efficiency and the bending stiffness of TCC are discussed in the results section.

Table 2: *Average MOE values of NLT beams*

Group	E_t (MPa)	$E_{t,notched}$ (MPa)	$E_{t,n\&c,FEM}$ (MPa)
SP1	7802	6907	7027
SP2	9618	7291	7921
SP3	7931	5941	6855
SP4	7900	4451	5488
SP5	8615	3311	4685
SP6	7677	6208	6622
SP7	8316	6493	6605
SP8	9790	6460	7925

Note: E_t is the MOE of NLT tested without notches; $E_{t,notched}$ is the MOE of NLT tested with notches; $E_{t,n\&c,FEM}$ is the MOE of NLT determined from the finite element model.

Figure 2: *Specimen preparation A) NLT with notches and screws B) Formwork for concrete casting C) After concrete curing*

The specimen preparation process is shown in Figure 2. To avoid the formation of voids around the corners of notches, the nominal maximum coarse-aggregate size in concrete was chosen as 10 mm. All the specimens were made from the same batch of concrete. To reinforce the concrete layer, HE-4550 steel fibres with 50 mm length and two bend ends were used in a volume reinforcement ratio of 0.5%. Three cylinders with a nominal diameter of 100 mm and a height of 200 mm were cast at the same time and tested according to ASTM C39/C39M-20 [15] after 28 days. The average compressive strength of concrete cylinders was 39.3 MPa, with a coefficient of variation of 1%. Concrete cylinders had a density of 2,325 kg/m^3. The Young's modulus of concrete was estimated as 28027 MPa based on the 28-day compressive strength (f_c') and density (γ_c) applying Eq. (1) [16]:

$$E_c = (3300\sqrt{f_c'} + 6900)(\frac{\gamma_c}{2300})^{1.5} \quad (1)$$

2.3 FINITE ELEMENT MODELS

2D finite element models of the NLT beams were developed in the general-purpose finite element software ABAQUS [17] to numerically evaluate MOE of the notched NLT with concrete filled in notches ($E_{t,n\&c,FEM}$). The contact between timber and concrete in the tangential direction was defined as penalty with a coefficient friction of 0.6 [18] and a hard contact in the normal direction. The model was verified for both solid and notched NLT beams. The results of MOE for the notched NLT filled with concrete are shown in Table 2. Compared to NLT without notches, the reduction of MOE with notches filled with concrete ranges from 10% to 46% depending on the notch configurations.

2.4 METHODS

The TCC beams were tested under three-point bending based on ASTM 198-15 [19], as illustrated in Figure 3. The supports were 100 mm wide to avoid indentation of wood. Two string potentiometers were used to measure the mid-span deflection, and four LVDTs were installed at two ends of each beam on both sides to measure the relative slip between timber and concrete. The deflection and load were recorded for calculating the bending stiffness and moment capacities. The displacement-controlled load was applied at a rate of 3 mm/min to ensure the specimens failed in roughly 20 minutes.

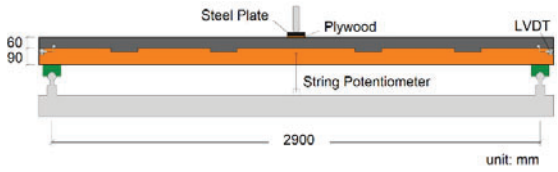

Figure 3: *Schematic of the bending test setup*

The serviceability bending stiffness (referred to as bending stiffness herein) of the floors was determined from Eq. (2) [19]:

$$EI = \frac{PL^3}{48\Delta} \quad (2)$$

where L is span and P/Δ is the slope of the load-deflection curve between 10% and 40% of peak load, regarded as the load level at serviceability limit states [20].

Eq. (3) was used to determine the ultimate bending stiffness of the beams [19]:

$$EI_{ult} = \frac{L^3}{48}\frac{0.8P_{max}}{\Delta_{0.8}} \quad (3)$$

https://doi.org/10.52202/069179-0421

where $\Delta_{0.8}$ indicates the mid-span deflection at 80% of the peak load [20].

The composite efficiencies of the tested TCC beams were evaluated by comparing them with non-composite and full composite TCC beams. The theoretical bending stiffness of a non-composite floor can be calculated using Eq. (4), where E_c and E_t are the concrete and timber moduli of elasticity, respectively; and I_c and I_t are the concrete and timber second moments of area, respectively [21].

$$EI_{no} = E_c I_c + E_t I_t \tag{4}$$

The bending stiffness for the theoretical full composite floor is determined according to Eq. (5) [21]

$$EI_{full} = E_c I_c + E_t I_t + \frac{\left(\frac{h_c + h_t}{2}\right)^2}{\frac{1}{E_c A_c} + \frac{1}{E_t A_t}} \tag{5}$$

where A_c and A_t are the cross-section areas of concrete and timber, respectively; and h_c and h_t are the concrete and timber depths, respectively.

The deflection-based composite efficiency [21] is calculated according to Eq. (6):

$$\lambda = \frac{\Delta_{no} - \Delta}{\Delta_{no} - \Delta_{ful}} = \frac{\frac{1}{EI_{no}} - \frac{1}{EI}}{\frac{1}{EI_{no}} - \frac{1}{EI_{full}}} \tag{6}$$

where Δ_{no}, Δ_{ful}, and Δ are the deflections of the non-composite, full composite, and tested beams under the same load (10% - 40% of peak load).

3 RESULTS AND DISCUSSION

3.1 LOAD-DEFLECTION RELATIONSHIPS & FAILURE MODES

The load-deflection curves and failure modes for each group are presented in Figures 4 and 5, respectively. As the load increased, the TCC beams deformed elastically at the beginning and then exhibited nonlinear deformation after surpassing certain load levels. Concrete shear cracks formed around notches and propagated diagonally or nearly vertically after reaching certain load levels, but the steel fibers limited the extent of crack opening. Since the NLT beams were attached using nails, the lumber planks failed individually, causing multiple peaks and drops in the load-deflection curves.

The failure modes of the specimens are summarized in Table 3. The majority of TCC beams failed in the timber layer due to tension or combined bending and tension, as shown in red circles in Figure 5. Notched connection configurations and the relative thicknesses of timber and concrete in TCC beams did not significantly impact the failure patterns.

In terms of concrete failure, almost all specimens had diagonal concrete cracking at the notched corners (shear cracks) that started in a diagonal or almost vertical orientation, then spread horizontally. Once the first timber bending failure happened, a gap between timber and concrete was formed. With more lumber failure and an increase in deflection, the notched connections in the concrete portion were sheared off, starting with one external notch near the support and then the internal notch on the same side. The failure of the notches caused the failure of the concrete layer.

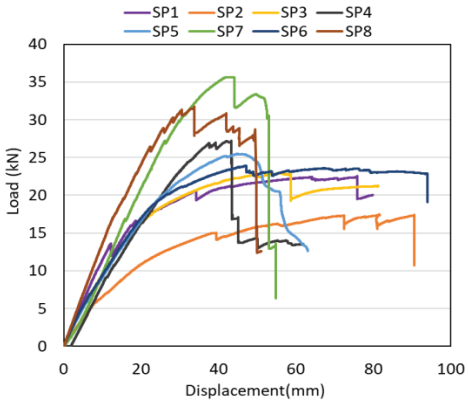

Figure 4: *Typical load-deflection curves of each group*

Figure 5*: Failure patterns of NLTCC beams under bending*

The specimens SP1, SP7, and SP8 with the same notched connections but different concrete-to-timber thickness

ratios exhibited slightly different failure patterns. SP1 experienced timber bending failure at mid-span without visible damage to the concrete layer. SP7 was able to withstand a higher load even after two lumber planks failed by bending. The steel fibres controlled the crack width in the concrete, resulting in higher loads and buckling failure of the concrete. In SP8, after the timber failure, concrete was buckled under compression. It is worth noting that the steel fibres limited the crack width and provided ductility. The progressive failure in NLT and the reinforcement of concrete using steel fibres are believed to be the reasons for the ductile behaviour observed in these groups.

Table 3: *Nail-laminated TCC beam failure modes*

Group	Failure mode
SP1	Timber combined bending and tensile failure
SP2, SP3 SP4, SP5 SP6	Timber combined bending and tensile failure & notch shear failure in concrete
SP7 SP8	Timber combined tensile and bending failure, notch shear failure in concrete & concrete buckling

3.2 BENDING PROPERTIES

The bending properties including the average peak load (P_{max}), bending stiffness (EI), ultimate bending stiffness (EI_{ult}), and bending stiffness reduction are listed in Table 4. Comparing load-carrying capacities among different groups, groups SP1 and SP2 exhibited similar load-carrying capacities, approximately 18.5 kN; Groups SP3-6 exhibited similar load-carrying capacities at around 24.0 kN; Groups SP7 and SP8 exhibited the highest load-carrying capacities of 32.5 kN. Comparing groups SP1-6, all of which had the same total beam thickness and concrete-to-timber thickness ratio, it is apparent that the number of notches had a positive impact on the floor load-carrying capacity. Interestingly, the depth of notches between 15 mm and 40 mm did not affect the load-carrying capacity when comparing groups SP3-6. No clear trend can be observed concerning the impact of the thickness ratio of concrete to timber on the strength properties of beams.

The notch configuration had slightly different effects on the serviceability and ultimate bending stiffness of beams. SP1,3-5 have similar serviceability bending stiffness values from 438 to 458 kNmm^2, while those of SP2 and SP6 had lower values from 382 to 398 kNmm^2. Although the NLT beams had higher bending stiffness in SP2 and SP6 (shown in Table 2), the lower connection stiffness in the two specimen series resulted in lower bending stiffness of composite beams. SP8 has the highest bending stiffness owing to the highest concrete-to-timber thickness ratio. However, the second-highest bending stiffness was observed in SP7 which had the lowest concrete-to-timber thickness ratio. It should be noted that small cracks can happen in concrete while moving the TCC beams before testing, and workmanship was not the same in all the specimens. SP7 seems to be the group with the highest quality, making it difficult to investigate the effect of notch configurations on beam bending stiffness.

The reduction of stiffness from serviceability state (EI) to ultimate state (EI_{ult}) varies among the groups from 1.4% to 28.0% without a clear pattern. Further analysis of the slip between the two layers in each group is required, as the notch configurations may have an impact on the actual connection stiffness in each group.

Table 4: *Summary of peak load and bending stiffness*

Group	P_{max} (kN)	EI (kNm^2)	EI_{ult} (kNm^2)	Reduction of stiffness
SP1	19.0	439	432	1.4%
SP2	18.0	382	274	28.0%
SP3	23.7	458	343	26.1%
SP4	25.5	458	394	13.8%
SP5	23.4	438	383	12.6%
SP6	25.3	398	382	3.6%
SP7	33.4	578	533	8.0%
SP8	31.9	684	581	15.2%

3.3 COMPOSITE EFFICIENCY

The calculated deflection-based composite efficiencies of the composite beams according to Eq. (6) are presented in Figure 6. The values are computed with different MOE values of NLT beams listed in Table 2. The values in blue are calculated based on the measured E_t of NLT beams without notches; values in red were based on the measured $E_{t,notch}$ of NLT beams with notches; and values in grey were based on $E_{t,n\&c,FEM}$ of NLT beams with notches filled with concrete determined from finite element models. The trend of composite efficiency among groups is similar to that of the serviceability bending stiffness. Groups SP7 and SP8 had higher composite efficiencies than the rest of the groups, while group SP2 has the lowest composite efficiency.

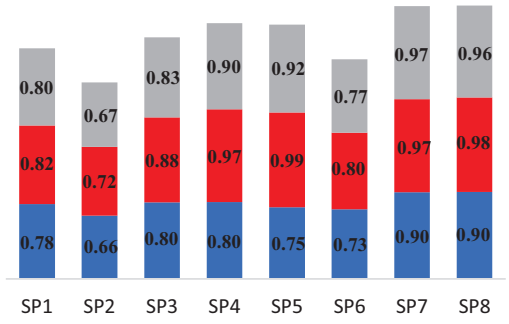

Figure 6: *Composite efficiency of deflection using different timber modulus of elasticity*

Not surprisingly, the higher the MOE used, the lower the composite efficiency was determined. The choice of MOE values of NLT beams can lead to different judgments of composite efficiency and composite action. For instance, for group SP5, the composite efficiency using the measured $E_{t,notch}$ is 24% higher than that using the

https://doi.org/10.52202/069179-0421

measured E_t, and is 7% higher than that using the $E_{t,n\&c,FEM}$. The same issue of choosing MOE of timber will arise when it comes to the prediction of bending stiffness of TCC beams with notches, which should be considered in the design practice.

4 CONCLUSIONS

The bending properties of 24 NLT-concrete composite beams with varied notched configurations and steel fibre reinforcement were investigated experimentally in this work. The following conclusions can be derived: 1) The notch number and concrete-to-timber ratio had major impacts on the beam bending performance, while notch location and depth had marginal impact. 2) The use of steel fibres can postpone shear failure in concrete and ensure a more controllable timber bending failure. 3) The effect of notches on the MOE of timber can lead to different interpretations of composite efficiency and prediction of bending stiffness of composite beams.

PUSH-OUT TESTS OF WET-PROCESS ADHESIVE-BONDED BEECH TIMBER-CONCRETE AND TIMBER-POLYMER-CONCRETE COMPOSITE CONNECTIONS

Matthias Füchslin[1,2], Philippe Grönquist[1,3,4]*, Sandro Stucki[5,6], Tim Mamie[7], Steffen Kelch[7], Ingo Burgert[5,6], Andrea Frangi[1]

ABSTRACT: For timber-concrete composite (TCC) elements, a stiff and rigid connection results in an enhanced shear stress transfer at the timber-concrete interface, and thus, reduces the necessary cross-section height. A full composite action can hypothetically be achieved using an adhesive connection. In this study, an adhesive system developed for a wet-process gluing of concrete to European beech glued-laminated timber (GLT) is investigated by means of push-out tests. The tests were conducted on a specimen series with three different sizes of varying shear length, and evaluated using digital image correlation (DIC). The bondline shear strengths showed a pronounced size dependency, while the connection stiffness remained similar but showed a very large variability. These findings challenge the interpretation of bondline connection properties derived from push-out tests of glued TCC elements. In addition to the wet-process adhesive system with cement-based concrete, bonding between timber and a polymer concrete was investigated as an alternative possibility for TCC.

KEYWORDS: Adhesive connection, Digital image correlation, Polymer concrete, European beech GLT

1 INTRODUCTION

For the design of timber concrete-composite (TCC) structures, reliable knowledge of the specific connection behaviour is important. While annex B of Eurocode 5 [1] provides the "γ-method" in order to approximate the composite's flexural rigidity, the value of γ itself is to be derived from the connection stiffness K, which in turn, is to be determined for each specific type of connection. For the determination of K, usually, one of two types of push-out tests is commonly used: (1) a symmetric double-shear push-out test, such as suggested in annex C of CEN/TS 19103 [2], or (2) a single-shear push-out test with asymmetrical samples. Both methods possess specific advantages and disadvantages, such as potential prevailing asymmetry due to variability in timber material properties in test (1) when both side parts are timber, or high friction forces between timber and concrete for test (2). Additionally, in both tests, due to the load path, moments are induced and the resulting stress state does not reflect pure shear. Nonetheless, both methods tend to result in reliable values of K for most of the available TCC connection types, i.e., prevalently for the different metallic fastener and notch types.

To maximize composite action, and thus maximize the static efficiency of the TCC cross-section, a glued connection can be used. In this case, for the design of slabs, a value of $\gamma = 1$ (fully rigid connection) is usually assumed without the need for more precise analysis of K [3,4]. In fact, a handful of previous studies analysed the load-bearing behaviour of adhesively bonded TCC using building component scale sized push-out tests [5-13]. In most of the cases, the push-out tests were solely used for the purpose of verification of the load bearing capacity of the adhesive bond, whereas the connection stiffness K was not investigated. An exception is the study by Tannert et al. [13] who reported $K \approx 1'160 - 1'340$ kN/mm for a two-component epoxy adhesive (*Sikadur-32 Hi-Mod*). However, the aforementioned drawbacks of the testing methods do not necessarily permit to derive reliable values of K and of the shear strength, especially in the case of a glued connection, due to the non-local but dispersed and complex force flow.

In this study, European beech glued-laminated timber (GLT) was bonded in a wet process to self-compacting concrete using a newly developed hybrid adhesive combining epoxy and silane-terminated polymers. In order to assess a size-dependency of the connection properties, symmetric double-shear push-out tests were conducted on three specimen series with different shear length each. Surface strain fields were measured using digital image correlation (DIC), and bondline connection stiffness K was determined from surface displacement fields. In addition, two specimen series using a directly-bonding polymer concrete were tested to provide a benchmark and assess the bonding behaviour of polymer concrete on beech timber.

2 MATERIALS AND METHODS

2.1 Specimen series design

Three pushout specimen series with different shearing lengths were designed. In the case of the adhesive-bonded

concrete in a wet process, the series were denoted as follows:

- **CL** (concrete large) with shearing length of 2 x 240 mm,
- **CM** (concrete medium) with shearing length of 2 x 180 mm, and
- **CS** (concrete small) with shearing length of 2 x 120 mm.

The shearing depth, and depth of all specimen components, was chosen as 240 mm. The detailed sample design is depicted in Figure 1. For series CL, CM, and CS, the predicted failure mode was a shear failure of the adhesive, while the probability of a shear failure of the concrete near the adhesive bond could not be entirely excluded. For the benchmark series using directly bonding polymer concrete, two series were chosen:

- **PM** (polymer concrete medium) with shear length of 180 mm, and
- **PS** (polymer concrete small) with shear length of 120 mm.

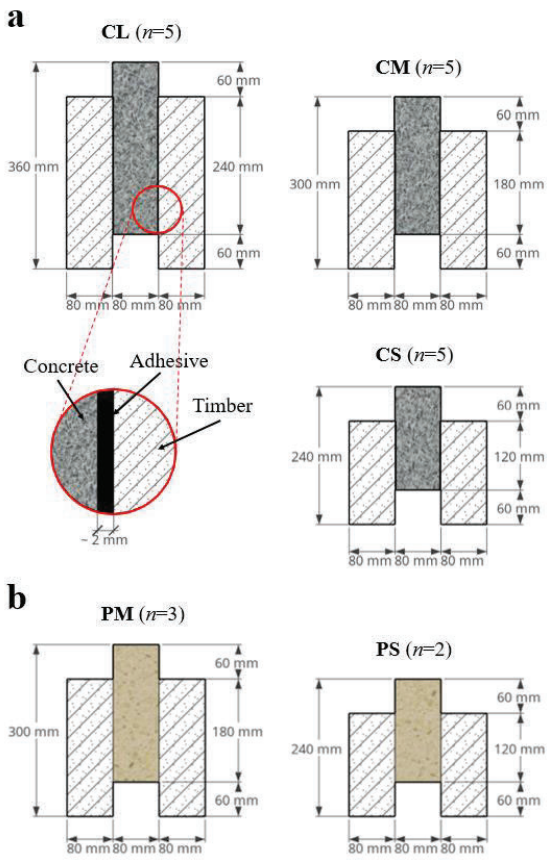

Figure 1: *Push-out specimen series with dimensions and number of tested specimens (n). Specimens have a constant depth of 240 mm (out of plane dimension).* ***a****: Series CL, CM, and CS for adhesively-bonded concrete in wet process.* ***b****: Series PM and PS for directly bonded polymer concrete.*

2.2 Specimen production

Defect-free GLT blocks of strength class GL48h were obtained from *Fagus Suisse SA*, made of European beech (*Fagus sylvatica*) wood of Swiss origin [14]. The blocks, were cut and planed to match the dimensions as shown in Figure 1. Their density was recorded as 722±20 kg/m^3, at an initial wood moisture content of approx. 8±0.5%. For the series CL, CM, and CS, for 5 specimens per series, a two-component silane-terminated polyurethane epoxy-hybrid (STP-E) adhesive, developed by *Sika Technology AG,* was evenly applied to both the timber side-parts of the pushout specimens. An amount of 1500 g/m^2 was applied on cleaned timber surfaces. After an initial phase of 25 minutes in horizontal position to allow for the adhesive to reach an optimal viscosity, see Figure 2a, the coated blocks were inserted into the formwork. *Sikacrete-16 SCC* [15], a self-compacting ready-mix concrete from *Sika Schweiz AG* of approx. grade C30/37 and maximal grain size of 16 mm, was cast in between the blocks, see Figure 2b. The specimens were left in the formwork for 5 days, and were tested after 28 days, meanwhile being covered by plastic foil during curing of the concrete to avoid drying.

For the series PM and PS, with 2 specimens each, the timber blocks were directly inserted into the formwork. *Sikadur 42 HE* [16], an epoxy-based grout from *Sika Schweiz AG*, in combination with quartz sand of grain size of < 4 mm, was cast. The specimens were left in the formwork for 5 days, and were tested after 28 days.

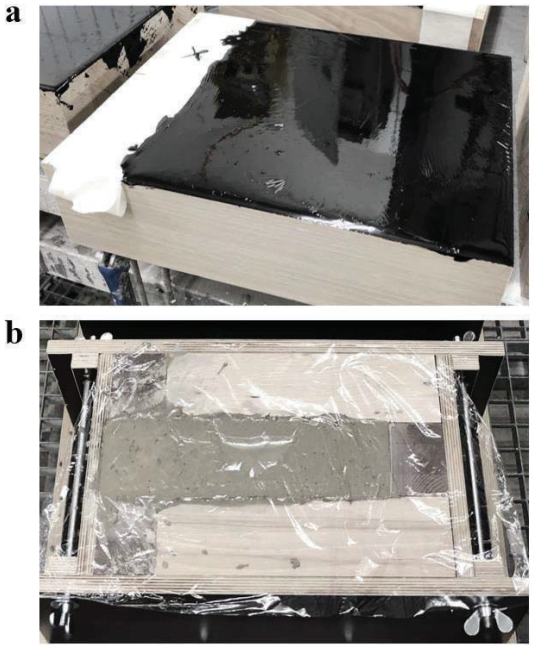

Figure 2: *Preparation of concrete specimens (CL, CM, CS).* ***a****: Application of controlled amount of STP-E adhesive (black).* ***b****: Casted self-compacting concrete mixture in formwork containing beech GLT with applied adhesive.*

2.3 Pushout testing

The specimens were tested using a displacement-controlled servo-hydraulic testing machine of type *Schenck 1600*, with a maximal capacity of 1600 kN (see Figure 3). Compressive forces were continuously recorded by a load cell. In addition to the machine displacement, redundant displacement measurements were conducted by three linear variable differential

transducers (LVDT) between the loading plates and surrounding the pushout specimens. Furthermore, a camera recorded an applied speckle pattern on the specimen sides in order to compute surface displacements and strain fields by means of digital image correlation (DIC). The specimens were initially loaded and unloaded twice until 30% of their estimated carrying capacity, and then ultimately loaded until failure.

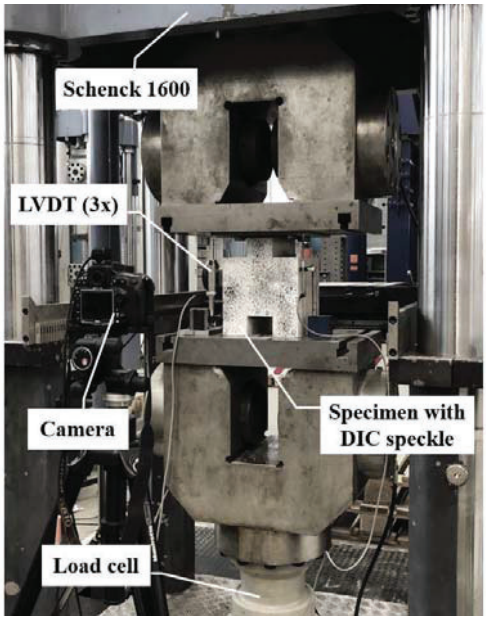

Figure 3: *Testing setup. Compressive Force applied by a displacement-controlled servo-hydraulic testing machine (Schenck 1600). Additional displacement measurements by three linear variable differential transducers (LVDT), and by digital image correlation (DIC).*

2.4 Determination of properties

The bondline shear strengths f_v were determined by dividing the maximum recorded forces F_{max} by the shearing area A_v:

$$f_v = \frac{F_{max}}{A_v}$$

The bondline connection stiffness K was determined for each of the two shearing lengths (right and left) per specimen separately, by dividing half of the applied force ΔF (force difference in a linear range of force-displacement) by the resulting average differential displacement between the timber and the concrete ($v_{m,t} - v_{m,c}$) parts:

$$K = \frac{\Delta F}{2(v_{m,t} - v_{m,c})}$$

The separate timber ($v_{m,t}$) and concrete ($v_{m,c}$) displacements were calculated locally for each of the parts near the bondline, but as averages over the whole shearing lengths, from computed displacement fields using the DIC technique. For DIC processing, *Ncorr*, an open source 2D DIC *Matlab*-based program was used [17].

3 RESULTS

Obtained results for shear strengths and bondline connection stiffnesses are shown in Figure 4 and Figure 5 as single data points, and summarized in Table 1 as mean values. An exemplary load vs. displacement curve is shown in Figure 6. A pronounced size-dependency in the shear-strengths across the different series CL (0.55 N/mm^2), CM (1.32 N/mm^2), and CS (2.22 N/mm^2) can be observed. However, these reported bondline shear strengths do not necessarily reflect the shear strength of the adhesive bond itself. As shown in Figure 7, the failure modes for the C-series (CL, CM, and CS) could be characterized as cohesive shear failure of the concrete near the bondline. For the same series, the connection stiffness shows no size-dependency, but instead, a very high scattering, as standard deviations surpass or are in the range of the mean values, see Table 1. Across all wet-process adhesive-bonded series, a mean value of 1.36 ± 0.72 N/mm^2 for the bondline strength at the moment of concrete cohesive failure at the bondline, and a mean value of 1'182 ± 1'469 kN/mm for the bondline connection stiffness can be reported.

The directly-bonded polymer concrete P-series (PM and PS) showed much better performances of the bondline, with overall mean values of 12.24 ± 3.34 N/mm^2 and 19'235 ± 25'202 kN/mm for the stress acting on the bondline at the moment of failure, and the bondline connection stiffness, respectively. Here, two failure modes were exclusively observed: Tensile-shear failure of polymer concrete and subsequent shear failure of timber, see Figure 7d. No size-dependency of the shear strengths is visible from the four tested specimens. However, an even higher standard deviation than for the adhesive-bonded specimens is reported for the bondline connection stiffness.

4 DISCUSSION

From the exemplary load displacement curves obtained by the three different methods (machine, LVDT, and DIC displacements) as shown in Figure 6, it can be seen that the measured DIC fields can be validated well by the LVDT measurements in regions of higher loads, after the curves are horizontally shifted to match at F_{max}. Therefore, justifying the use of DIC in order to calculate bondline stiffness values K. It can also be seen, that there is a pronounced stiffness difference between the three displacement-recording techniques, showing that both machine and LVDT displacements appear too compliant in comparison to DIC displacements, until ~70% of the maximal load.

Exemplary DIC fields are shown in Figure 8 for a specimen of series CS. From this data, it is clearly visible that for the C-series, a distinct bondline behaviour can be identified: The vertical displacements shown in Figure 8a differ significantly between concrete and timber, meaning that deformation happens primarily at the bondline. This is supported by the shear strains shown in Figure 8c, and in turn, supports the determination attempt of a bondline connection stiffness K in the case of wet-process adhesively-bonded pushout specimens, as presented in Table 1.

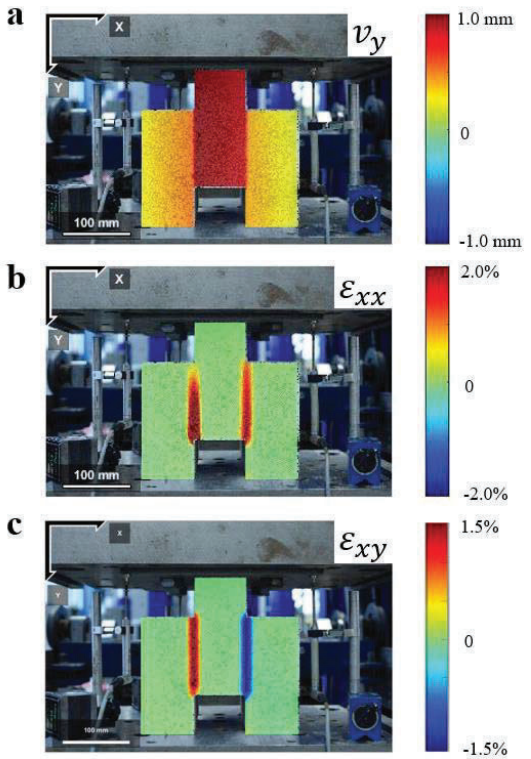

Figure 8: *Exemplary DIC analysis of a specimen of series CS at a force value close to failure of $F \approx F_{max}$ (133 kN).* ***a****: Vertical deformations (v_y), used for determination of bondline connection stiffness K.* ***b****: Horizontal strains (ε_{xx}).* ***c****: Shear strains (ε_{xy}).*

The observed size-dependency in the bondline shear strength may have been influenced by the superposition and interrelations of the following stresses acting at the bondline:

- Stresses induced by concrete shrinkage during hardening,
- possible stresses induced by timber swelling or shrinkage, caused by influences of the concrete water during hardening and subsequent testing hall climate,
- tensile stresses induced by the moment of eccentricity due to the load path inherent to the double-shear push-out setup ($\sigma_{ecc.} \propto b_t / l_v^2$, where b_t is the in-plane width of the timber side parts, and l_v is the shearing length).

These stresses tend to induce undesirable peeling stresses on the bondline, negatively influencing the obtained shear strengths. In addition, the fact these stresses, together with the main shear stresses from the vertical load, are typically shear-lag distributed over their respective shearing lengths, certainly affected the obtained values. In fact, size effects, supposedly stemming from such influences, are a well know phenomenon in testing of structural adhesives [18]. In standards where shear testing of adhesive bondlines with variable possible specimen sizes is possible, e.g. as in annex D of EN 14080 [19], corrections factors of shear strength are recommended for size deviations with respect to a reference size. However, in the present study and within its intents, it is not clear what specimen size could be considered as a suitable reference size.

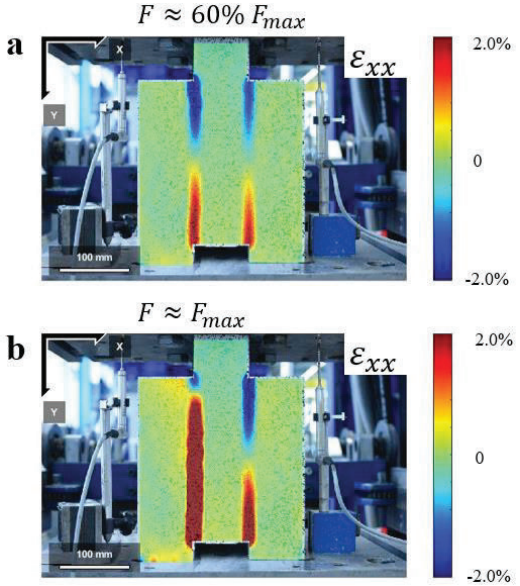

Figure 9: *Example of obtained horizontal strain (ε_{xx}) evolution for a specimen of series CL at two different load levels.* ***a****: At a force of $F \approx 60\% F_{max}$ (30 kN).* ***b****: At a force close to failure $F \approx F_{max}$ (51 kN).*

Moreover, additional influences such as friction at the bottom of the side timber parts between wood and metal plate, as well as slight but possible unevenness of the timber side parts may also have, and even to a greater extent, influenced the results. An example is shown in Figure 9: Here, the horizontal strain evolution at the bondline is shown for a specimen of series CL. While still

https://doi.org/10.52202/069179-0422

symmetrical at the lower load level, the horizontal strain is not symmetrical anymore across the two bondlines at the higher load level close to failure. In contrast, this behaviour could not be observed in the case of the CS specimen shown in Figure 8b. It is to be expected, that the horizontal stresses at the bondline highly affect the bondline performance, as e.g. they may directly reflect the amount of perpendicular tensile stress acting at the bondline. A symmetrical behaviour would a priori result in a better bondline performance.

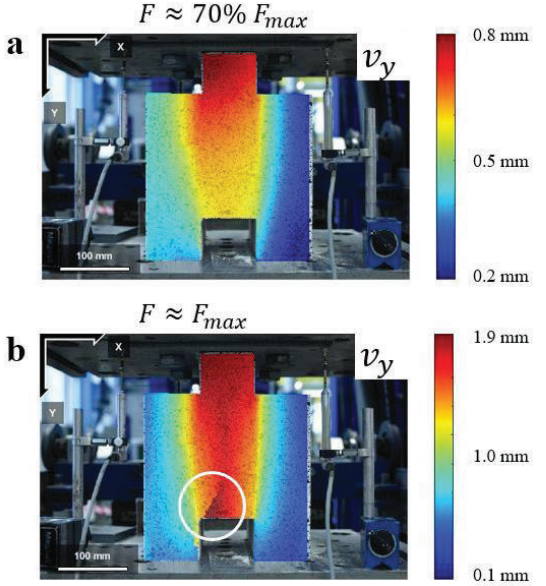

Figure 10: *Example of obtained vertical deformation (v_y) evolution for a specimen of series PM at two different load levels used for determination of bondline connection stiffness K.* ***a****: At a force of $F \approx 70\% F_{max}$ (890 kN).* ***b****: At a force close to failure $F \approx F_{max}$ (1230 kN), white circle shows polymer concrete tensile-shear failure.*

Furthermore, an additional aspect with high potential impact is the production process of the specimens. As can be seen in studies at small scale [20,21], slight variability in adhesive pot or open time, or concrete mixture (e.g. water to cement ratio), may influence measured values. A hint towards the latter influence can be seen in the shear failure surfaces shown in Figure 7. A rather smooth shear failure was consistently observed for the samples CL, while more rough surfaces were observed for the series CM and CS, which cannot be explained otherwise. Herewith, the series CS, with the highest bondline strength, displayed the roughest surface, where the roughness appears to be characterized by the size of the concrete aggregates. It should also be noted, that in particular for a brittle material such as concrete, the concept of pure shear failure can be questioned, as the shear strength (or as in this case a cohesive shear strength at the bondline) is not the result of a pure shear stress state, but always involves tensile stresses. Therefore, the strength values provided in Table 1 should be interpreted accordingly, meaning that the shear strength of the adhesive connection itself could in theory be higher. The reported values rather represent the acting shear stresses in the bondline at the moment of cohesive concrete failure, which is, as said above, to be considered specific for this pushout tests situation. Therefore, the problematics and relevance of the observed size effect for design can safely be relativized.

From a bondline strength perspective, the P-series proved to significantly outperform the adhesive bond of the C-series. This is explained by the fact that polymer concrete, in contrast to cement-based concrete, possesses a rather high tensile (cohesive) strength. The herein reported overall mean value for the push-out strength of 12.24 N/mm^2, at the moment of polymer concrete failure, is slightly higher than comparable polymer concrete alternatives bonded to softwood and tested in a push-out manner [22,23].

While the high variability obtained for the bondline connection stiffness of the C-series can be attributed, as the variability in bondline strength, to the overall variability of load-deformation behaviour (caused by the above mentioned effects), this is not entirely the case for the P-series. Here, as can be seen from the vertical deformation exemplarily shown in Figure 10 for a PM specimen, a distinctive bondline deformation behaviour cannot be identified. Instead, the whole interface region appears to deform continuously, as the vertical deformations happen in the timber and in the polymer concrete. Therefore, the bondline stiffness values of Table 1 for PM and PS do not possess any physical meaning, and for design, $\gamma = 1$ can be assumed straightforwardly. Note that this is also the case for the wet-process adhesive-bonded C-series, since for most specimens $K \gtrsim 1'000$ kN/mm. However, and in contrast, the physical meaning of K can be supported by the DIC fields shown in Figure 8a.

Finally, while pushout tests assessed by DIC were certainly insightful in these cases of continuous rigid connections, they proved to produce values that are difficult to be fully understood and interpreted. Therefore, alternative or additional testing methods, e.g. bending tests, can be recommended in order to characterize adhesive bonds for TCC elements.

5 CONCLUSIONS

The study showed that in the case of adhesive-bonded TCC connections produced in wet process, results of push-out tests need to be interpreted and used with caution. Shear strengths were found to be strongly size-dependent, and do not directly reflect adhesion strength, but rather cohesive strength of concrete at the bondline. Furthermore, and even though DIC proved to be a powerful characterization tool, a reliable derivation of connection stiffness K was hardly possible. However, for most specimens, $K \gtrsim 1'000$ kN/mm could still be reported, justifying the prevalent assumption of $\gamma = 1$ in the case of a continuous adhesively-bonded TCC connection. Finally, an alternative to the classical adhesive bonding of cement-based concrete to beech wood was demonstrated in the form of directly-bonding polymer concrete. Here, pushout tests showed a far superior performance of the bondline compared to wet-process glued cement-based concrete.

ACKNOWLEDEGEMTS

We sincerely thank Thomas Schnider for the preparation of the casting formwork and Dominik Werne and Pius Herzog for help with the testing setup. Furthermore, we would like to express our gratitude to the further involved project partners from *Fagus Suisse SA* and *Sika Technology AG*. This project was funded by *Innosuisse - Swiss Innovation Agency* (37233.1 IP-ENG *'Verklebter Holz-Beton-Verbund - Mit Buchenholz und Polymerbeton zu innovativen Lösungen'*).

SEISMIC FRAGILITY OF A NEW MASS TIMBER-STEEL HYBRID BUILDING SYSTEM EQUIPPED WITH CLT FLOOR DIAPHRAGMS

Chaoyue Zhang[1], Cristiano Loss[2]

ABSTRACT: An essential step in analysing a Seismic Force-Resisting System (SFRS) is to ascertain how lateral loads distribute within the structure in-between horizontal systems, such as roof and floor diaphragms, and vertical members, such as shear walls and bracings. Clear identification of load paths requires a proper assessment of the in-plane stiffness of floor diaphragms. Nevertheless, in the context of designing SFRS with diaphragms made of wood, neither comprehensive code provisions nor accurate computational methods exist to account for its in-plane flexibility. This shortage of knowledge becomes even more obvious if compared to the common reinforced concrete flooring systems. To investigate influences of the actual in-plane stiffness of diaphragms on the global response of the SFRS, this research performs incremental dynamic analysis (IDA) on a new mass timber-steel hybrid building system via the OpenSees platform and compares its collapse fragility to that of an ideal building model with rigid diaphragms. The SFRS of hybrid building entails concentrically X-braced steel frames, whose nonlinear responses are explicitly simulated, including global buckling, tensile yielding, and post-buckling behaviours. Overall, the fragility analysis concluded that the adoption of the proposed hybrid floor system, with the reinforcement of panel-to-panel connections that contributes to sufficient in-plane stiffness, can facilitate a comparable seismic performance as the building with the fully rigid diaphragm.

KEYWORDS: Mass timber-steel hybrid building, In-plane diaphragm flexibility, IDA, OpenSees modelling

1 INTRODUCTION

1.1 HYBRID MASS TIMBER CONSTRUCTION

Hybrid mass timber construction refers to structural assemblies that combine engineered wood products, such as cross-laminated timber (CLT), with concrete and/or steel. By leveraging the prefabrication method, massive production off-site and speedy assembly on-site of large timber members can be readily attained. With previous research mostly focusing on the lateral behaviour of CLT shear walls and bracing systems, attention is shifting to high-performance earthquake-resistant systems equipped with CLT floor diaphragms.

1.2 IN-PLANE DIAPHRAGM FLEXIBILITY

Floor diaphragms are designed to resist gravity loads and transmit lateral loads to adjoining vertical members of the Seismic Force-Resisting System (SFRS). As a convention in seismic design, rigid diaphragms distribute applied lateral shear forces by the relative rigidity of the SFRS, whereas flexible diaphragms distribute forces based on tributary area. Consequently, to properly assess diaphragm flexibility is imperative to quantify the lateral force demands and, as such, produce economic proportion and sizing of structural members of an SFRS. In terms of the dynamic response, the diaphragm's flexibility plays a pivotal role in affecting the global dynamic behaviour of buildings as well as the local distribution of inertia forces, shears, and bending moments along the edges of the diaphragm [1]. However, most building codes lack the criteria for specifying the actual in-plane stiffness of wood and mass timber diaphragms by explicitly specifying reduction factors used for seismic design. Practitioners must confront inevitable challenges when attempting to incorporate mass timber floor assemblies into a high-performance hybrid building system.

2 HYBRID TIMBER-STEEL BUILDING

2.1 DESCRIPTION OF THE BUILDING

Figure 1 shows the architectural view of the 4-story timber-steel building prototype that entails a Special Concentrically Braced Frame (SCBF) with repeatable modules of innovative CLT-steel floor diaphragms.

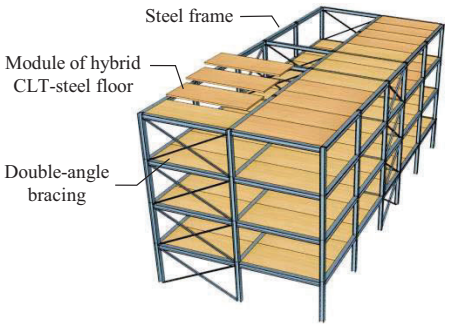

Figure 1: *Mass timber-steel hybrid building archetype*

[1] Chaoyue Zhang, Sustainable Engineered Structural Solutions Laboratory, The University of British Columbia, Canada, chaoyuez@mail.ubc.ca

[2] Cristiano Loss, Sustainable Engineered Structural Solutions Laboratory, The University of British Columbia, Canada, cristiano.loss@ubc.ca

https://doi.org/10.52202/069179-0423

The building has a 28.5 m long by 12 m wide footprint, with a 3.2 m inter-story height. Structural novelties of the hybrid floor modules are attributed to the composite action engaged between the CLT panels and steel beams. From the structural perspective, the high strength-to-weight ratio of CLT panels can impart the overall hybrid system with sufficient in-plane stability when subjected to horizontal forces. When subjected to severe earthquake excitations, the lightness of mass timber-based floors can effectively reduce the demands of the induced inertia forces acting upon each story.

2.2 DESIGN CONSIDERATIONS

The proposed CLT-steel hybrid building archetype was designed for residential usage, and located in Bucchianico, Chieti, Italy [2]. For the gravity design, a specified dead load (G_2) of 3 kN/m^2 plus a live load (Q) of 2 kN/m^{2}was adopted, factored by 0.3 (Ψ_2) according to the load combination parameters defined in the Italian Building Code [3] for multi-story residential buildings. The estimated total gravity load for stories 1 to 3 was 3.6 kN/m^2; the total gravity load for story 4 was 3 kN/m^2. The seismic design of the hybrid building followed the equivalent linear elastic force procedure of Eurocode 8 [4] with reference to "other" structure types. The design response spectrum was drawn given the soil class type C, typographical category type "t1", and a building life span of 50 years. The code-based fundamental period of the building was estimated at 0.34 seconds, based on the total height of the superstructure. Considering the local seismic hazard having a 10% probability of exceedance, corresponding to the life safety performance level defined in Eurocode (2004), the design base shear force for the 4-story building archetype was calculated as 1200 kN after applying a reduction factor *q* of 4 to account for system overstrength and ductility of typical braced steel frame structures.

Table 1: Selection of steel elements

Elements	Sections	Steel
Beams	IPE 360	S355
	IPE 300	S355
	IPE 220	S275
Columns	HEB 220	S275
	HEB 300	S275
	HEB 280	S275
	HEB 220	S275
Braces	2L 110X70X12	S275
	2L 100X65X10	S275
	2L 60X60X8	S275

The steel structs, including beams, girders, columns, and braces, of the SCBF employed parallel flange I-shaped (IPE), wide flange H-shaped (HEB), and L-formed hot rolled profiles with steel in S275 and S355 strength class [4], respectively. Table 1 lists the selected cross sections and materials of beams, columns, and braces. Notice that a stockier section (2L 110X70X12) is used for braces at the first and second story considering potential greater demands of seismic force and deformation at the lower stories during earthquake ground shakings. The SFRS of the four-story building adopted dissipative SCBFs, with steel struts and connections sized and detailed to enforce major inelastic deformation of bracing diagonals and maintain elastic deformation of beams and columns. Properly capacity-designed SFRSs provide the building with outstanding lateral strength and stiffness. Considering large and infrequent seismic events, the compressive buckling and yielding tensile behaviour of the bracing elements can offer incredible ductile deformability to accommodate the induced large inelastic drift demands and assure the satisfaction of intended performance levels. The beam-to-column joints of the unbraced frame consisted of shear tabs, while the beam-to-column-brace joints of the braced frame were reinforced by welding gusset plates.

2.3 HYBRID CLT-STEEL FLOOR DIAPHRAGMS

Figure 2 details the key components of the innovative hybrid CLT-steel floor module, which can be demounted into two main parts: the CLT panel and two customized cold-formed U-shaped beams. The 85 mm thick CLT panel of one floor module is 2.4 m in width and 5.83 m in length. Two U-shaped steel beams that attach to the CLT panel are 5.815 m long and are manufactured by 4 mm thick S355 steel sheets [4]. Moreover, the four 140 mm wide perforated steel plates at each end of the U-shaped beam are bounded to the CLT panel by pouring an epoxy-based resin into precut slots (A-A). In the middle section of the U-shape beam (B-B), 80 mm long full-threaded self-tapping screws (STSs) are driven into predrilled holes at a spacing of 500 mm to connect with the panel.

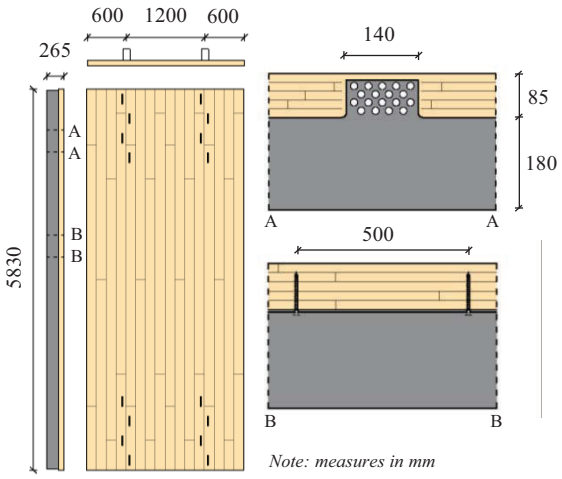

Figure 2: *Hybrid CLT-steel floor diaphragm module*

Each prefabricated hybrid floor module is installed into the braced steel frames by bolting special steel links to the ends of the U-shaped beams. Figure 3a shows the configuration of the beam-to-beam special links. Multiple pairs of STSs oriented at the designated angle, as shown

https://doi.org/10.52202/069179-0423

in Figure 3b, are used to fasten the edges of the CLT panels in order to create a continuous slab. Application of those special steel links between the steel frame and hybrid floor modules not only accommodates potential structural misalignment or imperfections but also allows for rapid replacement of any damaged components after major earthquake events. Furthermore, the prefabricated floor modules can greatly accelerate on-site assembly and, as such, effectively save total fabrication time and labour costs. Large-scale implementation of the proposed hybrid system can conceivably leverage most prefabrication techniques.

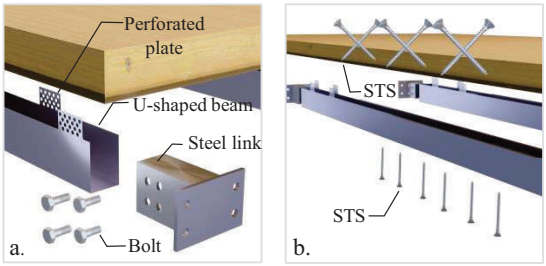

Figure 3: *Beam-to-beam and panel-to-panel connections*

3 NUMERICAL INVESTIGATION

3.1 MODEL OF FLOOR DIAPHRAGM

Finite-element (FE) sub-modelling approach aims to reproduce the in-plane shear stiffness and failure mechanisms recorded in the full-scale experiment of the hybrid CLT-steel floor diaphragm performed by [5]. Figure 4 shows features of the constructed test specimen assembled by staggering the hybrid prefabricated CLT-steel floor modules. The dimensions of the specimen were 6 m in width and 12 m in length. The location of the applied in-plane shear load, *F*, is also annotated in Figure 4. To highlight the contributions of the panel-to-panel connections to the in-plane shear stiffness of the diaphragm, to tests were performed on the same floor specimen by installing and removing the STSs at the edges of the CLT panels.

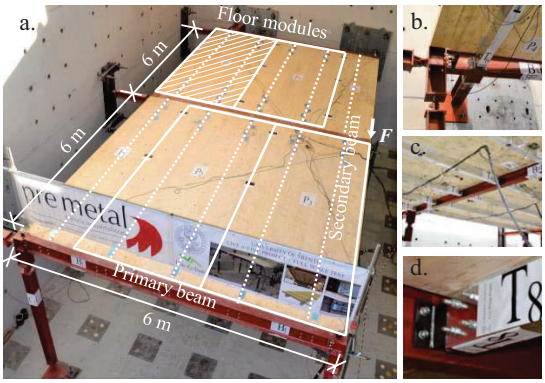

Figure 4: *Floor subassembly of the full-scale in-plane test*

3.1.1 Component modelling

It has been shown that the ductile and dissipative behaviour of the connections governs the performance of the tested hybrid steel-timber floor diaphragm. No damage in the 5-layer CLT panels was observed after each of the three in-plane shear tests performed. In OpenSees [6], CLT is thus modelled by the *ShellMIT4* element with the *PlateFiber* section and *ElasticOrthotropic* material. According to Loss and Frangi [5], the observed deterioration mechanism demonstrated superior composite actions between timber and steel elements together with weak component joints. Significant ductile deformation was found to concentrate at the beam-to-beam connections. The local shear-tension breakage of the bolts that fastened the outstanding flanges of the steel link outlined the ultimate failure point of the floor system. To replicate the distinctive nonlinear behaviour of the beam-to-beam connection, the numerical representation of the steel link consists of four parts linked in series: (i) a *ZeroLength* element that represents the bolt contact gap, (ii) a short hollow tube that slots in the U-shaped beam, (iii) outstanding flanges that are welded to the hollow tube, and (iv) bolts connected to the primary beam, as shown in Figure 5b. Both the steel tube with hollow section and the flange segment with rectangular section are modelled by the *forceBeamColumn* element with discretized fibre section and *Steel02* material. The two ends of the flange are connected to the primary beam by two nonlinear axial springs using the *ZeroLength* element. Figure 5a illustrates the boundary restraints of the floor subassembly, which are modelled as rollers with translative DOFs constrained only.

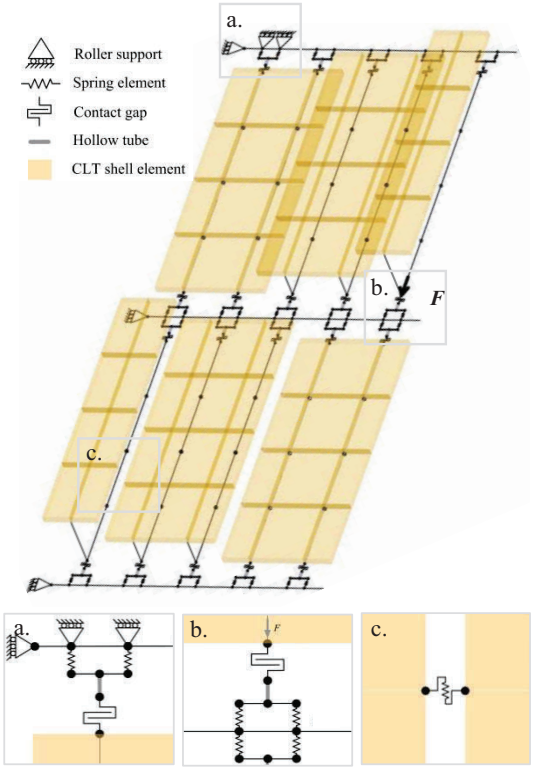

Figure 5: *OpenSees model of the hybrid floor subassembly*

In addition, under seismic actions, the induced in-plane shear transferred between CLT panels could place significant slip demands on the STSs. Datasets retrieved from cyclic tests of panel-to-panel STS connections performed by Loss et al. [7] were used to represent their hysteretic behaviour. In OpenSees, the *Pinching4* material was used to simulate the strength and stiffness degradation of the pane-to-panel connections in the in-plane shear direction.

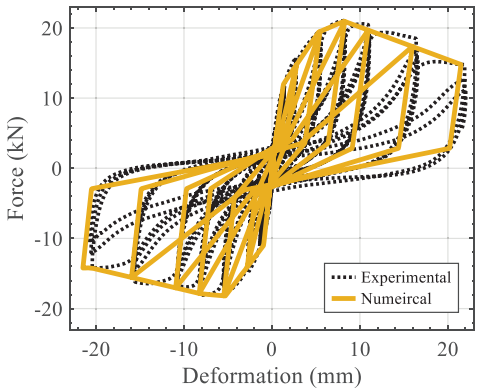

Figure 6: *Calibrated behavior of panel-to-panel connections*

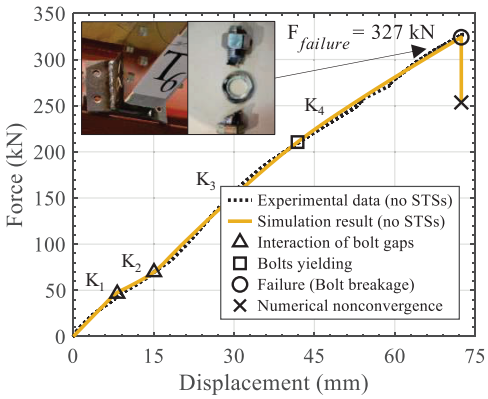

Figure 7: Validated response of floor model without STSs

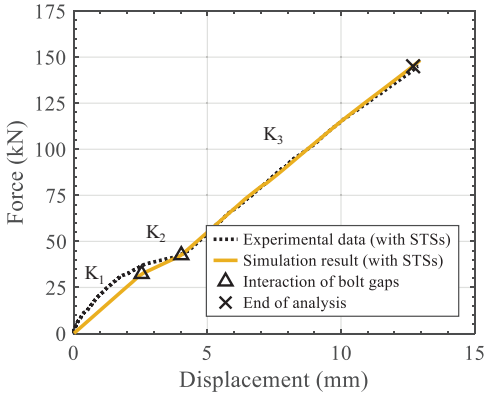

Figure 8: Validated response of floor model with STSs

Figure 6 shows the calibrated hysteretic response of the STS, which is characterized by a severe loss in stiffness in reloading. Such known pinching behaviour is not uncommon for steel mechanical connectors embedded in timber due to the crushing the wood fibers underneath the connector surface. Consequently, the calibrated material was assigned to the nonlinear translational spring using a *ZeroLength* element, as shown in Figure 5c. For simulating the test specimen without the panel-to-panel connections, the physical contact between panels was idealized by embedding the *ElasticPPGap* material into the *ZeroLength* element. High compressive stiffness and strength with zero tensile resistance were added to the material to prevent mutual penetration of CLT shell elements.

3.1.2 Model validation

Model validation of the CLT-steel hybrid floor diaphragm subassembly was accomplished by simulating T_2 and T_3 in-plane shear tests published in [5]. For the specimen subjected to a destructive monotonic test (T_3), the CLT panels were not tied together with STSs. Figure 7 plots the well-matched simulated results of the numerical model versus the experimental data, with a maximum error of about 13% in values in terms of in-plane stiffness K_2. The initial drop of stiffness, from K_1 to K_2, when displacement reaches about 7 mm, is attributed to the interaction of bolt-hole gaps between the hollow steel tube and the U-shaped beam. After the gap is closed, the in-plane stiffness restores to the initial level before the beam-to-beam connections bolts yield, which signifies a further small reduction of the overall shear stiffness. When the applied in-plane load increases up to approximately 327 kN, the deformation of the beam-to-beam connections reaches the maximum, which results in the breakage of bolts under combined effects of shear and tension, as annotated by the detached flange in Figure 7. In the numerical model, only the axial tensile resistance of the bolt is considered, and its ultimate capacity is ascertained by calibrating to the test result by warping *Steel02* material with *fatigue* material, which can trigger failure based on a predefined maximum deformation.

Figure 8 shows the simulation results of T_2 test, including the panel-to-panel connections. The simulated K_1 and K_2 have a relatively large deviation from the measured in-plane stiffness with a maximum error beyond 30%. It should be noted that the results of the original cyclic test program (T_2) published in [5] did not display a distinctive hysteretic or deteriorated response as for the in-plane shear force and displacement relationship. A marginal reduction in stiffness occurred during the unloading phase with a maximum relative residual deformation equal to 2 mm only. This slight offset from the original position was mostly due to the friction between the steel-to-steel surfaces of the beam-to-beam connections. No degradation of stiffness and strength was observed during the reloading phase. Therefore, the numerical model of the hybrid floor subassembly, inclusive of the panel-to-panel connections, was shown to capture the overall behaviour of the system and its members.

https://doi.org/10.52202/069179-0423

3.2 MODEL OF STEEL FRAME

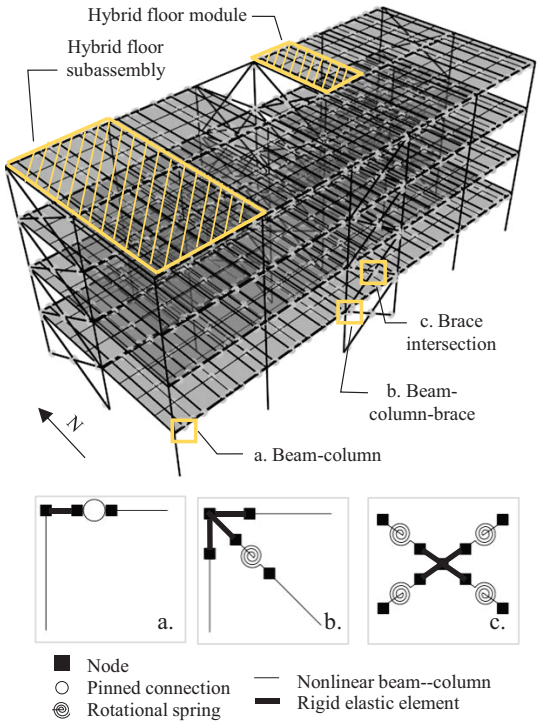

Figure 9: *OpenSees model of the hybrid building archetype*

To accurately predict the building's seismic performance throughout varying limit states, a reliable FE model should explicitly capture critical nonlinear deterioration modes and failure mechanisms of structural components. Numerical models of steel structs of the braced frame implemented in this paper, such as brace, beam, and column, take advantage of the state-of-art nonlinear frame elements in OpenSees [8]. Such frame element was created to explicitly simulate the nonlinear material response due to the post-yielding behaviours of the steel members, such as strain hardening. Being a fibre-type model, it applies the distributed plasticity theorem through numerical integrations of stress resultants over discretized sections along the member length.

3.2.1 Component modelling

Characteristic deterioration modes of braces include buckling in compression, yielding in tension, and post-buckling behaviour. In this work, multiple *forceBeamColumn* elements with finely meshed fibre cross sections were used to produce those highly nonlinear responses, as suggested by Uriz and Mahin [9]. This verified method applies to a range of cross-section shapes of braces, such as hollow circular, hollow square, I wide flange, and double angles. To account for geometric nonlinearities when brace buckles with substantial axial deformation under compression, the *forceBeamColumn* elements were assigned with *Corotational* transformation with exact nonlinear transformation of element displacement and forces between the global and local coordinate systems [10].

Large rotational and axial forces concentrated in bracing members also attract great nonlinearities to their adjacent components. Hsiao et al. [11] indicated that local yielding in beams and columns was significant based on previous experiments. To simulate the nonlinear behaviour of the beams and columns, the *dispBeamColumn* element was used.

Connections between beams and columns of unbraced bays were designed using shear tabs. The actual bending stiffness of shear tab connections along the strong axis of beams does not evidently contribute to the moment resistance of beam-to-column joints. Hence, it was simplified as a pin connection plus a short-length element equal to the half depth of the column, as shown in Figure 9a. The idealized pin connection was modelled by implementing the *EqualDOF* constraint with the designated rotational degree-of-freedom (DOF) released. For the braced bays, the presence of gusset plates provides additional reinforcement to the beam-to-column connection and, meanwhile, serves as the critical boundary condition for the brace. Yoo [12] suggested that the out-of-plane rotational stiffness of the gusset plate plays an important role in affecting brace buckling and post-bulking behaviours, given the considerable rotation demands. Therefore, the analytical model proposed by Hsiao et al. [11] was adopted, which is characterized by a combination of a nonlinear rotational spring located at the physical end of the brace and several rigid elements that represent regional enhanced stiffness, as shown in Figure 9b. Figure 9c shows the center part where four brace diagonals are connected by the gusset plate. The FE model adopts a similar approach by linking four nonlinear rotational springs with rigid elements intersecting at the centroid of the middle gusset plate.

3.2.2 Model validation

Validation of the numerical model of the double-angle L-shaped bracing strut intends to reproduce the hysteretic performance of specimen strut 8 tested under cyclic loading by Black et al. [13]. The simulated hysteretic response of the brace against the experimental data is presented in Figure 10. Considerable deterioration of strength and stiffness under compression is shown if compared to the stable performance in tension.

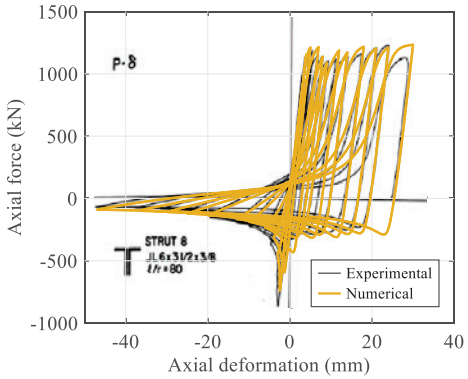

Figure 10: Validated hysteretic response of double-angle brace

https://doi.org/10.52202/069179-0423

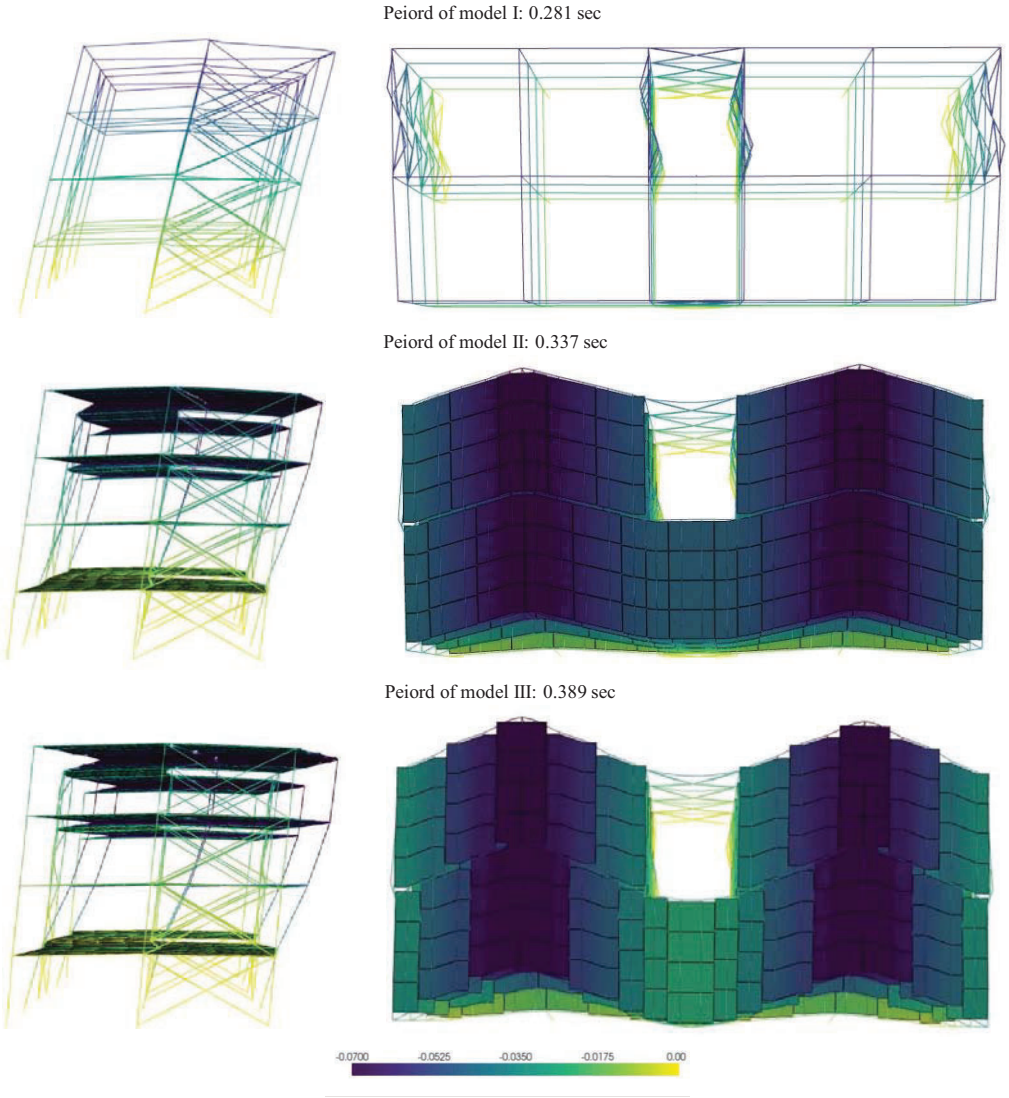

Figure 11: Mode shape 2 (translation in the south-north direction) of three building models

Three FE models of the building were analyzed. The building model with fully rigid floor diaphragms is denoted as Model I. With the hybrid CLT-steel floor system and panel-to-panel connections the building model is denoted as Model II. The companion model without the panel-to-panel connections is denoted as Model III.

4 MODAL RESPONSE

Table 2: Periods (sec) of first three mode shapes

Model	Mode 1	Mode 2	Mode 3
I	0.408	0.281	0.242
II	0.454	0.337	0.312
III	0.571	0.389	0.384

Modal analysis was conducted to calculate periods of the first three mode shapes: horizontal translation in the east-west direction, horizontal translation in the south-north direction, and torsion, as shown in Table 2. Figure 11 depicts the translational mode shape 2 of three building models. Specifically, the first two periods of Model II are both about 0.05 s longer than those of Model I. In case of hybrid CLT diaphragms without the panel-to-panel STS connections, the model has 40% higher periods, if compared to Model I, regarding the two translational mode shapes. For torsion, Model III has a period of 0.384 s and that is approximately 60% higher than that of Model I. It can be noted that the reinforcement of STSs between CLT panels conspicuously reduces the overall in-plane flexibility of diaphragms. Besides, the lack of restraints between CLT panels underpins the aggregated behaviour of in-plane shear deformation and rotation of individual

https://doi.org/10.52202/069179-0423

hybrid floor modules, which conceivably elongates the translational and torsional periods of the building archetype.

5 FRAGILITY ANALYSES

To retrieve a comprehensive evaluation of the seismic performance of different building models through IDA, a total of 20 ground motion records were selected from the Pacific Earthquake Engineering Research Center Shallow Crustal Earthquakes database [14], scaled to a minimum mean square error with respect to the target spectrum over a period range from 0 seconds to 2.5 seconds, which is determined by the period of dominance according to the local disaggregation results retrieved from the software REXEL [15] for site Bucchianico, Chieti, Italy. Figure 12 plots the uniform hazard spectrum, which corresponds to a hazard level of 10% probability of occurrence in 50 years, and the selected records.

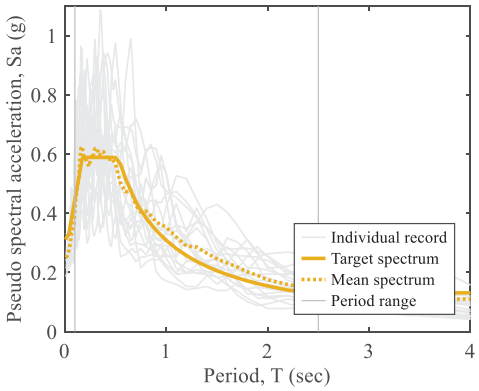

***Figure 12**: Target response spectrum and selected records*

Three damage states (DSs) are of interest when evaluating their exceeding likelihoods given a certain level of ground shaking intensity, as expressed by a cumulative distribution function and plotted by a fragility curve. Particularly, DS1 identifies the transition point between the model's elastic behaviour and the first nonlinearity. DS2 refers to a 2% maximum inter-story drift ratio (ISD), which is associated with the collapse prevention performance level for braced steel frames specified in FEMA 356 [16]. In addition, DS3 is determined by either the simulated collapse point, where a single IDA curve reaches a plateau due to deteriorating mechanisms or the last converged time-integration step.

Figure 13 shows the probability of exceeding different DSs as a function of the intensity measure (IM), which is represented by the 5%-damped spectral acceleration at the structure's fundamental period Sa (T_1, 5%).

By comparing three fractiles of IM, Model II has the highest spectral acceleration to exceed DS1. To be specific, 16% of records need to reach Sa $\geq$ 0.95g, 50% of records need to reach Sa $\geq$ 1.27g, and 84% of records need to reach Sa $\geq$ 1.70g. This suggests that implementation of the proposed hybrid CLT diaphragm enables the building to sustain a median intensity of ground motion up to approximately two times the intensity of the design uniform hazard (i.e., 0.59g), before any structural nonlinearity arises. The median Sa of Model II is 0.1g and 0.18g greater than those of Model I and III.

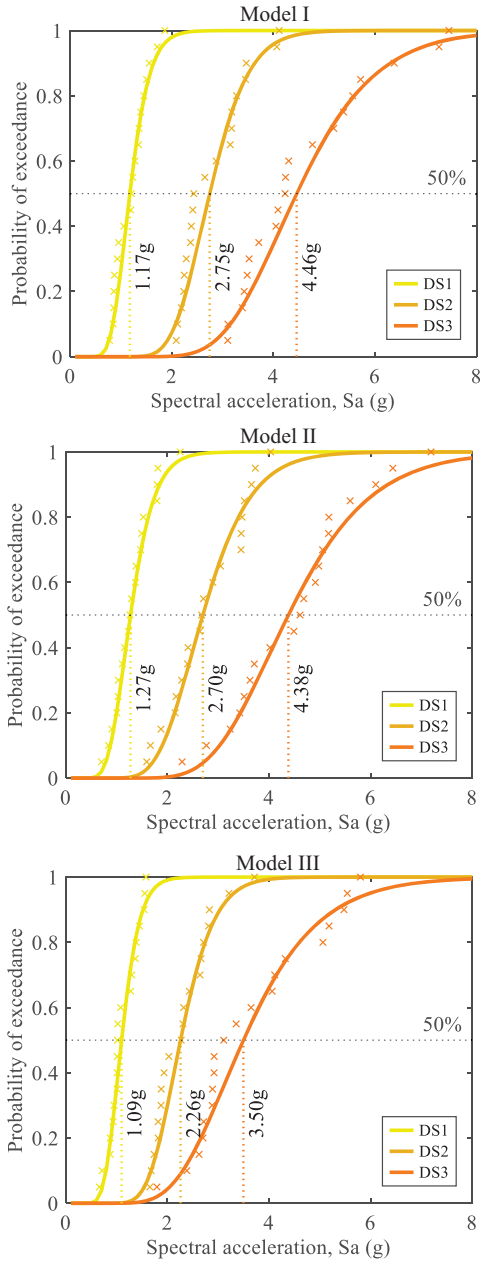

***Figure 13:** Fragility curves under three damage states*

In case of exceeding DS2, the 16% Sa capacity of Model I is approximately 8% and 23% higher than that of Models II and III. A trivial difference is observed in the median value between Model I and Model II. The intensity value at which 84% of the records need to be scaled to produce the demand δ = 2% is 3.54 g for Model II, which is significantly higher than the value of Model III, while

https://doi.org/10.52202/069179-0423

close to that of Model I. A similar trend was found concerning the global collapse limit state; and no major difference was observed in all three fractiles of IM between Models I and II. Compared to Model III, however, Model II has a 25% (i.e., 4.38 g) and 21% (i.e., 5.84 g) larger value at the 50% and 84% percentile, respectively. Consequently, it can be summarized that the required intensity for Model I and Model II to exceed DS2 and DS3 are comparatively similar; and that shaking level needs to be reduced by more than 20% for Model III to reach both DSs.

6 CONCLUSIONS

The seismic fragilities of an innovative mass timber-steel hybrid building archetype equipped with prefabricated CLT-steel composite floor diaphragms were presented. The 3D numerical model developed in OpenSees entailed critical nonlinearities primarily contributed by deteriorating behaviours of steel structs, such as the low cycle fatigue behaviour and section fracture mechanism of the bracing member. Particularly, the local failure modes were incorporated explicitly into the calibrated sub-models of the CLT-steel floor diaphragms, including the beam-to-beam connections. Building archetype assembled by the validated sub-models was subjected to the incremental dynamic analysis, assuming a suite of 20 ground motion records that were scaled up to the global collapse of the building. The building's seismic performance was assessed using fragility curves. Based on the probabilistic analysis results, it can be concluded that the overall seismic performance of Model II is comparatively similar to that of Model I in terms of the conditional probability of exceeding all three damage states, given any level of ground motion intensity. In the context of adopting the proposed CLT-steel floor diaphragm module, careful considerations should be placed on the panel-to-panel connections, as they are contributors to the overall in-plane stiffness of floor subassemblies.

STRUCTURAL BEHAVIOR OF TIMBER-STEEL-JOINTS WITH EITHER DOWEL-TYPE FASTENERS OR CONTINUOUS JOINTS

Simon Aurand[1], Jakob Boretzki[2], Peter Haase[2], Thomas Ummenhofer[2], Philipp Dietsch[1]

ABSTRACT: For the development of a new hybrid construction method combining the materials steel and timber for linear load-carrying elements subjected to bending loads, different joining methods were investigated. The joining methods were 1) dowel-type fasteners, partly in combination with higher friction in the shear plane and 2) continuous joints, mainly by bonding with adhesives. Tests were carried out to investigate the maximum load-carrying capacity as well as the stiffness of the joints, aiming to transfer the results to the linear load-carrying elements. Where applicable, nominal shear stresses were evaluated. The tests with dowel-type fasteners were mainly carried out to create reference values to compare to the other joining methods. The results with the modified surfaces to increase friction in the shear plane were quite promising regarding the initial stiffness, however, further research of the surface modification has to be carried out. The specimens with continuous joints can be regarded analytically as fully bonded. Bonded specimens with additional bolts combine high stiffness with a residual load-carrying capacity after shear failure of the timber of 30-40% of the maximum load.

KEYWORDS: timber-steel composite beams, dowel-type fasteners, adhesive bonding, continuous joints

1 INTRODUCTION

The results presented in this paper were determined as part of an ongoing research project. Its main objective is the development of a hybrid construction method by combining the materials steel and timber for linear load-carrying elements subjected to bending loads, similar to [1, 2]. The hybrid construction method is characterized by the shear-resistant embedment of a steel profile in a compact timber cross-section, see Figure 1. The bond between the steel profile and the timber cross-section is achieved either by dowel-type fasteners, by a continuous joint or by a combination of the two methods. In this way, the specific advantages of the two materials can be utilized in an optimized manner and the weaknesses of the materials can be compensated for by the composite partner. These hybrid members enable a significant increase in the possible spans, in comparison with conventional timber structures, as they result in a considerable increase in bending stiffness. All this while maintaining compact cross-sectional dimensions. In return, the timber profiles laterally support the thin steel profile and hence prevent its buckling failure. Also, the timber encapsulates and hence protects the steel profile in case of fire.

2 MATERIAL COMBINATIONS

By analytical investigation, suitable material pairings of timber and steel were identified, that are best utilized for different geometric configurations of the cross-section. In particular, a vertically embedded flat steel profile as well as two horizontally embedded profiles were investigated (see Figure 1). To calculate the degree of utilization of the two composite partners, a 4-point-bending test according to EN 408 [3] was chosen as static system. For simplification, full bond between the timber and steel was assumed, and that the cross-sections remain even. Characteristic values were applied in the investigation.

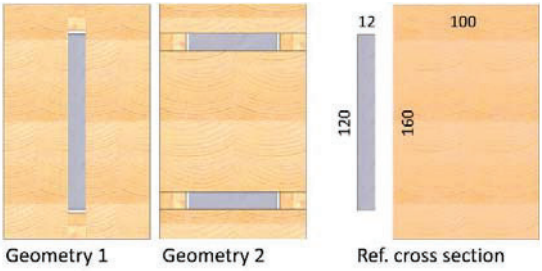

Figure 1: *Exemplary timber-steel hybrid cross-sections*

A variety of material combinations and cross-sections was analyzed. The investigation showed that for a low timber grade, a low steel grade is appropriate and high timber grades require high steel grades to realize equal degrees of utilization. Also, the availability of the used materials was considered. Based on the degree of utilization and the material's availability, two suitable pairings were chosen:

[1] Karlsruhe Institute of Technology (KIT), Timber Structures and Building Construction, Germany, mail: aurand@kit.edu, dietsch@kit.edu

[2] Karlsruhe Institute of Technology (KIT), Steel and Lightweight Structures, Germany, mail: jakob.boretzki@kit.edu, peter.haase@kit.edu, thomas.ummenhofer@kit.edu

https://doi.org/10.52202/069179-0424

First, commonly available glulam GL24h combined with normal steel S355, and second, common softwood LVL with only parallel layers (LVL48P according to [4]) combined with high-strength steel S460. For both combinations, the degree of utilization in both composite partners was nearly identical. For the combination GL24h+S355, the timber was decisive with a utilization of 100% compared to the steel with 93%. For the combination LVL48P+S460, the steel was decisive with a utilization of 100% compared to the timber with 92% (see Table 1).

Compared to the reference cross-section of only the timber part (100 x 160 mm²), the increase in stiffness of geometry 1 with one vertical steel profile was 87% for glulam and 72% for LVL. For geometry 2 with two horizontal steel profiles, the increase in stiffness was 213% for glulam and 176% for LVL (see Table 1). The decrease of deflection at mid-span, applying the same load level as the reference cross-section, was 47% for glulam and 42% for LVL for geometry 1 and 68% for glulam and 64% for LVL for geometry 2. The results for geometry 1 were also compared to a hypothetic cross-section consisting only of the vertical steel component (12 x 120 mm²), see Table 1. Buckling failure was excluded and not further considered for the analysis.

Table 1: *Exemplary results of analytical investigation*

Reference cross-section	Geometry 1		Geometry 2	
	GL24h + S355	LVL48P + S460	GL24h + S355	LVL48P + S460
	Degree of utilization

Steel:	-51%	-37%	-	-

3 JOINING METHODS AND THEIR MANUFACTURE

The studied joining methods can be categorized in two main groups:

- Dowel-type fasteners
- Continuous joints

3.1 Dowel-type fasteners

The idea behind the use of dowel-type fasteners was the wide availability of such fasteners and their ease-of-application. Especially self-tapping screws offer potential. Additionally, the possibility to increase the load-carrying capacity and especially the stiffness by modifying the steel surface was investigated.
Dowel-type fasteners commonly used in timber construction were chosen. All fasteners had a uniform outer diameter of 10 mm.

The following fasteners were investigated:

- Galvanized dowels for comparative tests
- Galvanized bolts with large washers (Ø = 50 mm)
- Partially threaded screws with a washer head (Ø = 22.5 mm) as well as a countersunk head (Ø = 17.0 mm)
- Fully threaded screws with a countersunk head (Ø = 18.5 mm)

The holes for the fasteners were drilled with a special twist drill, which allowed to drill through both materials, timber and steel without changing the drill bit. However, while drilling through the steel, the drill had to be constantly removed from the hole to allow for the clearing of the metal shavings. This resulted in a slightly greater hole diameter in one of the two side members, which was clearly noticeable when inserting the dowels, bolts, and screws. The fit of the fasteners was always tighter in the second timber side member. Also, the use of the timber-steel twist drill had the disadvantage of leaving one timber side member with a hole the size of the screws' outer diameter instead of the screws' shank diameter (for partially threaded screws) or the screws' core diameter (for fully threaded screws). This also resulted in a more loose fit of the fastener in one of the two side members. The second timber part of the specimens with screws was not pre-drilled for tests with GL24h. However, for tests with LVL48P, the second timber part was pre-drilled with 7 mm, according to their product specification [5, 6].

As mentioned before, the possibility of a surface modification in terms of higher friction in the shear plane was investigated. In [7], various surface modifications were studied, of which two surface modifications were tested in this project:

- Milled circular pattern
- Coated with quartz sand

The milling of the circular pattern into the steel surface was done by using a face mill with replaceable inserts, of which every second insert was removed. The rotational speed as well as the feed rate of the milling tool were both set quite high in order to achieve a rough circular pattern, as can be seen in Figure 2. To obtain a satisfying result, various pairings of rotational speed and feed rate were tested.

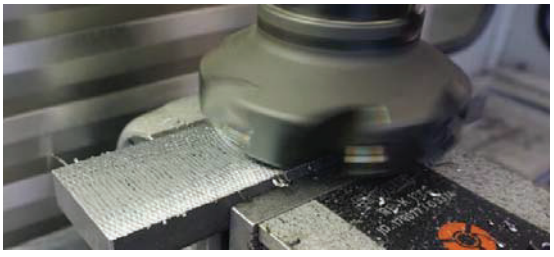

Figure 2: *Milling process of circular pattern*

https://doi.org/10.52202/069179-0424

For the coating of the steel with quartz sand a two component epoxy resin (2K EP [8]) was applied onto the steel surface. The surface was sandblasted and degreased with butanone. The adhesive layer had a thickness of ca. 0.5 mm and the quartz sand had a maximum grain size of 1 mm with about 90% of the grain size between 0.5-0.8 mm. The quartz sand was then pressed by hand into the resin and the resin cured according to the manufacturer's specification. Extracts from the manufacturing process and the final surface can be seen in Figure 3.

Figure 3: *Manufacturing process of coated specimens*

3.2 Continuous joints

The continuous joining was achieved by two different methods:

- Pressing in punched metal plate fasteners (nail plates)
- Adhesive bonding

The nail plates used consisted of 1 mm steel sheets with a nail length of 8.5 mm [9]. The nail plates were adhesively bonded to the steel surface, see Figure 4. Here, the same 2K EP was used as for the coated surface. Again, the steel and the nail plates were sandblasted and degreased before the adhesive was applied. The nail plates with the steel parts were then pressed into the timber parts. A pressing power of around 5 N/mm² was applied, partly exceeding the compressive strength perpendicular to the grain of the timber side members. This resulted in either deformed timber parts or only partially pressed-in nail plates. Therefore, the manufacturing order was changed and the nail plates were first pressed into the timber and afterwards the steel was bonded to the nail plates. Better results could also be achieved when placing the timber parts “edgewise”, i.e. pressing the nail plates in the side surface in multiple laminations/veneers.

Figure 4: *Bonding of nail plates to steel parts*

For the adhesive bonding of steel and timber, two different adhesives were chosen, a two component epoxy resin (2K EP [10]) and a two component polyurethane adhesive (2K PU [11]). For each combination, the respective pull-off adhesion strength was determined, see Figure 5 left. During these tests, a perpendicular force was applied to separate the bonded loading fixture from the surface. This easy and standardized test (e.g. [12]) allowed for a comparison of the adhesion properties of adhesives. Furthermore, different tools for their application were tested for both adhesives. Two requirements were pursued: an even and defined spread of the adhesive and a shape of the applied adhesive, which results in a preferably bubble-free adhesive layer. The best results were obtained with a notched spatula with 4 mm notches.

For the manufacturing of the composite test specimens, the steel parts were all sandblasted and cleaned with butanone before bonding. For the PU adhesive, a primer [13] had to be applied additionally. The timber parts were all planed directly before bonding. The bonding of the specimens was done in normal climate 20°C/65%rH.

All tests with continuous joints were performed with and without additional bolts. For the tests with additional bolts, the bolts were already used in the manufacturing process to apply the contact pressure.

A more detailed description of the selection of the adhesives and the manufacturing process of the adhesively bonded composite specimens is given in [14].

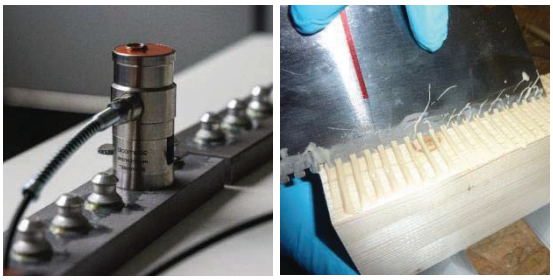

Figure 5: *Pull-off adhesion tests prior to final material selection (left) and spreading of adhesive with notched spatula (right)*

4 TESTS WITH STEEL-TIMBER JOINTS

4.1 TEST SETUP AND PROGRAM

Joint tests were performed to determine the joint properties. The test specimens were designed based on Johansen’s yield theory [15] with two shear planes for each fastener (see Figure 6). The timber parts were dimensioned in such a way, e.g. with an end distance $a_{3,t} = 7d = 70$ mm, that failure of the fasteners occurred with two plastic hinges per shear plane. The density of both timber side members was equal. An overview of the performed tests is given in Table 2. In total, 100 tests were performed of which an excerpt is presented in the following.

https://doi.org/10.52202/069179-0424

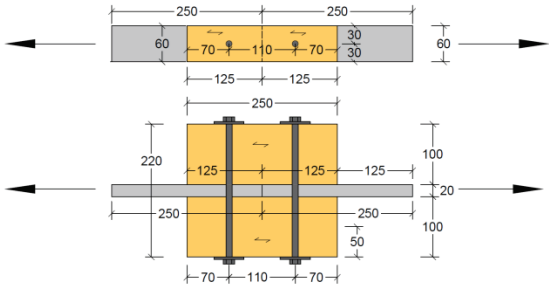

Figure 6: *Test specimens*

The joint tests were performed according to EN 26891 [16] with an unloading loop. Each test was stopped after failure of the specimen or after reaching a displacement of 15 mm in one of the shear planes. For all specimens and all shear planes, the relative displacement between the timber and the adjacent steel part was measured continuously. For this, a digital image correlation (DIC) system [17] was used, see Figure 7. The DIC system repeatedly took pictures of the test specimen with applied markers and the software calculated the displacement of the markers in each frame.

4.2 TEST RESULTS AND DISCUSSION

4.2.1 General

For each specimen, the maximum load F_{max} per shear plane was evaluated. The stiffness k_s was evaluated separately for all four shear planes in the range between 10-40% of F_{max}, unless otherwise stated. In order to take into account the influence of the manufacturing process as well as the surface treatment, the stiffness k_i was additionally evaluated in the range of 0-40% of F_{max}. On the one hand, the influence of the larger borehole diameter is shown for the test specimens with screws, and on the other hand, the influence of the surface treatment is taken into account for the test specimens with the roughened surfaces. The results for all tests with dowel-type fasteners are given in Table 3 and the exemplary load-displacement curves in Figure 10. For all tests with continuous joints, the results are given in Table 4 and exemplary load-displacement curves in Figure 14. The force F_{max} is the mean value of all three to five tests of one series per fastener and shear plane. The stiffness k_i and k_s is the mean value of all four shear planes and all tests of one series. For the specimens with continuous joints, a nominal shear stress f_v was evaluated. The shear stress was calculated with the mean value of F_{max} of all tests of one series and the generalized area of the shear plane, i.e. 60 mm x 125 mm less the hole diameter, for tests with fasteners. To better compare the different joining methods, the nominal shear stress was also evaluated for the specimens with dowel-type fasteners, although no shear failure occurred. The timber parts were stored at normal climate 20°C/65%rH and mean moisture contents of $u = 10\%$ for glulam and $u = 8.7\%$ for LVL were evaluated. The density of the glulam specimens varied between 388 and 488 kg/m³ and for LVL between 483 and 643 kg/m³ (see Table 3 and Table 4).

4.2.2 Tests with dowel-type fasteners

The reference tests with GL24h+S355 and dowels reached a mean load of 10.6±0.47 kN and a mean stiffness k_i of 3.97±1.16 kN/mm and with LVL48P+S460 a mean load of 14.9±0.33 kN and a mean stiffness k_i of 8.32±1.21 kN/mm. The stiffness k_s was evaluated between 20-50% of F_{max} and k_i between 0-50%. The specimens failed by splitting of one of the timber side members, before reaching a relative displacement of 15 mm in any of the four shear planes. The designed failure with two plastic hinges per shear plane was reached. However, for some dowels, the plastic hinges were barely visible. This leads to the assumption that the end distance $a_{3,t} = 7d = 70$ mm was not large enough.

The tests with bolts and large washers reached a mean load of 14.6±1.59 kN and a mean stiffness k_i of 5.85±1.65 kN/mm. The stiffness k_s was evaluated between 30-60% of F_{max} and k_i between 0-60%. Here, the two plastic hinges were clearly visible. Splitting of the timber occurred as well, however, did not result in a decrease of the load. Whereas the tests with dowels showed some initial slip, the tests with bolts and washer showed no slip at all because of the pre-stressing from tightening the nut. The slightly higher stiffness k_s of the dowel joints (see Table 3) might be due to the fact, that

https://doi.org/10.52202/069179-0424

the actual dowels' diameter was measured with $d = 10.0$ mm, while the bolts' actual diameter was only 9.4 mm, thus resulting in a tighter fit of the dowel joint.

The tests with bolts and modified surfaces both reached slightly higher results with $F_{max} = 17.1 \pm 0.60$ kN for the milled surface and 18.3±2.58 kN for the coated surface. The stiffness amounted to $k_i = 4.82 \pm 0.80$ and 5.80±1.06 kN/mm, respectively. For the tests with the milled surface, the stiffness k_s was evaluated between 40-60% of F_{max} and k_i between 0-60%. For the tests with the coated surface, the stiffness k_s was evaluated between 30-50% of F_{max} and k_i between 0-50%. The load-displacement curves showed a significantly higher initial stiffness, due to the increased friction between steel and timber. The tests with the milled surface remained in stick state up to almost one third of the total load, which is quite astonishing as there is almost no visible damage to the timber surface, as can be seen on the left in Figure 8. This was not the case for the tests with the coated surface, where large deformations were needed to properly press the quartz sand into the timber surface, which then led to high abrasion of timber fibers, as can be seen on the right in Figure 8. However, the tests showed that a surface modification in combination with laterally loaded fasteners is not as promising as in combination with mainly axially loaded fasteners, see [7].

Figure 8: *Milled surface with almost no abrasion and no damage to the timber surface (left) and coated surface with high abrasion of timber fibers (right)*

The tests with partially threaded screws reached the lowest loads with $F_{max} = 9.89 \pm 0.39$ kN for the screws with a countersunk head and 11.2±0.98 kN for the screws with a washer head. The stiffness was also quite low with $k_i = 1.27 \pm 0.10$ (countersunk head) and 1.29±0.15 kN/mm (washer head). The stiffness k_s was evaluated between 20-50% of F_{max} and k_i between 0-50%. The low results can be explained with the manufacturing process of the specimens, where a 10 mm hole was drilled through one timber side member and through the steel. So for the smooth shank to be in contact with the timber, approximately 1.5 mm displacement had to be reached first. This also resulted in the formation of only one plastic hinge per shear plane on the side of the shank, as can be seen in Figure 9.

The fully threaded screws performed better with a mean load of 16.5±0.41 kN for GL24h and 18.9±1.60 kN for LVL48P and a mean stiffness k_i of 2.90±0.39 kN/mm and 4.35±0.84 kN/mm, respectively. The stiffness k_s was evaluated between 10-35% of F_{max} and k_i between 0-35%.

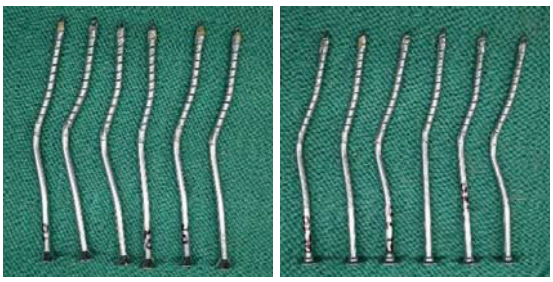

Figure 9: *Partially threaded screws after tests with countersunk head (left) and washer head (right)*

The coefficient of variation (COV) of the resulting maximum loads is within the expected range with 2% to 14% for GL24h and 2% to 8% for LVL48P. The COV of the evaluated stiffness values is significantly higher with 7% to 35% for GL24h and 12% to 26% for LVL48P, again as expected. In general, the tests showed that screws are not able to provide the desired composite properties in this project. The maximum loads are mainly reached at large displacements of 15 mm, see also Figure 10. The stiffness is correspondingly low and feature a large scatter, see also Figure 11.

4.2.3 Tests with continuous joints

The tests with the nail plates resulted in a higher maximum load F_{max} = 21.3±0.47 kN and a significantly higher stiffness k_i = 116±46.2 kN/mm. The specimens failed brittle by shear failure in the timber, in the plane of the nail tips, see Figure 12. A nominal shear stress of f_v = 2.84±0.06 N/mm² was evaluated. For the tests with additional bolts, the maximum load increased to F_{max} = 26.2±3.78 kN, the stiffness however decreased to k_i = 84.1±21.7 kN/mm. This might be due to the fact, that the size of the nail plates decreased by the bolt's cross-section, thus decreasing the joined area. Again, the specimens failed by shear failure of the timber side members. Here, the evaluated shear stress was 3.53±0.51 N/mm². The lower shear stress for the tests without bolts might be due to the fact that these were the first specimens, where the nail plates were not properly pressed in, thus reducing the area to transfer loads. After initial failure, the load-carrying capacity dropped to about half the maximum load. Splitting of the side members occurred, but was regarded as secondary failure. Exemplary tests showed that the load-carrying capacity could be further increased if the timber parts were oriented "edgewise" thus pressing the nail plates in multiple laminations/veneers.

Figure 12: *Failed specimen of test with nail plates, glulam and additional bolts (left) and test with nail plates and LVL (right)*

The tests with bonded specimens reached the highest loads with F_{max} = 24.8±4.19 kN for the 2K EP and 29.3±4.38 kN for the 2K PU. Stiffness values of k_i = 655±166 kN/mm and 464±63.3 kN were evaluated. The displacements at the time of failure were very small with only 0.2 mm. Shear failure occurred in the timber mainly very close to the contact surface with the steel (see Figure 13). Shear stresses of 3.31±0.56 N/mm² and 3.90±0.58 N/mm² were evaluated for the two adhesives. Again, for the tests with additional bolts, the load-carrying capacity dropped to about 30 kN after the shear failure occurred, which approximately was the maximum load of the tests on solely bolted joints. The load level then only slightly increased with increasing displacement. At a displacement of 15 mm, the tests were terminated.

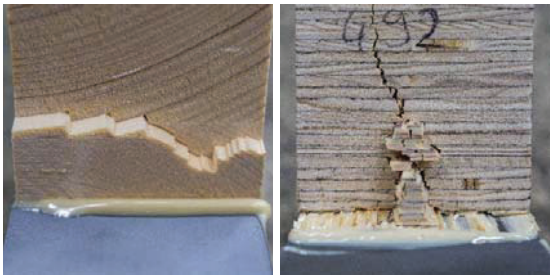

Figure 13: *Failed specimen of test with 2K EP and glulam (left) and test with 2K PU, LVL and bolt (right). Splitting was secondary failure and occurred after sudden shear failure*

In general, no differences of the used adhesives could be observed in the test results. In Figure 14, load-displacement curves for the tests with continuous joints are given. Because of the very small displacements at the time of failure of the adhesively bonded specimens paired with the ductile behavior and large deformations of the specimens with additional bolts, the scale of the x-axis is split into two sections with different intervals.

The COV of the resulting maximum loads is within the expected range with 2% to 17% for GL24h and 8% to 11% for LVL48P. The COV of the evaluated stiffness values is significantly higher for GL24h with 6% to 40%, as expected and rather low for LVL48P with 8% to 19%, see also Figure 15. Because of the very small displacements at the time of failure, the measurement uncertainty has to be considered and will be evaluated in future steps.

5 SUMMARY AND OUTLOOK

The test results give a comprehensive overview of the different joining methods studied in this research project on hybrid timber-steel beams. All tests were carried out with the same sized specimens. The outer diameter for all dowel-type fasteners was the same, as well as the bonded area for the tests with continuous joints. The tests showed that dowel-type fasteners are not suitable for the desired purpose. Also, both surface modifications did not have the desired effect and only slightly increased the results. For the joining methods with continuous joints, fully bonded hybrid beams under bending load can be assumed. The tests also revealed valuable information about the use of bolts with bonded joints and the ductile behavior after initial shear failure of the timber.

In a further step, the behavior of the joining methods under varying environmental conditions is to be investigated. In future tests, the specimens are subjected to changing climatic conditions while simultaneously being loaded with a percentage of the load established in the here presented tests. Here, the climatic conditions of service class 1 (dry conditions, indoor environment) as well as service class 2 (more humid conditions, protected outdoor environment) are of interest.

For adhesives, the surrounding temperature is also of great importance. Each adhesive has its own specific glass transition temperature, which characterizes the range of temperature above which the glassy, brittle adhesive becomes rubbery and ductile. Once the glass transition temperature is reached, the adhesive's mechanical properties are reduced significantly. Also, the material properties of timber decrease with increasing temperature. Therefore, tests with high temperatures and adhesively bonded specimens will be performed in future tests.

Following the small scale tests with the different joining methods, full scale tests of timber-steel-composite beams are planned. In this realm, the two geometries presented in chapter 2 will be tested. The cross-sections and the dimensions of the beams will be analogous to the analytical investigation. The four-point bending tests will be performed according to EN 408.

SEMI-INTEGRAL FULL-SCALE STUTTGART TIMBER MODEL BRIDGE

Simon Aicher[1], Kai Simon[2]

ABSTRACT: This paper reports on the on-set, design and realization of the Stuttgart Timber Model Bridge (STMB), which represents worldwide the largest full-scale demonstrator of a novel concept for timber bridges. The demonstrator bridge, erected at the Campus of University of Stuttgart in 2016, has been developed within two consecutive EU-research projects. It comprises several so far novel solutions concerning supports and superstructure. All derived novelties aim at a new generic type of robust timber bridges being significantly superior vs. premature degradation experienced at many of today´s timber bridges. In pursuing of the project aim first an extensive assessment of present deficiencies of mostly untreated timber bridges including a field study at 120 bridges has been performed. Based hereon, new construction concepts and detailing for the supports and the superstructure were derived. Major novelties are the realization of an integral fully rigid timber-reinforced concrete (RC) joint and of detached member-embankment connections. The build-up of the superstructure includes a double-water shielding and the implementation of a most advanced remote-controlled moisture monitoring system. The robustness of the novel bridge concept has been positively evaluated for a period of seven years with planed partly over-excessive mechanical and water loadings.

KEYWORDS: timber bridge, integral timber-RC-joint, detached cantilever support, novel robustness concept, superstructure with double water-shielding, advanced remote moisture monitoring

1 INTRODUCTION

The aim of the research task, pursued within two consecutive EU-research projects at Timber Department of MPA University Stuttgart consisted in the development of a visionary, robust timber bridge of highest possible durability. The novel design should overcome the weakness of the existing bridges significantly without implementation of any wood preservative treatments. In order to achieve the envisaged goal in a first step a thorough analysis and field study was conducted at 120 timber bridges of different build-ups and ages. Based hereon in total 16 recurring damage scenarios were identified and attributed to different generic bridge types such as e.g. truss, trough and deck bridges [1], [2].

Based on the classification and understanding of the damage on-sets a novel bridge type was conceived, detailed, designed and finally a full-scale prototype, the so-called Stuttgart Timber Model Bridge (STMB) was built (Figure 1). The demonstrator, representing the world´s largest research demonstrator bridge, erected at the Campus of Stuttgart University, was inaugurated in June 2016 by the state minister of rural affairs and is publicly accessible since then. The bridge serves for continued extensive measurements of strains, displacements, forces and moisture evolution based on latest measurement technology. The bridge can also be used on request by external researchers for specific investigations, e.g. regarding static and dynamic loading or advanced sensorics.

Figure 1: *Rendering view of the Stuttgart Timber Model Bridge (STMB)*

2 INTEGRAL AND SEMI-INTEGRAL BRIDGES

2.1 GENERAL

So-called integral structures, here in specific integral bridges, are designed without joints and bearings as defined e.g. in the German guideline for the design, construction and equipment of civil engineering structures, part 2, section 5 [2]. According to the definitions in [2], the superstructure of an integral bridge is continuous without joints along the entire length of the bridge and is not separated from the piers, abutments and pillars by joints or bearings. All components are monolithically connected to each other. Figures 2 a) – c) [3] schematically illustrate the essential differences of a common bridge structure with bearings and expansion

[2] Materials Testing Institute (MPA), Department Timber Constructions, University of Stuttgart, Germany, Kai.Simon@mpa.uni-stuttgart.de

https://doi.org/10.52202/069179-0425

joints in the super-structure-abutment-transition as well as in the sliding pillar-superstructure connection (Figure 2a) vs. a frame-like integral bridge structure (Figure 2b).

The definitions for semi-integral bridge constructions are not throughout consistent in North America and Europe. Here the definition acc. to [3] is used whereby a semi-integral bridge features a monolithic connection of the super structure with the middle support(s) whilst the end supports rest on bearings and can slide as in a usual bridge construction (Figure 2c). This definition can be extended, when e.g. looking at the symmetry conditions at the middle pillar, to a semi-integral bridge construction where abutment and superstructure are rigidly connected at one (end) pier whilst the other end and eventual intermediate supports allow expansion and sliding in longitudinal direction and partly orthogonal hereto. The latter definition can then be immediately applied to the constructed Stuttgart Timber Model Bridge (STMB). The fact that the STMB comprises two sliding supports is owed to the curvature of the bridge in the ground elevation.

Integral bridge structures, which up to now are constructed almost exclusively in reinforced concrete and steel composite construction show a number of significant advantages over conventional bridges with sliding bearings and joints, whereby some specifics apply when using timber for the superstructure. It should be mentioned that the concept of integral and semi-integral bridges is (almost) not considered in the present or newly drafted timber bridge design codes EN 1995-2 [4], [5]. Draft EC5-2 mentions integral abutment bridges in chapter 7.5, hereby referring exclusively to draft EC0 [6], which addresses soil aspects. However, integral timber-concrete joints being a prerequisite for integral and semi-integral timber bridges are not addressed at all.

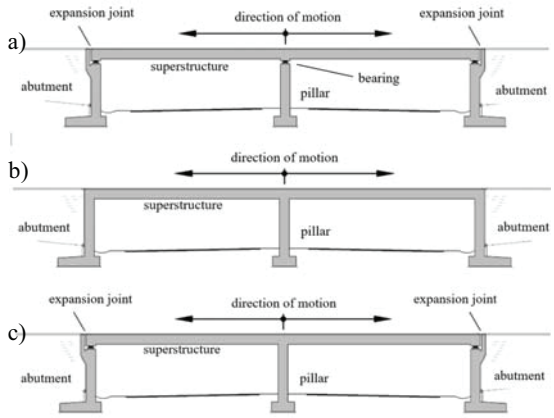

Figure 2: *Bridge construction concepts a) standard bridge superstructure with bearings and expansion joints, b) integral bridge with monolithic connections of superstructure, pillar and abutments, c) semi-integral bridge with rigid connection at the middle pillar*

2.2 ADVANTAGES OF INTEGRAL BRIDGES

The most important advantage of an integral bridge consists in the complete elimination of bearings and expansion joints, which are particularly susceptible to damage and are highly maintenance-intensive. For this aspect precise data is available for the area of steel and concrete construction. The maintenance costs of the two groups of components mentioned are about 10% of the total maintenance costs, while their share of the pure construction costs is only 3% [7]. Furthermore, bearings and expansion joints often cause damage to the overall structure, too, which also applies to a considerable extent to timber bridges [1]. A second significant advantage resulting from the monolithic connection between superstructure and the abutments consists in the significantly smaller section forces due to the clamping effect, which enable very slender, more aesthetic and more cost-effective constructions.

The magnitude of section force reductions of integral and semi-integral bridges can be illustrated in approximative manner by a comparison of a both- or one-sided clamped beam vs. a simple supported (bridge) beam. It should be noted that the comparison of rigid clamping vs. sliding supports represents a theoretical limit case as the abutment shows a finite rotational stiffness depending on soil conditions and abutment wall height. In the following a uniform loading is assumed.

In case of a both-sided clamped beam (i.e. integral bridge) the extreme moment ($ql^2/24$) at the support is 1,5 times smaller as compared to the field moment ($ql^2/8$) of a simply supported beam. In case of the semi-integral substitute model (one-sided clamped, opposite side simply supported) the clamping moment equals the field moment of the simply supported situation. However along most of the beam length a significantly reduced moment exists, whereby the extreme field moment ($ql^2/14,2$) reduces by a factor of 1,8. Additionally to section forces from external gravity loading (self-weight, traffic, …) stresses from constrained internal forces, not occurring in simply supported bridges have to be considered, what is regarded below.

Irrespective of the mentioned superimposed eigenstress-related forces integral structures are more robust overall and have significant load redistribution reserves as a result of the static overdetermination.

2.3 DISADVANTAGES OF INTEGRAL BRIDGES

For integral RC and steel composite bridge structures, the constrained internal forces resulting from concrete shrinkage, temperature and non-uniform lowering of the supports, which interact to a large extent with the ground conditions, i.e. the ground stiffness, have a disadvantageous effect. In the case of integral bridges, a realistic consideration of the soil parameters is therefore of significantly greater importance than for bridges with sliding bearings. Hereby it is not sufficient to work with characteristic lower parameters [2], [8]. Depending on the respective foundation and pier stiffnesses, integral structures suffer comparable longitudinal deformations as

https://doi.org/10.52202/069179-0425

bridges with sliding bearings. These displacements and rotations are passed on directly to the backfill via the monolithically connected abutments. In the Northern Hemisphere the annual climate change results in positive and negative constrained internal forces. This leads to monotonic and cyclic deformations of the abutment wall that act on the backfill (see Figure 3). In case of integral timber bridges the constrained internal forces result from a superposition of changes in temperature but most important from moisture variations.

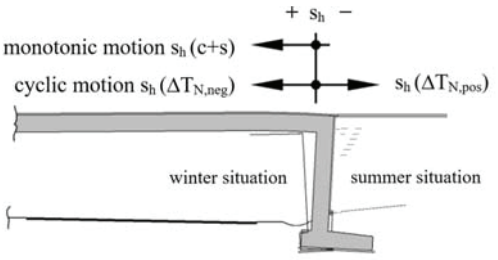

Figure 3: *Displacements of an integral abutment during seasonal change*

2.4 INTERNAL FORCES FROM TEMPERATURE AND MOISTURE CHANGES

In the design of timber structures, the effect of temperature induced movement (expansion / contraction) as opposed to the moisture induced movement (swelling / shrinking) is rarely considered. However, in structures with hindered movment possibilities as in case of integral bridges this feature has to be taken into consideration as being beneficial.

The temperature expansion coefficient of softwoods (spruce and fir) parallel to fiber can be roughly assumed as $\alpha_{T,0} = 0{,}4 \cdot 10^{-5}$ [1/K], hence being about one third as compared to steel. The moisture expansion coefficient parallel to fiber is generally taken as $\alpha_{u,0} = 10 \cdot 10^{-5}$ [1/1%Δu]. Although this value is 25 times higher as $\alpha_{T,0}$, this is partly compensated by the much higher temperature ΔT than moisture Δu changes.

In case of integral RC bridges the two general design scenarios of a uniform and linearly varying temperature distribution along cross-section depth of the superstructure are regarded. In a well-ventilated timber pedestrian bridge, it is considered sufficient to assume a rather symmetric parabolic temperature and moisture distribution over the beam cross-section as illustrated in Figure 4 (see also [9]).

For an exemplary illustration of the temperature-moisture expansion interaction in a timber bridge the parabolic distribution is approximated by a linearly stepped function. It is assumed (common for climate in Germany) that the conditions at bridge erection are: $T_0 = 10°C$ and $u_0 = 12\%$. In the summer load case the outer 1/6 of the cross-section depth d experience at the centroid a reduced moisture content of 8% (Δu = 4%) while in the center part comprising 4/6 of d the reduced moisture content amounts to 10% (Δu = 2%). The Temperature the centroid of the outer parts is assumed to be 30°C (ΔT = 20°C) and at the center at 25°C (ΔT = 15°C). The ratio of the restrained normal forces resulting from temperature (N_T) vs. moisture (N_u) generally reads

$$\frac{N_T}{N_u} = \frac{\varepsilon_T}{\varepsilon_u} = \frac{\alpha_T \, \Delta T_N}{\alpha_u \, \Delta u} \tag{1}$$

For the outer beam parts the summer situation then delivers

$$\left[\frac{N_T}{N_u}\right]_{Sommer} = \frac{0{,}4 \cdot 10^{-5} \cdot 20}{10 \cdot 10^{-5} \cdot (-4)} = -0{,}2 \tag{2}$$

which means that the tension force at the joint location induced by the moisture depended wood shrinkage is reduced by the counteracting temperature extension by 20%. The resulting restrained normal force of the outer cross-section parts then reads

$$\begin{aligned} N_{T,u,summer} &= (\alpha_T \Delta T + \alpha_u \Delta u)\, EA \\ &= (0{,}4 \cdot 20 + 10 \cdot (-4)) \cdot 10^{-5} \cdot EA \\ &= |-32 \cdot 10^{-5}| \cdot EA \quad \text{(tensile force)} \end{aligned} \tag{3}$$

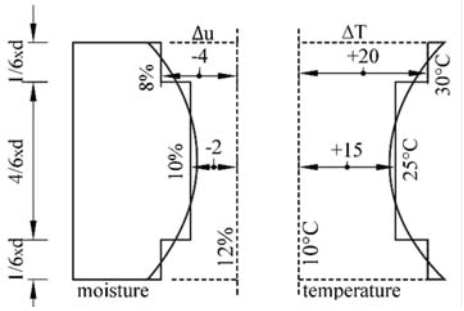

Figure 4: *Assumed moisture and temperature gradient of the timber (GLT) superstructure member in the summer period (erecting state: T = 10°C, u = 12%)*

3 THE STUTTGART TIMBER MODEL BRIDGE

3.1 DURABILITY ORIENTED DESIGN AND DETAILING APPROACH

Architecturally driven the Stuttgart Timber Model Bridge (STMB) was developed as a so-called deck-bridge, i.e. an open construction without a weather sheltering roof, considered outdated in modern architecture. The structural concept and the details of the build-up of the STMB was then in particular driven by an intention to avoid any of the previously identified 16 generically different durability damage scenarios ([1] and [10]). To do so and to deliver a trustworthy, reliable show case of the effectiveness of all newly or stringent consistently pursued ideas it was considered inevitable to verify all detailing in a full-scale demonstrator building with dimensions immediately transferable to practical use. In more detail, the following constraints were considered mandatory for the bridge layout:

- No penetration of covering and superstructure by any mechanical fastener from top to lower or bottom surfaces. This aims to avoid an extremely often

https://doi.org/10.52202/069179-0425

occurring damage / decay situation where water penetrates – gravity wise – along the periphery of nails, screws, dowel type fasteners as the surrounding hole in the wood gets enlarged over time. The interacting mechanical, moisture and temperature loading causes small cavities which enable unhindered and hardly to detect water penetration.

- Avoidance of any access and accumulation of decay generating greenery, dirt, split, water and snow at the supports. This necessitates a revision to the typical bridge end-support-abutment detailing shown in Figure 5, where the end-grain face(s) of the superstructure beam(s) or plate ends close to the rear wall of the abutment. The cavity between the timber end grain face and the abutment rear wall, unless cleaned frequently, fills with greenery or dirt over time causing numerous bridge damages. An enlargement of the cavity width *a* to a sufficiently high distance of about 0,5 to 1 m is in general considered being uneconomic as this necessitates a much larger support bank / bridge benching of the abutment. In order to overcome the sketched decay prone support situation two new on-sets were developed, outlined below.
- Realization of a redundant two-layer water shielding of the main superstructure beam
- Segmented, easy demountable and repairable bridge pavement elements made from durable wood species. Note: Due to funding issues Douglas fir boards of rather low durability (class 3-4 according to EN 335 [11]) were used in the STMB.
- Enabling of easy inspection access especially of the superstructure from the narrow faces by shutters which can be opened by hinges.
- Continuous monitoring of the moisture evolution at discrete points.
- Segmented linear sensors for leakage detection at the lower sealing layer.

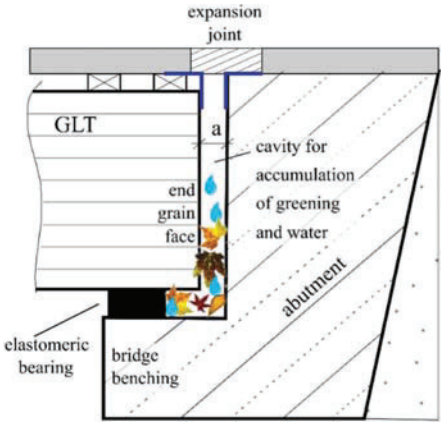

Figure 5: *Frequent damage / decay prone detail of superstructure – abutment transition of bridges with sliding end supports where the narrow cavity between GLT end grain face and abutment wall is subject to accumulation of greening and water*

3.2 BASIC CONSTRUCTION DETAILS

The Stuttgart Timber Model Bridge (STMB) was realized as a pedestrian and cycling bridge, but the principle is applicable to heavy traffic purposes, as well. Generically, the bridge can be termed a semi-integral deck bridge. The bridge is curved in plan view with a length of 22 m. The clear width of the superstructure is 2 m (see Figures 6, 7 and 8). The main load carrying member is a block-glued GLT beam (GL 24h) with a cross-section of 40 cm x 120 cm, which is supported at both ends and at mid-span at the location of highest curvature.

The bridge design considered a uniformly distributed characteristic load of 5 kN/m^2, a characteristic point load of 10 kN as well as front and rear axle loads of a service/rescue car of 40 kN and 80 kN, respectively.
At the north-east (NE) end the GLT superstructure member is rigidly clamped to the concrete abutment by a novel integral joint, specified in more detail below. The abutment is backfilled with a paved sloping ramp enabling car access to the bridge.

The supports at mid-length and at the south-east (SE) end are constructed as sliding supports with two rubber bearings, each. At the mid-span support sliding is unrestricted in any horizontal direction whilst at the SE support the sliding is prevented normal to beam longitudinal axis. The rubber bearings which are positioned at the quarter-points of the cross-sectional width of the GLT member rest on a horizontal steel frame which itself is supported by four steel screw piles at the mid-span and at the SE end support, respectively. It should be mentioned that screw piles present excellent options for cheap but robust sustainable foundations of light-weight (timber) bridge structures which can be erected and remounted very fast.

The SE end support was constructed in view of the above outlined end-support decay scenario by a so-called detached transition from the embankment to the bridge superstructure.

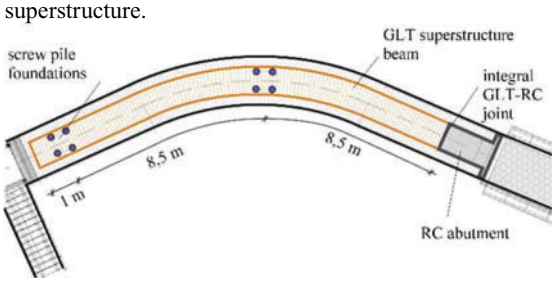

Figure 6: *Plan view of the Stuttgart Timber Model Bridge*

4 DETAILS OF SUPPORT CONSTRUCTIONS

4.1 INTGRAL RIGID TIMBER-CONCRETE ABUTMENT JOINT

The north-east (NE) support was realized for the first time in timber bridge construction as a fully integral - moment, torsion, shear force rigid timber-reinforced concrete (RC) joint (see also [10] and [12]). The connection is based on rebars (n = 34, d_{rod} = 16 mm, strength grade B500) glued

https://doi.org/10.52202/069179-0425

into the GLT beam with an epoxy resin, then protruding by about 1,2 m from the end grain face (see *Figure 7* a) – c)). The GLT rebars were aligned/connected with the rebars of the reinforcement cage cased by the concrete formwork and then the assembly of the GLT and the cage bars was cast in a single step to form a rigid connection without any gap. This novel support construction, fully apart from mechanical considerations, provides the possibility to overcome in conjunction with a continuous decking the present onsets of timber decay starting from the GLT end grain face through greenery/earth and hence moisture accumulation between GLT and abutment wall as illustrated schematically in Figure 5.

The load capacity of such a joint has been verified in previous investigations reported in [13]. These tests demonstrated a superior moment and shear force transfer. The bending stiffness and capacity results in a first conservative assumption exclusively from the normal forces in the rods glued-in parallel to grain at distance e = 284 mm. This holds entirely true for the rebars located at the bending tension side, here located at the top side, due to the negative bending moment at the clamped joint, at the top. At the bending compression side, however, it is reasonable to assume an additional load transfer via contact compression between the GLT end grain face and the concrete abutment. The load sharing between rod and contact forces can in first instance be assessed by a parallel system model which undergoes significant variations over time depending on moisture changes and relaxation. This aspect is quantified separately.

The shear force transfer evolves somewhat more complicated as outlined below. As a full understanding of the mechanism and hence of a reliable capacity assessment of the shear force transfer in the GLT was on-going at time of the bridge construction, the shear force transfer was realized in redundant manner via two complementary approaches A and B:

Mechanism A is represented by the behaviour of a ribbed dowel type fastener glued-in parallel to grain and loaded laterally. The capacity may then be assessed by a Johansen model for a dowel type fastener loaded in single shear between GLT and a thick steel plate. For a laterally loaded dowel type fastener a high risk of splitting parallel to fiber and premature failure of the total joint exists in case the dowel / rebar is positioned close to the tension loaded GLT edge $a_{4,t}$. This, however, cannot be avoided in the given case as a high moment capacity necessitates a large internal lever arm e (see Figure 7 c) of the rebars glued-in the GLT cross-section. In the STMB the edge distances of the rebars (d = 16 mm) were chosen as $a_{4,t}$= 58 mm = 3,6 · d. To overcome the splitting risk the surrounding wood was reinforced by fully threaded self-tapping screws inserted from the bottom side, i.e. bending compression edge of the superstructure GLT.

The second shear force transfer mechanism B was based on some rebars at the bending tension and bending compression edge which were bonded-in with an inclination angle of 20°. These inclined bears then transfer the shear force by tension in the bar and embedment compression stresses in the timber. A details analysis of both shear force transfer mechanism is presented in a separate contribution.

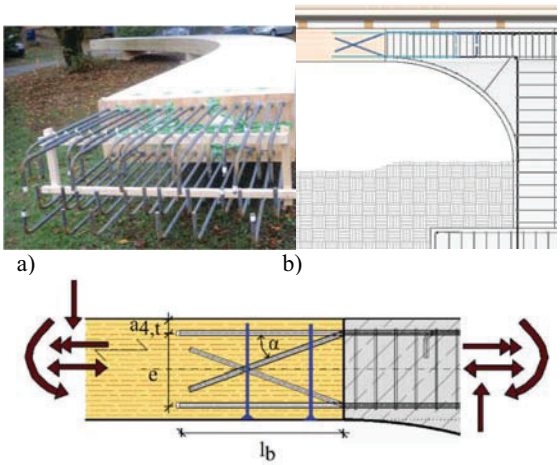

Figure 7: *Integral GLT-RC support embankment a) primary superstructure GLT beam with glued-in rebars; b) scheme of the integral joint/support solution, c) detail section of the integral joint*

4.2 DETACHED CANTILEVER-TYPE BRIDGE-EMBANKMENT TRANSITION AND CENTER SUPPORT

The SE end support consists of a plain rubber bearing where a translation displacement is restricted only in direction perpendicular to the bridge axis. The bridge related novelty consists in the fact that the GLT-RC joint exceeds the NE support cantilever-like by about 1,5 m. At the SE end the transition to the embankment is fully decoupled by means of a perforated steel grid plate supported by L-shaped steel brackets fixed to the pier front. This solution again enables a full detachment of the end grain face of the timber / superstructure from the embankment and hence exclusion of biodegradation.

The mid-span and the SE flexible supports consist of screw-piles, which are especially apt for light-weight, easily demountable sustainable foundations.

5 CROSS-SECTIONAL-BUILD UP OF THE BRIDGE

The cross-sectional-build-up of the superstructure is shown in Figure 8 a). In brief, two decoupled water shielding planes were constructed (Figure 8 b) and c)). The cross-ply LVL plate was then covered by a bonded fiber reinforced roofing membrane layer inclined at a small angle (6°) vs. the horizontal plane to enable a water drainage to the lower bridge edge. The inclination is then compensated with regard to a horizontal plane by tapered support beams for the pavement. An important feature of the superstructure build-up is that no mechanical fastener penetrates any structural and water proofing component / layer from top. The connection of the cross-ply LVL plate as well as for the hand rail is realized by angle brackets connected to the narrow faces of the structural GLT beam.

https://doi.org/10.52202/069179-0425

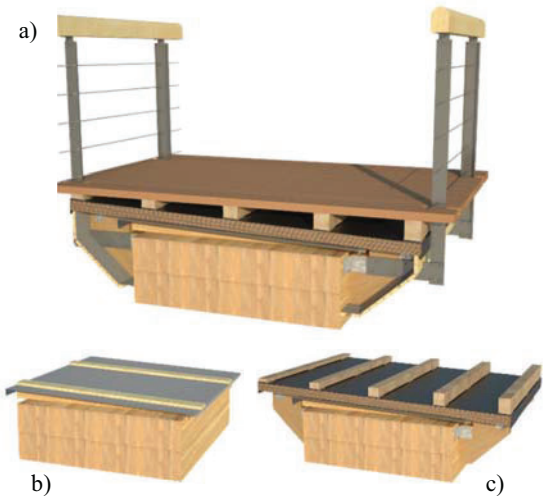

Figure 8: *build-up of STMB a) total cross-section, b) lower water shielding, c) upper water shielding*

6 INSTALLED MONITORING SYSTEMS

The monitoring of the bridge comprises the mechanical aspects (displacements, strains, forces) and hygro-thermal issues such as moisture and temperature evolutions. All data are sampled at multiple points within the cross-section and along the bridge length and are recorded continuously remote. Special novel line sensors are applied to register eventual water penetration despite the double water proof shielding.

The detailing of the Stuttgart Timber Model Bridge (STMB) results from above mentioned research project [1]. To ensure and prove the function of the implemented construction preservation measures a monitoring concept with the following components was installed (see Figure 9):

- 16 sensors for punctual moisture content (u) measurement in different depths (electrical resistance method)
- 3 sensors for climate (cli) located beside and under the GLT superstructure beam and between the GLT structure and the sealing layer
- 3 sensors for wood temperature (T_{timber})
- 11 sensors for leakage detection at the second sealing layer (L)
- 1 displacement transducer for temperature and moisture dependent length variation of the GLT (d_L)
- 5 displacement transducers for vertical and horizontal relative displacements at the integral GLT-concrete abutment connection (d_v, d_h)
- 8 strain gauges on the surface of the GLT beam to obtain the stresses at the integral support (ε_{Timber})
- strain gauges on 8 of the glued-in rods at the integral GLT-concrete connection (ε_{rod})

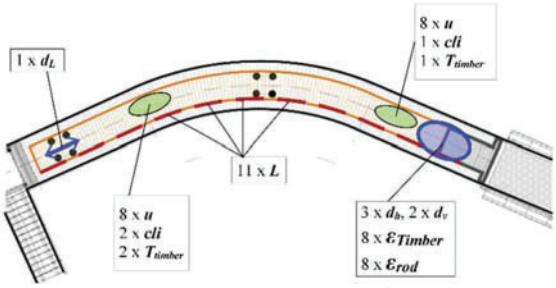

Figure 9: *Overview and locations of the different monitoring sensor-types*

All systems are running continuously and send wireless their data in a regular interval to a server. A big challenge of the combination of five different data logging systems consists in the consolidation and evaluation of the data. Five data loggers of different manufacturers are necessary for the functioning of the of the installed systems. Every system has its own method to record, transcript and send the data to the web. Some are sending the files via email protocol, others are using the File Transfer Protocol (FTP) to a local server and others are sending the data via FTP to a remote server of the manufacturer. At the homepage related to STMB (www.stuttgarter-bruecke.de) results of the monitored values are shown and updated continuously. Further investigations [14] at MPA University Stuttgart aim to compile a monitoring system with one centralised logger and computing unit which can handle all of the installed sensors.

7 RESULTS

7.1 CLIMATE AND MOISTURE MEASUREMENTS

In a rough summary of the climate measurements throughout seven years it can be stated that the temperature (daily mean values) varied over a year's season in the range of -5°C and +26°C. The relative humidity daily mean values varied from 45% in summer to 90% in winter. Based on the climate recordings the resulting surface moisture content derived by [15]

$$u(T,rH) = 10^{-2}\left[\frac{-T\cdot\ln(1-rH)}{0{,}13\cdot\left(1-\frac{T}{647{,}1}\right)^{-6{,}46}}\right]^{\frac{1}{110\cdot T^{-0{,}75}}} \quad (4)$$

is shown in Figure 10. It can be summarized that the calculated surface moisture (daily means) varied from 8% to 20% with a mean value over seven years of about 14,5%.

https://doi.org/10.52202/069179-0425

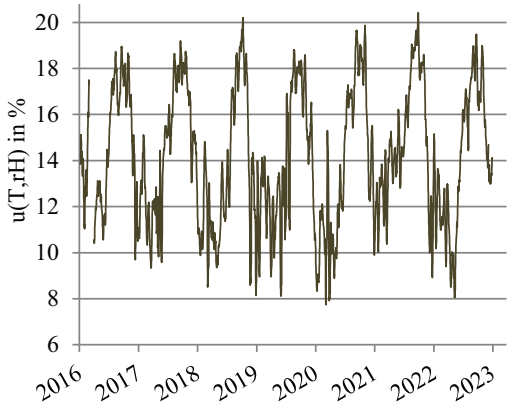

Figure 10: *Theoretical surface moisture content calculated from monitored air temperature and humidity by Eq. (4)*

The recording of the moisture content in different locations of the superstructure GLT beam by electrodes positioned at different depths of 1 cm, 3 cm and 6 cm is depicted exemplary in Figure 11. The graph shows that the moisture in 1 cm depth conforms rather well with computed surface moistures presented in Figure 10. Further it can be seen that the moisture amplitudes closer to mid-depth are significantly reduced. In a rough approximation the moisture contents vary in the cross-sectional center part in the range of 13,5 % to 16 % with a mean value of roughly 15 %. Further details and improvements regarding the moisture monitoring are presented in [14].

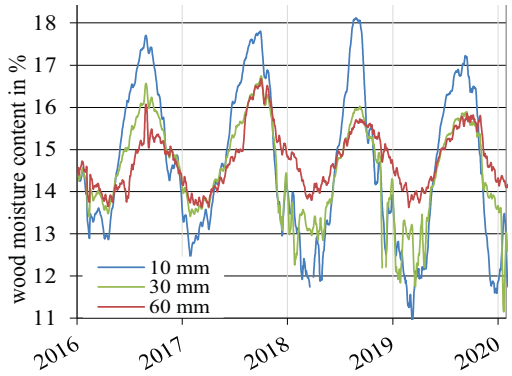

Figure 11: *Results of wood moisture monitoring of the GLT superstructure beam in cross-sectional depths of 10 mm, 30 mm and 60 mm*

7.2 MECHANICAL LOAD TESTS

In order to acquire a thorough understanding and experimental verification of the load carrying mechanisms of the integral joint of GLT and RC-abutment different static and dynamic load tests of the STMB were conducted. Due to page limitations, here one exemplary test is presented.

To activate a high bending moment in the rigid integral joint, a dead load in form of steel plates and concrete blocks were located at the mid-point of the first bridge field for a long-term test lasting six months. The 8.000 kg dead load was carried up in eight steps by a fork lift with an empty weight of 2.000 kg, shown in Figure 12.

Figure 12: *Load application for a long-term test with a fork lift*

The results of the measurements during this step-wise load application represented by rod forces calculated from strain gauges applied on the glued-in rebars are given in Figure 13. The correlation of strain and force was calibrated for all of the monitored rebars in a test machine before bonded into the GLT. The graph shows the results of four rebar forces, whereby two rebars are located at the upper bending tension edge and two at the lower bending compression edge of the joint. The tension rebar forces after full load application amount to 12,7 kN and 11,2 kN whereby the difference of the values results from the additional torsion moment because of the curved geometry of the GLT superstructure (Figure 13). In contrast hereto, the compressive forces show a much lower value of 4,3 kN in both cases being roughly 35% of the tension forces. The reason for the significantly smaller compression rebar forces can be attributed to the superimposed contact pressure of the GLT end-grain face to the RC-abutment whereas the tensile forces have to be transferred exclusively via the rebars. Figure 13 also shows the force peaks of the additional weight of the fork lift itself. The characteristic load carrying capacity in tension of a single rebar glued into the GLT is about 80 kN hence much higher than the forces resulting of the here applied bending moment.

A detailed analytical and numerical analysis of the integral joint, presented separately, reveals a satisfactory agreement between calculated and measured rebar forces.

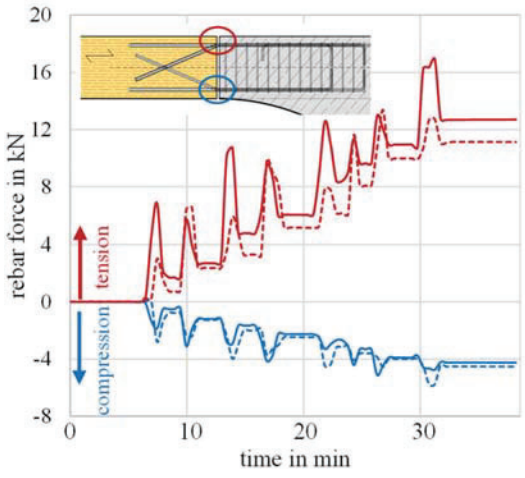

Figure 13: *Tensile and compressive forces in the rebars of the integral joint during stepwise application of 8.000 kg dead load*

https://doi.org/10.52202/069179-0425

8 EXPERIENCE AFTER SEVEN YEARS OF SERVICE LIFE

So far, all recorded mechanical and hygro-thermal results conformed well to the expectations/calculations. The agreements of the measurements are in all cases superior to the anticipated values [3]. In the follow-up of the STMB three public pedestrian bridge with both-sided integral timber-RC joints were realized and are monitored by MPA University of Stuttgart.

9 ACKNOWLEDGEMENT

The financial support of the research in two consecutive research projects RWB-EFRE No 051203 and 051303 by EU and state of Baden-Wuerttemberg is gratefully acknowledged. Many thanks are owed to the co-funding of University of Stuttgart enabling the continuous monitoring.

Special thanks to the sponsors listed below without whose support the construction of the "Stuttgart Timber Model Bridge" would not have been possible:

LIMBERLOST PLACE: A 10-STOREY SLAB-BANDED STRUCTURE

Md Shahnewaz[1], Robert Jackson[2]

ABSTRACT: The $150M Limberlost Place (previously known as "The Arbour") is a 10-storey, 16,250 m^2, exposed tall wood building located on George Brown College's waterfront campus in Toronto, Canada. This project will serve as an educational hub for George Brown College, housing the Tall Wood Research Institute, a childcare centre in addition to a significant amount of teaching and social spaces for their architectural program. Fast + Epp developed an innovative large span beamless structural system that is comprised of CLT timber-concrete composite (TCC) slab bands with perpendicular CLT infill panels supported on glulam columns. This long-span flat plate system allows for flexibility in architectural programming and unobstructed mechanical distribution. An extensive testing program on the TCC slab bands was completed at the University of Northern British Columbia in 2020, which has provided valuable engineering information to the design community for future tall wood projects and composite systems. To facilitate innovation, the project received funding through the National Resources Canada Green Constriction Wood Program, alongside other partners.

KEYWORDS: Timber concrete composite, cross-laminated timber, connections, tall timber, slab band

1 INTRODUCTION

The 10-storey 52.5m tall Limberlost Place is poised to transform Toronto's skyline with the construction of a mass timber tall wood, net-zero carbon emission building (Figure 1). The building name was inspired by a nearby forest the "Limberlost Forest and Wildlife Reserve", Huntsville, ON, Canada. The building is located on George Brown College's waterfront campus in the East Bayfront district of Toronto, Canada. The building will facilitate classrooms and lecture halls, and host The Tall Wood Institute.

Figure 1: *Rendering of Limberpost Place*

To reflect the purpose of the building and to develop economic and environmental structural solutions, a holistic design approach with mass timber as the primary structural material was chosen. The building has a footprint of 62m×37m and was designed for load conditions as required by the 2017 edition of the Ontario Building Code (OBC) [1] and the 2015 edition of the National Building Code of Canada (NBCC) [2]. The 9.2m long timber concrete composite (TCC) slab bands will be exposed from the underside in some locations, for architectural expression. These floors will be supported on glulam columns from the ground floor to the upper roof (Figure 2). The typical glulam columns were designed to provide additional distribution areas for shear stresses and reduce the weak-axis bending in the panels. This project is one of the first tall timber buildings to proceed with "assembly" occupancy in Canada – where many of the existing tall timber buildings are for commercial or residential occupancies.

The structure was designed for a two-hour fire event, with all structural timber designed for full exposure. A char analysis was completed with the provisions given in Annex B of CSA O86 [3]. In addition to this char analysis, supplemental calculations were also undertaken using the Ministry of Municipal Affairs and Housing Supplementary Standard, SB-2 Fire Performance Ratings, in subsection 2.11 of the OBC for glue-laminated timber beams and columns. The structural steel also met the requirements to achieve a two-hour fire-resistance rating and through detailing with drywall encapsulation. The fire rating and associated alternative solutions were a

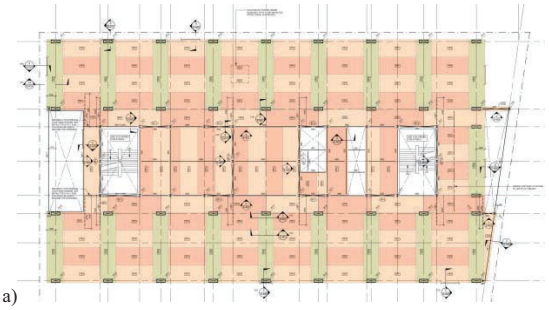
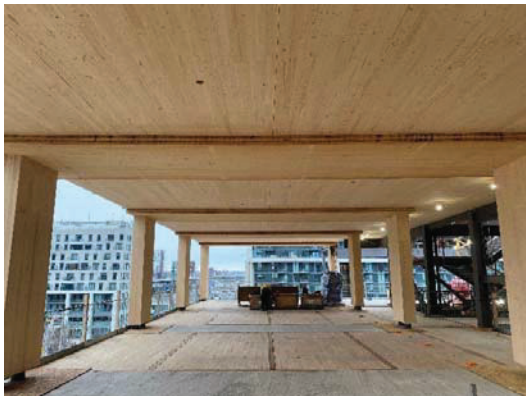
significant part of this project, undertaken by GHL Code Consultants Ltd, alongside CHM Fire Consultants Ltd.

2 SUPERSTRUCTURE

The ground floor structure consists of a 300 mm thick reinforced concrete slab supported on concrete columns and walls below. The transition from concrete columns to glulam columns is made 500 mm above the ground level slab, jacketing the steel column bases in concrete. From level 2 to 8, the TCC slab bands serve as the primary floor structure and eliminate the need for deep glulam beams, providing more headroom and space for mechanical and electrical components. The 244 mm thick 7-ply CLT panels act compositely with 150 mm concrete topping spanning 9.2 m in the north-south direction and support the non-composite 191 mm thick 7-ply CLT infill panels between them, as shown in Figure 2a. A photo of the slab bands and infill panels can be seen in Figure 2b.



a)



b)

Figure 2: *a) Typical floor plan, b) Typical slab bands.*

The TCC slab bands are supported by 422 × 1210 mm glulam columns, designed and positioned beneath the slab-bands to resist the effects of unbalanced loading. The column connection (Figure 3) is configured to provide direct load transfer between the vertical elements rather than transmitting forces through the TCC floor panels. Glulam columns arrived on-site with a steel connecting plate and Hollow Structural Section (HSS) stubs, secured to the end-grain of the column with glued-in rods. The glulam column above had a a similar connection with smaller diameter HSS stubs allowing a 'sleeve in' connection. Stubs are connected using bolts, which allow for simple installation and act as a tension connection in the extreme event where a column below is eliminated, according to progressive collapse principles. CLT floor panels were notched around the HSS tubes and bear directly on the column below.

The CLT roof panels support additional loading from the weight of the green roof and the snow, however public access is restricted at those green roofs on the north and south side of Level 9, in order to match the design loading with that of the floors below. At the south green roof, however, there will be additional double glulam beams underneath each TCC band to support the column loads above. The columns above, which partially support the roof, are anchored to the top of the TCC bands at the mid-span. The typical "wallumns" are terminated at this level. Where the building continues up to Level 10 and the upper roof, the "wallumns" transition into smaller 430 x 456 mm glulam columns.

At Level 10, a 245 mm thick 7-ply CLT deck spans north-south between glulam purlins abd steek beams, supported by columns below. The structural steel members in the core area are the same as the floor below. All structural components within this space have been designed for a 2hr fire rating. The same glulam columns supporting Level 10 will continue up to support the roof. There, 245 mm thick 7-ply CLT panels span between purlins, along the slope of the roof. On the west and east sides of the upper roof, side roofs will also be made of 7-ply CLT panels supported on a series of steel purlins. In the middle of these side roofs, large louvred openings are to be created to serve as solar chimneys.

Figure 3: *a) Typical slab band section, b) Mock-Up*

https://doi.org/10.52202/069179-0426

3 LATERAL SYSTEM

The primary means of lateral stability consists of a long central core of concentric limited ductility steel braced frames coordinated with the stairs, elevators, and mechanical spaces in the center of the building (Figure 4). Several timber options, including CLT shear walls and glulam braced frames were explored, as was a conventional concrete core system. Ultimately, a steel braced frame system (Figure 4) was found to be the best fit for the project due to the following reasons. Firstly, the steel braces are much more slender than a glulam equivalent, allowing for greater flexibility for wall openings for architectural and required services. Secondly, the steel braced frame cores add more ductility and overstrength to the overall structure in comparison to a timber braced frame system, allowing for a more efficient seismic force-resisting system. Thirdly, the de-centralized mechanical rooms require a significant number of services into the 'core' space, meaning many holes in the walls which would be practically feasible. Fourthly, the steel components can be erected simultaneously with the timber components, resulting in a faster erection period sharing the hook of one crane. The steel braces HSS, while the beams and columns within the cores are various sizes of wide-flange sections. These steel components are concealed, thus requiring no further fire protection. The design of the steel core members is governed by wind versus seismic forces in both E-W and N-S directions.

4 STRUCTURAL TESTING

A comprehensive experimental testing program was conceived and executed on the TCC slab bands to inform the project design. The CLT specimens were prepared by Structurlam, in Penticton, BC and the concrete for slab bands was poured by Datoff Bros Construction Ltd, Prince George. All tests were conducted at the University of Northern British Columbia's Wood Innovation and Research Laboratory in Prince George, BC.

4.1 MATERIALS

The tested CLT panels for the slab bands were 245 mm thick 7-ply, grade E1M5 [3]. The panels were manufactured as per PRG320 [4] with Spruce-Pine-Fir (SPF) 2100 Fb-1.8E machine-stress rated and No.3 grade for the major and minor strength axis laminations, respectively. Two-thirds of the slab bands were reinforced at two intensity levels (high level: 9 rows of screws spaced at 75 to 225 mm and low level: 6 rows screws spaced at 300 mm). The concrete topping on the slab bands is 150 mm with a minimum specified strength of 35 MPa. The concrete was reinforced with 10M longitudinal rebar spaced at 150 mm top and bottom, and stirrups were 10M spaced at 300 mm.

Three types of composite connectors were used. Type A: Fully threaded self-tapping screws (ø11×250 mm) installed at an angle of 45º; Type B: perpendicular steel plates 2100mm x 75mm x 6.4 mm (length x depth x thickness) hammered into a 7mm saw kerf, and Type C: parallel 90mm x 2mm HBV plates glued into saw kerfs using a polyurethane-based adhesive.

4.2 CONNECTOR TESTS

A total of 18 small-scale shear tests were conducted to investigate the capacity, stiffness, and failure mechanisms of steel kerf plates as TCC shear connectors with varying embedment depths. Steel kerf plates of 6 mm thick and 200 mm wide were installed in the CLT in a 7 mm wide saw kerf at 5^0 back bevel as shown in Figure 5a-c. The steel plate embedment depths into the CLT were varied: i) 35 mm deep, ii) 70 mm deep, and iii) 90 mm deep. The specimens were tested under in-plane shear by rotating 12°, similar to the procedure suggested in EN-408 [5]. The loads were applied according to EN-26891 [6] with a displacement-controlled protocol at a rate of 5 mm/min as shown in Figure 5d.

https://doi.org/10.52202/069179-0426

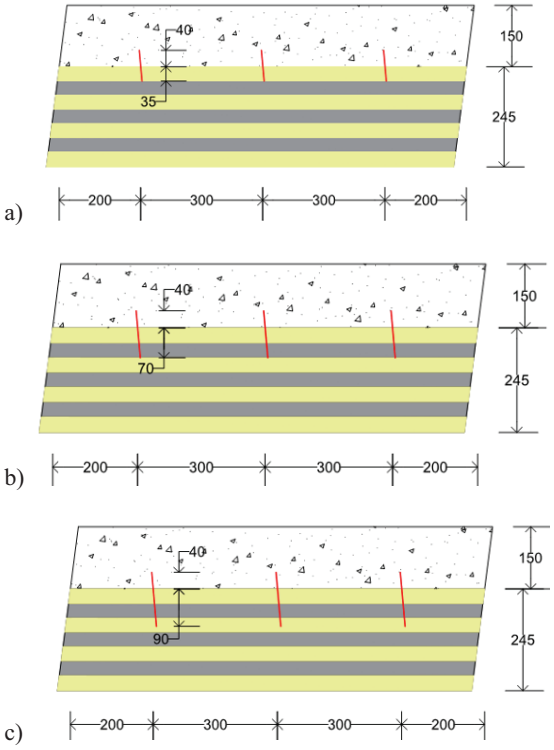

Figure 5: *a-c) Specimens including steel kerf plate embedment variations, d) Small-scale test setup.*

4.3 HALF-SCALE TESTS

The half-scale TCC slab bands were tested to assess their shear capacity and failure pattern at high shear zones with different levels of CLT shear reinforcements, to evaluate the performance of the TCC floors with different shear connectors and shear reinforcing. The test series are summarized in Table 1. The floors were connected to 430×1,178 mm glulam columns by 12-ø16×250 mm glued-in rods.

Table 1: Overview of Test Series

Series		ID	Reinf.	Connector	Test Type	#of tests
half-scale	S2	S2-UR	-	NA	B	2 each
		S2-HR	low			
		S2-FR	high			
	S3	S3-UR-A	-	Type A	B	2 each
		S3-HR-A	low			
		S3-FR-A	high			
	S4	S4-UR-B	-	Type B	B	2 each
		S4-HR-B	low			
		S4-FR-B	high			
	S5	S5-UR-C	-	Type C	B	2 each
		S5-HR-C	low			
		S5-FR-C	high			
full-scale	S6	S6-HR-A	low	Type A	B	2 each
		S6-HR-B		Type B		
		S6-HR-C		Type C		
	S7	S7-HR-A	low	Type A	T	1 each
		S7-HR-B		Type B		
		S7-HR-C		Type C		

Note: B – bending, T-torsion

Test series S2 is the control series, consisting of 5030 mm long raw CLT panels (no concrete topping) (Figure 6). Test series S3 to S5 (Figures 7 to 9) are TCC slab bands consisting of 5030 mm long CLT panels with 150 mm concrete topping. The three different connector layouts (Type A to C) are shown in Figure 7 to Figure 9. Two replicates from each unreinforced, low-reinforced, and high-reinforced CLT panels and TCC slab bands were provided, for a total of 6 raw CLT panels on the control side, and 18 TCC slab bands.

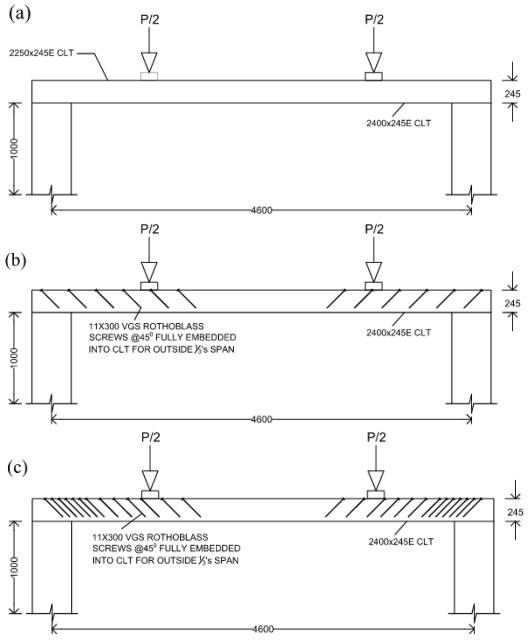

Figure 6: *Test series S2- half-scale raw CLT panels: a) unreinforced, b) low, and c) high reinforced CLT panels.*

https://doi.org/10.52202/069179-0426

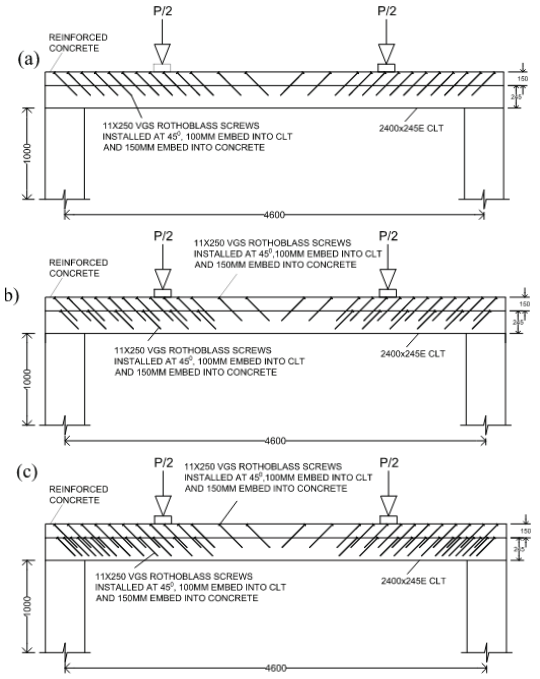

Figure 7: *Test series S3: half-scale TCC with screw connectors: a) unreinforced, b) low reinforced, and c) high reinforced CLT panels.*

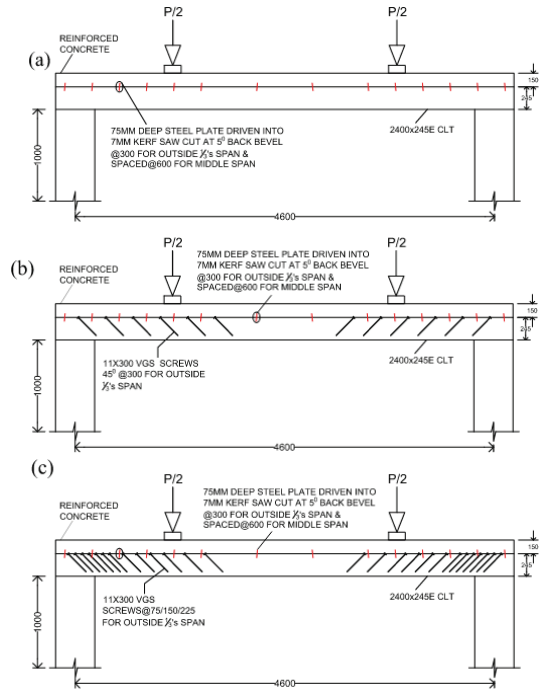

Figure 8: *Test series S4: half-scale TCC with kerf plate connectors: a) unreinforced, b) low, and c) high reinforced CLT panels.*

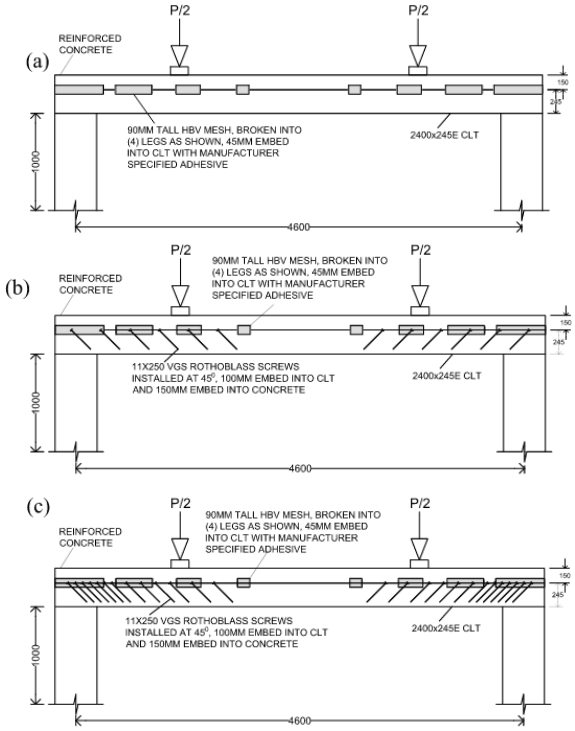

Figure 9: *Test series S5: half-scale TCC with HBV connectors: a) unreinforced, b) low, and c) high reinforced CLT panels.*

The tests on half-scale specimens were conducted under 4-point bending as shown in Figures 10a and 10b on raw CLT panels (Series S2) and TCC slab bands (Series S3-S5), respectively. The loads were applied at one-third points using two 500 kN and two 250 kN actuators for a total maximum load of 1,500 kN, and were distributed at the third-point lines using steel spreader beams. When the specimens did not fail after reaching the 1500 kN maximum actuator load, the spreader beam was moved to mid-span to re-test the specimen under three-point loading. All specimens were tested under displacement-controlled loading at a constant rate of 15 mm/min.

Figure 10: *Schematic of 4-point bending tests.*

4.4 FULL-SCALE TESTS

Similar to the half-scale, all full-scale specimens were comprised of 245 mm thick, 7-ply CLT panels with 150 mm concrete topping connected with self-tapping screws, steel kerf plates, and HBV shear connectors (Type A, B, C respectively, as laid out in Table 1). These specimens were tested under four-point bending (Series S6) and torsional loading (Series S7). Series S6-S7 consisted of 9.6 m long, low-reinforced CLT panels with 150 mm concrete topping, with three specimens of each connector type, as shown in Figure 11.

Similar to half-scale specimens, the loads in series S6 were applied at one-third points using two 500 kN and two 250 kN actuators, for a total of 1500kN maximum, and were distributed at the third-point lines using spreader beams. The torsional specimens were tested with edge loading using one 500 kN and two 250 kN actuators, for a total of 1500kN maximum. All specimens were tested under displacement-controlled loading at a constant rate of 15 mm/min. The CLT panels of all full-scale slab bands specimens in S6 and S7 were low-reinforced. Two replicates of S6 and one replicate of S7 from each connector types were tested, a total of 6 and 3 TCC slab bands from series S6 and S7, respectively.

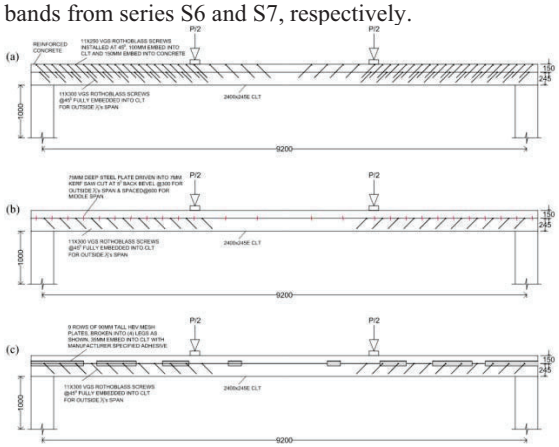

Figure 11: *Test series S6 and S7: full-scale TCC self tapping screw connections, kerf plates, and HBV.*

5 TEST RESULTS AND DISCUSSION

5.1 CONNECTOR TESTS RESULTS

From the small-scale tests, the connector performance was evaluated at the maximum load F_{max}, displacement at maximum load d_{Fmax}, serviceability stiffness K_{ser}, and ultimate stiffness K_u. The mean values of various metrics from the in-plane tests are listed in Table 2. The detailed analysis results were reported in a previous publication [8]. The load-deflection from small-scale series S1 tests are shown in Figure 12. Typical failure patterns are shown in Figure 13. The post-yield behaviours of the connectors with three different embedment depth were different. Connector type S1-A with 35 mm embedment resulted the highest deformation capacity, while connector Type S1-C with 90 mm embedment resulted the lowest deformation capacity with a steep decrease in load after reaching its maximum. Type S1-A connectors had the lowest load-carrying capacity, yield, and ultimate strengths (F_{max} = 350 kN), while Type S1-B and Type S1-C connectors' capacities were slightly higher, i.e. on average 7% and 5%, respectively higher compared to Type S1-A. All connector types had started yielding at similar range deformations of between 0.8 to 0.9 mm. Results showed that there are some reductions in deformation capacity when the kerf plates were embedded beyond the first layer of CLT. The stiffnesses observed both at serviceability and ultimate loads for Type S1-A, Type S1-B connectors, and Type S1-C connectors were similar (Table 2). In sum, with deeper the embedment depth beyond first layer of the CLT panel did not provide any improvement in the connection performance, therefore, the floor specimens for the full-scale testing were manufactured with Type S1-A steel plate connectors.

Series	CLT embedment	#of tests	F_{max}	d_{Fmax}	K_{ser}	K_u
			[kN]	[mm]	[kN/mm]	
S1-A	35 mm deep	6	350	3.3	416	444
S1-B	70 mm deep	6	376	2.9	395	354
S1-C	90 mm deep	6	368	3.0	438	453

5.2 HALF-SCALE TESTS RESULTS

Half-Scale CLT Panels

The load-deflection curves from series S2 on CLT panels shows three segments until failure, ascending elastic and elastic-plastic segments, and descending segment from peak loads to failure (Figure 14). Typical failure patterns from series S2 in unreinforced, low and high-reinforced panels are shown in Figure 15. The unreinforced CLT panels failed in a sudden brittle manner due to rolling shear failure near the support (Figure 15a) at an average load of 885 kN. The low-reinforced panels also failed in shear (Figure 15b), at a higher load of on average 968 kN. The failure mechanism in the high-reinforced panels pushed from shear to bending (Figure 15c).

https://doi.org/10.52202/069179-0426

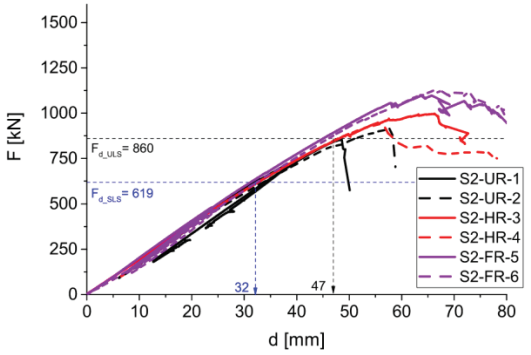

Figure 14: *Load-deflection curves for series S2- CLT panels*

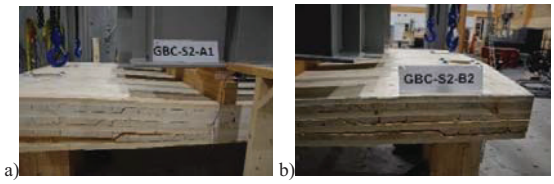

Figure 15: *Typical series S2 failures on CLT: a) unreinforced, b) low-reinforced specimens,*

Half-Scale TCC Slab Bands

Typical failure pattern in slab bands with screws are shown in Figure 16. The unreinforced specimens S3-UR failed in shear as seen in Figure 15a at an average load of 1,445 kN. One of the low-reinforced panel S3-HR slab band failed in shear (Figure 17b) at an average load of 1,487 kN. The other low-reinforced slab did not fail in 4-point bending tests as it reached actuators capacities, therefore, after retest under 3-point loading, it failed in bending at mid-span (Figure 17c). Similarly, both high reinforced slab S3-FR only failed after being re-tested in a three-point bending (Figure 17d) at an average load of 1,968 kN.

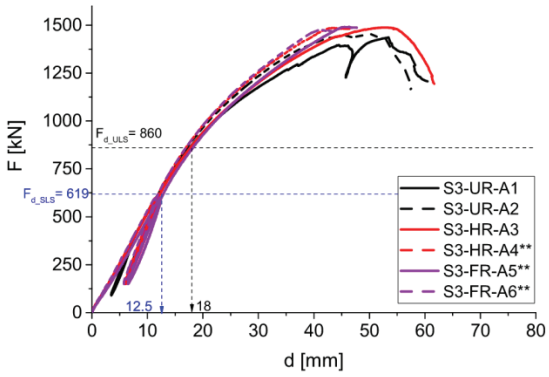

Figure 16: *Load-deflection curves for series S3- half-scale TCC bands with screw connectors*

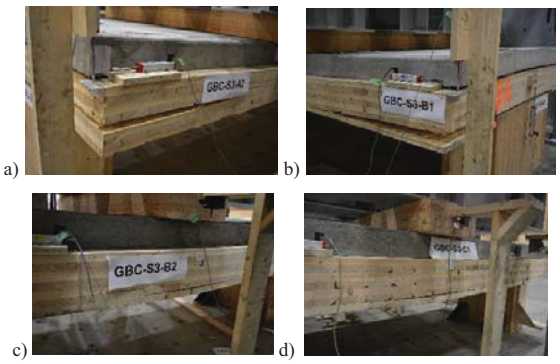

Figure 17: *Typical series S3 failures on TCC slab bands with screws connectors: a) unreinforced, b-c) low-reinforced specimens, and d) high-reinforced specimen*

Failure patterns in series S4 slab bands with kerf plates are shown in Figure 18. The unreinforced specimens S4-UR failed in shear as seen in Figure 19a at an average load of 1,482 kN. Both low S4-HR and high reinforced S4-FR slabs were failed at mid-span bending after being re-tested in a three-point loading (Figure 19 b-c) at an average load of 2,586 kN and 2,441 kN, respectively.

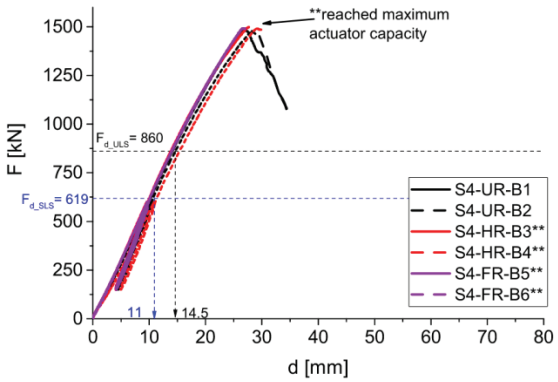

Figure 18: *Load-deflection curves for series S4- half-scale TCC bands with kerf plates connectors*

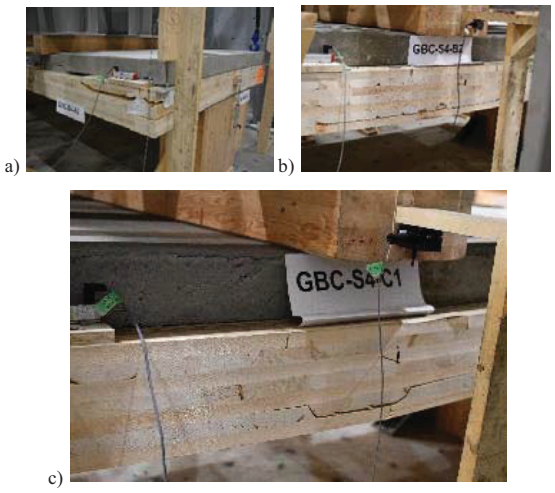

Figure 19: *Typical series S5 failures on TCC slab bands with HBV connectors: a) unreinforced, b) low-reinforced specimens, and c) high-reinforced specimens*

https://doi.org/10.52202/069179-0426

Failure patterns in series S5 slab bands with HBV are shown in Figure 20. All series S5 TCC slab bands with HBV failed in shear (Figure 21 a-c) at support at an average load of 1,261 kN, 1,316 kN and 1,493 kN, in S5-UR, S5-HR, and S5-FR, respectively.

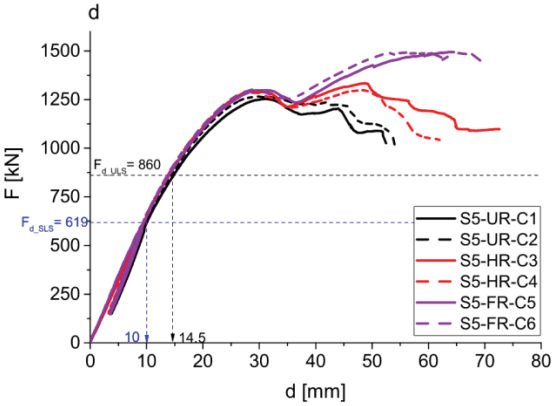

Figure 20: *Load-deflection curves for series S5- half-scale TCC bands with HBV connectors*

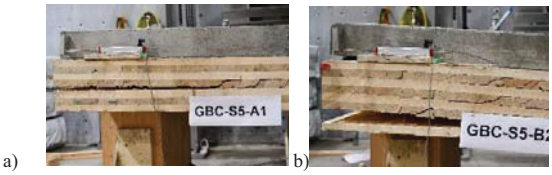

Figure 21: *Typical series S5 failures on TCC slab bands with HBV connectors: a) unreinforced, b) low-reinforced specimens*

5.3 FULL-SCALE TESTS RESULTS

The mid-span load-deflection curves of the full-scale TCC slab bands in series S6 are shown in Figure 22 and typical failure patterns are illustrated in Figure 23. The slabs bands with screws composite connector failed in bending at mid-span at an average load of 706 kN and estimated bending moment capacity of M_{max} = 1,100 kNm. Similarly, slab bands with Type B kerf plates connector also failed in mid-span bending, however, at 47% higher loads compared to Type A screw connectors. The average failure load was observed 1,040 kN and estimated bending capacity of M_{max} = 1,619 kNm. The TCC slab bands with Type C composite connector HBV failed in connector shear at an average load of 670 kN which was the lowest among the three connector types and the estimated bending capacity was M_{max} = 1,043 kNm. Although HBV connectors in TCC slab bands failed initially, the final subsequent failure occurred at mid span due to bending.

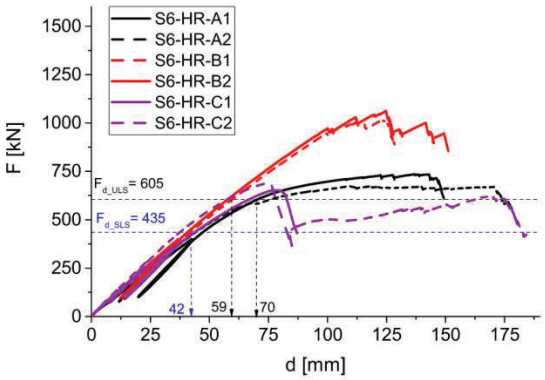

Figure 22: *Load-deflection curves for series S6- full-scale TCC bands -under 4-point bending tests*

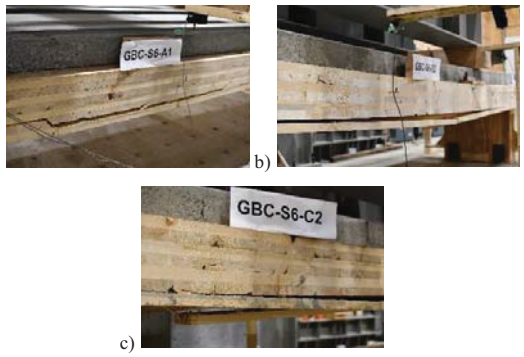

Figure 23: *Typical series S6 failures under 4-point bending on full-scale TCC slab bands with: a) screw connectors, b) kerf plates connectors, and c) HBV connectors*

The mid-span load-deflection curves of the full-scale TCC slab bands in series S7 under torsional loading are shown in Figure 24 and typical failure patterns are illustrated in Figure 25. The TCC slab bands with Type A screws composite connector reached first failure at 285 kN, and a maximum load of 442 kN at a deflection of 255 mm. The TCC slab bands with Type B kerf plates composite connector reached first failure at 234 kN and a maximum load of 489 kN at a deflection of 261 mm. The TCC slab bands with Type C HBV reached first failure at 257 kN, and a maximum load of only 413 kN at a deflection of 159 mm. Under torsional loading in series S7, the first failure was always triggered by the pull-out of the glued-in rod from the column support as shown in Figure 25c followed by failure in bending at mid-span on the loaded side at ultimate loads (Figure 25a). Therefore, in the final project design phase, all glued-in rods are capacity protected using 15 ø16×400 mm glued-in threaded rods were used instead of 12 ø 16×250 mm rods used in tests, see Figure 25c.

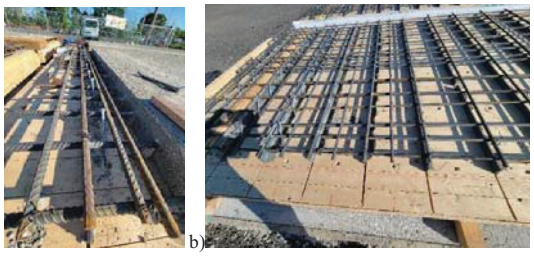
6 CONCLUSIONS

Fast + Epp initiated an ambitious design approach to one of Toronto's tallest timber buildings. The innovative 'slab banded' gravity system allows for flexibility in architectural programming and unobstructed mechanical distribution. By coupling this timber gravity system to a steel braced frame core, the superstructure can be erected as a prefabricated 'kit of parts', alongside the envelope system.

The extensive testing program evaluated the performance and efficiency of TCC slab bands with various composite connectors. The screw reinforcement in the CLT significantly increased the shear capacity of the panels. The failure modes also shifted shear to bending failure in some heavy reinforcing specimens. The 150 mm concrete topping compositely connected to the CLT panel improved the out-of-plane shear capacity by up to 167% when compared to bare CLT panels. Weak-axis shear failure was observed in some TCC specimens due to warping over the glulam columns and this can be avoided by adding diagonal reinforcing screws in transverse direction at the end of slab bands, which was incorporated in the final design phase (as seen in Figure 26a). TCC with steel kerf plates exhibited the highest capacity and stiffness and were priced by multiple suppliers to be the most economical option, therefore, final design was moved forward with this solution (Figure 26b). Torsion tests showed pull-out failure of glued-in rods, which must be avoided, so lengthening of the rods and increasing the number of rods was deployed in final design.



a) b)

Figure 26: *a) Diagonal screws at 45^0 in weak axis, b) typical slab band reinforcement before concrete pour*

The structural testing program allows a low-cost timber composite system, provide invaluable design information to the engineers. It is currently under construction, with structural completion targeted for late 2023.

ACKNOWLEDGEMENT

The project was supported by Natural Resources Canada (NRCAN) through the Green Construction Wood (GCWood) program. The CLT specimens were prepared by Structurlam, in Penticton, while the concrete was poured by Datoff Bros Construction Ltd, Prince George. The support by the UNBC technicians Michael Billups and Ryan Stern and undergraduate research assistant Anthony Bilodeau is greatly appreciated.

STRUCTURAL DESIGN OF HYBRID STRUCTURE WITH CLT SEISMIC PANELS AND STEEL FRAME

Kouji Fukumoto [1], Marina Koda[2], Hiroshi Isoda[3]

ABSTRACT: We have developed a new hybrid structural system with fire-resistance performance, combining CLT infill panels and a steel frame, for middle- and high-rise buildings. This structural system draws out the potential structural performance of CLT panels by holding them in the steel frames. Steel frames, without considering CLT panels, can support gravity loads of a high-rise building during fires so that it may be possible to omit the fireproof covering of the CLT panels and to specialize CLT panels to support seismic forces. This paper shows the details of the developed hybrid system as well as the seismic design and fire resistance experimental result, with an actual example project.

KEYWORDS: CLT, Steel frame, Hybrid structure, Seismic panel, Seismic performance, Fire-resistance performance

1 INTRODUCTION

Since the Japanese government notification related to CLT (Cross Laminated Timber) was enforced in 2016, the manuals on design have been developed [1], and the buildings using CLT are becoming more and more in use in Japan as well as in other countries. The high-rise buildings utilizing CLT (for example, Reference [2]) have been already constructed in Europe and North America where CLT is in widespread use prior to other countries. In Japan as well, the efforts to apply timber structures to middle- and high-rise buildings have become active. Although CLT is expected to be usable as leading structural material for that purpose, currently, its use for middle- and large-scale buildings has not been widespread partly because of the needs to meet higher seismic standards and fire protection standards than in other countries.

Under the circumstances, the authors had an opportunity, in 2018, to design the structure of the Hyogo Forestry Hall, a five-story office building aimed at becoming a model for encouraging broad use of CLT by making effective use of CLT.

However, in case of using a CLT panel construction method in an urban central area like Kobe City, fireproof covering for timber structural members to meet the requirement for ensuring the one-to-three-hour fire resistance performance according to the application area and scale of the building as specified in the Building Standards Act of Japan not only conflicts with the architectural request for representing wood in a space but also raises issues of labour and cost for installing fireproof covering. Thus, securing the fire-resistance performance of a timber structure involves multifaceted issues. Furthermore, large-section glued laminated timber is required to achieve a large span exceeding 10 meters necessary for a work space of office with a timber structure. If fire resistive glued laminated timber is used for that purpose, it would be more disadvantageous in terms of cost.

Besides, application of CLT to high-rise buildings is difficult because if CLT is used as seismic structural elements in a timber frame as has been before or if a structure is assembled only with CLT panels, the surrounding timber frame will fail before CLT exhibits its strength to the full as shown in Figure 1. Moreover, with the CLT panel construction method or a structural system in combination with the conventional timber structure, it will be difficult to rationally attain high axial force retention and a large span frame which are indispensable to a high-rise building, with consideration for economical efficiency as well.

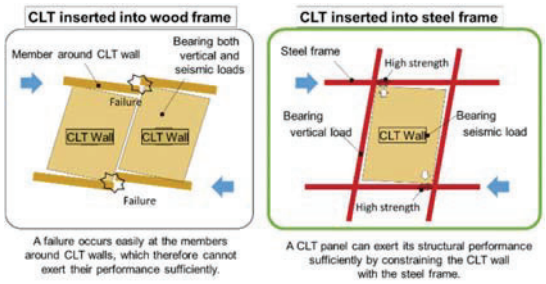

Figure 1: *CLT panels inserted into steel frame*

Therefore, the authors had an eye on a structural system with CLT as seismic structural elements built in a steel

structure as reported in [3], which was aimed at achieving high axial force retention and a large span rationally and economically through a steel structural frame by constraining CLT with the steel frame and thereby letting CLT exhibiting its inherent structural performance. Additionally, we specialized CLT panels as seismic structural elements and eliminated the need for fireproof covering to improve the design, workability and economic efficiency.

This paper presents the structural design method taking an actual project, and also shows the verification results of the effect of the combustion of CLT on the fire-resistance performance of the surrounding steel in case without fireproof covering for CLT seismic panels in order to ensure the fire-resistance performance of the structural system. Furthermore, the paper reports the construction condition focused on the joints.

2 STRUCTURAL DESIGN METHOD IN "HYOGO FORESTRY HALL"

2.1 OUTLINE OF STRUCTURAL SYSTEM

Figure 2 shows the outline of the Hyogo Forestry Hall, a case of the authors' design, and Figure 3 shows a structure rendering of the same building. As shown in Figure 4, the

Designed by	: Takenaka Corporation
Built by	: Takenaka Corporation and Daiwa House Industry (Special Construction JV)
Building area	: 310.49 sq. m
Gross floor area	: 1567.10 sq. m
Scale	: 5 above ground floors and one penthouse floor
Structure	: CLT and Steel
Construction period	: March 2018 to January 2019 (10 months)

Figure 2: *Outline of Hyogo Forestry Hall*

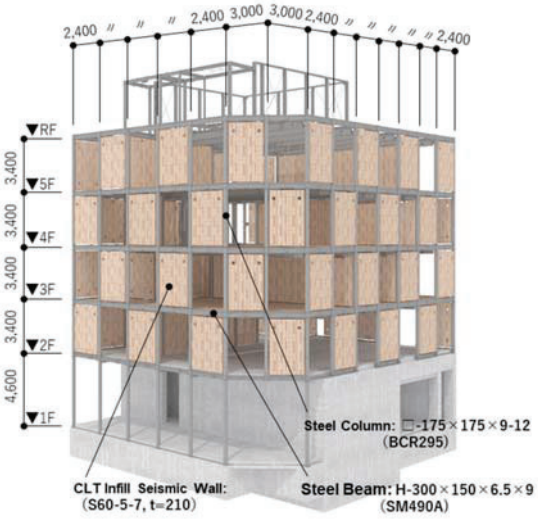

Figure 3: *Structure rendering*

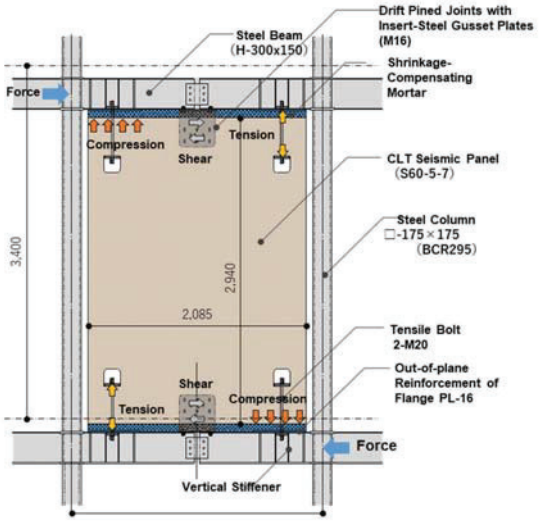

Figure 4: *CLT panel inserted in steel frame*

standard configuration consists of a CLT infill seismic wall S60-5-7 (210 mm thick with 5 layers and 7 plies), steel columns (□-175x175x9, BCR295) and steel beams (H-300x150x6.5x9, SM490A). A CLT seismic panel, 2.940 m high and 2.085 m wide (H/L =1.41), is placed on a steel grid at the floor height of 3.4 m with columns arranged at a spacing of 2.4 m. Tensile bolts 2-M20 (ABR400) are placed at four corners of a CLT panel for the tensile joints, while the drift pined joints with insert-steel gusset plates (drift pin diameter 16 mm) are provided at the center for the shear joints. We also filled the space between CLT panels and steel beams with shrinkage-compensating mortar to make sure of the later described fire-resistance performance and stress transmission.

2.2 RELATIONS BETWEEN JOINT STRENGTH AND SHEAR FORCE BORNE BY CLT INFILL SEISMIC WALL

Table 1 shows the relations between the joint strength and the shear force borne by CLT panels in the above structural system. The horizontal strength depends upon the equilibrium between the moment by the couple of vertical forces due to the yield tension strength of tensile bolts (T_y) and the bearing strength of the upper and lower bearing area (C_c) and the moment by the couple of shear forces (Q_j) in upper and lower shear joints caused by horizontal forces as shown in Figure 5. The CLT panel was S60-5-7 (210 mm thick), however the compressive strength of the bearing area was assumed to be S60-5-5 (150 mm thick) by not considering the outermost plies since the beam flange was 150 mm wide.

The analytical result indicated that the transmission of the compression stress in the bearing area of CLT panels that depends upon the shear yield strength of boundary beams (Q_v) was 56% of that in case of depending upon the bearing strength of CLT panels (C_c). In that case, assuming that the tensile bolts have tensile-yielded simultaneously, the shear stress of CLT panels (τ) is 0.62 N/mm^2. However, the tensile yield strength was set for tensile bolts to prevent prior failure at the position around

https://doi.org/10.52202/069179-0427

a square hole in a CLT panel as shown by the dotted line in Figure 6. Its contribution rate to the whole horizontal force ($M_{Ty}/\Sigma M_R$) is 23.3% when calculated using the rotational resistances in Table 1.

This project is also intended to minimize steel members by utilizing the structural performance of CLT panels. However, the section of steel beams can be increased to further increase the bearing force of CLT. Although the steel beam flanges receive the out-of-plane force due to the bearing force from CLT panels, vertical stiffeners are installed on the beams as shown in Figure 4. The compression stress from CLT panels is designed to allow the shear yield of steel beams. These vertical stiffeners also help prevent the steel beam web plates from shear buckling.

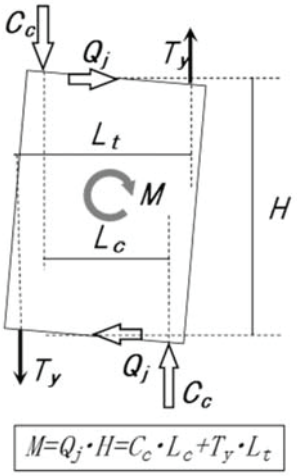

Figure 5: *Conceptual diagram of rotational resistance*

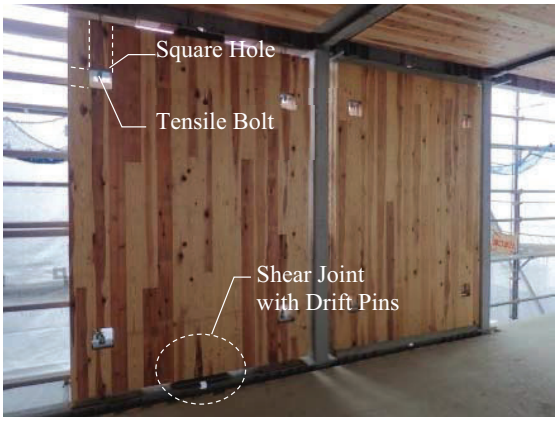

Figure 6: *Joints of CLT panels*

2.3 DESIGNING OF SHEAR JOINTS

The drift pined joints with insert-steel gusset plates were applied for the shear joints. The hybrid structure with CLT seismic panels and a steel frame can account for the frictional force effectively because the structure system makes the compression stress predominant by constraining CLT panels.

Thus, this study considers the horizontal resistance force caused by frictional force with the coefficient of 0.3.

Table 1: *Rotational resistances of CLT infill seismic walls in Hyogo Forestry Hall*

CLT wall	Height	H	2940	(mm)
	Width	L	2085	(mm)

CLT horizontal strength		Q_R	272.3	(kN)
CLT shear stress		τ_R	0.622	(N/mm^2)
CLT shear reference strength		F_S	2.700	(N/mm^2)

The structural performance of drift pins was designed by using the results of the previous joint experiment [4] using CLT panels (S60-5-5) and drift pins, 16 mm in diameter. In addition, considering the strength reduction coefficient 0.8 for arrangement of one row of several pins, the yield shear force per piece of drift pin, 16 mm in diameter, (q_{dpy}) was set to 22.7 kN per piece, and the initial stiffness (K_s) was set to 13.0 kN/mm per piece.

The design had an enough allowance for the primary design stage. The number of drift pins was determined so that the displacement of shear joint element springs under

https://doi.org/10.52202/069179-0427

the horizontal load-carrying capacity might not exceed the ultimate displacements at the shear joints as later described. The authors have reached the conclusion, through the above described designing process, that the shear stress (τ) that the CLT seismic panels can bear is 0.62 N/mm^2.

2.4 FLOW OF STRUCTURAL DESIGN

Figure 7 shows the structural design flow of the Hyogo Forestry Hall. For this building, the allowable stress for sustained loading was designed without CLT seismic panels to specialize them as seismic structural elements. On that condition, we went through the following processes in a sequential order in compliance with the Seismic Calculation Route 3 as a steel structure under the Building Standards Act of Japan: Designing of the allowable stress for sustained and temporary loading; checking of the story deformation angles, modulus of eccentricity and story stiffness ratio; calculation of the horizontal load-carrying capacity; and checking of the ultimate displacements at the joints. Since the required horizontal load-carrying capacity has not been calculated in the previous studies, this study reduced the whole building to an equivalent single-degree-of-freedom system and then used a method of calculating the reduction rate of the required horizontal load-carrying capacity (structural characteristics factor: D_s) from the ductility factor on the assumption of the property of energy conservation.

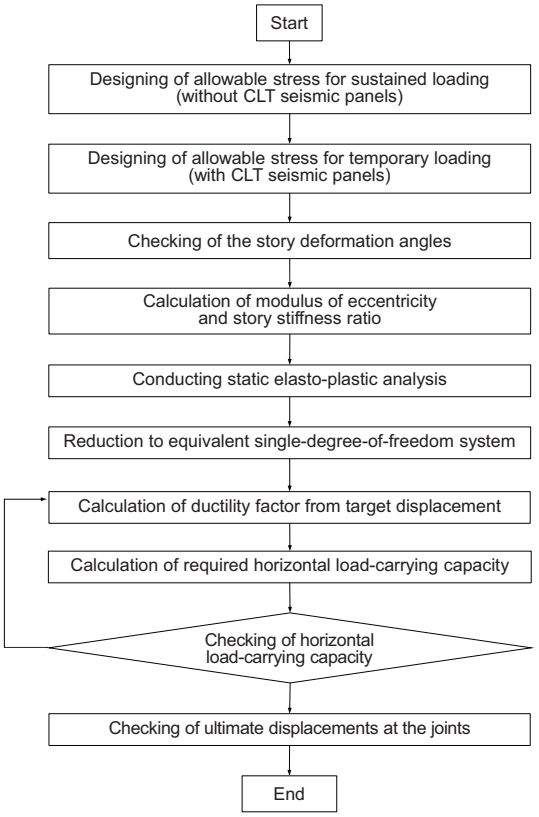

Figure 7: *Flow of structural design*

2.5 STRESS ANALYSIS MODEL

Figure 8 shows a stress analysis model of the Hyogo Forestry Hall. CLT panels were replaced by equivalent linear materials, which were analyzed as elastic bodies. The upper and lower ends of the wall had rigid beams as wide as the wall, and tension and compression springs at the wall joints on the ends and shear springs in the center were placed as nonlinear elements.

As regards the tension springs at tensile bolts, the springs of the following three elements in series were used as the initial stiffness (K_{CTB}) for calculation in accordance with the Japanese CLT Manual: the initial stiffness caused by the bearing stress of the timber immediately under the washers for the tensile bolts (K_C), the initial stiffness caused by the tension of the timber at the both ends of notches (K_T) and the tensile axial stiffness of the tensile bolts (K_B), where they are arranged so that the strength might depend upon the tensile yield of tensile bolts without causing the prior tensile or shear failure of CLT to occur around the square holes. The elastic-plastic properties were modelled to be bilinear.

The compression springs in the bearing area were modelled to be bilinear, by calculating the bearing spring stiffness (K_P) on the assumption that the bearing stiffness per unit area (k_c) was 15.6 N/mm^3 for the bearing area of $0.25d \times t$ and then calculating the compression stress (P_{PY}) from the compressive strength (F_c), in compliance with the Japanese CLT Manual [1].

The shear springs at the shear joints, using the yield strength per piece of drift pin shown in Section 2.3, were considered to be rigid (K_{S1}) until the frictional force (P_F) based on the assumption that the friction coefficient was 0.3 against the compressive strength of the bearing area. After that, the stiffness according to the number of drift pins (K_{S2}) was given, and they became trilinear type with a break point at the strength (P_{SY}) as a result of adding the yield strength of drift pins (P_{DPY}) to P_F. Although the tensile and compression spring elements were placed at the nodes of corners of wall panels for the sake of simplicity, the spring stiffness and strength require corrections (reduction) in consideration for the effect of the actual stress positions. By referring to the Japanese CLT manual [1], we set the correction factor (R) to $0.83d/D$, and multiplied the stiffness by R^2 and the strength by R.

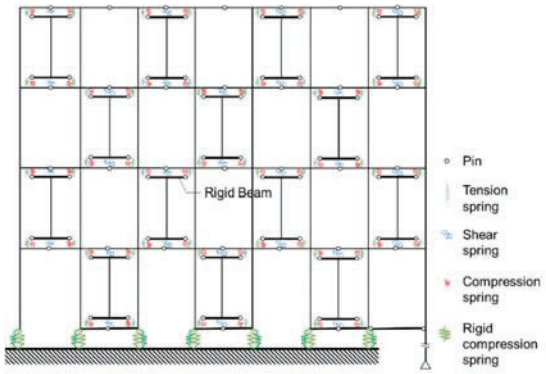

Figure 8: *Overview of stress analysis model*

https://doi.org/10.52202/069179-0427

Table 2 shows the calculation results for the joint springs in the standard configuration in Figure 4 by using the above procedure. A steel frame was modelled with linear elements, and the bilinear elastic-plastic properties were defined at the member ends. Although the shear yield of steel beams occurs due to the features of CLT panel layout in this structural system, the authors referred to the Reference [5] for the restoring force characteristics against the shear yield of steel plate reinforced by stiffeners and set the decreasing rate of the shear stiffness from the initial stiffness after the shear yield to 0.015.

Table 2: *Joint element springs*

Compression spring			Tension spring			Shear spring		
k_C	(N/mm^3)	15.6	K_C	(kN/mm)	101.9	μ		0.3
d	(mm)	1855	K_T	(kN/mm)	1767.8	P_F(=μ·P_{PY})(kN)		202.8
0.25d	(mm)	464	K_{CT}	(kN/mm)	96.3	DP		φ16

			K_B	(kN/mm)	223.0	K_{S1}	(kN/mm)	10000.0
			K_{CTB}	(kN/mm)	67.3	K_{S2}	(kN/mm)	143.0
			P_{BY}	(kN)	115.1	P_{SY}	(kN)	452.5

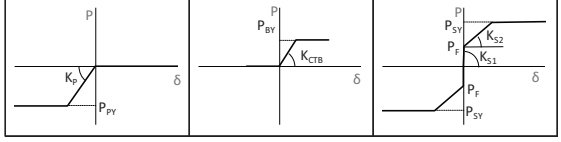

Table 3: *Stress analysis results*

Direc-tion	Story deformation angle (rad)	Modulus of eccentricity	Story stiffness ratio	Shear force sharing rate of CLT (%)	Mean shear stress of CLT (N/mm^2)
X-direc-tion	1/494 (FL level 4)	0.13 (FL level 4)	0.74 (FL level 4)	79.1 (FL level 2)	0.36 (FL level 2)
Y-direc-tion	1/469 (FL level 2)	0.12 (FL level 3)	0.74 (FL level 2)	84.9 (FL level 2)	0.40 (FL level 2)

2.6 STRESS ANALYSIS RESULTS

Table 3 shows the stress analysis results. In the primary design, the shear force sharing rate of a CLT infill seismic wall is as high as about 80%, the story deformation angle could be also reduced to slightly less than 1/500, smaller than the target value 1/200. Thus, the results indicated that the stiffness of a CLT infill seismic wall was fully contributory.

2.7 HORIZONTAL LOAD-CARRYING CAPACITY CALCULATION

For the Hyogo Forestry Hall, the authors developed the above stress analysis model, and then performed static elasto-plastic analysis and calculated the horizontal load-carrying capacity as shown by the flow diagram in Figure 7, where the problem was how to set the required horizontal load-carrying capacity. There were no experimental findings about the deformation performance and energy absorption of a hybrid structure with CLT seismic panels and a steel frame. Therefore, we reduced the building to an equivalent single-degree-of-freedom (SDOF) system (Figure 9) and then calculated the reduction rate of the required horizontal load-carrying capacity (structural characteristics factor: D_s) from the equation on the assumption of the property of energy conservation with ductility factor. The seismic force based on the Building Standards Act of Japan was caused to act on each floor (P_i), which was followed by static elasto-plastic analysis, where the horizontal displacement distribution on each floor in each step was reduced to the representative displacement Δ and acceleration A of an equivalent single-degree-of-freedom system (Equations (1) and (2)). If you set a freely-selected target displacement Δn against this $A-\Delta$ curve and establish an energy-equivalent, perfect elasto-plastic model, then that determines the ductility factor (μ), and the value of structural characteristics factor (D_s) to calculate the required horizontal load-carrying capacity (Q_{un}) will be calculated in Equation (3) based on the property of energy conservation (Equations (3) and (4)). From this relationship between a freely-selected target displacement Δn and the D_s value, the acceleration (A_n) equivalent to the required horizontal load-carrying capacity converted into acceleration can be obtained. The intersection between this $A_n-\Delta n$ curve and the $A-\Delta$ curve becomes a point to determine the horizontal load-carrying capacity.

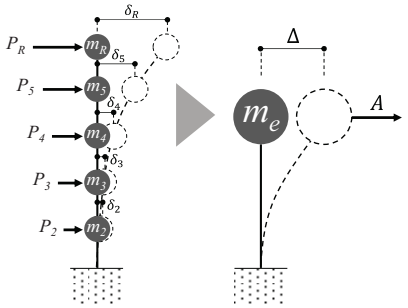

Figure 9: *SDOF System*

$$A = Q_B \cdot \frac{\sum m_i \cdot d_i^2}{(\sum m_i \cdot d_i)^2} \quad \cdots(1)$$

$$\Delta = \frac{\sum m_i \cdot d_i^2}{\sum m_i \cdot d_i} \quad \cdots(2)$$

$$D_s = \frac{1}{\sqrt{2\mu - 1}} \quad \cdots(3)$$

$$\mu = \frac{\Delta_u}{\Delta_y} \quad \cdots(4)$$

$$Q_{un} = D_s \cdot F_{es} \cdot Q_{ud} \quad \cdots(5)$$

where Q_B = story shear force of the lowest floor, m_i = mass of the level-i floor, d_i = displacement of the level-i floor, Δ_y, Δ_u = yield displacement and ultimate displacement of perfect elasto-plastic model, bilinear (refer to Figure 12), Q_{un} = required horizontal load-carrying capacity, F_{es} = shape factor (1 in this case) and Q_{ud} = story shear force when the base shear coefficient is 1.

Figures 10 and 11 respectively show the moment diagram and hinge diagram under the horizontal load-carrying capacity. Figure 12 shows the story shear force - story deformation relationship by floors in the +X direction, and Figure 13 illustrates the acceleration – representative displacement curve of an equivalent SDOF system obtained from Figure 12.

https://doi.org/10.52202/069179-0427

The result of performing the horizontal load-carrying capacity calculation for all the cases by the above method was as shown in Table 4, which indicates that the D_s values were between 0.57 and 0.63. The replacement by a bilinear type with an equivalent area has resulted in the calculation result larger than 0.55, the maximum D_s value of RC constructions that is specified in the Building Standards Act of Japan, because of the displacement (Δ_y) increased at yield, preventing the ductility factor (μ) from increasing.

The yields of joints, bending yields of steel columns and shear yields of steel beams occurred as shown by the hinge diagram in Figure 10. Generally, there is a concern of the web buckling in response to the shear force at the steel beam ends. However, as they are reinforced with stiffeners at a spacing of 100 to 140 mm in this case, the shear deformation performance can be expected. As a whole, the behavior with deformation performance is considered to be indicated. Therefore, the D_s values higher than those of strength type RC constructions are slightly unreasonable calculation results, which lacks evidence data to support them in the current situation. Accordingly, performance verification by such means as structure experiments is required in the future.

Furthermore, the sharing rates of the CLT seismic panels under horizontal load-carrying capacity were 68.9 to 77.1%, as shown by the horizontal load-carrying capacity calculation results in Table 4, which shows lower percentages than in the primary design stage. Still, the mean shear stress (τ) was approximately 1.0 N/mm^2. Finally, it was confirmed that the deformations of the spring models of joint elements at the joints did not exceed the ultimate deformation (δ_u). For the tensile joints, the ultimate displacement was considered to take place at the time when the tensile strain of tensile bolts was 10%. As for the shear joints by the drift pined joints with insert-steel gusset plates, the ultimate deformation (δ_u) was set to 32 mm in accordance with the experimental results in Reference [4].

3 SECURING FIRE-RESISTANCE PERFORMANCE

Even if used in a fireproof building, CLT seismic panels are not required to have fire-resistance performance under

https://doi.org/10.52202/069179-0427

the Building Standards Act of Japan because they do not support sustained loads but bear only horizontal forces. However, there is a possibility that the CLT seismic panels will continuously self-burn even after the end of fire, and the steel frame to which the panels are installed may be subjected to heating beyond the legally required fire-resistance performance. Hence, the authors performed the full-scale heating test on this structural system to verify the fire-resistance performance.

Figures 14 to 16 show the diagram and photos of the full-scale heating test specimens, and Table 5 shows a list of specimens. In the standard configuration shown by Figure 4, the upper part of the vertically divided panel was called the Specimen No. 1, and the lower part was called the Specimen No. 2. The Specimen No. 1 included the assumed CLT floor, which was covered on the upper and lower surfaces with reinforced gypsum boards for fireproofing and installed up to about one meter from the frame center. The space between a CLT seismic panel and a steel beam was filled with 80 mm thick shrinkage-compensating mortar both to transmit compression stress and to cover the beam flanges for fireproofing. We used calcium silicate boards as fireproof covering for the steel of these specimens and gypsum boards for the floor.

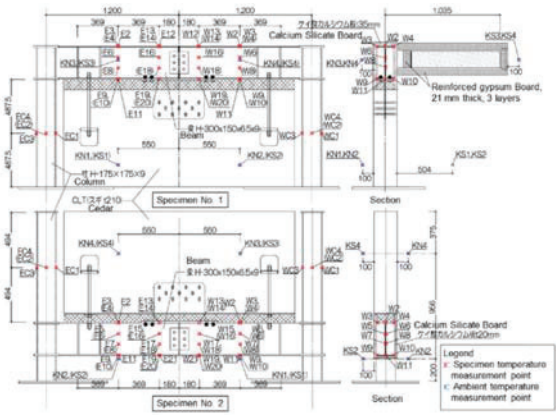

Figure 14: *Full-scale heating test specimen diagram*

Table 5: *List of full-scale heating test specimens*

Specimen No.	Steel column	Steel beam	Fireproof covering (Calcium silicate board)
No. 1	□-175x175x9 (STKR400)	H-300x 150x6.5x9 (SS400)	Column: 1 hr. (20 mm) Beam: 2 hrs. (35 mm)
No. 2			Column: 1 hr. (20 mm) Beam: 1 hr. (20 mm)

Figures 17 to 20 show the temperature histories at the measuring points of the specimens (the measuring points with the W-codes shown in Figure 14 represent the beam measurement results). It was confirmed that the CLT seismic panels of the both specimens reburned two to four hours after the end of heating and that the ambient temperatures of the specimens rose again up to about 700 degrees Celsius, and the CLT seismic panels burned down about one hour after that. This re-increase of the ambient temperatures after the end of heating is considered to have been attributable to the fact that the continuous burning from the both sides of the CLT seismic panels even after the end of heating turned into violent reburning when penetrating the CLT seismic panels. For the Specimen No. 1, we reinforced the fireproof covering of the beams to achieve 2-hour fire rating against the temperature rise of the CLT seismic panels due to reburning, which resulted in reducing the beam steel temperature to about 230 degrees Celsius. Consequently, the temperature dropped after reaching the peak 360-420 minutes after the start of heating. Though a temporary rise in the temperature was observed immediately after 60 minutes have passed since the start of heating, that was caused by the hot air that entered through the corners of the floor's butt ends which normally were not heated surfaces. The tensile bolts and shear joints that join CLT seismic panels to steel beams become thermal bridges and cause the steel temperatures to rise. However, keeping 80 mm thick shrinkage-compensating mortar limits the temperatures near the joints (W19 and W20 of No. 1 and W13 and W14 of No. 2) to about 250 degrees Celsius and consequently reduces the effect of the thermal bridges to be minor.

Figure 15: *Test specimen No. 1*

Figure 16: *Test specimen No. 2*

As described above, the maximum temperature of steel after heating for 60 minutes becomes about 450 degrees Celsius, which is considered to have the remaining strength beyond this building's stress due to sustained loading.

4 CONSTRUCTION OF JOINTS

4.1 JOINTS TO TRANSMIT TENSION STRESS (TENSILE BOLT JOINTS)

Figure 21 shows the joint detail of a CLT and steel hybrid structure. Tensile bolts are placed at the four corners of the CLT infill seismic wall to transmit the tension stress generated due to the bending stress of the wall, and joined to the steel beam flanges.

As shown in Figure 22, the upper and lower surfaces of a CLT panel are filled with shrinkage-compensating mortar to transmit the compression stress and to provide steel beams with fire-resistance performance against the burning of CLT in case of fire as described in Chapter 3. A preliminary execution test was performed on the filling properties of shrinkage-compensating mortar, which verified that the mortar enabled the filling close to 100%.

Figure 21: *Tensile bolt joint*

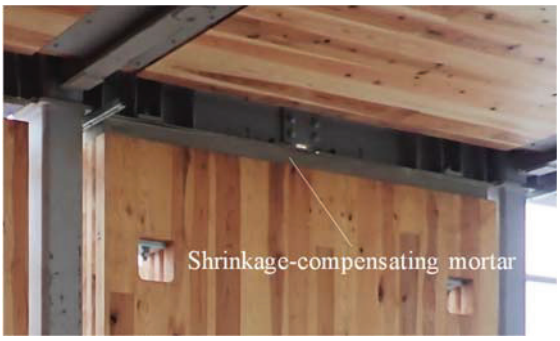

Figure 22: *Shrinkage-compensating mortar*

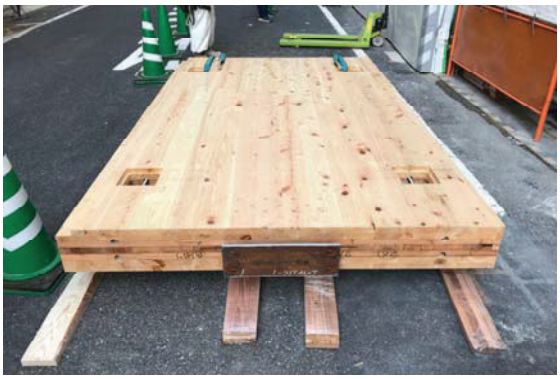

Figure 23: *Shear joint*

https://doi.org/10.52202/069179-0427

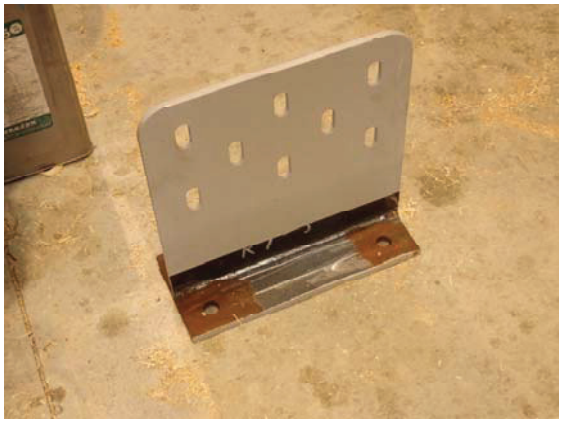

Figure 24: *Shear joint*

4.2 JOINTS TO TRANSMIT SHEAR STRESS (SHEAR JOINTS)

Refer to Figures 23 and 24. The drift pined joints with insert-steel gusset plates are used to transmit the shear stress. The insert-steel gusset plates are joined to the steel beam flanges through baseplates with high strength bolts. The drift pin holes in the insert-steel gusset plates are vertically loose so as not to be affected by the rotational deformation caused by the bending of a CLT panel and to allow level adjustments during construction.

4.3 JOINTS OF CLT FLOOR PANELS

Figures 25 and 26 show the joints of the CLT floor panels to the steel beams. The CLT floor panels are placed on the angle brackets installed on the steel beam webs and fixed with wood screws from the underside of the angles. Installation of angle brackets enables alignment of the CLT floor panels with the top level of the steel beams, which contributes to an increase in the effectiveness to the floor height. Besides, since wood screws do not require prepared holes, there is no need for strict precision management during construction. Hence, use of wood screws brings a great improvement in the construction efficiency during erection, compared with the cases of using drift pins or bolts.

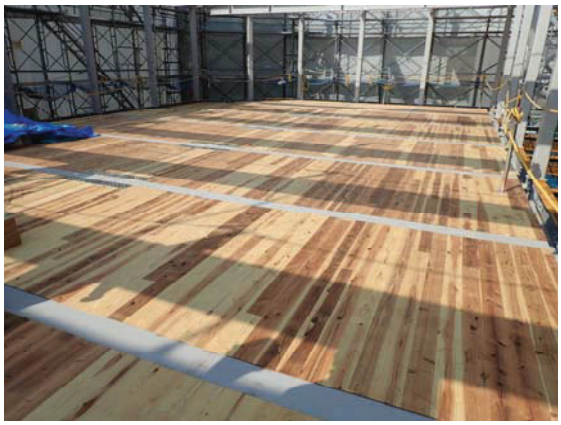

Figure 25: *CLT floor panels*

Figure 26: *CLT-floor-panel to steel-beam joint*

Thus, the joints between the CLT panels and steel frame of this building have contributed to the establishment of joining methods in consideration of fire-resistance performance and workability as well as the enhancement of the structural performance.

5 CONCLUSIONS

The above discussion shows that incorporation of CLT seismic panels into a steel frame makes it possible to exhibit the structural performance of the CLT panels efficiently. Additionally, this paper presents a series of structural design method including horizontal load-carrying capacity calculation through an actual case of design and confirms the usefulness of this structural system including fire-resistance performance.

TECHNICAL CONCEPT AND FEASIBILITY OF STEEL SHEET REINFORCED SYNTHETIC WOOD BEAM

Shogo Oda[1], Chikako Tabata[2], Yoshito Tomioka[3]

ABSTRACT: This paper is intended to explain the technical concept of steel sheet reinforced synthetic wood (SSRW). SSRW focuses on improving the integrity of wood and steel to increase the strength and toughness of hybrid materials. The composition includes laminated wood inserted with thin steel sheets prepared with adhesive holes and dowels. We conducted scale-model experiments to evaluate the feasibility of SSRW. We found that the vertical insertion of steel sheets demonstrated notable gains in rigidity and strength. Further, we observed that SSRW achieves 1.9 to 2.1 times greater bending rigidity as well as gains in strength than the unreinforced specimen.

KEYWORDS: Laminated wood, Adhesive opening, perforated steel metal

1 INTRODUCTION

Steel sheet reinforced synthetic wood (SSRW) is a wood-steel-hybrid-material for structural members, with a steel sheet reinforcement inserted in the cross-section of synthetic wood, as shown in Figure 1.

The purpose of SSRW is to compensate for the discontinuity of potential defects. Inserting the steel sheets between adhesive surfaces of wood can mitigate inconsistency in material strength.

In addition, this can moderate the localized stress concentration at the joint, which tends to be a critical part of structure design.

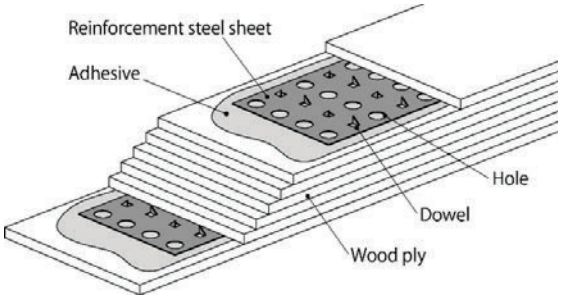

Figure 1: *Composition of SSRW*

Figure 1 shows the composition of SSRW.

Thin steel sheets are inserted and sandwiched between the adhesive layer of engineering wood.

The steel sheet has holes through which the adhesive penetrates and dowels that bite into the wood for temporary mechanical fixing and alignment.

2 PREVIOUS INVESITIGATIONS

Here, we discuss two recently proposed wood-steel hybrid beams.

Tanaka et al. (2007) prepared synthetic wood specimens with a 200 mm × 100 mm cross-section and added 6 mm-steel plates.

There were two specimens: plates on the bottom sides only, and on both the top and bottom. This was done using lag screws without adhesive.

They conducted a 3-point bending test with a span of 4 m and found that in both specimens, the maximum strength was approximately 1.2 times greater than that of plain wood.

The fracture behaviour of the specimens showed cracks in the wood material stressed by lag screws.

This is significant, especially on the tension side (bottom), where the wood was separated with a gap because the stretch of wood material could not follow that of the steel plate.

Winter et al. (2012) prepared 360 mm × 160 mm cross-section of synthetic wood inserted with cold formed or welded H shaped 4 mm-thick steel plate in wood material grooves by four threaded rods.

They conducted 4-point bending tests with a span of 6 m and found that the maximum loads of cold-formed and welded sheets were similar.

The fracture behaviour of both specimens was wood material rupture on the tension side.

This fracture occurred because the wood material could not follow the bending of the steel plate inside the beam.

These previous investigations were generally aimed at achieving high rigidity and high strength in hybrid beams. The hybrid material was wood with thick steel plates, which had low integrity.

https://doi.org/10.52202/069179-0428

Additionally, beam fractures were caused by the rupture of the wood on the tension side of the hybrid material.
In SSRW, a very thin steel sheet is used as the reinforcing material to obtain uniform rigidity with wood.
We focused on improving the cross-sectional integrity and bending performance of wood material and steel plates.
This hybrid beam aims to improve toughness rather than rigidity.

3 EXPERIMENT OUTLINE

We conducted 3-point and 4-point bending tests in three phases. The bending tests were performed until the specimen fractured.
A scale-model was used for the specimens to comprehensively study many experimental parameters in a short time and at a low cost.
We observed the maximum proof strength, initial rigidity and fracture behaviour in the bending tests.

3.1 TEST SETTING

1) Phase 1 and Phase 2
Phase1 and 2 were 3-point bending tests.
The span of each specimen was 600 mm.
Figure 2 shows the test setting.

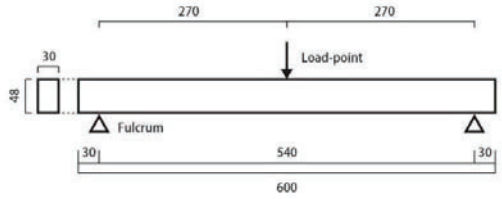

Figure 2: *Test setting in phase 1 and phase 2*

2) Phase 3
Phase 3 consisted of 4-point bending tests.
The span of the specimen was the same as that used in the previous phase.
Figure 3 shows the test setting in phase 3.

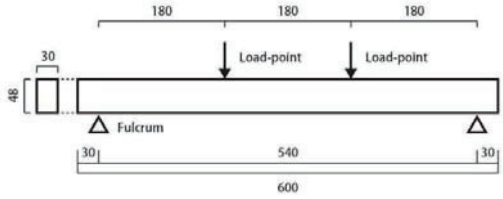

Figure 3: *Test setting in phase 3*

3.2 SPECIMEN PREPARATION

Figure 4 shows the specimen production process.
The specimens were 30 mm × 48 mm in cross-section and 600 mm in length and were made of 6 mm thick falcata laminated wood bonded with an epoxy resin adhesive.
Galvalume steel sheets 0.27 mm thick were used as the reinforced steel sheets.

The test specimen fabrication method:
(a) Markings were made directly on the steel sheet where the hole was drilled.
(b) Steel sheets of 0.27 mm thick were cut to 680 mm × 36 mm size.
(c) Holes were punched along the markings.
(d) The holes and cutting edges of the steel sheet were planar compensated using a plastic hammer.
(e) The surface of the steel sheet was degreased with ethanol.
(f) Steel sheets were placed along the markings of the lamina, and the lamina and buck sheets were laminated.
(g) The specimen was temporally fixed with a clamp.

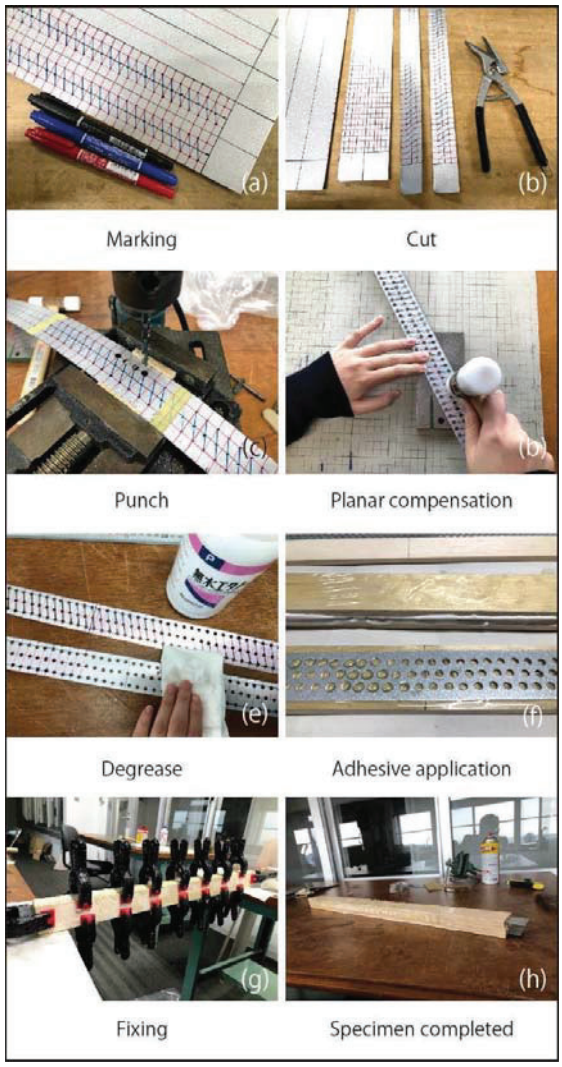

Figure 4: Specimen preparation

https://doi.org/10.52202/069179-0428

4 EXPERIMENTS

The experiment was conducted in three phases.

4.1 [PHASE 1]: EFFECT OF INSERTION DIRECTION

In phase 1, specimens with steel sheets inserted vertically and horizontally were prepared, as shown in Figure 5 and 7.
The main parameter of phase 1 was the cross-sectional insertion direction to confirm its effect on the performance of the specimen.
The parameter was also prepared to examine the effect of dowels.

1) Specimen parameters
In phase1, we used 7 specimen types.
One laminated wood beam with only lamina stacked vertically in cross-section was prepared.
Three specimens were prepared with steel sheets inserted vertically, and three specimens were prepared with steel sheets inserted horizontally.

2) Results: Load-deflection relationship
Figure 6 shows the load deflection relationship in the vertical insertion group.
This group of specimens significantly outperformed the unreinforced specimens in terms of initial rigidity and maximum proof strength in all the tests.
The initial rigidity was 1.9 to 2.1 times higher, and the maximum proof strength was 1.3 to 1.5 times higher.
The V-N specimens exhibited the highest initial rigidity, but the lowest maximum proof strength.
The lack of holes in the steel sheets caused premature delamination of the lamina and steel sheets.
V-4Hm-3.3 with holes showed the greatest maximum proof strength.
V-3Dm-4 with dowels applied to the holes performed worse than V-3Hm-3.3 in terms of both, initial rigidity and maximum proof strength.
Figure 8 shows the load deflection relationship in the horizontal insertion group.
These specimens behaved similarly to the unreinforced specimens.
The superiority of openings and dowels was not clear in these specimens.

3) Fracture behaviour
Figure 9 shows the fracture behaviour of vertical series.
The cross-section of the specimen with the wood cut away is shown.
The beam fractured in bending tension from the centre of the beam.
In V-4Hm-3.3, the facture shape shows that the wood fracture progress roughly along the rupture of the steel sheets.
V-3Dm-4 showed a similar fracture shape.
Figure 10 shows the fracture behaviour of H-N.
Bending and tensile fracture from the centre of the beam.
The steel sheet on the tension side was broken from the band.

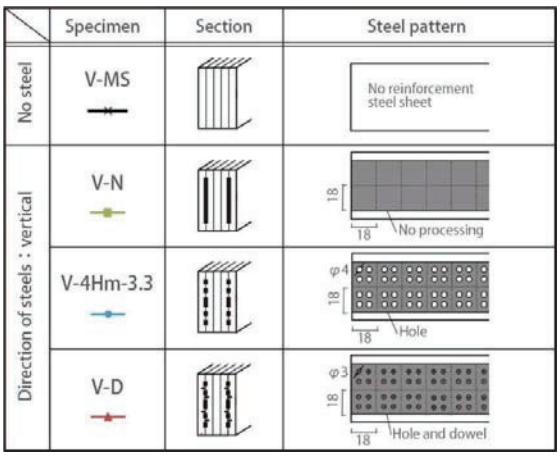

Figure 5: *Specimen parameters of vertical series in phase 1*

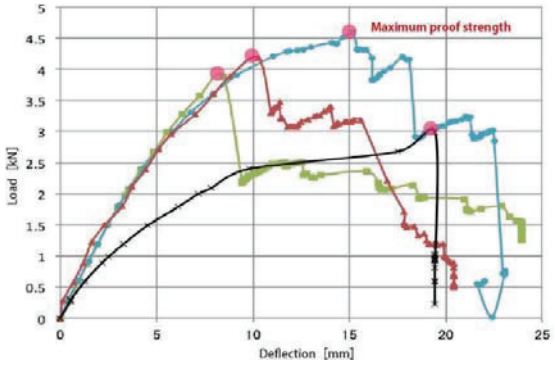

Figure 6: *Load-deflection relationship in vertical series*

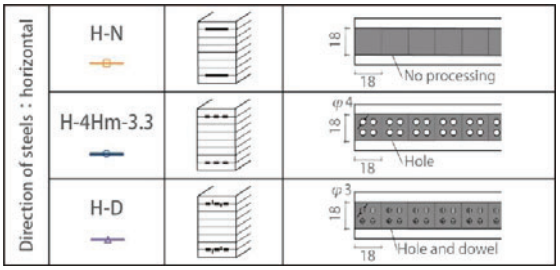

Figure 7: *Specimen parameters of horizontal series in phase 1*

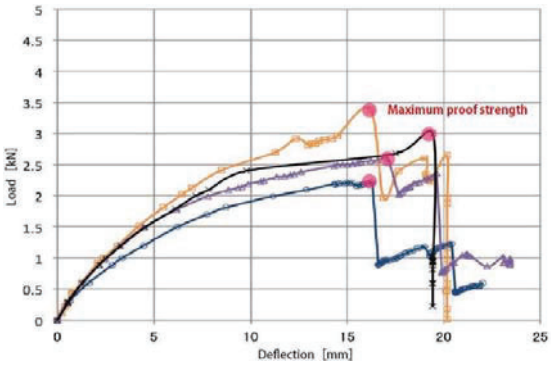

Figure 8: *Load-deflection relationship in horizontal series*

https://doi.org/10.52202/069179-0428

4) Discussion
The specimens with vertically inserted steel sheets had better initial rigidity and maximum proof strength.
Specimens V-4Hm-3.3 and V-3Dm-4, in the load-deflection diagram showed an increase in toughness with repeated load decreases and recovery after the maximum proof strength.
The progression of the fracture from the outermost band to the next band of the steel sheet on the tension side was repeated, and the wood followed the fracture.
The thin steel sheet and its holes resulted in a highly integrated cross-section of wood and steel.
V-3Dm-4 with dowels applied to the holes performed worse than V-3Hm-3.3 in both, initial rigidity and maximum proof strength.
This experiment did not confirm the superiority of dowels. The reason for this is thought to be a defect in the processing method of the dowel section, inferred from the V-3Dm-4 fracture developed from the v-cut section at the base of the dowels.

4.2 [PHASE 2]: EFFECT OF HOLE PLACEMENT

In this phase, specimens were limited to a group of vertically inserted steel sheets.
The main parameters of phase 2 were the placement and size of holes in the steel sheet to confirm if they affected bending performance.

1) Specimen parameters
Figure 11 shows specimen parameters in Phase2.
Specimens were prepared in 6 types.
Three different hole sizes (5.5 mm, 6.5 mm, and 7.5 mm) were prepared.
One specimen had a grid arrangement of holes in the steel sheet (V-5Hg-6.5) and three had staggered holes.
V-MS and V-N had the same configuration as the specimens in phase 1.

2) Results: Load-deflection relationship
Figure 12 shows the load deflection relationship in phase 2.
Initial rigidity was improved for all specimens over that of simple laminated wood beams.
Almost all the specimens had higher maximum proof strength than simple laminated wood beams. Only V-5Hg-6.5 was inferior.
V-5Hg-6.5 was likely defective because the behaviour of the load-deflection diagram was unstable during the early stages of loading.
V-N had the largest initial rigidity and maximum proof strength, but low toughness.

3) Fracture behaviour
Figure 13 shows the fracture behaviour of V-N.
The specimen fractured in the middle of the beam so that the fibres of the tension side wood were severed.
The steel sheet band lifted approximately 3 mm from the wood.
Figure 14 shows the fracture behaviour of V-5Hg-6.5.
The specimen fractured in bending tension from the centre of the beam.

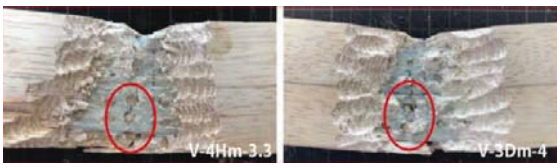

Figure 9: *Fracture behaviour of vertical series*

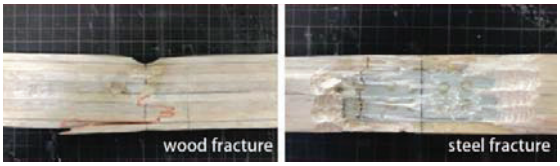

Figure 10: *Fracture behaviour of H-N*

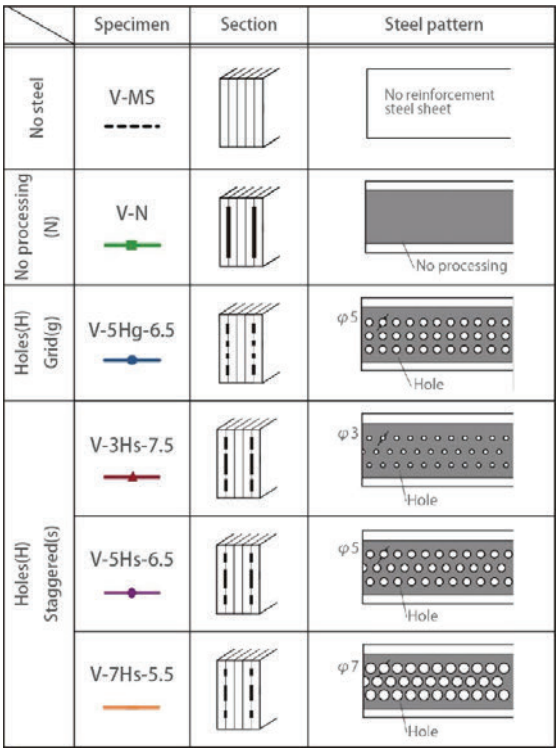

Figure 11: *Specimen parameters in phase 2*

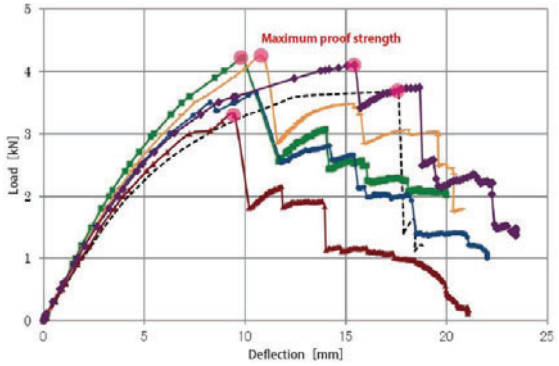

Figure 12: *Load-deflection relationship in phase 2*

https://doi.org/10.52202/069179-0428

The steel sheet band lifted approximately 0.9 mm from the wood.

4) Discussion
Apart from V-5Hg-6.5, the initial rigidity and maximum proof strength of the specimens were higher than those of simple laminated wood beams.
The insertion of steel sheets improves bending performance.
The specimen reinforced with a steel sheet without holes showed the greatest initial rigidity and maximum proof strength, but the steel was lifted from the wood up to the neutral axis after unloading.
The specimens reinforced with steel sheets with holes showed better toughness.
Hole size showed a trend towards improved performance for larger sizes.

4.3 [PHASE 3]: EFFECT OF BANDWIDTH

Specimens were limited to a group of vertically inserted steel sheets in phase 3.
The main parameter was steel sheet bandwidth, which was tested to see if it affected bending performance.

1) Specimen parameters
Figure 15 shows specimen parameters in phase 3.
Specimens were prepared in 6 types.
Steel sheets were prepared with holes in a staggered arrangement (V-5Hg-6.5, V-5Hs-4, V-5Hs-3, and V-4Hs-3) and modular arrangement.
V-5Hs-6.5 and V-4Hm-3.3 had the same composition as the specimens in phases 1 and 2.

2) Results: Load-deflection relationship
Figure 16 shows the load-deflection relationship in phase 3.
V-5Hs-4 had the greatest initial rigidity.
The specimen with the greatest maximum proof strength and toughness was V-4Hs-3.

3) Fracture behaviour
Figure 17 shows the behaviour of V-4Hs-3.
The tension side of the wood fractured near the loading point.
In the tension side, the band lifted1.2 mm out of plane.
Figure 18 shows the behaviour of V-5Hs-4.
V-5Hs-4 also showed a similar fracture shape to V-4Hs-3.

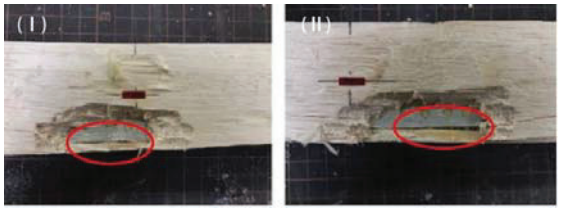

Figure 17: *Fracture behaviour of V-4Hs-3*

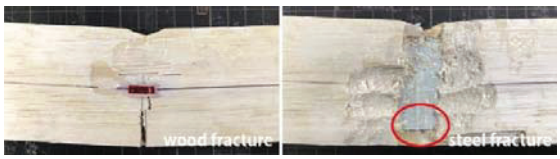

Figure 13: *Fracture behavior of V-N*

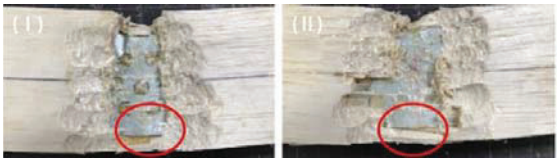

Figure 14: *Fracture behavior of V-5Hg-6.5*

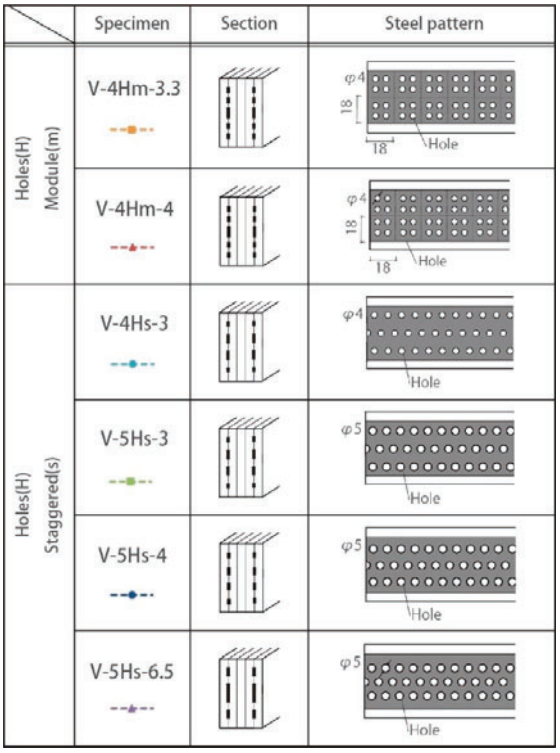

Figure 15: *Specimen parameters in phase 3*

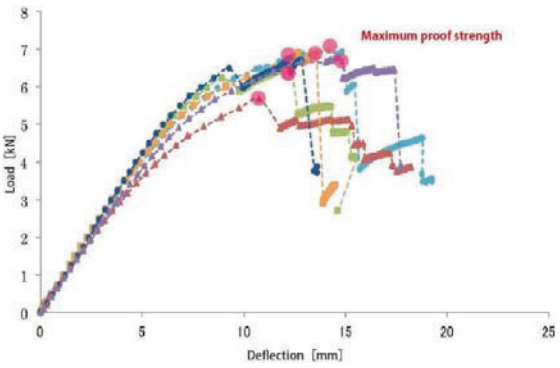

Figure 16: *Load-deflection relationship in phase 3*

https://doi.org/10.52202/069179-0428

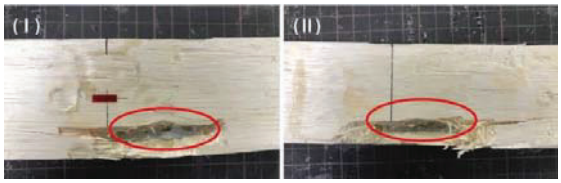

Figure 18: *Fracture behaviour of V-5Hs-4*

4) Discussion
No clear effect of the bandwidth parameter on bending performance could be observed.
Regarding the placement of holes, there was a slight performance improvement trend towards staggered placement.
The staggered arrangement may be due to the homogenisation of stress transmission in the cross-section, as the bands of the steel sheets intersect at an angle.

5 GENERAL OBSERVATION

The insertion of steel sheets was observed to improve bending performance.
Specimens with vertically inserted steel sheets had better initial rigidity and maximum proof strength than those with steel sheets inserted horizontally.
This result suggests that the vertical reinforcement of steel sheets with wood materials is a more effective than the horizontal reinforcement.
The hole size parameter showed a trend towards improved performance for larger sizes.

6 CONCLUSION

The observations from our study can be summarised as follows:
1) Bending performance is improved by inserting steel sheets into the laminated wood.
2) Vertical insertion of the steel sheet is more effective than horizontal insertion.
3) Holes in the steel sheet improve the integrity of the steel and wood sections.

ACKNOWLEDGEMENT

The results of this research are greatly attributed to the efforts of Ms. Yoko Aoyama.

TIMBER-CONCRETE-COMPOSITE BEAMS WITH DISCRETE PERFORATED STEEL PLATE SHEAR CONNECTORS

Dolores Otero-Chans[1], Javier Estévez-Cimadevila[2], Emilio Martín-Gutiérrez[3], Félix Suárez-Riestra[4], José A. Vázquez-Rodríguez[5]

ABSTRACT: This paper describes an experimental research on timber-concrete-composite (TCC) beams made with discrete perforated steel plates shear connectors. The research included shear tests on different connectors made with perforated steel plates glued with epoxy in timber ribs and short and long-term test on beams with 8.88 meters of span. An unbonded tendon along with a self-tensioned system was used to limit the deflections of the beams on some of the short-term tests. A locked tendon was also used in long-term tests.

The different proposals of shear connectors made with discrete perforated glued steel plates showed a great strength and stiffness, with almost negligible slip between timber and concrete in service. This shear connectors, were used to design 8.88-meter span beams that showed a behaviour close to the full composite action in short-term tests, indicating a great potential to design medium and long-span beams and floors.

Some of the beams have been subjected to long-term loads for more than two years in an interior and uncontrolled environment. After that, the stiffness of the beams was evaluated under different test configurations and they were finally tested until failure.

KEYWORDS: long-span floors, timber-concrete composite, discrete shear connector, glued steel plates.

1 INTRODUCTION

Extensive research has been carried out in recent years around TCC systems, due to the enormous advantages they offer compared to only wood or only concrete solutions. The efficiency of these systems lies in the design of the shear connections between both materials, which must limit the relative slip in order to achieve a composite action as full as possible.

Traditionally, these connection systems have been classified into three large groups: notched connections, screwed connections and glued connections [1]. Within glued solutions, it can also be distinguished between direct glued solutions, in which the adhesive is the only connecting element between the wood and the concrete; and solutions with bars or plates glued into the wood, these being the ones that act as connectors with the concrete layer.

A considerable number of experimental studies have been carried out on connectors made with glued bars. Some studies have been carried out with continuous glued steel meshes used as shear connector, most of them linked to the system HBV® [2]. The studies carried out with short steel sheets placed discreetly along the length of beams or floor elements to constitute TTC systems are much smaller.

This paper summarizes the studies carried out by our team on the behaviour of a system based on the use of discrete perforated steel plates as shear connectors. The study carried out includes the experimental study of various arrangements of the perforated plates and the bending test of pieces with spans of 8.88 m in both short-term and long-term configurations. The effect of a unbonded but locked tendon was studied in short- and long-term tests. In some of the short-term bending tests, a tensioning system has been used to improve the behaviour of the floor in service.

2 SHORT-TERM TESTS ON SHEAR CONNECTORS

The specimens consisted of a fibre-reinforced concrete slab with 80 mm thickness and a rib of glued laminated timber with a cross-section of 120x160 mm and GL28h strength class. The Fibre-reinforced concrete, made from CEM II/B-M (V-L) 32.5N cement with a content of 350 kg/m3 and polyolefin macro-fibres Sika-Fiber48, was used to minimize the effect of shrinkage. The shear connectors were made from hot-galvanised 5-mm

https://doi.org/10.52202/069179-0429

thickness steel plates, with 10-mm staggered holes every 15 mm. Two 8-mm thickness slots were made on the upper face of the wooden ribs to place the perforated galvanized steel plates glued using a two-component epoxy adhesive with a thickness of 1.5 mm.
Two batches of tests were carried out to evaluate different shapes of the connectors. In the first batch tests were carried out on 3 types of connectors: only with the plate, including transverse reinforced bars passing through the holes in the plates, including longitudinally welded reinforced bars on the plates (Figure 1).

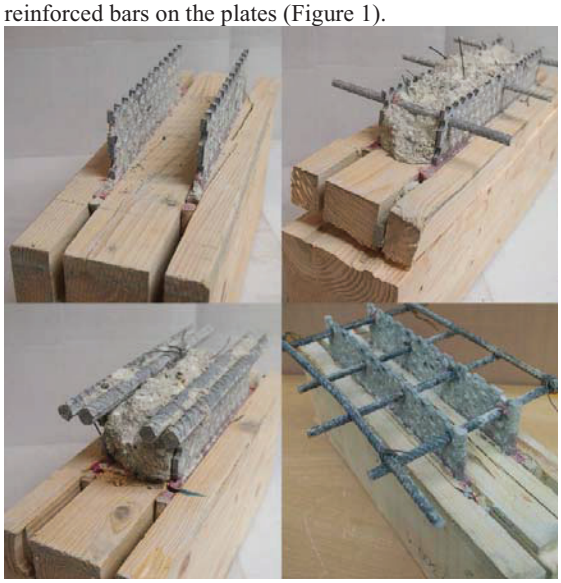

Figure 1: *Shear test specimens open after failure to check gluelines.*

Two connector lengths, 180 and 300 mm, were studied for each type of specimen. 18 specimens of 6 different types were subjected to failure in a shear test, obtaining the failure values, failure modes, and relative slip between the wood and the concrete [3]. All the specimens failed mainly by shear in timber (Figure 1).
Failure load ranged from 157.1 to 195.1 kN (average 179.1 kN) for 180-mm specimens and from 232.9 to 326.4 kN (average 260.4 kN) for 300-mm specimens. Specimens with longitudinally welded bars obtained, in average, the better results, although the difference between the three types was small. The load-slip behaviour of the connections lead to slip moduli between 707.5 and 1164.3 kN/mm for 180-mm specimens and between 2301.9 and 4298.1 kN/mm for 300-mm specimens.
In the second batch 6 new types of specimens were tested including vertically welded reinforced bars at the ends of the plates that were inserted a longer length in pre-drilled holes in the timber member (Figure 2). The types tested included three different configurations of bars and plates, varying the height of the plates and the anchorage length of the bars. For each of these configurations, two connector lengths, 180 and 300 mm, were tested again [4].

Figure 2: *Gluing of shear test specimens with plate+rods arrangement.*

All the specimens failed mainly by shear in timber again. Those made with plates+rods showed a greater ductility because of the anchorage of the rods although there was not significant difference for ultimate failure load when comparing specimens with the same length of the connector. In this case, failure load ranged from 175.1 to 213.6 kN (average 194.7 kN) for 180-mm specimens and from 213.6 to 318.6 kN (average 265.6 kN) for 300-mm long specimens. Slip moduli ranged between 959.8 and 1259.4 for 180-mm specimens and between 2103.0 and 3407.3 kN/mm for 300-mm specimens.
From these results, a simple predictive analytical model was proposed to determine the ultimate capacity of the shear connection [5].
Given that all the connectors tested showed high resistance and k_{ser} values, the simplest system was used for the elaboration of specimens for the full-scale beam tests.

3 SHORT-TERM TESTS ON TCC BEAMS

Eight beams with a total length of 8.88 meters and a T-section were made. The upper concrete slab had a dimension of 720x60 mm and the lower wooden rib had a section of 180x210 mm. An additional 30-mm thickness formwork board makes up a total height for the beam of 300 mm and a slenderness L/30. The characteristics of the materials were similar to those used in the previous shear tests. A 30x60 mm longitudinal groove was made on the underside of the wooden rib to house a tendon in some of the test configurations (Figure 3).
Four of the eight beams housed a tendon of 20 mm in diameter and the other four of 26.5 mm in diameter. Tendons were Y1100H Steel Dywidag threaded bars (with ultimate tensile strength 1100 MPa, and yield strength 900 MPa). The tendons were not adhered to the timber joists. Figure 3 shows the temporary blocks used solely for the purpose of positioning the tendons within the grooves.
Perforated S235 grade galvanized steel plates with dimensions 300x105x5 mm were used as shear connection between timber and concrete The pattern of the holes in the plates was similar to that of the previous shear push-out tests. A two-component epoxy adhesive was used to glue the plates to the timber joist. The perforated plates were arranged with variable spacing along the beam, as can be seen in figure 4. The minimum distance between them was 450 mm and the maximum 650 mm. In the area of the centre of the span, section

https://doi.org/10.52202/069179-0429

without shear, a distance between connectors of 1390 mm was disposed.

Figure 3: *Geometrical configuration of 8.88-m long beams.*

Four different test configurations were carried out, with the aim of evaluating the difference in deflections between them: test of pieces without tendons (test 1); test with non-adherent tendons and no pretensioning force, but with the tendons affixed at the ends of the beams (test 2); test with non-adherent tendons and a pretensioning force of 30 kN (test 3) and test with non-adherent tendons fixed to a self-tensioning system patented by the authors (test 4) [6].

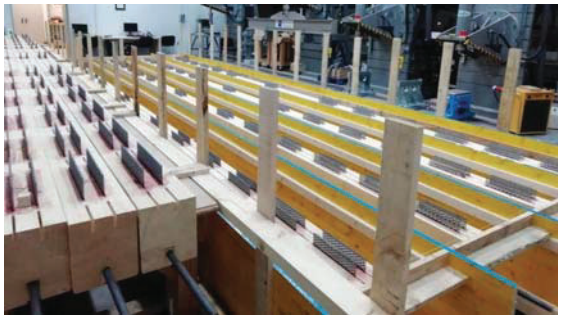

Figure 4: *Arrangement of the beams previous to the pouring of the concrete.*

For tests 2 to 4, four results were available for each of the tendon diameters studied. Tendon washer-type load cells were place at both end of tendons in tests 2 to 4 to record the loads reached in the tendons.

Figure 5: *Short-term test on 8.88-meter span beams.*

Beams were tested under a four-point bending test. Two load hypotheses were studied in each type of test: a quasi-permanent load hypothesis (with a value of 4.0 kN/m^2) and another full load hypothesis (with a value of 7.5 kN/m^2). For all tests the relationship between load and displacement at the midpoint was recorded. Additionally, a measurement was made in the central area of the beam corresponding to the relative deformation of two points separated 2 meters from each other, with the aim of determining the local stiffness (EI_{local}) in the area where there is only flexion since the shear is null. For this, a rigid aluminum bar was arranged as shown in Figure 5. Finally, six of the eight beams were tested until failure, reserving the remaining two for long-term tests. All the beams failed due to tension in the lower fibre of the wooden rib (Figure 6). No significant damage or cracks were observed in the concrete slab.

Figure 6: *Tensile failure in the lower fibre of the timber joist.*

Discreetly placed glued plate connections (at variable distances along the beams) resulted in a composite action close to 99% in all cases. Additionally, the use of non-adherent tendons allows reducing the deflection of the beams. The reduction in deflection was around 10% in the case of non-prestressed tendons and reached values close to 30% when the self-tensioning system was used [7].

https://doi.org/10.52202/069179-0429

In any case, the timber-concrete composite section proved to be very efficient in bending even in non-tensioned solutions, with deflections lower than 1/400 of the span for a ratio span/height of 30.
Finally, thebeams were tested until failure keeping the tendons locked.
Failure loads ranged from 69.3 to 122.2 kN, with no significant differences between the mean failure load of the beams with 20 or 26 mm diameter tendons.
The analysis of the two proposed service load hypotheses showed practically linear load-displacement curves in all cases.

4 LONG-TERM BEHAVIOUR OF TCC BEAMS

Two 8.88m-spam beams were subjected to long-term loads for more than two years (823 days), from October 2019 to December 2021, in an interior and uncontrolled environment (in Lugo, Spain). The test protocol during that period included the measurement of the environmental conditions (relative humidity and temperature), the humidity content of the beam components and the deflection at different moments of the process. The environmental conditions were continuously recorded by a thermo-hygrometer model LASCAR EL-USB-2 that collects data at half-hourly intervals. Periodically, the moisture content of the wood was recorded with a moisture meter model GANN Hydromette RTU 600.

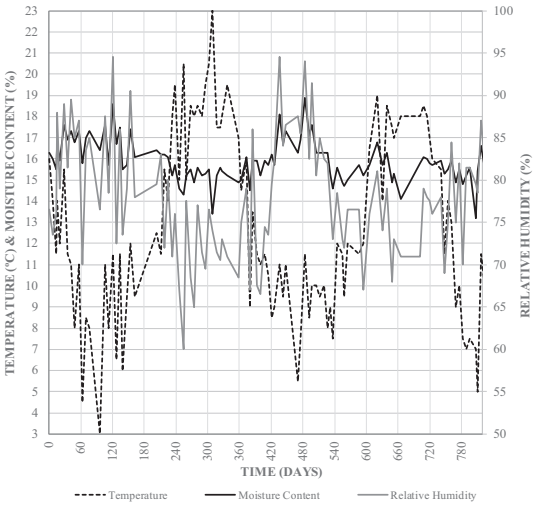

Figure 7: *Variation of the environmental conditions and the moisture content of the wood during the test period.*

The ambient temperature varied during this period between a minimum of 3.0 and a maximum of 23.0º Celsius (average value 13.5ºC), and the relative humidity between 60.0 and 94.5% (average value 76.5%). The average moisture content of the wood (determined from the measurement made at various points on the beams) ranged from a minimum of 13.2% to a maximum of 18.9%, with an average value of 16.5% (Figure 7).

Figure 8: *Arrangement of the long-term test.*

The beams were arranged as simply-supported. One of them had the Dywidag tendon affixed at the ends, without any pre-tensioning force. Washer-type load cells were arranged to record the variation in tendon load over time. The other beam was completely free, the cross-section only with timber and concrete, without any tendon blockage.
The self-weight of the beams was evaluated in 1.44 kN/m. The imposed load was applied by boxes filled with water which represents a uniform imposed load of 1.60 kN/m and an equivalent load of 5.0 kN/m^2, including self-weight (Figure 8).
Figure 8 shows the deflection values recorded throughout the entire period. The instantaneous deflection values, 13 and 11.3 mm for the beam without and with tendon, respectively, correspond only to the imposed load. The deflection values throughout the period respond to the total load (including self-weight), and respond both the deflection due to creep and the deflection derived from environmental variations. Considering the ratio between the self-weight and the imposed load, the instantaneous deflection corresponding to the total load would be about 24.7 and 21.5 mm, respectively. Figure 8 also represents the load value recorded in the blocked tendon and the moisture content of the wood. The relationship between deflection variations, tendon load, and moisture variation are evident.
Figure 9 shows the difference in deformation of the beam with a blocked tendon and the beam with an unblocked tendon. The instantaneous deflection of the beam with a locked tendon is 86% of that of the one without the locked tendon. This proportion remains substantially constant throughout the process, varying between 79 and 95%. The difference between both deformations decreases as time progresses, until reaching that 95% towards the end of the period.

https://doi.org/10.52202/069179-0429

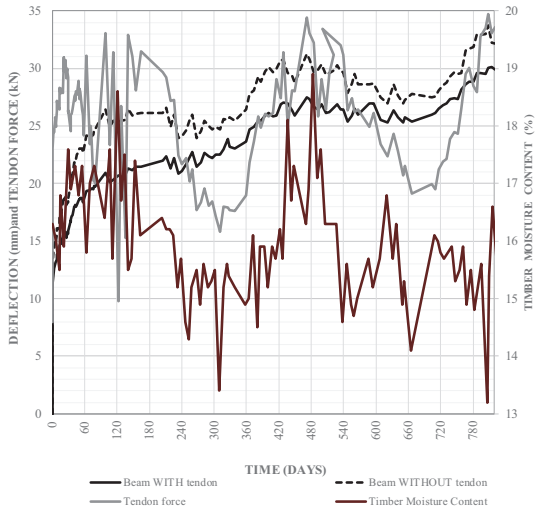

Figure 9: *Evolution of the total deflection during the long-term test along with the force in the tendon and the timber moisture content.*

In Figure 10 only the creep deformation is represented, also related to the moisture content and the force in the tendon. In this figure, it is more evident how the creep deformation of the two beams tends to equalize over time. Figures 9 and 10 also shows the relationship between the increase in deformation and the increase in the moisture content of the wood. The efficiency of the tendon is greater when the moisture content of the wood increases, since in the Figures 8 and 9 it can be seen that in these cases the difference between the creep deflections of the two beams also increases.
The creep deformation after two years is somewhat lighter than the instantaneous deformation (the total deformation is slightly below than twice the instantaneous).

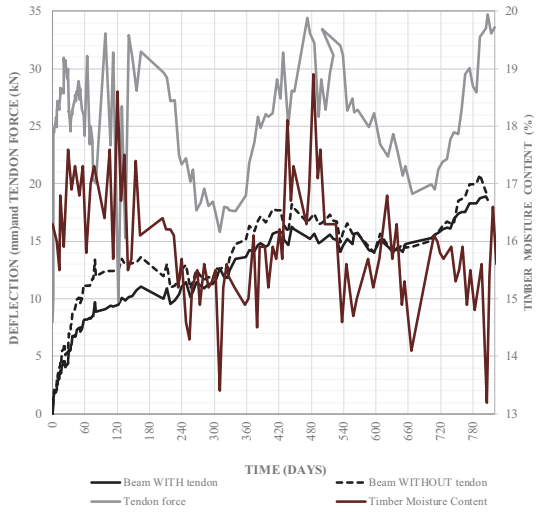

Figure 10: *Evolution of the creep deflection during the long-term test along with the force in the tendon and the timber moisture content.*

5 SHORT-TERM TESTS OVER PRELOADED BEAMS

After the long-term test, the beams were unloaded and remained supported along their entire length for about 60 days. Then, the beams were tested again in short-term. Two types of test were carried out: type A and type B.
In test type A the beams were arranged as simply-supported with two cantilevers, with a span between supports of 6.90 meters. In test type B the beams were arranged as simply-supported with a span equal to 8.7 m. A schematic representation of the load arrangement can be seen in Figure 11.

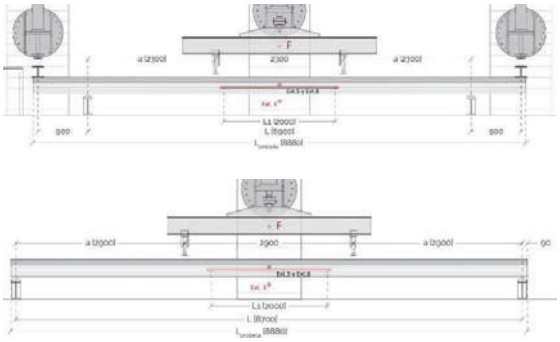

Figure 11: *Type A and type B arrangements for the short-term tests made after long-term tests.*

In test type A, the beams were loaded three times. The first load is carried out with the tendon unlocked and without any restriction at the ends of the cantilevers. The beams are loaded to a maximum of 7.5 kN and the deflection at the midpoint is recorded. Subsequently, the ends of the beams were blocked at a distance of 0.9 meters from the supports, generating a reaction to the upward vertical displacement of the ends. To achieve this blocking, loads were applied by means of two load cells located at the ends of the cantilevers that remained in a fixed position after applying a load of 1 kN. In this situation, the beam was again loaded to a maximum of 7.5 kN in two different situations, the first without locking the tendons and the second locking the tendons by means of end locking nuts. In both cases, the descent of the midpoint and the load at the ends were recorded (Figure 12).
Given that a very linear load-deflection behaviour had been observed in the previous tests, low-magnitude loads were applied in this case to measure the bending stiffness in order not to damage the pieces in the different configurations tested. The load was applied by constant speed according to EN 408:2010+A1. A hydraulic testing machine equipped with a 600 kN load cell was used. In the same way as in the previous short-duration tests, a deflection measurement was carried out in the central area of the beam of the relative deformation of two points separated 2 meters from each other, with the aim of determining the local stiffness (EI_{local}), using a rigid aluminium bar as indicated in Figure 11.

https://doi.org/10.52202/069179-0429

Figure 12: *Type A test arrangement, with cantilevers at the end of the beam.*

In the type B test, the beams are arranged as simply supported with a span of 8.7 meters. In this case, a first load phase is carried out with a maximum value of 9.8 kN and the deformation of the pieces with the tendons not locked and with the tendons locked is recorded. Finally, the pieces are tested until failure with the tendons not locked.

The type A test allows verifying the ability of the fibre-reinforced concrete slab to withstand small-magnitude tensions without cracking, which would allow the design of continuous elements over several spans.

Table 1 shows the mean values of breaking load and flexural stiffness (EI) for the tests carried out before and after long-term tests.

Table 1: *Failure loads of simply-supported beams.*

Tests	Locked tendon	Average failure load [kN]	Average bending stiffness EI [kN·m]
First short-term tests	No	-	11660
	Yes	93.7	12680
Second short-term tests (after long-term load)	No	68.9	10660
	Yes	-	12580

The increase in the global bending stiffness of the beams with the tendon locked with respect to the tendon without locking is between 9% and 32%. The difference between the beams that have been subjected to long-term tests and those that have not undergone long-term tests is bigger for beams without tendon. The result is practically the same in the case of tests performed with the tendon locked. To this regard, it is necessary to remember that in the case of beams from long-term tests, only two specimens are available, so conclusions must be taken with caution.

The failure load is not comparable between the two tests, since in one case the beams were tested until failure with the tendon locked and in the other without it. But, considering the little difference in behaviour observed in terms of stiffness, it could be concluded that the arrangement of a locked tendon (without pre-stressing) could increase the bending strength of the beam by up to 27%.

6 CONCLUSIONS

Discrete perforated glued steel plates constitute a very effective solution for the development of timber-concrete-composite systems.

Shear connection with perforated steel plates between timber and concrete can be improved by using additional steel bars. However, the improvement in performance is slight, so the use of additional bars must be justified by other design criteria.

Full scale short-term tests were made on TCC beams with 8.88-meter span. The use of perforated plates as shear connector showing a composite action close to 100%.

The use of non-adherent tendons allows to reduce de deflections in beams between 10 and 30%, depending on the pre-tensioning force of the self-tensioning device used.

The use of non-prestressed tendons can also reduce long-term deflections, especially when the moisture content of the wood is high.

A NEW BUILDING STRUCTURAL SYSTEM USING TIMBER-CONCRETE-COMPOSITE MEMBERS

Javier Estévez-Cimadevila[1], Dolores Otero-Chans[2], Emilio Martín-Gutiérrez[3], Félix Suárez-Riestra[4], José A. Vázquez-Rodríguez[5]

ABSTRACT: This paper presents a novel system for the construction of building structures based on the use of timber-concrete-composite pieces (floors, beams and columns). Beams and floors are composed of a prefabricated lower glued laminated timber (GLT) flange glued to one or more plywood ribs that are linked to an upper concrete slab poured in situ using an efficient timber-concrete connection of holes made on the ribs.

An extensive experimental campaign was carried out to validate the solution: shear tests of wood-wood and wood-plywood glue line; delamination tests of wood-wood and wood-plywood glued planes; shear tests of the timber-concrete connection with different configurations; finally, full scale four-point bending tests of simple supported beams and three-point bending tests of pieces in an overhanging configuration.

In order to know the performance of the system, sizing curves using the Gamma Method were developed. Results indicates a light, slender and high stiffness structural solution very suitable to be used in building construction.

KEYWORDS: Timber-concrete-composite, structural building systems, timber flooring, mixed beams, shear connection

1 INTRODUCTION

The advantages of the timber-concrete structural solutions are well known and are referenced in many papers [1-3]. A suitable design of timber-concrete composite (TCC) sections allows to take advantage of the properties of both materials to achieve a more efficient structural solution than only-timber structures with lower self-weight than only-concrete solutions.

The behaviour and performance of these systems fundamentally depends on the efficiency of the shear connection between both materials. This efficiency is based on achieving a high strength against shear forces with low slip of the connection; thus achieving a high composite effect and a ductile behavior. The state of the art includes different timber-concrete connection systems such as steel fasterners and plates, glued solutions, or the mechanical transmission of forces through the use of notches, grooves or slots in the wood [4-7]. These connections show very different characteristics in strength, stiffness and ductility of the joint.

This paper describes a complete solution for the construction of building structures using perforated plywood or laminated veneer lumber (LVL) as timber-concrete connection. The paper contains a summary of the different experimental campaigns carried out to validate the behaviour of the system. This includes not only the experimental analysis of the connection but also bending full-scale tests of simply supported beams and pieces in a an overhanging configuration. Results obtained allow to conclude the high strength and stiffness behaviour of the system proposed.

2 DESCRIPTION OF THE SYSTEM

The system is based on the use of prefabricated timber pieces complemented with concrete poured in situ [4]. The system is composed of the following elements:

Floors. The floor is formed by prefabricated T or π shaped pieces composed by a lower flange of glued laminated timber (GLT) glued to one or more perforated plywood or LVL ribs (Figure 1). The connection between this pieces and the upper concrete slab is made using the holes filled by the in situ poured concrete.

Beams. The beam solution is very similar to flooring pieces. A π-shaped piece composed by a lower GLT flange glued to two perforated plywood or LVL ribs which ends are machined to conform the connection to the columns. The use of reinforcement bars makes it possible

https://doi.org/10.52202/069179-0430

to create an efficient semi-rigid connection with the columns.

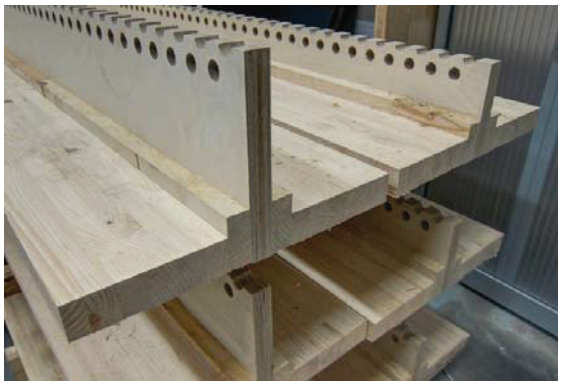

Figure 1: *Prefabricated T-shaped flooring pieces with different heights*

Columns. The columns are composed of a perforated plywood box section that satisfied two objectives: formwork of the concrete and support the flooring structure during the period in which the concrete is not sufficiently strong.

Figure 2 shows a computer-generated image of the complete system using cardboard blocks as infill formwork during the concrete pouring.

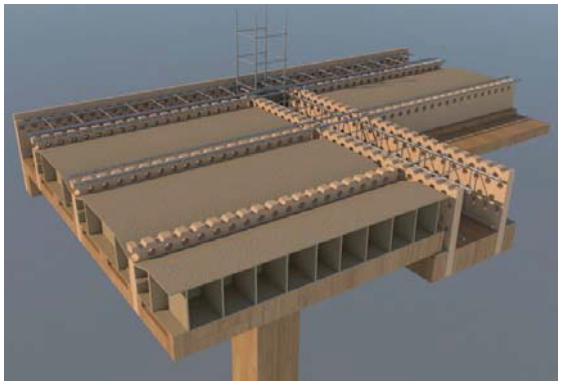

Figure 2: *Image of the complete system*

3 TEST CAMPAIGN

In order to validate the solution five test campaigns were carried out.

3.1 SHEAR TEST IN THE GLUE LINE

96 glue lines (72 wood-wood and 24 wood-plywood) of 8 samples of 390x50x50 mm, consisted of 7 *Picea abies* wood layers, strength class GL28h, and 2 birch plywood layers glued at both ends, were tested according to the UNE-EN 14080:2013 (Figure 3).

The results showed the efficacy of the connection in terms of strength with an average value of shear resistance of 9.63 N/mm^2 for wood-wood glue line and 7.16 N/mm^2 for wood-plywood glue line [8].

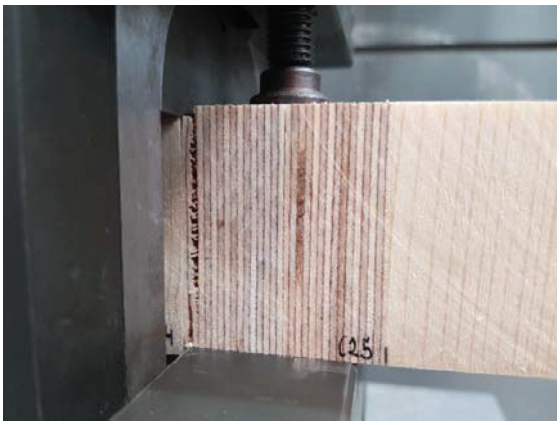

Figure 3: *Shear test in the glue line*

3.2 DELAMINATION TEST IN THE GLUE LINE

32 glue lines (24 wood-wood and 8 wood-plywood) of 8 samples of 195x75x77 mm were tested according to the UNE-EN14080:2013 (Figure 4). In 79.2% of wood-wood lines and in 62.5% of wood-plywood lines no delamination occurs. In the other lines average delamination was of 8%. Consequently, the results guaranteed the integrity of the glue lines [8].

Figure 4: *Delamination test in the glue line*

3.3 SHEAR TEST OF TIMBER-CONCRETE CONNECTION

An experimental analysis of the shear connection was carried out using push-out shear test according to EN 26891:1992 (Figure 5).

https://doi.org/10.52202/069179-0430

Figure 5: *Push-out shear test of timber-concrete connection*

Twelve samples of 480x300x300 mm were tested in a first campaign. Six of specimens were constituted with two 15 mm thick birch plywood boards joined to a 50–120 mm thick concrete slab. In the other six specimens the thickness of the boards was increased to 21 mm. 3 reinforcement bars of 8 mm, B500S steel grade, were placed in concrete slab crossing the upper file of holes of the board.

A second campaign was carried out with 45 samples of nine types of specimens in which different parameters were analysed: configuration of boards (one of 42 mm thick or two of 21 mm thick each one), holes disposition and diameter (2 rows, 20 mm diameter and 50 mm spacing or 1.5 rows, 30 mm diameter and 62 mm spacing), and use or not of B500S grade steel reinforcement bars.

Tests results show a very high stiffness and consequently a favourable composite action with k_{ser} values from 283.5 to 887.7 kN/mm per unit length depending of different configurations analysed [8, 9]. Moreover, load-slip curves for each tested showed a ductile failure that is a very positive characteristic in TCC solutions (Figure 6).

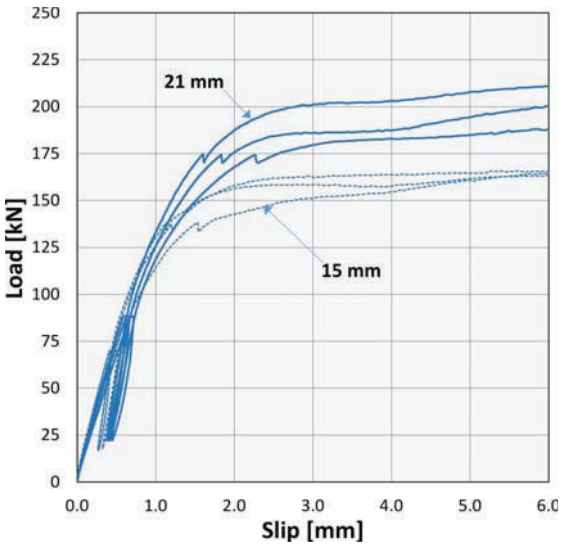

Figure 6: *Load-slip curves of specimens with two birch plywood boards of 15 mm and 21 mm thick.*

3.4 FULL SCALE FOUR-POINT BENDING TESTS OF SIMPLE SUPPORTED TCC BEAMS

Based on the results obtained in the shear test connection analyzing different parameters, the solution of a single 40 mm thick board with 1.5 rows of 30 mm diameter roles and 62 mm spacing has been chosen. This configuration combines efficiency and simplicity.

Full scale four-point bending tests of nine simple supported TCC beams according to standard EN 408:2010+A1:2012 were carried out with 3 different configurations: 3 samples of 6 m span and a height of 25 cm; 3 of 7.2 m and 30 cm; 3 of 8.4 m and 35 cm. In all cases the slenderness ratio was L/24 (been L the span of the beam).

The specimens consist of an inverted T-shaped piece formed with a 600x60 mm glulam flange made with *Picea abies* GL24h and a 40 mm thick birch plywood board with 30 mm diameter perforations. This board is joined to an upper concrete slab of 600x50 mm with polyolefin macrofibres added. Compression test of concrete specimens provided a mean strength value of 39.9 N/mm^2 at 28 days. 8 mm diameter and 120 mm long rebars were inserted through every three perforations of the boards (Figure 7). Additionally, a 200x200 mm ϕ6 mm steel mesh was placed to control cracking caused by shrinkage of concrete. Light cardboard blocks were designed to acting as lighten infill and formwork during the concrete pouring.

https://doi.org/10.52202/069179-0430

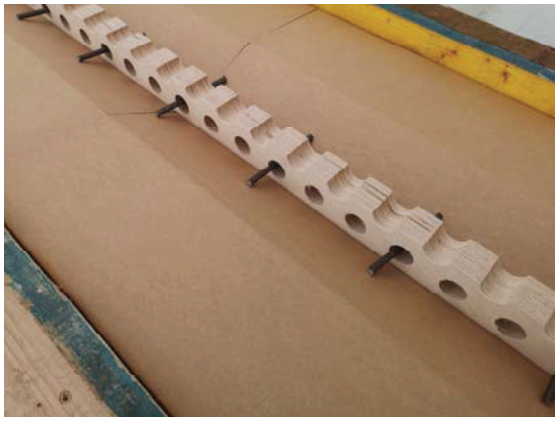

Figure 7: *Specimen with carboard bloks and rebars positioned previously the concrete pouring of 50 mm thick upper slab. In the photograph, the steel mesh has not yet been placed.*

Figure 8: *Bending test of a 7.20 m span specimen*

The lowest ultimate load value obtained in the tests corresponds to a total equivalent surface load of 39.04 kN/m^2, which represents a value 7.8 times higher than the total load of floors for residential use (self-weight+light partitions and finishes+ variable load=5.0 kN/m^2) [10].

Failure occurs suddenly, affecting the glulam flange of the central part of the beam in areas of knots or finger joints and extending due to longitudinal shear failure up to the beam supports (Figure 9).

The most unfavorable relative deflection obtained for service load of all samples tested was L/1069 for a total service load of 5.00 kN/m^2 and L/573 for a load of 9 kN/m^2 (been L the span of the beam), that would correspond to a building for public use. Therefore, the results indicate a high bending stiffness of the pieces and the effectiveness of the composite action despite the high slenderness of the pieces (L/24) and the unfavorable configuration that represents, from the point of view of the deformations, the simply supported beams condition [10].

Figure 9: *Longitudinal failure of the glulam flange*

3.5 FULL SCALE THREE-POINT BENDING TESTS OF TCC PIECES IN A AN OVERHANGING CONFIGURATION

One of the outstanding advantages of the developed system is that it allows the construction of floors and beams with pieces serving several spans or in an overhanging configuration. This results in a more efficient use of materials thanks to a more favorable distribution of bending moments and better behaviour in service at the deformation level. Three–point bending tests were carried out of eight specimens to evaluate the behavior against negative bending. 3 with a height of 250 mm an a overhanging span of 1.5 m; 3 with a height of 300 mm an a overhanging span of 1.8 m and 2 with a height of 350 mm an a overhanging span of 2.1 m. A slenderness ratio of L/6 was adopted in all cases.

Figure 10: *Specimen with the steel mesh and the rebars positioned in the area of negative bending moments.*

The specimens tested have the same section and material characteristics as those already described for the four-point bending tests, with the only difference being that

https://doi.org/10.52202/069179-0430

there is a reinforcement in the area of negative bending moments made up of two 12 mm diameter rebars (Figure 10).

Figure 11: *Test of 1.80 m overhanging span specimen*

Figure 12: *Cracking process in the concrete upper slab*

Two types of failure modes have been observed in the tests: tensile failure of plywood rib in three of the specimens and shear failure at the glulam joint between flange and plywood rib in the remaining five pieces. In all cases, when load is approaching to the ultimate load value, an important cracking process of concrete slab occurs (Figure 11).

The lowest value of ultimate load obtained for all specimens tested was 8.03 times the design load considered for residential buildings (5.0 kN/m^2). Attending to service state limitations, a relative deflection of 1/358 of overhanging span was obtained for a design load of 5.0 kN/m^2.

Both results obtained, ultimate load and relative deflection, indicates a very favourable behaviour of the structural system proposed.

4 SYSTEM PERFORMANCE

With the aim to know the performance of the floor system preliminary sizing curves were developed using the Gamma Method, usually recommended for the analysis of TCC structures [11]. These curves are no final sizing solutions but simply establish the appropriate range of use of the floor system developed and its possibilities [8].

Gamma Method is highly accurate for simply supported beams but its error increases significantly in pinned-clamped beams and clamped-clamped beams as Girhammar pointed in [12]. However, the error can be significantly reduced by applying the Gamma Method but using effective beam length la distance between points of zero moment.

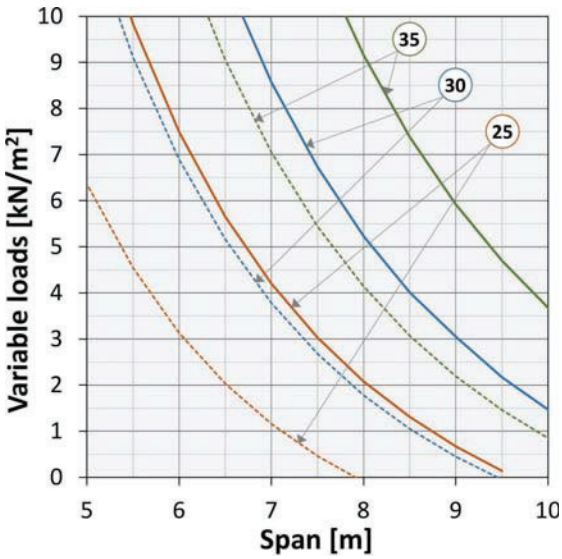

Figure 13: *Floor sizing curves.*
Symply supported pieces. Permanent load 2.5 kN/m^2.
Deformation: L/300-continuous line; L/500-dashed line

Figure 13 shows the most unfavorable case at the dimensioning level of the floor, since it corresponds to simply supported pieces. Creep deformation was considered with the total permanent load and a 30% of the variable load. The results indicate that for residential use and a deflection limit of L/500, a floor with a slenderness of L/24 has adequate sizing for a permanent service load of 2.5 kN/m^2 and an additional variable load slightly

https://doi.org/10.52202/069179-0430

higher than 3.0 kN/m^2. This range of slenderness increases to L/30 and L/35 for extreme and internal spans, respectively.

These results indicate the efficient use of mechanical qualities of the materials of the system thanks to the high composite action and, consequently, its suitability for the execution of building structures.

5 CONCLUSIONS

Timber-concrete-composite system developed show very interesting properties for the construction of building structures: low self-weight of 1.80 kN/m^2, high stiffness, slender flooring solutions, semi-rigid connections between elements and an easy construction process.

The system is based on an efficient timber-concrete connection characterized by the use of boards perforated in their entire length crossed by the in-situ poured concrete. Shear test results show a very favourable combination of high stiffness and efficient composite action with a ductile failure, desirable characteristic in TCC solutions.

Full-scale four and three-point bending test results indicate a very strength and stiff behaviour of the system proposed.

STUDY ON FAILURE MECHANISMS OF HYBRID STRUCTURE OF REINFORCED CONCRETE FRAME WITH CLT INFILL

Hamood Alwashali[1], Ahmad Ghazi Aljuhmani[2]

ABSTRACT: The objective of this study is to clarify the possible failure mechanisms and strength of RC frames with CLT infill, and to investigate the CLT panel compression strut width. Five failure mechanisms and a simplified strength evaluation method were proposed based on a literature review of the RC frames with different material infills. Experimental tests of diagonal compression of CLT panels were conducted and results were used in finite element analysis to evaluate the change of failure mechanisms based on strut width and relative stiffness for the RC frame and CLT.

KEYWORDS: Hybrid structures, Reinforced concrete buildings, CLT infill panels, Seismic capacity

1 INTRODUCTION

Hybrid reinforced concrete (RC) and timber structures are getting much attention, and their numbers are increasing rapidly as an eco-friendly solution to contribute towards the sustainable societies prescribed in the UN's Sustainable Development Goals (SDGs). Cross-laminated timber (CLT) has relatively high shear strength, is lightweight, and has low carbon emissions. Using CLT panels as shear walls in RC or steel structures can increase the seismic capacity of the building with also securing lower seismic demand due to CLT's low mass. In addition, CLT walls have relatively greater deformation capacity than RC shear walls, resulting in improving not only the lateral strength of the structure but also its ductility. However, the insertion of CLT panels in the RC frames could also lead to unwanted failure mechanisms (e.g., brittle failure). Therefore, it is essential to understand and investigate the possible failure mechanisms and seismic behaviour of these structures.

Recently in Japan, RC frames or steel frames with CLT infill buildings were constructed, as shown in Figure 1. Worldwide, several researchers have started investigating the effect of CLT infill on RC or steel frames. A parametric study on different types of steel frames with CLT infill using static pushover analysis was carried out by Dickof et al. [1] to clarify the ductility and overstrength values. It was found that CLT infill is effective in the case of lower ductility frames, whereas it does not have much influence in the case of ductile frames. [1] focused only on the influence of CLT infill on the ductility factor and the increase of strength for the RC frame. However, the possible failure mechanism, as well as an evaluation method, were not considered in [1]. Another numerical simulation has been carried out by Stazi et al. [2] to understand the effect of CLT infill on RC frames. This study also focused only on the overall influence of the CLT panel on the increase of the strength and stiffness of the RC frame. Several experiments on five 1/3 scale RC frames with different CLT infill types were conducted by Haba et al. [3]. In [3], even though several specimens with the same RC frame and different CLT panels' specifications were tested, only one failure was observed, which is a shear failure in the RC columns. As for Steel structures with CLT infill, there have been few recently constructed buildings in Japan [4] and several experiments tested by Fukumoto et al. [5]. However, there is a lack of research on RC buildings with CLT shear walls, and in the previous studies[1-3], researchers have only investigated the increase in strength and ductility of the frame due to the insertion of the CLT panel. In addition, research on the different possible failure mechanisms of such structures is still lacking, and evaluation guidelines and standards for engineering practice are still unavailable.

Therefore, the objectives of this study are: first, clarify the possible in-plane failure mechanisms of RC frames with CLT panels infill. Finally, Investigate the effect of different parameters (e.g., compression strut width and CLT-to-RC connections) on the expected failures.

2 EXPECTED FAILURE MECHANISMS

Although CLT Infill in RC frames is a new concept, infill walls or post-installed walls are common practices, such as masonry infill walls and steel braces. The main difference is that the material properties of the CLT panel are different, which may completely alter the RC frame performance compared to other conventional methods, and this has not been investigated in past studies. Possible failure mechanisms and evaluation methods of lateral strength capacity were investigated. In this section, the possible failure mechanisms of RC frames with CLT infill systems are investigated based on previous research or based on comparisons with other infill materials.

2.1 COLUMN SHEAR FAILURE

This failure was observed in experiments by Haba et al. [1] and is shown in Figure 2 and illustrated in Figure 3. 1/3 scale specimen with CLT panels along the entire width of the frame (1540 mm) was tested. The height of the CLT infill was 840 mm, and it was fixed with the RC frame using epoxy resin. Two panels of Japanese Cedar CLT (Mx60b-3-3 grade) were used with 60 mm thickness (30 mm for each panel). In this case, the RC columns are shear-critical columns (the shear capacity for the RC columns is less than the flexural capacity). Thus, the frame does not have enough deformation capacity for the CLT infill to fail first, and the dominant failure will be column shear failure.

In this case, A simple estimation of the maximum strength capacity is proposed to be calculated by adding three components: the strength of the two RC columns and the strength of connections at the top of the CLT panel, and is shown in Equation (1), with reference to Figure 3.

$$Q_{sh} = 2 \times Q_{su} + Q_{joint} \quad (1)$$

Where Q_{su} is the column shear strength calculated as prescribed in the Japanese AIJ code [6], or it can be calculated using any other adequate standards or method. The Q_{joint} is the strength of the CLT to RC joint on top, in the test by [1], it was estimated using the strength of the epoxy material injected between the RC frame and CLT infill. If there are no connections between the CLT panel and the RC frame, then Q_{joint} can be ignored.

Figure 2: *Column shear failure as observed in [3]*

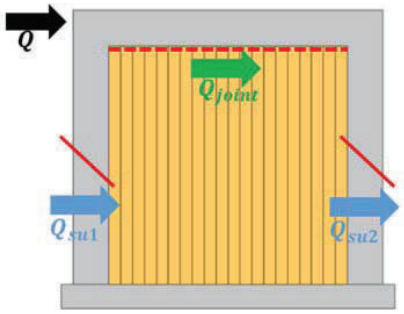

Figure 3: *Column shear failure for RC frame with CLT*

2.2 PUNCHING SHEAR FAILURE

Having relatively strong and very stiff walls within an RC frame could cause a punching shear failure, which is observed in RC frames with strong steel braces as in Ishimura et al. [7], as shown in Figure 4 and in Figure 5 in Japanese seismic evaluation standard JBDPA [8]. Punching shear failure of RC frame is also observed with other types of infill walls such as masonry infill that were retrofitted by ferrocement, mentioned by Sen et al. [9]. This failure could happen in the case of a very strong CLT infill relative to the surrounding RC frame.

In this case, maximum strength capacity can be estimated by adding three components. The first component is the RC column (windward) which has punching shear failure. The second component is the connections at the top of the CLT panel and RC beam. The third component is the leeward RC column, which could fail in either shear or flexural, and can be calculated by Equation (2), with reference to Figure 6.

$$Q_{pun} = PQ_{c1} + Q_{joint} + min(Q_{su}, Q_{mu}) \quad (2)$$

Where PQ_{c1} is the punching shear capacity of the first column as prescribed in JBDPA [8], Q_{su} is column shear strength, and Q_{mu} is column flexural strength.

Figure 4: *Punching shear failure as observed in [7]*

https://doi.org/10.52202/069179-0431

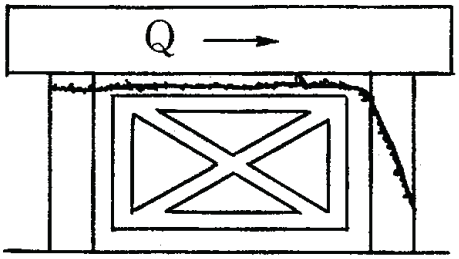

Figure 5: *Punching shear failure illustrated in JBDPA [8]*

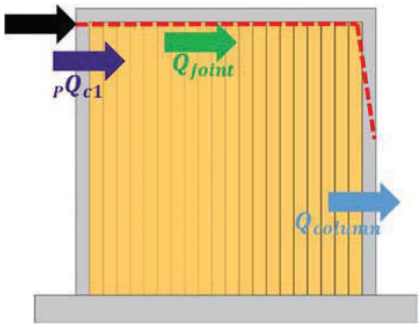

Figure 6: *Punching shear failure for RC frame with CLT*

2.3 FRAME OVERALL FLEXURAL FAILURE

Figure 7 shows the overall flexural failure that could occur when the CLT infill is stiff relative to the RC frame and the CLT panel is strongly connected to the RC frame.

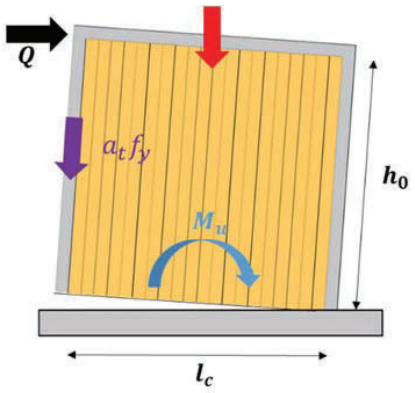

Figure 7: *overall flexural failure of the composite structure*

In this case, the RC frame and CLT panel will act as a single component similar to a cantilever flexural wall. There are no experimental tests of RC frames with CLT infill having an overall flexural failure. However, similar behaviour is observed with other infilled walls, such as tests by Laughery et al. [10] on RC frames with post-installed RC walls shown in Figure 8. It can occur as well with masonry infills such as tests by Sen et al. [9]. In this failure, maximum strength capacity can be estimated by the overall flexural capacity (Q_{fl}) as a cantilever flexural wall as shown in Figure 8. The maximum strength could be calculated using Eq. 3 and Eq. 4 which are adopted from JBDPA [8] with reference to Fig.7.

$$Q_{fl} = M_u / h_0 \quad (3)$$

$$M_u = a_t f_y l_c + 0.5 N l_c \quad (4)$$

Where M_u is moment capacity, h_0 is the clear height of the column, a_t is longitudinal reinforcement area for one column, f_y is the yield strength of the column's longitudinal reinforcement, l_c is the distance between the centers of the boundary columns, and N is the total axial load applied on the entire frame. It should be noted here that the maximum strength is calculated entirely based on the RC frame strength. There is no contribution for the CLT panel by assuming there are no tension connections between the CLT panel and the RC frame at the bottom. If connections are added at the bottom of the CLT panel, then the tensile of the CLT panel could also contribute to the flexural capacity and need to be added to Eq. 4.

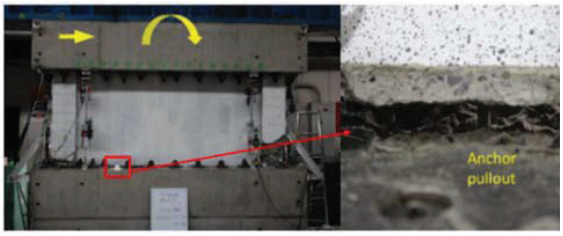

Figure 8: *Overall flexural failure as observed in [10]*

2.4 CLT PANEL SHEAR FAILURE

No experimental studies are showing the shear failure of CLT walls in RC frames. However, other infill materials such as masonry infill walls in RC frames had a shear failure, such as those shown in Figure 9. For CLT infill, it could occur in a ductile RC frame with relatively lower stiffness for CLT. In this case, the columns are flexural columns (the flexural capacity of the column is less than the shear capacity of the column). Thus, the frame has enough deformation capacity for the CLT infill to deform, and the dominant failure will be CLT failure. Capacity can be calculated by adding the flexural strength of the two columns to the shear strength of the CLT panel itself, as shown in Equation (6) and Equation (7) with reference to Figure 10. It should be noted here that Q_{mu} needs to be calculated assuming the clear height h_0 to be around half of the column clear height.

$$Q_{CLT-s} = Q_{mu1} + Q_{mu2} + S_{CLT} \quad (6)$$

$$S_{CLT} = \tau_{CLT} \times L_{CLT} \times t_{CLT} \quad (7)$$

Where Q_{mu1} and Q_{mu2} are windward and leeward column capacity, S_{CLT} is CLT panel shear capacity, and τ_{CLT}, L_{CLT}, and t_{CLT} are CLT panel shear strength, length, and thickness, respectively.

https://doi.org/10.52202/069179-0431

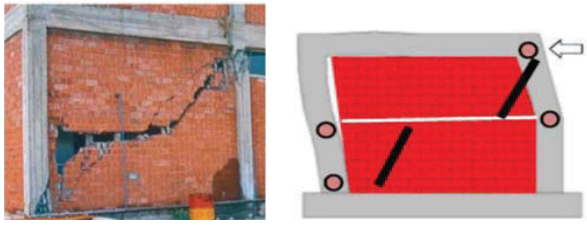

Figure 9: *Masonry shear failure in 1999 Turkey EQ (left figure) [11], and as observed in Sen et al. [9] (right figure)*

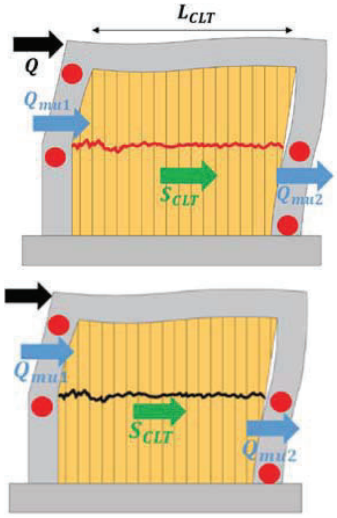

Figure 10: *CLT shear failure for RC with CLT infill*

2.5 CLT PANEL COMPRESSION FAILURE

There are no experimental studies yet showing the failure of CLT diagonal compression failure in RC frames but there are recent tests of steel frames with CLT infill such as experimental tests by Fukumoto et al. [5] and shown in Figure 11. However, Fukumoto`s tests are of steel frames without any boundary columns attached to CLT infill as shown in Figure 11, which is different from the concept investigated here of RC frames confining the CLT infill. In addition, other infill materials in RC frames, such as masonry walls, had a shear failure considering diagonal compression failure, which was observed in the experiment done by Alwashali et al. [12] on masonry infill, as shown in Figure 12. It is thought that CLT infill could also have a similar failure mechanism.

This failure is similar to the CLT panel shear failure; however, in this case, CLT compression capacity (C_{CLT}) is less than CLT shear capacity (S_{CLT}).

This failure capacity can be calculated by Equation (8) and Equation (9) with reference to Figure 13.

$$Q_{CLT-c} = Q_{mu1} + Q_{mu2} + C_{CLT} \quad (8)$$

$$C_{CLT} = \sigma_{CLT} \times W_{strut} \times t_{CLT} \times \cos\theta \quad (9)$$

Where C_{CLT} is CLT panel shear capacity, σ_{CLT} is CLT panel compressive strength, W_s is compression strut width with, θ is the angle between the RC base and the strut with reference to Figure 13. The estimation of the strut width (W_s) is a complex topic that has not been studied previously for CLT infills. The following section will investigate the strut width based on simple diagonal compression tests and finite element analysis.

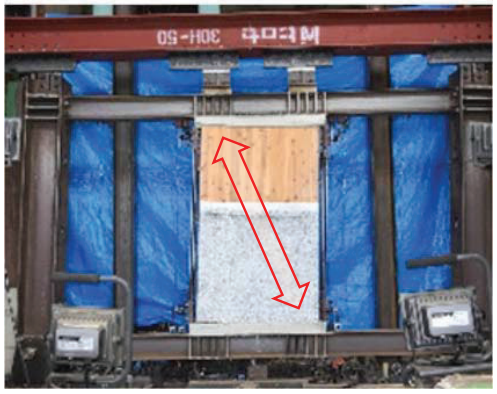

Figure 11: *Experiments of Steel frame with CLT infill tested by Fukumoto et al. [5]*

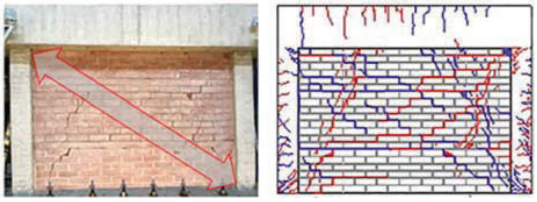

Figure 12: *Compression strut failure of RC frame with masonry infill [12]*

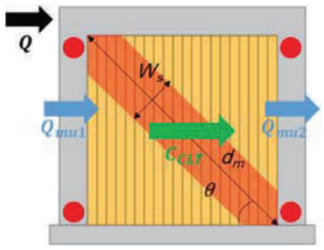

Figure 13: *overall flexural failure of the composite structure*

3 COMPRESSION STRUT MECHANISM

The capacity evaluation for all the failure mechanisms mentioned above, except CLT compression strut failure, is relatively well understood and thought that could be directly applied. However, the failure of the compression strut of CLT infill as well as its width is still poorly understood. Thus, in this section, we investigated the strut width based on conducting diagonal compression tests on CLT walls and then model the CLT infill using finite element analysis to investigate the strut width.

https://doi.org/10.52202/069179-0431

3.1 DIAGONAL COMPRESSION STRUT

In the case of CLT infill, no calculation approaches nor empirical equations were proposed for strut width. One simple approach is to assume the methods used for masonry infill might also be applicable to CLT infill. In this study, the two methods by FEMA-306 [13] and Sen et al. [9] only are compared. The values of strut width to the diagonal length that are calculated by the two methods for different flexural relative stiffness (frame flexural stiffness divided by CLT panel flexural stiffness) are shown in Figure 13. The calculations of strut width by [9] and [13] showed large variations, as can be seen in Figure 14. This could lead to uncertainty in estimating strength by the failure mechanism of the strut.

In order to adequately estimate the strut width of CLT infill in the RC frame, simple diagonal tests were conducted, and then finite element models were developed and validated by the diagonal test. The FE analysis is then used to simulate the CLT infill in the RC frame to estimate the compression strut width.

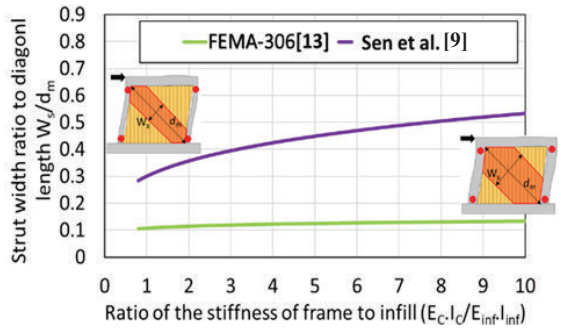

Figure 14: *Strut width relation with relative flexural stiffness of RC frame to CLT infill*

3.2 DIAGONAL COMPRESSION EXPRIMENT

The interaction between the CLT infill panel and the RC frame under lateral forces is shown in Figure 15. The transmitted forces to the CLT panel at the corner of the actual RC frame could be reproduced using a diagonal compression test configuration, as shown in Figure 15. Therefore, this test-set up was used to obtain the characteristics of CLT panels under compression forces.

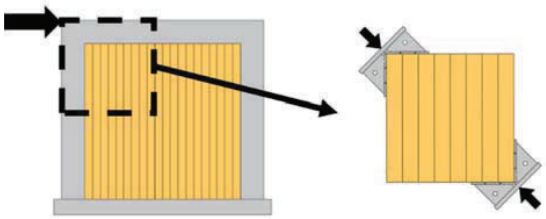

Figure 15: *Behaviour of CLT panel under lateral load*

A hydraulic Jack was used to apply a monotonic vertical downwards force on a 1200 mm by 1200 mm CLT panel (loading rate in the range of 0.15~0.2 mm/s). Three replicates were tested, and all the panels were 5-layer 150 mm thick panels made from Japanese cedar with Mx-60-5-5 grade. Each panel was installed vertically between two steel 'shoe' caps as shown in Figure 16 and Figure 17, which were designed to distribute the load such that local bearing failure of the CLT panel does not occur.

LVDTs were attached along the two diagonals of the CLT panel to calculate shear deformation. Shear deformation was calculated using Equation (10) with reference to Figure 18.

$$\gamma = \frac{\Delta x + \Delta y}{900 \times \sqrt{2}} \qquad (10)$$
$$\delta = \gamma \times 1200$$

Where Δx and Δy are the values obtained from the horizontal and the vertical overall LVDTs, respectively.

In addition, digital image correlation (DIC) was also used in the tests and the properties and details of the DIC setup are shown in Figure 19, and data were analyzed using the DIC Software OPTECAL [14].

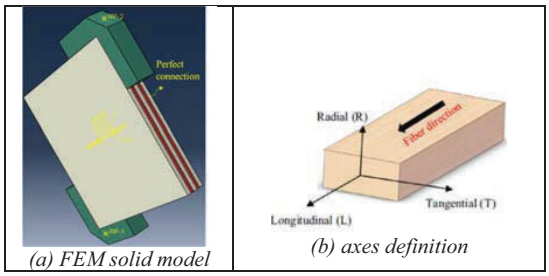
3.3 SIMULATION USING FEM MODEL

A numerical model was created using the FEM software Abaqus [15]. The CLT panel was modelled as a solid element. The model consists of five layers, and the interaction between each CLT layer was assumed to be a tie constraint with no slip. Each layer was modelled as an elastic orthotropic material with three directions (L, R, T): longitudinal (in the direction of the grain), radial, and tangential as shown in Figure 20. Each CLT layer has an axis orientation perpendicular to the adjacent layers. The mechanical properties of each layer are shown in Table 1, which was taken from the Japanese Wood Handbook [16].

Table 1: *Japanese Cedar material properties [16]*

Species	Young modulus (MPa)			Shear modulus (MPa)			Poisson ratio		
	E_L	E_R	E_T	G_{LT}	G_{LR}	G_{RT}	ν_{LT}	ν_{LR}	ν_{RT}
Japanese cedar	8700	620	260	460	650	15	0.58	0.405	0.901



(a) FEM solid model

(b) axes definition

Figure 20: *CLT panel FEM model properties*

A comparison between shear displacement-shear force curves for the FE model and experiment is shown in Figure 21. The stiffness obtained from the FE model (100.4 kN/mm) was relatively close values to the average value from the experiment (106.3 kN/mm).

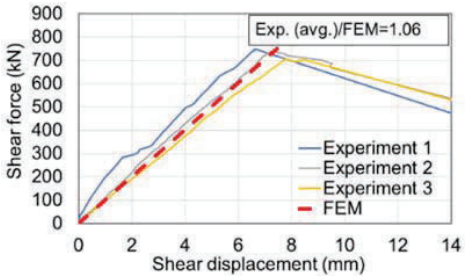


Figure 21: *Comparison between FEM and experiments*

A comparison between the strain obtained from the experiment by DIC and FEM results is shown in Figure 22. In this case, horizontal (ε_x) and vertical (ε_y) axial strain distribution were compared at the point just before maximum load P_{max}. Overall, the strain distribution is similar in both FEM and DIC, showing that the response is governed by one main compressive strut, indicating that FEM can capture the general stress paths and give close strain values.

3.4 FEM MODEL FOR RC FRAME WITH CLT INFILL

FEM software Abaqus [15] was used to model the RC frame with CLT infill. Only concrete was modeled with elastic solid elements for simplicity, since the main focus is the strut width in the CLT infill. Young's modulus and Poisson's ratio for RC were taken as 23000 MPa and 0.2, respectively. The CLT model was the same as the model used in the diagonal compression model (section 3.3). The frame was fixed in all directions at the bottom and free at the top. The interaction between the CLT panel and the RC frame was assumed as hard contact with no penetration between the CLT and RC elements with no friction interaction. A total of 10 frames was modelled, and the difference between each model is the relative flexural stiffness between the RC columns and the CLT infill (infill thickness was fixed, and the RC columns' dimensions were increased).

Regarding stiffness increase due to the CLT infill, the initial stiffness of bare frame F1 (the frame with the smallest relative stiffness) was 17.5 kN/mm, and stiffness increased to 75.4 kN/mm after adding the CLT infill with an increase of about 4.3 times. The initial stiffness of bare frame F2 (the frame with the largest relative stiffness) was 121.9 kN/mm, and stiffness increased to 185.9 kN/mm after adding the CLT infill with an increase of about 1.5 times. The results of strain in the diagonal strut direction for the F1 frame and F2 frame are shown in Figure 23. Although the strain values differ slightly between these two frames, the strut width almost does not vary much. In order to compare quantitative values of the strut width, a method proposed by Jin et al. [17] was used. In this FEM analysis, a total of 12 sections were taken, and, for each section, the average strain was calculated by taking the equivalent strain area for the actual strain curve as shown in Figure 24.

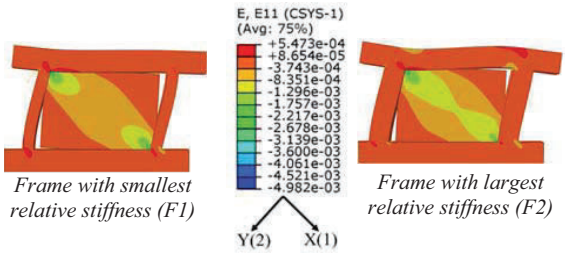

Figure 23: *Normal strain in X-direction (strut direction)*

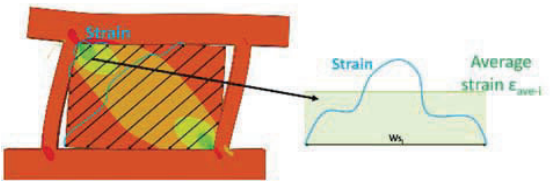

Figure 24: *Strut sections and average strain calculations*

The strut width obtained from the FEM analysis for different relative RC to CLT stiffness is shown in Figure 25. In Figure 25, The strut width ranges between $0.34d_m$ and $0.36d_m$ with different relative RC to CLT stiffness. When also compared to the two masonry infill methods [9,13], it was found that FEM analysis has a similar tendency with FEMA-306 [13] for masonry infill; however, FEM analysis gave larger strut width values.

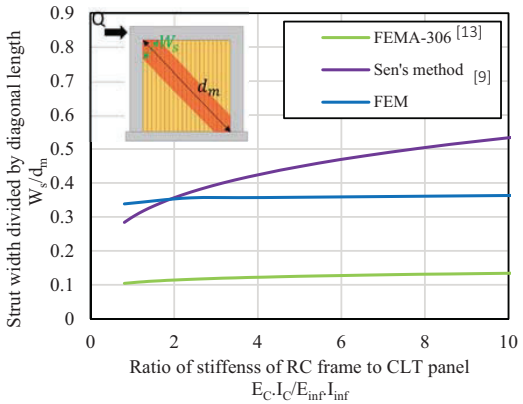

Figure 25: *Comparison of strut width obtained by FEM modelling CLT versus other methods*

3.5 EXAMPLE OF STRENGTH EVALUATION

In this study, the lateral strength of the RC frame with CLT infilled (Q_{cal}) is proposed to be calculated by taking the minimum of the calculated lateral capacity based on the five different failure mechanisms discussed previously in section 2, as shown in Equation (11).

$$Q_{cal} = min\left(Q_{sh}, Q_{pun}, Q_{fl}, Q_{CLT-c}, Q_{CLT-s}\right) \qquad (11)$$

A case study of the RC frame tested by Alwashali et al. [12] with masonry infill (specimen F-1.5) will be presented to understand the failure mechanisms well. This RC frame will be used here, assuming CLT infill as shown in Figure 26. The thickness of the CLT panel is assumed to be 60 mm, and shear and compression strength for CLT are assumed to be 4.1 MPa and 174 MPa, respectively. These values are based on the material tests conducted based on the diagonal compression test presented in section 3.2.

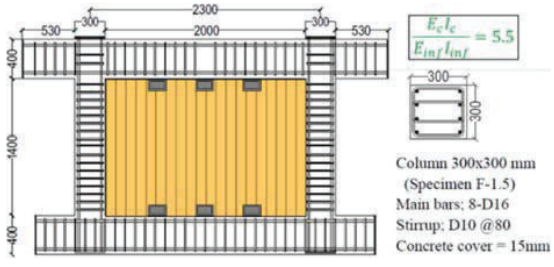

Figure 26: *A case study on RC frame for capacity evaluation (from Alwashali et al. [12])*

https://doi.org/10.52202/069179-0431

A comparison between several methods for only the compression failure strength of the case study frame is shown in Figure 27. It should be noted that deformation capacity evaluation is out of the scope of this paper and thus the story drift axis in Figure 27 and Figure 28 is used for illustration only. As shown in Figure 27, there is a large variation between the estimation of maximum strength for the diagonal compression failure considering previous studies for different materials. The FE analysis investigated in this study gives around 2 times (1037kN) the value estimated using the FEMA 306 method (548kN). This uncertainty and the lack of CLT strut width experiments will lead to significant variations in the expected strength capacity and failure mechanisms.

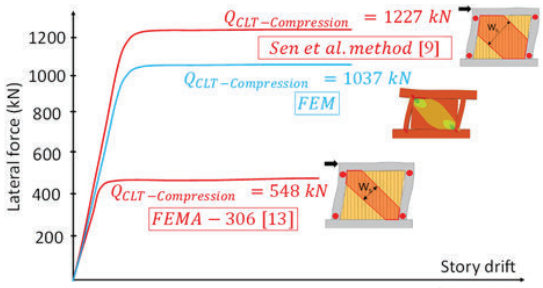

Figure 27: *Failure strength for the case study frame*

The expected lateral strength capacity of the case study frame for all the five expected failure mechanisms is as shown in Figure 28.

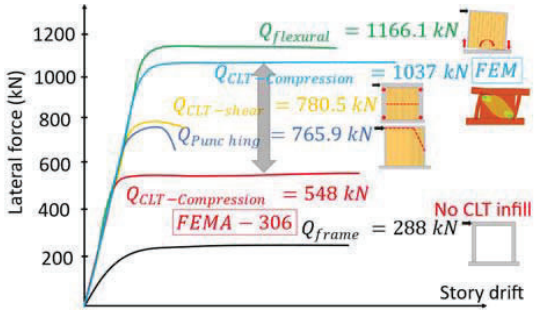

Figure 28: *Calculated capacity of the case study frame*

Three shear connections were assumed at the top and at the bottom of the CLT infill to make the example shown here more practical. This number was also assumed to avoid punching shear failure. Each shear connection has a shear strength of 80 kN (total of 240 kN as Q_{joint} in Eq(2). For CLT compression strut failure, the FEMA 306 [13] (for masonry) and FE analysis results (presented in this study) were used to calculate the strut width. As shown in Figure 28, compression failure gives the minimum strength value and is expected in a case assuming the strut width of masonry as in FEMA-306 [13]. However, in the case of strut width obtained from the FE analysis, the capacity of compression failure increased, and thus punching shear failure becomes the most probable failure type. The influence of the strut width is crucial in seismic design since it affects not only the maximum capacity but also the expected seismic behaviour, which could change the behaviour from desirable ductile failure to undesirable brittle punching shear failure. Experimental verification and investigation to understand the behaviour of CLT infills are still needed.

4 CONCLUSIONS

This study presented different expected failure modes for hybrid structures of Reinforced concrete (RC) frames with CLT infill based on previous studies and observations for RC frames with other infills. Also, a FEM model was developed and verified by component compression test to study the effect of CLT compression strut width on the expected failure. The main conclusions are as follows:

1. Five different possible failure modes for RC frames with CLT infill were studied based on the literature review for RC frames with other material infills.
2. The seismic capacity and in-plane failure mechanism of RC frames with CLT infill could be predicted based on the evaluation method presented in this paper.
3. Compression strut width methods for RC frames with masonry infill have big variations when used with CLT.
4. FEM analysis showed that the compression strut width does not change much by changing the relative stiffness of the RC frame and the CLT infill (the margin was between 0.34 and 0.36 of the strut length).
5. CLT compression strut width and CLT-to-RC shear connections could significantly affect the probable failure mechanisms, changing it from ductile to brittle failure. Therefore, further experimental investigations are needed to predict the probable failure mechanism.

ACKNOWLEDGEMENT

The study was partly supported by the agency of Japan Society for the Promotion of Science (JSPS) and project KAKENHI Grant Number 21K14283 (Principal investigator: Hamood Alwashali, Okayama University).

World Conference on Timber Engineering Oslo 2023

PRELIMINARY STUDY ON THE TENSION-ONLY BRACED SELF-CENTERING STEEL-TIMBER HYBRID FRAME

Fei Chen[1], Minghao Li[2], Minjuan He[3], Zheng Li[4]

ABSTRACT: A lateral load resisting system called tension-only braced self-centering steel-timber hybrid frame (TOB-SCSTHF) is proposed. The system utilizes the self-centering steel-timber hybrid joints to provide the self-centering action to the frame. Tension-only braces (TOBs) are used to increase the lateral strength and stiffness of the system. Experimental results on the hybrid joints were taken as the basis to develop the numerical model of the beam-column joints. The model was then extended to the frame model, which was used to explore the hysteretic behavior of TOB-SCSTHF. It was found that the combined use of steel angles in the beam-column joints and the TOBs was efficient in enhancing the structural performance, including the strength, stiffness, energy-dissipation, and the self-centering capability.

KEYWORDS: Steel-timber hybrid joints, Self-centering, Tension-only braces, Lateral performance

1 INTRODUCTION

With the development of engineered wood products (e.g., glued laminated timber, GLT) [1], heavy timber frames have been increasingly used in multi-story buildings. However, heavy timber moment frames are often found to have low stiffness under wind and seismic loads [2]. To increase the lateral stiffness, timber braces can be added to form braced frames. Despite increased stiffness, research has shown braced frames have significant reduction in system ductility and the permanent deformations due to the potential failure of the timber braces and significant residual deformations in the brace end connections. Researchers also attempted to add buckling-restrained braces (BRBs) to GLT frames [3]. Test results revealed that both the stiffness and the ductility of the GLT frames were enhanced. However, the residual deformations of the BRB braced frames were significant.

In this paper, as shown in Figure 1, a lateral load resisting system, TOB-SCSTHF, is proposed. The system consists of two critical components: the self-centering steel-timber hybrid joints (hereafter referred to as hybrid joints) and the tension-only braces. The self-centering capability and lateral stiffness of the system are provided by the hybrid joints and TOBs, respectively. Quasi-static loading tests on two joint specimens were conducted. Further, a numerical model for the hybrid joint was developed within the OpenSees platform. The model was extended to explore the hysteretic response of the TOB-SCSTHF.

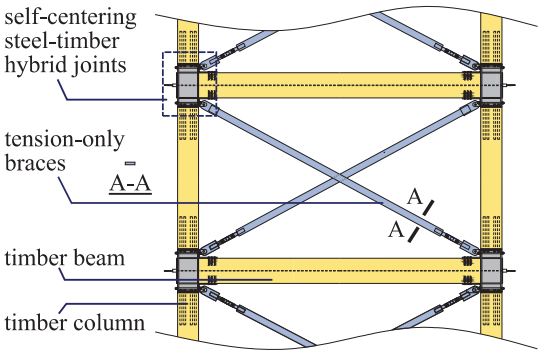

Figure 1 : Tension-only braced self-centering steel-timber hybrid frame (TOB-SCSTHF)

2 CYCLIC TEST ON HYBRID JOINTS

Two hybrid joints were prepared for the cyclic loading test. The details of the test results are available in [2]. A brief introduction of the tests is provided as follows. Two hybrid joint specimens were named Imp-S1 and Imp-S2, respectively. Different from conventional self-centering timber beam-column joints, the hybrid joint used a steel panel in the beam-column interface, as shown in Figure 2 (a). After the post-tensioning of steel tendons, the steel panel resisted the compression from the beam. Glued-in rod (GIR) connections were used to connect the steel panel to the GLT columns. Two-component epoxy resin and grade 4.8 M16 steel rods (each with a slenderness ratio of 25) were used to fabricate the GIR connections. To make a fair comparison, the size of the hybrid joints

was kept the same as that of self-centering timber joint specimens reported in [5]. The initial post-tensioning force for Imp-S1 and Imp-S2 was 54.87 kN and 76.20 kN, respectively. The CUREE loading protocol was used in the test. The moment-rotation curves of the two specimens are shown in Figure 2 (b) and (c). With the use of the steel panel, the gap opening was easy to form in the beam-column interface. As a result, the final failure of two specimens was the fatigue failure of steel angles. Compared with conventional self-centering timber joints, the hybrid joint had higher stiffness, energy-dissipation capability, and connection ductility [4]. The development of the numerical model for the hybrid joint is desired to facilitate further investigation of hybrid joints.

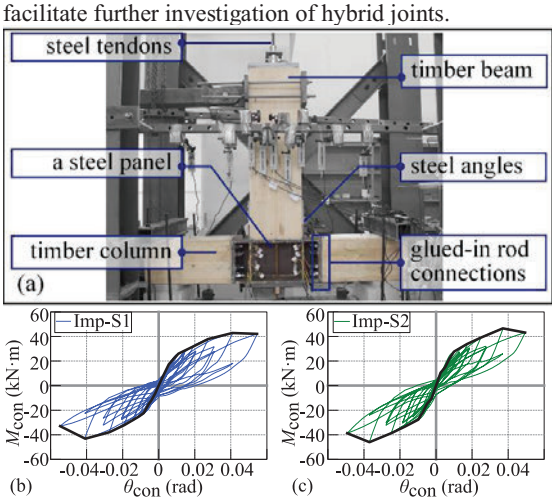

Figure 2 : Cyclic loading test on hybrid joints

3 NUMERICAL SIMULATION ON HYBRID JOINTS

3.1 DETAILED MODEL

The hybrid joint was simulated in OpenSees. There were three key points in the simulation: 1) the modeling of the gap-opening at the timber beam to steel panel interface; 2) the moment-rotation behavior of the GIR connections; and 3) the slip behavior of the self-tapping screws connecting steel angles to the beam.

3.1.1 Modeling of the gap-opening mechanism

As per [6], for self-centering timber joints, the gap-opening mechanism can be simulated with a series of compression-only springs at the beam-column interface. These springs are placed in parallel after being assigned with the Elastic-No Tension (ENT) material property. After post-tensioning, these springs are evenly compressed. The beam-column interface is opened when the edge spring resists zero compression. However, the distributed spring modeling technique might not be ideal in the simulation of the self-centering steel-timber hybrid joint. The reason is that the accumulative damage at the beam end for a hybrid joint is unable to be considered. During the cyclic loading test, permanent compression deformation was observed at the end of the timber beam. After the test, the compression deformation was most obvious at two toes of the beam end. After the gap opening, the compression force was concentrated into the toe which acted as a rocking pivot. The wood crushing occurred when the GLT compression strength was reached. As a result, the compression stiffness was different for laminations along the height of the beam. The stiffness of the top and bottom laminations degraded faster than that of the inner laminations. The distributed springs with the ENT material however assumed that the springs remained elastic and had no degradation of stiffness, which was different from the test observations. In the paper, the Hyperbolic Gap (HG) material was used for the distributed springs. The HG material is also compression-only. But given compression yield strength F_{ult}, accumulative damage can be considered by HG. The compression stiffness is zero upon a larger compression deformation required for the element with the HG material. Both the strength and stiffness parameters are required in defining the HG material. To determine the strength parameter F_{ult}, the principle of strength equivalence was used. The compression resisted by all springs equaled the compression capacity of the timber beam. Given the rectangular cross-section for the beam, F_{ult} is given by Equation (1). To determine the initial stiffness of the HG material K_{max}, the principle of stiffness equivalence was used with consideration of the end-effect at two ends of the timber beam. As illustrated in Figure 3, the compression stiffness of TB1 was set the same as that of TB2. TB1 corresponded to the beam with two end-effect zones. It can be modelled as three springs in serial. To consider the end effect, two side springs have a reduced axial stiffness represented by $k_{gap}E_{para}/l_e$. TB2 was the beam used in the detailed model for the hybrid joint. TB2 was the beam with only one end-effect zone. One spring connected with a distributed spring model can be used to represent TB2. Assuming the axial stiffness of TB1 equals that of TB2, the initial stiffness K_{max} is obtained with a consideration of the end-effect, as given by Equations (2)-(4).

$$F_{ult} = \frac{f_{para} b_b h_b}{N A_1} \tag{1}$$

$$K_{max} = k_{end} E_{para} \tag{2}$$

$$k_{end} = \frac{L_0}{\frac{\lambda+2}{\lambda} \cdot \frac{L_b - 2l_e}{A_b} - \frac{L_b^*}{A_b}} \tag{3}$$

$$\lambda = \frac{k_{gap}\left(L_b - 2l_e\right)}{l_e} \tag{4}$$

where F_{ult} = yielding compression stress, f_{para} = wood strength parallel to the grain, b_b = beam width, h_b = beam section height, N = number of springs in parallel, A_1 = tributary section area of each spring, A_b = beam section area, k_{end} = reduction factor, k_{gap} = end-effect factor, E_{para} = elastic modulus parallel to the grain, L_0 = length of the offset region, L_b = length of TB1, L_b^* = length of TB2, and l_e = length of the end-effect zone.

https://doi.org/10.52202/069179-0432

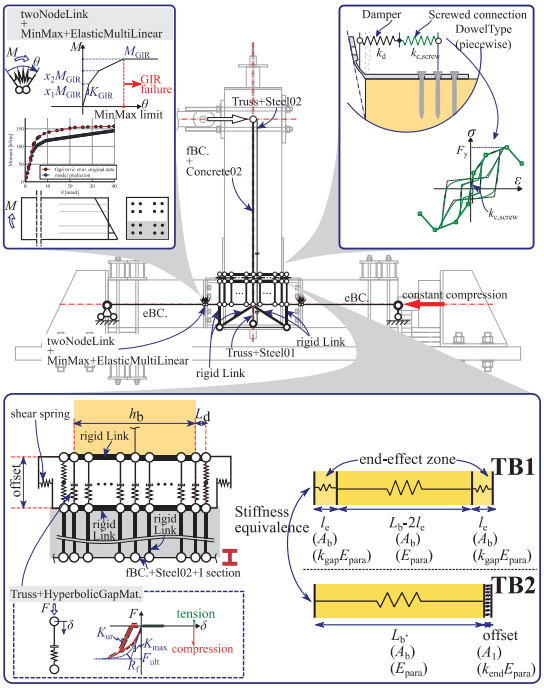

Figure 3 Stiffness equivalence and model illustration

3.1.2 Modeling of the GIR connection

To model the GIR connection, the twoNodeLink element was used to link two overlapped nodes and their degrees of freedom (DOFs) were controlled with the EqualDOF command in OpenSees. Except for the rotational DOF, two translational DOFs of the two nodes were kept the same because only the moment-rotation behavior was modelled. The twoNodeLink element was assigned with ElasticMultiLinear material wrapped with the MinMax material. ElasticMultiLinear material model represented the rotational behavior of GIR connections as a polyline model. The analytical prediction of the GIR connections was conducted based on the model proposed by Ogrizovic et al [7]. The prediction result was in the polyline form and was used as the input for the ElasticMultiLinear material model. The design of GIR connections aimed to ensure that GIR connections had the moment capacity over the possible demand. While the MinMax material was still used to simulate the possible failure of GIR connections. The maximum rotation was specified in the MinMax material. When the relative motion between the two nodes exceeded the limit specified, the MinMax material was activated to fail the ElasticMultiLinear material.

3.1.3 Modeling of the connector between steel angles and beam

The mechanical behavior of self-tapping screws (STSs) connecting steel angles to the timber beam was considered to ensure that the connection stiffness was not overestimated. During the test, the relative slip between one leg of the steel angle and the side face of the timber beam was observed when the gap opening was large. The DowelType model [8] was used to simulate the behavior of STS connections. The Bezier envelope was used as the backbone curve. Based on the European Yield Model, strength of each STS connection was calculated and used as the input for the DowelType model. The initial stiffness of the STS connections was taken as the minimum value obtained from different STS stiffness models. As per Dong et al. [3], there was a uniform model for the prediction of the shear stiffness k_{ser} of a single inclined STS, as given by Equation (5). The formula was originally proposed by Mirdad et al. [9] for the STS connection between concrete and solid timber. Dong et al. [10] further proved that with the proper selection of the embedment stiffness K_h and the withdrawal stiffness K_{ax} per unit area, the equation was also applicable in calculating the stiffness of the STS connection between the steel member and the GLT member. As per Equation (5), the contribution of the withdrawal stiffness to the total lateral stiffness of STS connections is zero when the angle between the axis of a single STS and the grain direction is 90 degrees. As given by Equations (6)~(8), three different formulas of K_h were used to calculate the lateral stiffness of STS connections. The lowest value among the three prediction results was taken as the input for the initial stiffness of the DowelType model. k_{ser} was calculated to be 992 N/mm. Other material parameters were adopted as the values suggested in [8].

$$k_{ser}=\frac{3E_{STS}Id\left[2\left(3l_f+2l_{ef}\right)K_{ax}\pi l_{ef}\left(\cos^2\theta+0.5\mu_f\sin 2\theta\right)\right]}{6E_{STS}I\left(3l_f+2l_{ef}\right)+K_h dl_{ef}^2 l_f^3\sin^2\theta}+\frac{3E_{STS}IdK_h l_{ef}^2\left(\sin^2\theta-0.5\mu_f\sin 2\theta\right)}{6E_{STS}I\left(3l_f+2l_{ef}\right)+K_h dl_{ef}^2 l_f^3\sin^2\theta} \quad (5)$$

$$K_h=\frac{0.00011\rho_m^{2.443}d^{-0.956}}{7.663\cos^2\theta+2.645\sin^2\theta} \quad (6)$$

$$K_h=\frac{\left(0.22+0.014d\right)\rho_m d^{-1}}{1.17\sin^2\theta+\cos^2\theta} \quad (7)$$

$$K_h=\frac{2\rho_m^{1.5}\dfrac{d_{ef}}{23}}{dl_{ef}} \quad (8)$$

where E_{STS} = elastic modulus of STS, $I=\pi d^4/64$ the moment of inertial of the STS, d = nominal diameter of the STS, l_f = free length of the STS, l_{ef} = effective penetration length of the STS, θ = angle between the axis of STS and the direction of the wood grain, μ_f = friction coefficient, ρ_m = mean value of the wood density, d_{ef} = effective diameter of the STS.

3.1.4 Comparison against experimental results

The comparison between the numerical simulation results and experimental results was shown in Figure 4. The hysteretic curves from the simulation and the test recording are overlapped in the first two subfigures. The model prediction agreed well with the test results in terms of both the strength and the residual deformation. However, the decompression point of the model was lower than that of the test. One possible reason was that the stiffness degradation of the springs at the beam-column interface was severe than in the real situation. After a few cycles of loading, the two side springs had significant stiffness degradation and could not support the rocking of the beam. Inner springs then picked up the load

and acted as the rocking pivot. As a result, the decompression point was slightly lower than the test results. The numerical model also performed well in predicting the variation of the post-tensioning force and energy dissipation, as shown in Figure 4 (c)~(f).

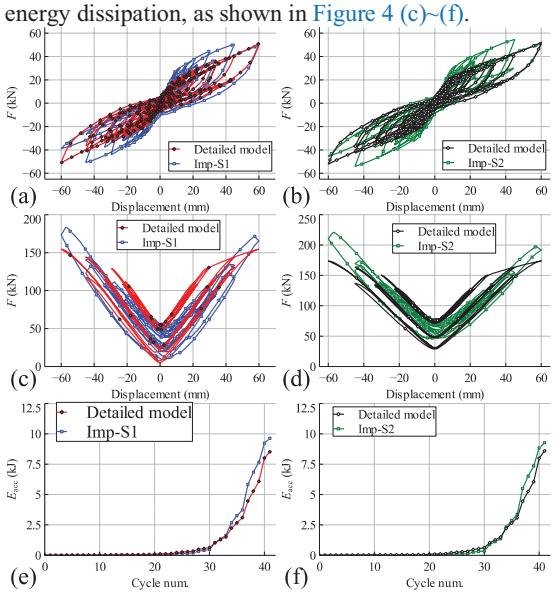

Figure 4 : Numerical simulation against experimental results

3.2 PHENOMENOLOGICAL MODEL

The integration of the aforementioned detailed model into the frame model might be difficult due to the complexity of the joint model. To avoid the convergence problem, a phenomenological model was further developed for the hybrid joints. To mimic the hysteretic behavior of hybrid joints, SelfCentering and DowelType materials were combined in parallel as the candidate material for the phenomenological model. The number of parameters required for SelfCentering and DowelType material was 4 and 17, respectively. The genetic algorithm was used to build the automatic calibration process for the phenomenological model. NSGA-II [11] was selected to conduct the multi-objective optimization. One of the desirability functions is given by Equation (9). The function F_1 was used to ensure that the force-displacement curve of the simulation results match the test results. In addition, the second desirability function F_2 was defined in terms of energy dissipation, as given by Equation (10). Constrained by F_2, the model error of the accumulative energy dissipation was expected to be controlled.

$$F_1 = \sum_{i=1}^{n} \omega_i \left(F_{it} - F_{im}\right)^2 \tag{9}$$

$$F_2 = \sum_{i}^{n} \frac{\left|E_{it} - E_{im}\right|}{\left|E_{it}\right|} \tag{10}$$

where ω_i,i=1~n = the weight factor for the ith data point, F_{it} = target force of the ith data point, F_{im} = model force of the ith data point, E_{it} = target energy dissipated upon the ith data point, E_{im} = model energy dissipated upon the ith data point.

The flowchart of the parameter calibration process is shown in Figure 5. To ensure that the optimized parameters can be obtained, the number of generations was 20. It means that the set of parameters was obtained after 20 times of evolution. Within each round of evolution, the number of candidates was 5000. For each candidate, the value of each model parameter was randomly set within the rational range. The final results were obtained after the comparison between 10000 (20 times 5000) combinations of parameters. More than one set of parameters was available after the multi-objective optimization. All the final outputs were non-dominated solutions, which meant each of them, i.e., one set of parameters, was a suitable compromise to minimize both desirability functions.

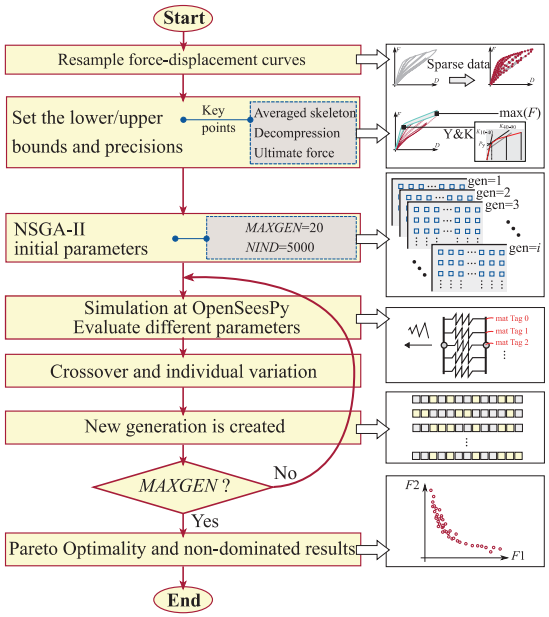

Figure 5 : Flowchart for determining the optimized parameters for the phenomenological model

Taking one of the non-dominated solutions to make the simulation in OpenSees, the prediction from the phenomenological model was presented in Figure 6, together with the results from the detailed model. The comparison validated the accuracy of the phenomenological model. The model was then integrated into the frame model in the next section.

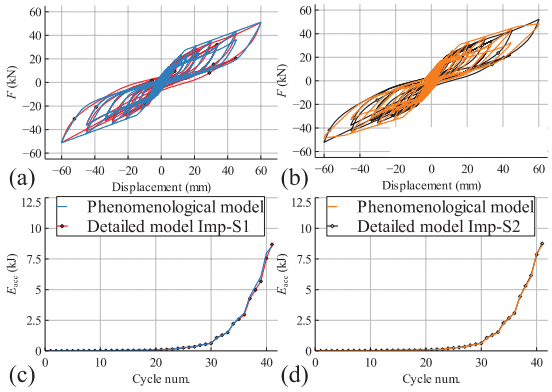

Figure 6 : Flowchart for determining the optimized parameters for the phenomenological model

4 NUMERICAL SIMULATION OF TOB-SCSTHF

The hysteretic behavior of TOB-SCSTHF was explored based on the phenomenological model of the hybrid joint. The modeling method of TOBs is first introduced and validated against theoretical solutions. It is then followed by the numerical simulation on TOB-SCSTHF with or without steel angles installed at the beam-column joints.

4.1 MODELING OF TOBs

Compared with common steel braces, TOB is characterized as a steel brace with negligible compression resistance. It is expected that TOBs provide zero resistance to the self-centering frame during the load reversal. An equivalent model was proposed for TOBs by Ying et al. [12] in ABAQUS. The modeling technology was recreated within OpenSees. As shown in 错误!未找到引用源。, the model has four truss elements connected end to end.

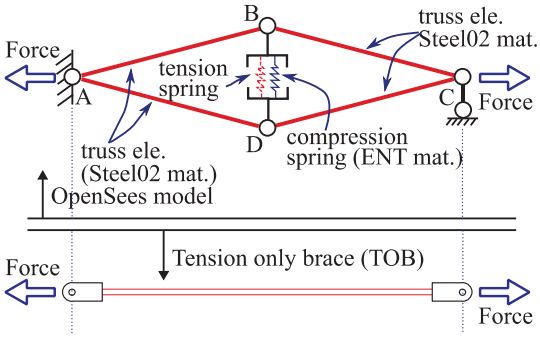

Figure 7 : OpenSees model for a single TOB

Nodes A and C are the two ends of a single TOB. When the TOB is in tension, nodes A and C depart from each other, and element BD is under compression. When the TOB is in compression, nodes A and C are getting closer and the element BD is in tension. Element BD is assigned with two materials in parallel: ENT and Elastic material. ENT material is a compression-only material and Elastic material has a close to zero tension stiffness. So element BD can resist compression only. When the TOB model is under tension along the AC axis, element BD resists the compression, so the TOB model has the tension stiffness. The TOB model has no compression resistance because the BD element has zero tension stiffness.

The TOB with the flat bar was simulated by using the TOB model. Under the reversed cyclic loading, the hysteretic curves of TOBs with three different thicknesses (4/6/8 mm) were obtained. The simulation results are shown in Figure 8. The analytical prediction on the yielding force and the initial stiffness of a single TOB were also annotated in Figure 8. The satisfactory agreement validated the modeling method for TOBs.

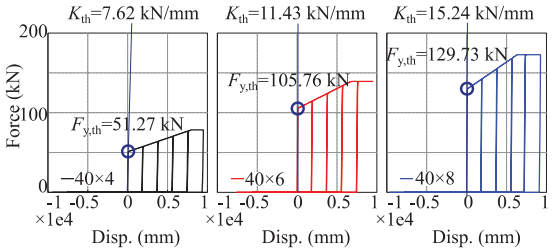

Figure 8 : Numerical predictions on the TOBs with different thickness

4.2 MODELING OF TOB-SCSTHF

Both the hybrid joint model and the TOB model were integrated into the OpenSees model for TOB-SCSTHF. The basic geometry and material information of the frame are listed in Figure 9.

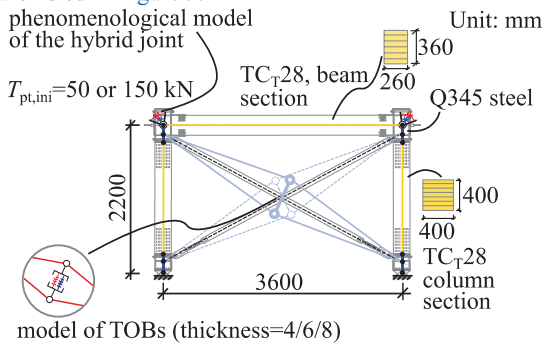

Figure 9 : Numerical model of TOB-SCSTHF

Five numerical models were built corresponding to the five TOB-SCSTHFs listed in Table 1.

Table 1 : Information of five TOB-SCSTHF models

Model ID	TOB[a]	$T_{pt,ini}$ (kN)	Steel angles at beam-column joints
M1	40×4	50	w/o
M2	40×6	50	w/o
M3	40×8	50	w/o
M4	40×4	150	w/[b]
M5	40×6	150	w/[c]

[a] Numbers represent cross-sections of TOB in mm;
[b] The steel angles had reduced thickness of 7 mm;
[c] The steel angles had reduced thickness of 5 mm.

https://doi.org/10.52202/069179-0432

TOBs with three thicknesses were used in the same SCSTHF ($T_{pt,ini}$=50 kN, without steel angles). The hysteretic curves of the three TOB-SCSTHFs are shown in Figure 10 (a). The hysteresis of the TOB-SCSTHF was in a flag shape and almost zero residual deformation was found when the lateral force was zero. The stiffness and strength of the SCSTHF were enhanced along with the increase in the thickness of TOBs. At the same time, the difference in TOBs used in the frame didn't change the residual deformation. All three frames had a full re-centering after the cyclic loading. Without the degradation of the self-centering capability, TOBs can be used when SCSTHF has insufficient lateral strength or stiffness. The introduction of TOBs into SCSTHF also changed its energy dissipation capability. As shown in Figure 10 (b), there is a plateau on the curve of accumulative energy. When no beam-column dampers are used in the SCSTHF, TOBs are the only component dissipating energy. The plastic deformation and the related energy dissipation can only happen within the first loading cycle if multiple loading cycles with the same loading amplitude was applied to the TOBs. After the first loading cycle, the TOB is elongated due to plastic deformation. It means that a larger deformation is required to make the TOB under tension again. To increase the energy dissipation of TOB-SCSTHF, steel angles were installed at the beam-column joints. Two models with steel angles were simulated and their responses are shown in Figure 10 (c). Their hysteretic curves were still in the flag shape and an increase in the residual deformation was also noticed. The increase was due to the use of steel angles. Since the use of TOBs had no influence on the self-centering performance of the frame, the installation of the steel angles was a compromise solution to the frame. The accumulative energy dissipation curves of the two new frames were shown in Figure 10 (d). Owing to the energy dissipation by the steel angles, a continuous increase is observed in the two curves. It means that the combined use of steel angles and TOBs in SCSTHF is a promising solution when there is a requirement for different structural aspects, including strength, stiffness, energy-dissipation, and residual deformations.

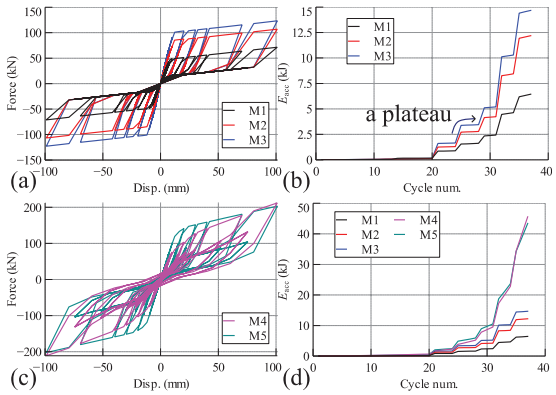

Figure 10 **:** Hysteretic responses of TOB-SCSTHF with or without steel angles

5 CONCLUSIONS

This paper presents a preliminary study on the hysteretic performance of a new lateral load resisting system called TOB-SCSTHF for heavy timber frames. The cyclic test on the hybrid beam-column joints proved their capability to provide sufficient re-centering action to the frame. Based on the experimental results, both detailed and phenomenological models were developed for the hybrid joints. The joint model was then integrated into the numerical model of TOB-SCSTHF. The simulation results showed that the introduction of TOBs increased the lateral resistance and stiffness of the frames. Being different from the BRBs, the use of TOBs did not impair the self-centering capability.

DEVELOPMENT OF HYBRID RIGID FRAME STRUCTURE METHOD USING SEMI-RIGID TIMBER BEAMS

Akihiko Miyake,[1] Ryoma Murata[2]

ABSTRACT: The authors are working to develop a construction method that incorporates semi-rigid timber beams into a steel frame structure to form a rigid frame structure. In structures constructed by this method, the joints of the semi-rigid timber beams, consisting of drift pins inserted into steel plates, resist seismic moments, generating a bending yield at the root end of the inserted U-shaped steel plates. We believe this explains the specified bearing strength and deformability achieved. We performed experiments and analysis to verify the structural performance of structures incorporating CLT semi-rigid beams. This paper describes the results of full-size in-plane bending tests performed on semi-rigid beam joints; tensile tests performed on individual drift pin joints; and the finite element method analysis used to assess the experimental results.

KEY WORDS: Medium- and large-scale timber building, hybrid structure, CLT, semi-rigid beam, inserted steel plate and drift pin joints

1 INTRODUCTION

There has been growing interest in recent years in using timber—particularly for medium- and large-scale buildings—to promote a low-carbon society and to make more effective use of domestic forestry resources. In Japan, growing numbers of medium- and high-rise buildings feature timber construction or hybrid construction incorporating timber.

This study discusses the development of a rigid frame construction method that incorporates timber beams into a steel structure (Figure 1).

This method involves connecting semi-rigid timber beams to steel columns. The inserted steel plate and drift pin joints at the ends of the beams function as rigid frame beams and resist lateral forces during an earthquake. The timber beams bear the bending moments and shear forces generated by an earthquake, while the steel beam located nearby bears the vertical loads associated with the slabs and interior and exterior materials, so that the timber beams are not subject to constant loading.

Figure 2 shows the joint. Cross laminated timber (CLT) is used for the semi-rigid timber beams. Slits are cut into the center, into which U-shaped steel plates are inserted, allowing joints using drift pins. The steel columns have brackets welded to them. Friction joints incorporating high-strength bolts between the brackets and attached plates allow the transmission of bending moments and shear forces during an earthquake. In the event of a major earthquake, it is expected that both the drift pin joints and the roots of the U-shaped steel plates will yield, ensuring deformability.

As part of this study, we performed full-size in-plane bending tests on the end of a semi-rigid beam removed from a joint between a semi-rigid timber beam and a steel column. We also performed tensile tests of individual drift pin joints to determine their characteristic values and assessed the results via finite element method analysis. This paper presents the test results, comparisons of the test results and analytical modeling results.

2 BEAM END JOINT FULL-SIZE IN-PLANE BENDING TEST

2.1 TEST AIMS

To confirm the behavior, load deformation relationship, and failure characteristics of a joint at the end of a semi-rigid timber beam subject to lateral forces during an earthquake, we extracted the section of a semi-rigid timber beam from the end to the center of the span. We then performed in-plane bending tests of the joint by repeatedly applying alternating positive and negative loads.

2.2 TEST PIECE OVERVIEW

Figure 3 shows the test piece. The CLT used for the test piece was S60-5-7 (in JAS) Japanese cedar (with the joints of the two outer-layer side-by-side plies shifted by half). One test piece was cut from each of the three parent boards. Table 1 gives the specifications for the CLT used in the tests. The test pieces here are referred to as "Cn-F," with the "n" indicating parent board number 1, 2, or 3. The inserted steel plate was made of SN400B (in JIS G3136, yield strength from 235 to 355 N/mm^2 and tensile strength from 400 to 510 N/mm^2) machined into a U-shape. The drift pins were made of SNR400B (in JIS G3138, yield strength from 215 to 335 N/mm^2 and tensile strength from 400 to 510 N/mm^2), with 55 pins arranged as shown in Figure 3. Table 2 gives the mechanical properties of the drift pins and the inserted steel plate. The holes in the CLT have a clearance of 0 mm with respect to the 16 mm diameter drift pins; the holes in the inserted steel plate have a clearance of + 1 mm; and the slit in the CLT has a clearance of + 2 mm with respect to the 19 mm thickness of the inserted steel plate.

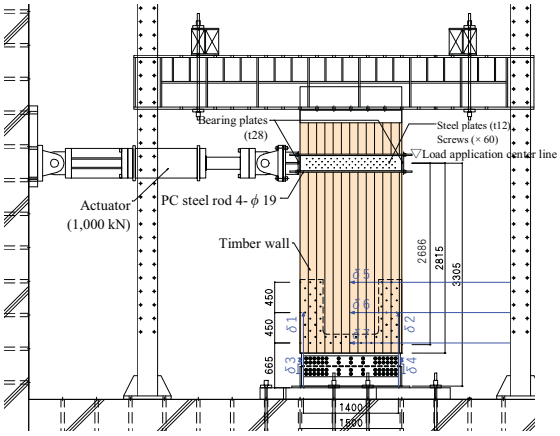
Material	σ_y [N/mm^2]	σ_{max} [N/mm^2]	Yield strain [μ]
Driftpin	326 (0.9%)	459 (0.3%)	-
Steel plate	297 (1.2%)	429 (0.5%)	1434 (0.6%)

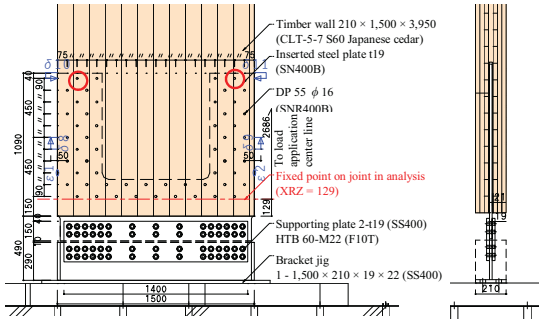
* Figures in parentheses are standard deviation values.

2.3 TEST METHOD

Figure 4 shows an overview of the test setup. The test piece was set up by rotating the semi-rigid beam by 90°, clamping the lower end to the test bed with a bracket jig, and applying a force at the point assumed to be the center of the span (the reflexion point of the anti-symmetric bending moment attributable to the seismic force). The force was applied by pushing and pulling the side of the semi-rigid beam using a bearing plate attached to an actuator. To keep the bearing plate from becoming embedded in the timber, we secured steel plates ($t \times H$ = 12 × 225) of identical thickness as the specimen on both sides of the test piece using 60 screws with a diameter of



(a) Loading diagram



(b) Joint vicinity

Figure 4: *Overview of vertical wall end joint full-size in -plane bending test*

https://doi.org/10.52202/069179-0433

8 mm and length of 90 mm. We applied the loading by rotating the joint by 1/600, 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, and 1/50 rad three times in succession in the positive and negative directions, and then by 1/30 rad once in the positive and negative directions. We then applied this same loading until the joint had turned by 1/15 rad in the positive direction or until the load declined to 0.8 times of the maximum load. We used Equation (1) to calculate the angular rotation of the joint from the displacement.

$$\theta = \frac{(\delta_2 - \delta_4) - (\delta_1 - \delta_3)}{1{,}400} \quad (1)$$

Here, δ_1 and δ_2 are the displacements (absolute vertical displacement for the CLT) for the 1st and 2nd displacement meters, while δ_3 and δ_4 are the displacements (relative vertical displacement for the CLT and bracket jig) for the 3rd and 4th displacement meters (see Figure 4 (a)). Moment M at the joint is obtained by multiplying the shear force Q measured by the load cell inside the actuator connected to the jack by the distance 2.686 m from the load application point to the fixed point on the joint in the analysis (129 mm from the CLT end; refer to Section 4.4.2 for the definition of the fixed point on the joint in the analysis). Strain gauges (ε1 and ε2) were also attached to the sides of the U-shaped root of the inserted steel plate.

2.4 TEST RESULTS

Figure 5 shows the relationship between the joint moment and rotation angle for all three test pieces. Table 3 lists the characteristic values obtained from the tests. Here, we calculated rotational stiffness K_θ as the mean secant stiffness at the first peak on the positive and negative sides for a control deformation angle of 1/300 rad. We calculated the yield strength of the drift pin joint by setting the mean value of the positive and negative loads as drift pin joint yield strength ${}_{DP}M_y$ for the yield moment of the joint at the point at which the individual drift pin joint on which the greatest stress acts reaches the mean yield point displacement value of 2.65 mm discussed in Section 3. Here, based on the analysis in Section 4, the individual drift pin joint subject to the most severe stress was determined to be the drift pin circled in Figure 4 (b). The corresponding displacement δ_{FDP} was obtained using Equation (2).

$$\delta_{FDP} = \frac{1}{2}\left(\sqrt{\left(\frac{600}{800}\cdot\delta_8\right)^2 + {\delta_{10}}^2} + \sqrt{\left(\frac{600}{800}\cdot\delta_9\right)^2 + {\delta_{11}}^2}\right) \quad (2)$$

Here, δ_8 and δ_9 are the displacements (relative vertical displacement for the CLT and inserted steel plate) for the 8th and 9th displacement meters (see Figure 4 (b)), while δ_{10} and δ_{11} are the displacements (relative lateral displacement for the CLT and inserted steel plate) for the 10th and 11th displacement meters (see Figure 4 (b)).

We calculated the yield strength of the inserted steel plate by setting the mean value of the positive and negative loads as the inserted steel plate yield strength ${}_{PL}My$ for the joint moment at the point at which the strain gauges (ε1 and ε2) mounted on the root of the U-shape of the inserted steel plate reach the tensile yield strain of 1,434 μ (see Table 2) for the inserted steel plate.

We calculated ultimate strength as the mean of the positive and negative loads for moment M_u for which the area of the trapezoid for the elastic perfectly plastic model in which the moment is M_u with the rotational stiffness as the primary gradient within the range up to 1/50 rad is equivalent to the area enclosed by the experimental joint moment and joint rotation angle plot and the X axis.

Behavior was virtually identical for all three test pieces up to a joint rotation angle of 1/30 rad, with none exhibiting significant failure. When the C3-F test piece was pulled beyond 1/30 rad, group shear failure occurred at the drift pin joint under tension at around 1/20 rad. The load dropped to approximately 60%, accompanied by a breaking sound, at which point we stopped the test. The C1-F and C2-F test pieces reached 1/15 rad with no significant reductions in load or group shear failure; we stopped the tests at this point. Figure 5 shows that the drift pin joint yield (${}_{DP}M_y$) and inserted steel plate yield (${}_{PL}M_y$) occurred almost simultaneously.

Figure 6 shows the condition of test piece C1-F after disassembly. Each drift pin is deformed at one or three hinge points along its length. The deformation of the drift pin is more severe in the area framed in red in Figure 6 (a-1) and less severe in the area framed in blue, clearly indicating that the extent of the deformation varies with location. This appears to be because the magnitude of the stress occurring in each drift pin differs with distance from

the center of rotation of the joint. The inserted steel plate is deformed in the direction of the stress acting on the drift pin joint. The root area of the U-shape exhibits delamination of the blackened layer, demonstrating that residual deformation starts at the root area. In conjunction with the state of the test piece, this led us to conclude that the inserted steel plate had yielded at the drift pin joint and the root area of the U-shape.

Figure 7 shows the horizontal displacement (δ_5 to δ_7 in Figure 4 (a)) of the test piece at the positive initial peak in the 1/300 rad cycle. The horizontal axis represents lateral displacement, while the vertical axis represents the distance from the semi-rigid beam end. The fixed point of the joint indicates the distance from the CLT end at which the length of the section is 0 (the horizontal displacement is 0) when a regression line is plotted from the horizontal displacement for each test piece at the corresponding peak. Section 4.4.2 provides more information on the joint fixed point.

3 INDIVIDUAL JOINT TENSILE TEST

3.1 TEST AIMS

With this construction method, drift pins joined to the CLT in the inserted steel plate configuration provide bending resistance, which ensures the specified strength, rigidity, and deformability. A thorough understanding of the performance of the drift pin joint is required to predict the actual rigidity and strength of the joint. At the same time, it is not possible to use the same equations to calculate rigidity [1] and strength [2], as CLT features a laminar configuration with mixed and perpendicular fiber directions. Since the angle θ between the direction of the stress from the drift pin and the direction of the strong axis of the CLT varies depending on the position of the drift pin, it is necessary to identify the effects due to θ.

Thus, we performed tensile tests on individual drift pin joints to confirm individual drift pin joint performance and the effects due to θ.

3.2 TEST PIECE OVERVIEW

The test pieces were manufactured by cutting out pieces of CLT measuring 300 mm in width for each of the four angles, as shown in Figure 8. The CLT used the same parent board as used for the full-size test described in Section 2 (see Table 1 for specifications). The test pieces are referred to as "Cn-Eθ," with "n" indicating parent board number (1, 2, or 3) and "θ" indicating the angle of the applied load with respect to the strong axis of the CLT (0, 30, 60, or 90). The inserted steel plate was made of SN400B, and the drift pins were made of SNR400B. We used two drift pins of each. Table 4 presents the mechanical properties of the drift pins and inserted steel plates. We prepared three test pieces for each of the four angles, with one piece cut out from each parent board. As in Section 2, the holes in the CLT had a clearance of 0 mm with respect to the drift pins, while the holes in the inserted steel plates had a clearance of + 1 mm. The slit in the CLT had a clearance of + 2 mm with respect to the inserted steel plate.

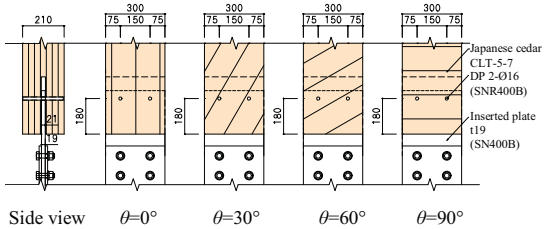

Figure 8: *Overview of individual joint tensile test pieces*

Table 4: *Mechanical properties of steel used in tests*

Material	σ_y [N/mm^2]	σ_{max} [N/mm^2]
Driftpin	326 (0.9%)	459 (0.3%)
Steel plate	312 (2.0%)	431 (0.4%)

* Figures in parentheses are standard deviation values.

https://doi.org/10.52202/069179-0433

3.3 TEST METHOD

Figure 9 shows the loading configuration. Loads were applied using 1,000 kN center hole jacks for tensioning and compressing. Axial forces were measured using pressure transducers connected to each jack. We measured the relative displacement between the inserted steel plate and the CLT at two points (on the front and back) and used the mean value as the joint displacement. We performed positive and negative loading three times and treated tensile loading as positive loading. These loads were applied by repeatedly applying displacements of $\delta pt \times 1/2$, 1, 2, 4, 6, 8, 12, and 16, based on the yield displacement of δpt = 1.55 mm in the preliminary test done at θ = 0°, until the load declined to 0.8 times of the maximum load or until the displacement reached 30 mm.

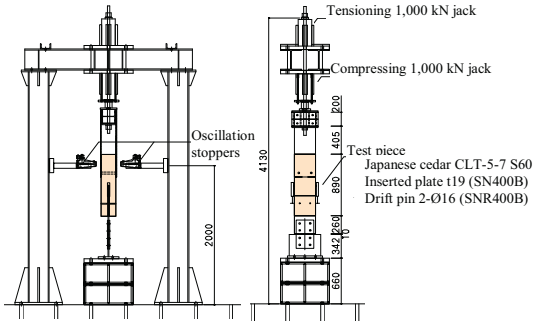

Figure 9: *Individual joint tensile test loading configuration*

3.4 TEST RESULTS

Figure 10 shows the relationship between load per drift pin and deformation for each angle. Table 5 shows the mean characteristic values (θ = 0, 30, 60, and 90 values are mean values for three test pieces; ALL values are mean values for all 12 test pieces) obtained in the tests. We calculated characteristic values such as yield strength and initial stiffness by the method described in reference [3]. The red lines in Figure 10 indicate the mean values for the tri-linear models with test pieces corresponding to each specification. Here, the first breakpoint of the tri-linear model is the point (P_y, δ_y), and the second breakpoint of the tri-linear model is the point (P_{max}, δ_{max}). After testing, we removed the drift pins, assigning those showing zero bending points to Yield Mode I, those with one bending point to Yield Mode III, and those with three bending points to Yield Mode IV. Figure 11 shows some of the disassembled test pieces.

The load-displacement relationship shown in Figure 10 confirmed that stiffness for all test pieces begins to decline at a relative displacement of approximately 2 mm. When the test pieces were disassembled, the drift pins demonstrated behavior corresponding to Yield Mode III or IV. This suggests that drift pin yield occurred and that bearing yield occurred in timber parts in contact with the drift pins. Ultimately, the load declined with each repetition for 16 × δ_{pt} cycles. Examination of the drift pins after disassembly showed that many had failed from the area at which they were in contact with the inserted steel plate near the center. We estimate that fatigue fracture occurred at 16 × δ_{pt} cycles.

When we compared the direction θ of the stress acting from the drift pin, we found no obvious differences due to θ for initial stiffness or joint yield strength. Based on this, we conclude that the effects on individual drift pin performance due to the direction θ of the stress acting from the drift pin are negligible.

Table 5: *Characteristic values obtained from tests*

Actual angle [°]	Yield strength P_y [kN] / Yield displacement δ_y [mm]	Maximun strength P_{max} [kN] / Displacement at Pmax δ_{max} [mm]	Initial stiffness K_1 [kN/mm]	Secondary stiffness K_2 [kN/mm]	Mode

4 FINITE ELEMENT METHOD ANALYSIS

4.1 ANALYSIS AIMS

We performed our analysis by the finite element method for the semi-rigid beam end joint full-size bending test performed in Section 2. We then compared the analysis results to the test results. Here, we drew on the measurements obtained in the tests described in Section 3 to assess individual drift pin joint and material strength for the inserted steel plate.

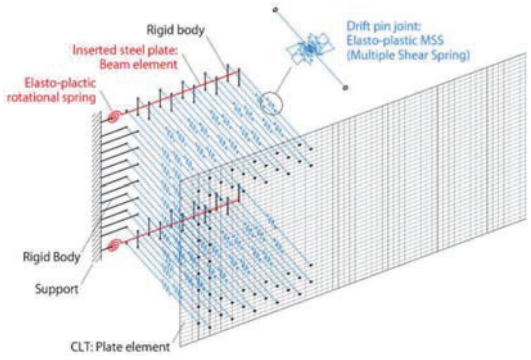

Figure 12: *Overview of analysis model*

Table 6: *Analysis model details*

Element	Element type	Details
CLT	Plate element	t=210mm, E_0=4,285kN/mm^2, E_{90}=1,714N/mm^2, G=0.5kN/mm^2
Drift pin	MSS (n=4)	k_1=5.90kN/mm, p_1=10.52kN k_2=0.342kN/mm, p_2=15.45kN
Inserted steel plate	Beam element	B×D = 19mm×340mm Elasto-plastic spring for root area (See Figure 13.)

* E_o : Young's modulus in strong axis direction,
E_{90} : Young's modulus in weak axis direction
G : Elastic shear modulus
k_1,k_2: Stiffness of each shear spring
p_1,p_2: Strength of each shear spring

4.2 ANALYSIS MODEL

Table 6 lists the details of the analysis model. Figure 12 provides an overview of the model. CLT stiffness is specified as described in reference [4]. We modeled the inserted steel plate individual drift pin joint as a tri-linear model using a multiple shear spring (MSS, with number of partitions n = 4). We calculated individual shear spring stiffness value k_1 and k_2 and yield load p_1 and p_2 by applying the following equations, as in reference [5].

$$k_1 = {K_1}\Big/{\sum_{i=1}^{n} \sin^2 \frac{1}{n}\pi} \quad (3)$$

$$k_2 = {K_2}\Big/{\sum_{i=1}^{n} \sin^2 \frac{1}{n}\pi} \quad (4)$$

$$p_1 = {P_y}\Big/{\sum_{i=0}^{n-1} \sin \frac{1}{n}\pi} \quad (5)$$

$$p_2 = {P_{max}}\Big/{\sum_{i=0}^{n-1} \sin \frac{1}{n}\pi} \quad (6)$$

Here, k_1 is the initial stiffness of each shear spring [kN/mm], p_1 is the first yield load for each shear spring [kN], k_2 is the secondary stiffness of each shear spring [kN/mm], p_2 is the second yield load for each shear spring [kN], K_1 is the initial stiffness of the individual joint [kN/mm], K_2 is the secondary stiffness of the individual joint [kN/mm], P_y is the yield strength of the individual joint [kN], and P_{max} is the maximum strength of the individual joint [kN]. Each Characteristic value of the individual joint are treated as independent of angle based on the test results described in Section 3, in which we observed no obvious differences due to angle for either. Thus, we used the mean values of the test results for all 12 test pieces (see Table 5 for values).

We modeled the inserted steel plate root area as a rotational spring with tri-linear restoring force properties, as shown in Figure 13. The initial stiffness was set to K_0 = 135,912 kNm/rad, derived from the elastic analysis of the U-shaped steel plate. With the rotational spring, we replaced the skeleton curve obtained from the results of equations (7) to (13) while reducing the stiffness by the ratio of the cross-sectional moment of inertia of the residual elastic region to the cross-sectional moment of inertia of the entire cross section with a tri-linear model.

$$M_y = Z \cdot \sigma_y \quad (7)$$

$$M_p = Z_p \cdot \sigma_y \quad (8)$$

$$M_i = M_y + (M_p - M_y)i/m \quad (9)$$

$$x_i = \sqrt{\frac{3D^2}{4} - \frac{3M_i}{B\sigma_y}} \quad (10)$$

$$I_i = \frac{B(2x_i)^3}{12} \quad (11)$$

$$K_i = I_i / I_0 \, K_0 \quad (12)$$

$$\theta_i = \theta_{i-1} + \frac{(M_p - M_y)/m}{(K_i + K_{i-1})/2} \quad (13)$$

Here, M_y is the yield moment [kNm]; Z is the section modulus [mm^3]; σ_y is the inserted steel plate yield stress (= 297) [N/mm^2]; M_p is the fully plastic moment [kNm]; Z_p is the plastic section modulus [mm^3]; i is the number of steps; m is the number of divisions (= 10); M_i is the bending moment for step i [kNm]; x_i is the non-plasticized part thickness for step i [mm]; D is the steel plate thickness (= 340) [mm]; B is the steel plate width (= 19) [mm]; I_i is the cross-sectional moment of inertia for step i [mm^4]; K_i is the rotational stiffness for step i [kNm/rad]; and θ_i is the rotation angle for step i [rad].

The first break point with the tri-linear model occurs when the yield moment M_y is reached. The second break point occurs when the fully plastic moment M_p is reached. These were determined so that Area 1 and Area 2 in Figure 13 are identical. The calculations here for M_y and M_p assume the inserted steel plate yield stress of 297 kN/mm^2 (see Table 2) used in Section 2 for the inserted steel plate yield stress.

https://doi.org/10.52202/069179-0433

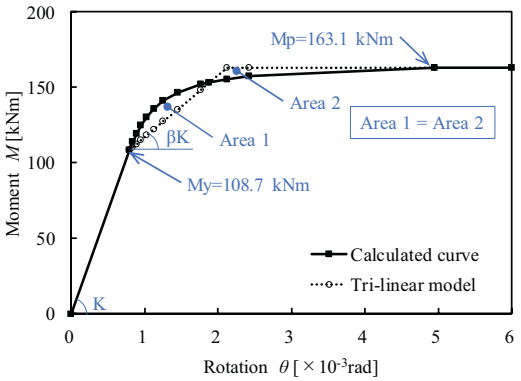

Figure 13: *Rotational spring of inserted steel plate root area*

4.3 ANALYSIS CONDITIONS

The model set was subjected to static incremental loading analysis. Figure 14 shows the analysis conditions. Incremental loading analysis was performed by positioning the load 2,815 mm from the end of the CLT in the same way as in the full-size tests, with the 41 nodes at that position connected to rigid beam elements. A nodal load was applied to the uppermost node.

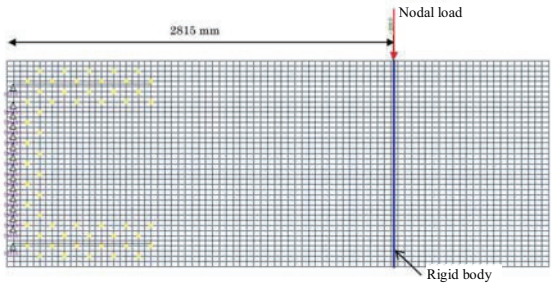

Figure 14: *Analysis conditions*

4.4 ANALYSIS RESULTS

4.4.1 Moment-rotation angle relationship

Figure 15 shows the relationship between moment and rotation angle for the joint. Joint moment M is defined as the value obtained by multiplying the shear force applied to the model by the moment arm length (described later) of 2.686 m. The solid lines indicate the results for the three test pieces. The dashed lines indicate incremental analysis results. The "×" symbols (M = 785 kNm, $\theta = 3.91 \times 10^{-3}$ rad) on the dashed line indicate the point at which the displacement of the first drift pin reaches the yield displacement δ_y 2.65 mm of the individual joint in the incremental analysis. The joint load moment at this point is defined as the yield moment ${}_{DP}M_y$ of the drift pin joint obtained from the analysis. The "○" symbols (M = 917 kNm, $\theta = 4.99 \times 10^{-3}$ rad) indicate the point at which bending yield occurs at the root of the inserted steel plate in the incremental analysis (when M_y in Figure 13 is reached). The joint load moment at this point is defined as the yield moment ${}_{PL}M_y$ of the drift pin joint obtained from the analysis. Figure 15 shows that the drift pin yield and inserted steel plate bending yield in the analysis relatively near-simultaneously.

Table 7 compares the mean test results and analysis results for the rotationnal stiffness, yield strength, and ultimate strength of the joint. Ultimate strength M_u in the analysis results is defined as the joint moment when a bi-linear curve is drawn so that the initial gradient is the rotational stiffness and the area is equivalent to the joint moment-rotational angle relationship in the range up to 1/50 rad.

From Figure 15, the finite element method analysis was able to track the experimental results with good accuracy. The load increase after yielding can be reproduced by inputting the spring of the drift pin joint and the inserted steel plate at root area of the U-shaped part with a tri-linear type. The difference between the analysis results and the experimental results is large in the range of after 1/50 rad, but this is considered to be because the decrease in strength after reaching the maximum strength of each element was not reproduced in the analysis.

4.4.2 Joint fixed point position

This paper defines as the joint fixed point the point on a semi-rigid beam joint at which no displacement occurs when a load results in rotational deformation. The distance from the point at which the force is applied to the fixed point of the joint is used as the moment arm length for the calculation of the joint moment.

Figure 7 shows the 1/300 rad cycle positive peak for the semi-rigid beam end joint full-size in-plane bending test, together with the analysis results for the same load conditions. The analysis results at this point are within the elastic range. Figure 7 confirms that the joint fixed point generally coincides with the test results. Based on these results, we defined the y-intercept (= 129 mm) of the analysis results (dashed line) as the joint fixed point position. Based on the dimensional relationship shown in Figure 4, we calculated the moment arm length to be 2,686 mm (= 2,815 mm - 129 mm).

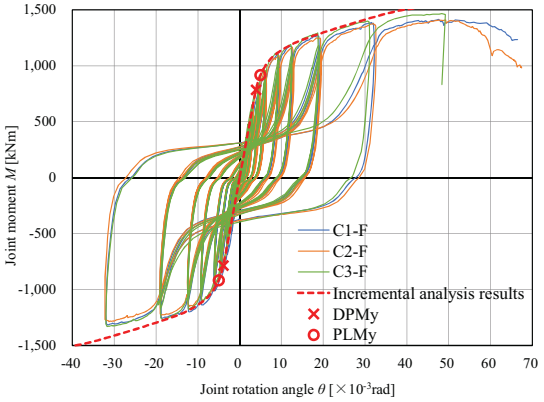

Figure 15: *Joint moment-rotation angle relationship (Comparison of test results and analysis results)*

Table 7: *Comparison of test data and analysis data*

Test Ppiece	Rotational stiffness K_θ [kNm/rad]	Driftpin joint yield strength ${}_{DP}M_y$ [kNm]	Steel plate yield strength ${}_{PL}M_y$ [kNm]	Ultimate strength M_u [kNm]
Test data (mean of 3 values)	203,576	852	938	1,119
Analysis data	202,716	785	917	1,168
Analysis data/Test data	1.00	0.92	0.98	1.04

https://doi.org/10.52202/069179-0433

5 CONCLUSIONS

We carried out full-size in-plane bending tests on the end joint, and finite element method analysis to verify the performance of joints on semi-rigid timber beams using CLT. Our findings are presented below.

- Full-size in-plane bending tests on the end joint of semi-rigid timber beams using CLT demonstrated the capacity to achieve the specified strength and deformability.
- The bending yield of individual drift pin joints and the bending yield of the U-shaped inserted steel plate root area may improve the deformability of semi-rigid timber beam joints.
- Both individual joint initial stiffness and joint strength had minimal dependence on angle, given the specifications used in the individual joint tensile tests.
- The results confirm that an analysis model based on the finite element method can accurately evaluate the experimental values.
- The position of the point at which displacement does not occur (joint fixed point) was determined from the analysis results. The results for the joint fixed point were generally consistent with test results.

ACKNOWLEDGEMENTS

This study was carried out using materials kindly provided by Meiken Lamwood Corp. We are grateful for the support of all those involved.

AN EXPERIMENTAL AND NUMERICAL INVESTIGATION ON A DOVETAIL NOTCHED CONNECTION FOR CROSS-LAMINATED-TIMBER-CONCRETE COMPOSITE SLABS

Vanthet Ouch[1], Piseth Heng[2], Hugues Somja[3], Thierry Soquet[4]

ABSTRACT: A specific dovetail notched connection has been proposed for CLT-concrete composite slabs. The particularity of this notched connection is its dovetail shape that provides a mechanical locking to limit the uplift without metallic screws. The experimental pushout results showed high stiffness and resistance. However, low ductility was obtained due to the failure by rolling shear of CLT. The performance and failure mechanism of the notched connector can be influenced by numerous variables. This paper presents a numerical study on the effect of different parameters related to the geometry and material properties, on the performance of the notched connection. First, an advanced 3-dimensionnal finite element model of the experimental test considering the nonlinear properties of the materials and the orthotropic behaviour of the CLT has been developed. The results of this model were validated against the experimental ones obtained from static pushout tests. A good agreement of the force-slip curves was obtained, and the model was able to reproduce the failure observed in the tests. Having validated the FE model, the parametric study was conducted to better understand the notched connector under the influence of variations in geometrical and material properties. Two different failure modes were obtained : the concrete shear at the notch and the rolling shear of the cross-layer of the CLT panel. The rolling shear failure of the CLT panel should be avoided in order to improve the post peak-performance of the notched connector. Reducing the notch length and increasing the heel length provoke the concrete shear failure of the notch, which improves the ductility of the connector if sufficient V-shape rebars are placed inside the notch. The stiffness of the connector can be influenced by changing the parameters such as the concrete resistance, the thickness of the concrete panel, the amount of V-shape rebars, the notch length and the heel length.

KEYWORDS: Dovetail notched connector, Pushout test, Parametric study, CLT-concrete composite slabs.

1 INTRODUCTION

Being responsible for around 39 percent of all carbon emissions around the world, the building and construction sectors are considered as the main contributor to the climate change [1]. The devastating consequences of climate changes urge the involved organizations to revolutionize building materials and construction methods in order to achieve 100 percent net zero emissions buildings by 2050. With such an objective, sustainable solutions for buildings have been widely studied. As an alternative to the traditional concrete or timber structures, Timber Concrete Composite (TCC) slabs might be an interesting solution that balance environmental impacts with structural and economical performances. A TCC slab is formed by laying a concrete panel on top of a timber panel and connecting them together using shear connection systems. This combination benefits the high performances of concrete in compression and of timber in tension. The structural response of the composite system is ordinarily governed by the strength, stiffness, and ductility performance of the connection system.

Different types of shear connection systems have been developed in the past including steel fasteners, notches, and glue in order to enhance structural performance and cost-efficiency of TCC structures [2]. Among them, notched connection might be considered as the most effective system due to its high strength, stiffness as well as construction convenience. However, for this notched connection, steel fasteners are in general inserted in the timber and connected to the concrete notch to improve the shear strength and ductility of the connection as well as the uplift resistance between the concrete and timber. These steel fasteners are expensive and time-consuming in the construction process.

In response, a dovetail notched connection for CLT-concrete composite slabs has been proposed by T. Soquet and investigated by the authors [3]. The particular shape

https://doi.org/10.52202/069179-0434

of the proposed notch configuration provides a geometrical constraint to limit the uplift without the need for metallic elements (see Figure 1). Experimental pushout tests have been conducted to determine the mechanical properties of the notched connection. It was found that the connection system showed high strength and stiffness with brittle failure due to the limited rolling shear resistance of the cross-layers of the CLT panel.

This paper presents a numerical study on this notched connection using Abaqus/Explicit [4] in order to determine the influence of selected parameters on the behaviour of the notched connection. First, a 3D FE model of the pushout test was developed and validated against the experimental results. Then, a parametric study on the variables defining the geometry and the materials was carried out.

2 SUMMARY OF THE EXPERIMENTAL WORK

2.1 MATERIAL CHARACTERISATION

The concrete was tested to determine the actual properties on the same day as pushout tests. Two series of three-cylinder specimens with a dimension of 11×22cm were tested for compressive strength f_{cm} and tensile strength f_{ct}. Table 1 presents the results obtained from concrete characterisation.

Table 1: *The results obtained from the concrete test*

Test	f_{ct} [MPa]	f_{cm} [MPa]
1B-1	3.20	34.51
1B-2	2.56	29.12
1B-3	3.39	39.51
Average (Var.)	3.05 (0.36)	34.38 (4.24)

CLT panels TOT'm X [5] were used. They are constituted of wooden planks with a thickness of 33 mm each, stacked in crossed layers at 90° and glued together over their entire surfaces (except the edge surfaces). Small-scale characterisation tests including longitudinal compression tests and rolling shear tests were conducted. The longitudinal compression tests were carried out in accordance with EN 408 [6] on 12 samples while the rolling shear tests using a configuration proposed in previous research [7] were carried out on 5 samples with three lamination layers (one cross layer sandwiched by two longitudinal layers). These samples had dimensions of 99 mm thick by 140 mm large by 269 mm long. Table 2 presents the value of longitudinal compression strength $f_{c,0}$,rolling shear strength f_v, and rolling shear modulus G_r obtained from characterisation test.

Table 2: *The results obtained from the timber test*

Test	$f_{c,0}$ [MPa]	G_r [MPa]	f_v [MPa]
Avg.	31.26	127	1.49
(Var.)	(5.33)	(25)	(0.17)

Steel rebars for the concrete panel and the notch connector have a nominal yield strength of 500 MPa.

2.2 RESULTS OF PUSHOUT TESTS

A series of three identical symmetrical pushout tests (1B-1, 1B-2 and 1B-3) were performed in order to determine the shear resistance, the stiffness, the deformation capacity and the failure mode of the dovetail notched connectors. The dimensions of the three specimens are presented in Figure 1. Specimen 1B-1 has a width of 500 mm, whereas specimens 1B-2 and 1B-3 have a width of 400 mm. The specimen was placed vertically on a support table, and the load was applied on the top surface of the CLT panel using a force jack with the capacity of 1500 kN (see Figure 2a). The test procedure described in Annex B of Eurocode 4 part 1-1 (2004) [8] was followed. The relative slip at the contact layer between concrete and timber panel was measured using Digital Image Correlation method with a precision of ± 0.1 mm. Two cameras were employed to record the relative displacements in the back face and the front face of the tested specimens.

(a) Test setup *(b) Failure mode*

Figure 2: *Description of pushout test setup and failure mode*

Figure 3 and Table 3 present the force-slip curves and the results obtained from the pushout tests, respectively. The test results showed high shear resistance and stiffness for all the three tested specimens. However, a low ductility

was obtained, as the failure mode was governed by the shear failure of one cross-layer of the CLT panel (see Figure 2b). The maximum relative slip obtained from the experimental tests ranged between 0.8 mm and 1.6 mm. The maximum loads attained per connector per meter width (F_{max}) were 420 kN/m, 428 kN/m and 464 kN/m for test 1B-1, 1B-2 and 1B-3, respectively. The slip modulus to be used at serviceability limit state (SLS) K_s and ultimate limit state (ULS) K_u reported in Table 3 were computed following the method proposed by Ceccotti [9].

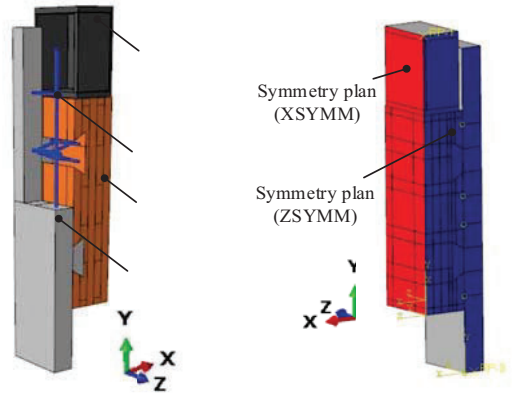
3 NUMERICAL STUDY

As mentioned above, the numerical study is divided into two steps. The first step consists of developing a 3D FE model of the experimental pushout test using ABAQUS/Explicit. The results of this model are validated against the experimental results. In the second step, the validated model serves to carry out a parametric study on the influence of various parameters on the behaviour of the notched connection.

3.1 MODEL ESTABLISHMENT

3.1.1 Geometry and boundary condition

To improve the computation speed, only one fourth of the test configuration was considered by taking advantages of the symmetric disposition and boundary conditions. All the components of the specimen as well as the steel loading block were modelled (see Figure 4a). The symmetric boundary conditions were applied at the highlighted surfaces in red and in blue colour (See Figure 4b), constraining the displacements in X-direction and Z-direction, respectively.

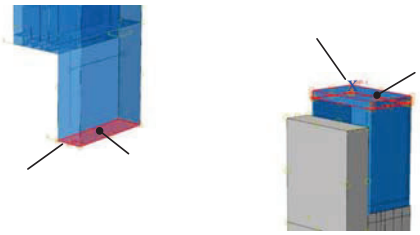


(a) Geometry *(b) Symmetry condition*

Figure 4: *Geometry and symmetry condition of the FE model*

The support was modelled by applying a rigid constraint to the bottom surface of the concrete panel that rigidly follows the movement of a reference point (see Figure 5a). All the degrees of freedom of this reference point were fixed.

The loading was simulated by applying an imposed displacement to another reference point that governs a rigid displacement of the top flange of the loading block HEA-300 (see Figure 5b).



(a) Support *(b) Loading*

Figure 5: *Support and Loading condition of the FE model*

3.1.2 Material modelling

Concrete was considered as a non-linear isotropic material [10]. The concrete damaged plasticity (CDP) model available in Abaqus/Explicit was adopted [11] to reproduce properly the two main behaviours of concrete (compression crushing and tensile cracking). The actual concrete strength obtained from cylinder tests was used. Moreover, the parameters to define the flow potential and the yield surface including the dilatation angle Ψ, the eccentricity ϵ, the ratio of biaxial compressive strength to uniaxial compressive strength f_{b0}/f_{c0}, the shape factor for yield surface K_c, and the viscosity parameter μ were defined as in Table 4.

Table 4: *Parameters of concrete damaged plasticity model*

Ψ [^{0}]	ϵ	f_{b0}/f_{c0}	K_c	μ
40	0.1	1.16	0.67	0

Timber was considered as an orthotropic material using the assumption that the stiffness and the strength in radial

https://doi.org/10.52202/069179-0434

and in tangential directions were identical. The mechanical stiffnesses were derived from the technical specification [5] except the rolling shear modulus G_r. The latter was taken from a specific shear test (see Table 5).

Table 5: *Mechanical stiffnesses of the timber*

E_1 (MPa)	$E_2=E_3$ (MPa)	$G_{12}=G_{13}$ (MPa)	G_{23} (MPa)	ν (-)
11000	370	690	127	0

Note: The subscription 1,2,3 refer to longitudinal, transversal, and radial directions, respectively.

The plasticity of the timber was defined using the orthotropic yield criteria proposed by Hill [12]. This criterion is an extension of Von-Mises yield criterion that consider the orthotropic behavior of the material. The stress potentials are related to the compressive strength parallel to grain $f_{c,0}$ and the shear strength of the timber f_v [13]. The timber strength was adopted from the characterization tests with $f_{c,0}=31$ MPa and $f_v=1.49$ MPa. Therefore, the six input parameters in ABAQUS were determined and are presented in Table 6.

Table 6: *Stress potentials adopted in the FE model*

R11	R22	R33	R12	R13	R23
1	0.0965	0.0965	0.22	0.22	0.084

Steel rebars were considered to be an isotropic material and to exhibit a bilinear elastic-plastic behaviour in the FE model. Properties based on experimental tests from literature [14] were used and are summarized in Table 7.

Table 7: *Tensile properties of steel reinforcement*

f_y (MPa)	f_u (MPa)	E (GPa)	ε_y [-]	ε_u [-]
500	635	200	0.00317	0.14559

3.1.3 Mesh definition and contact interaction

The concrete panel, the CLT panel and the HEA-300 loading block were meshed using hexahedral element with reduced integration and hourglass control (C3D8R) while the steel rebars were modelled using two-node beam element, B31. A finer mesh (5 mm) was generated in the neighbouring region of the connection system (see Figure 6). The rest had a size of 10 mm.

Surface-to-surface contact between concrete panel and CLT panel as well as between loading block (HEA 300) and CLT panel (see Figure 7) had to be considered. The contact properties were defined by hard contact and friction penalty formulations for the normal and tangential behaviours, respectively. In this study, the friction coefficient for the contacts between concrete and timber, and between steel and timber were 0.62 [15] and 0.50 [16], respectively. Apart from that, an embedded constraint was adopted for the interaction between the steel reinforcement and the concrete panel.

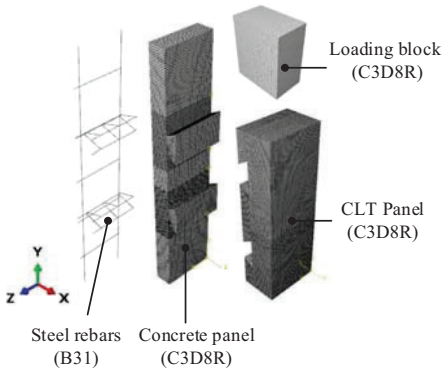


Figure 6: *The mesh of components in the FE model*

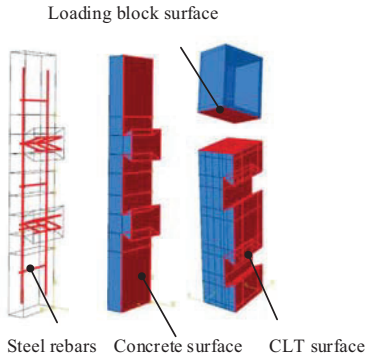

Figure 7: *Contact surface of each component in the FE model*

3.2 MODEL VALIDATION

The failure mode from the simulation was governed by the rolling shear failure of the CLT panel, reproducing the same failure mode as in experimental tests. Figure 8a,b illustrates the deformed shape and rolling shear stress at a maximum load obtained in FE model. Due to the configuration of the loading block that covers all the top surface of the CLT panel, a part of the load was transferred directly to the concrete notch in form of compressive force in the longitudinal layer and the rest was transmitted via rolling shear action of the cross-layers (see Figure 8c). Therefore, the real rolling shear resistance should be lower than the maximum force obtained in the test.

Figure 9a presents the comparison of force-slip curves obtained from the FE model and from the experimental tests. It can be seen that the FE model estimated a peak load at around 431 kN that is in good agreement with the experimental value, with approximately 2 percent difference. However, the behaviour of the notched connector in the FE model is stiffer, as smaller slip was obtained at the peak load compared to the experimental results. In fact, during the experimental tests, several cyclic loadings were applied, and rather frequent pauses were taken to observe the cracking in the concrete. This has generated additional slips due to additional creep strains. In order to be able to compare the results with the ones from the FE model, the slips caused by the cyclic loadings and the pauses were removed from the results. Figure 9b presents the new load-slip curves. A better

https://doi.org/10.52202/069179-0434

agreement of the curves was obtained. The comparison between the results obtained from FE model and the ones from experimental tests are summarized in Table 8. The differences of maximum force F_{max} and corresponding slip $\delta_{F_{max}}$ were respectively 2 percent and 3 percent while higher discrepancies of slip modulus were noticed with 22 percent and 8 percent for the values at SLS and at ULS, respectively. The precision of the Digital Image Correlation technique adopted in the pushout tests was 0.1 mm. Hence, it is difficult to obtain accurate experimental values of the slip modulus, as the connection is very stiff.

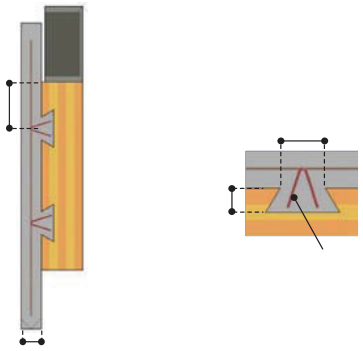
3.3 PARAMETRIC STUDY

3.3.1 Parameters investigated

To gain a thorough understanding of the mechanical behaviour and to predict the possible mechanisms of the notched connection system, a parametric study was conducted using the validated FE model. The investigated parameters were divided into two groups. The first group of parameters involved general parameters, including the concrete strength f_c, the thickness of the concrete panel h_c, and the heel length of the CLT panel l_t (see Figure 10a). On the other hand, the second group of parameters (see Figure 10b) were associated with the notched connector, including notch length l_n, notch depth d_n, and cross-sectional area of the V-shape reinforcement inside the notched connection A_s. However, the material and geometrical properties of the CLT (mechanical properties and thickness of the CLT panel) is invariable since they are fixed in the industrialized solution. Additionally, the notched angle of 59.04^0 is fixed to maintain the notched shape, while the V-shape rebars can be adjusted to fit inside the notched connector.



(a) First group of parameters *(b) Second group of parameters*

Figure 10: *Geometrical parameters studied*

3.3.2 First group of parameters

Table ***9*** describes the details of the first group of parameters. C1, C2, and C3 simulations investigated the parameter of concrete strength, thickness of the concrete panel, and heel length of the CLT panel, respectively. In Case C3-1, the heel length of the CLT panel was increased from 187.5 mm to 375 mm.

https://doi.org/10.52202/069179-0434

Table 9: *The details of the first group of parameters*

Parameter		f_c [MPa]	h_c [mm]	l_t [mm]
Reference		35	80	187.5
C1	C1-1	25	80	187.5
	C1-2	45		
C2	C2-1	35	50	187.5
	C2-2		100	
C3	C3-1	35	80	375

The force-slip curves of all the cases in the first group of parameters are drawn in Figure 11. The results obtained from the numerical simulation are presented in Table 10. The value in bracket refers to the difference of peak loads in the different cases to the one in the reference case.

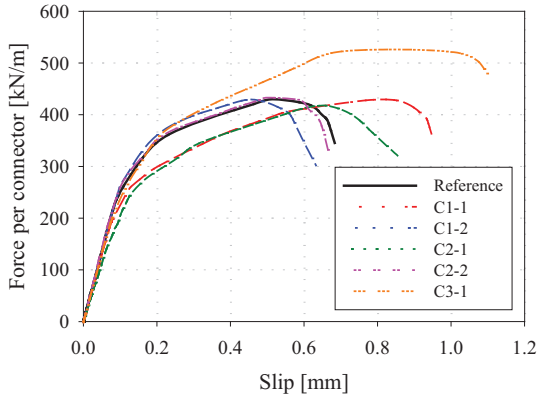


Figure 11: *Force-slip curve of numerical study of C1/C2/C3*

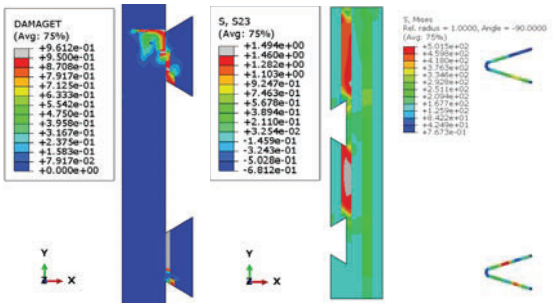
Table 10: *Results obtained from numerical study of C1/C2/C3*

Test	F_{max} [kN/m]	δ_{Fmax} [mm]	K_s [N/mm/m]	K_u [N/mm/m]	Failure mode
Ref.	431 (1.00)	0.52	2.73×10^6	2.43×10^6	RS
C1-1	429 (1.00)	0.78	2.58×10^6	2.03×10^6	RS
C1-2	430 (1.00)	0.45	2.73×10^6	2.63×10^6	RS
C2-1	419 (0.97)	0.66	2.17×10^6	1.96×10^6	RS
C2-2	435 (1.00)	0.48	2.87×10^6	2.62×10^6	RS
C3-1	526 (1.22)	0.72	2.51×10^6	1.95×10^6	CS

Note: RS refers to Rolling shear of the CLT while CS refers to Concrete shear of the concrete panel.

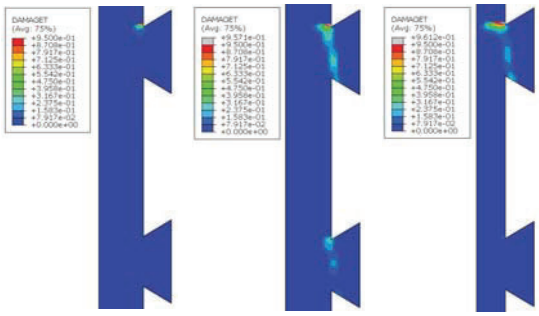
Except for Case C3-1, the failure of the notched connector was governed by the rolling shear failure of the cross-layer of the CLT panels. The maximum force ranged from 419 kN to 435 kN and was logically not influenced by the parameters related to the concrete. The maximum difference was approximately 3 percent compared to the reference case. In Case C3-1, the failure was governed by the concrete shear in the lower notched connector, even if the rolling shear stress was large in the cross-layer of the CLT panel. Figure 12 illustrates the tensile damage in the concrete panel, rolling shear stress of the CLT panel, and V-shape rebars stresses under the maximum load. The damage in the critical shear plane in the concrete was close to 1.0, while the V-shape rebars were experiencing the yielding stress (of 500 MPa) in the lower notched connector at the maximum load. It can be inferred that the simulation of Case C3-1 provides an estimation of the connection resistance on the concrete side. A 22 percent increase in the maximum force was observed compared to reference case.



(a) Tensile damage *(b) Rolling shear stress* *(c) Stress of the rebars*

Figure 12: *Tensile damage in concrete and rolling shear stress of the CLT at the maximum load in Case C3-1*

In terms of the force-slip relationship, the curves exhibit similar trends in linear elastic region until a load level of approximately 270 kN. From this load level, Cases C1-1 and C2-1, which adopt lower concrete strength and smaller concrete thickness, respectively, show larger slips than other cases for the same load. The change of the parameters in these cases led to an earlier tensile damage of the concrete panel (see Figure 13). Regarding Case C3-1, a plateau of force-slip curve was noticed, starting from 0.72 mm of slip, where the first failure of the lower notched connector was obtained and ending at 0.99 mm of slip, where the other connector failed and the V-shape rebars in both notches experienced the yielding stress.



(a) Reference case *(b) Case C1-1* *(c) Case C2-1*

Figure 13: *Tensile damage of the concrete panels at the load level of 270 kN*

In addition, high stiffness was observed in both service and ultimate conditions in all cases, and slips at the maximum load of the first group ranged from 0.45 mm to 0.78 mm. In cases where the failure was related to rolling shear of the CLT panel, the ductility was limited. In case C3-1, as the maximum load was governed by the shear failure in the concrete, a higher slip of approximately 1.1 mm was achieved in Case C3-1.

Regarding other cases, it can be assumed that the concrete strength and the thickness of the concrete slab had little influence on the load bearing capacity of the notched connector since the connector behaviour was limited by the rolling shear resistance of the CLT panel. It is worth to remind that the real rolling shear resistance is lower than the experimental maximum load due to the loading

block configuration that resulted in some loading being transferred directly to the concrete panel via longitudinal compression of the CLT panel. However, lower concrete strength and smaller thickness of the concrete panel reduced the stiffness of the notched connector due to the early damage of the concrete panel.

3.3.3 Second group of parameters

The details of the parameters in the second group are described in Table 11. C4, C5, and C6 simulations investigated the influence of the notch length l_n, the notch depth d_n, and the cross-sectional area of V-shape rebar A_s, respectively. In the reference case, 5 V-shape 6-mm rebars with 90-mm spacing were used in the notched connection, corresponding to a section of 141.37 mm^2. For Case C6-1, no V-shape rebar was used in the notch, whereas 2 6-mm V-shape rebars were included in the notch for Case C6-2.

Table 11: *The details of the second group of parameters*

Parameter		l_n [mm]	d_n [mm]	A_s [mm^2]
Reference		90	50	141.37
C4	C4-1	40	50	141.37
	C4-2	140		
C5	C5-1	90	25	141.37
C6	C6-1	90	50	0
	C6-2			56.55

Figure 14 presents the force-slip relationships for all the cases in the second group of parameters. The results obtained from the numerical simulation are summarized in Table 12. The same two types of failure modes were observed: rolling shear of the CLT panel and concrete shear.

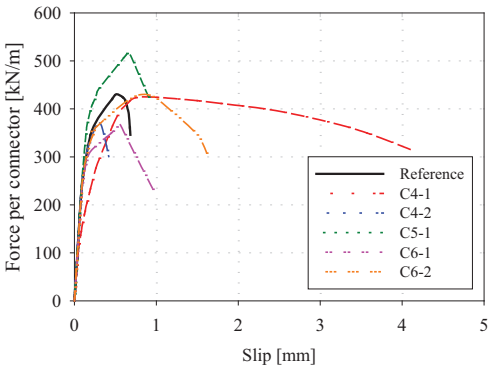


Figure 14: *Force-slip curve of numerical study of C4/C5/C6*

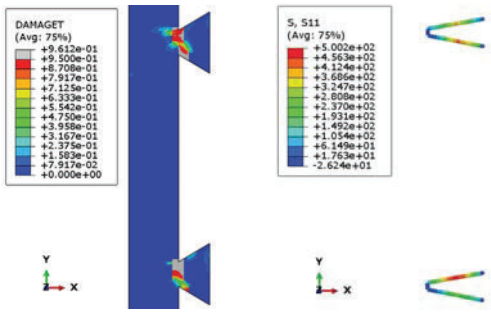
Table 12: *Results obtained from numerical study of C4/C5/C6*

Test	F_{max} [kN/m]	δ_{Fmax} [mm]	K_s [N/mm/m]	K_u [N/mm/m]	Failure mode
Ref.	431 (1.00)	0.52	2.73×10^6	2.43×10^6	RS
C4-1	425 (0.99)	0.85	1.51×10^6	1.11×10^6	CS
C4-2	370 (0.86)	0.30	2.88×10^6	2.80×10^6	RS
C5-1	516 (1.20)	0.65	2.78×10^6	2.54×10^6	CS
C6-1	364 (0.84)	0.53	2.63×10^6	2.60×10^6	CS
C6-2	427 (0.99)	0.75	2.68×10^6	2.36×10^6	RS+CS

Note: RS refers to Rolling shear of the CLT while CS refers to Concrete shear of concrete panel.

In cases C4, the change of notch length resulted in modifying the area of the cross layer of the CLT panel. The decrease of the notch length from 90 mm to 40 mm in Case C4-1 contributed to the higher rolling shear resistance of CLT panel and to the lower shear resistance and stiffness in the concrete. In this case, the failure was governed by the shear failure of concrete in notched connector with a maximum force of 425 kN and a corresponding slip of 0.85 mm. Figure 15 shows the damage in tension of the concrete panel and yield stress of the V-shape rebars inside the notched connection at the maximum load. From force-slip curves, Case C4-1 exhibits higher slip in the elastic region compared to other cases.



(a) Tensile damage *(b) Stress in tension*

Figure 15: *Concrete shear failure and stress of V-shape rebar in Case C4-1 at maximum load*

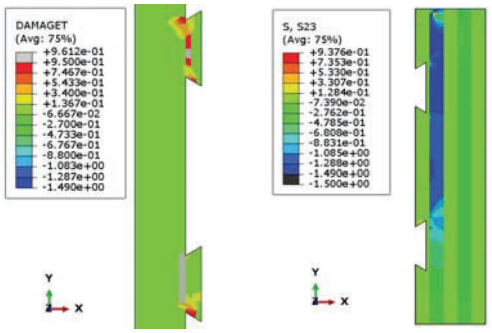
Besides, Case C4-2 resulted in rolling shear failure at the maximum force of 370 kN and a corresponding slip of 0.30 mm. In this case, the increase of notched length (140 mm) led to the decrease of approximately 14 percent in rolling shear cross-section (resistance) while the corresponding slip decreased nearly two-fold. As shown in force-slip curves, the behaviour of the notched connector remained in the elastic region when the brittle failure happened in the cross-layer of CLT panel.

Decreasing the notch depth from 50 mm to 25 mm, which is smaller than the first longitudinal layer's thickness (33 mm), increases the working rolling shear section of the CLT panel in Case C5-1. This resulted in a failure that was limited by the shear failure of the concrete at a maximum force of 516 kN and a corresponding slip of 0.65 mm. It can be seen that the load bearing capacity increased by 20 percent compared to that in the reference case. The failure started from the lower notched connector, followed by the upper one as shown in Figure 16a. At the maximum load, high rolling shear stresses were found from the loading surface to the lower notched connector (blue colour) with a maximum rolling shear stress of approximately 1.49 MPa (see Figure 16b).

It should be noted that the failures in Case C5-1 of second group parameters and Case C3-1 of first group parameters, both with the same notch length, were governed by concrete shear. The maximum force in Case C3-1 was 2 percent higher compared to Case C5-1. However, the ductility of Case 3-1 is slightly better than

https://doi.org/10.52202/069179-0434

that of Case C5-1, possibly due to the different anchorage length of the V-shape rebars placed inside the notches.

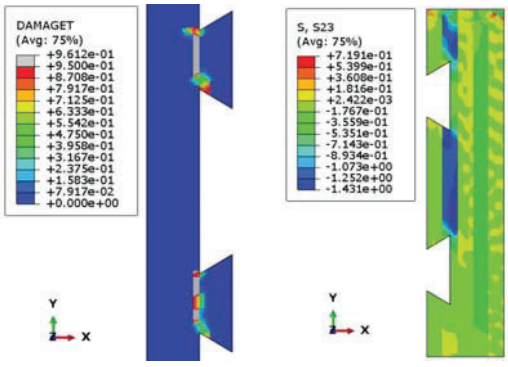


(a) Tensile damage *(b) Rolling shear stress*

Figure 16: *Tensile damage in concrete and rolling shear stress of the CLT at the maximum load in Case C5-1*

The number of V-shape rebars was investigated in Case C6-1 and Case C6-2. It was found that the maximum force decreased when the amount of V-shape rebars was reduced.

The failure mode of Case C6-1 was governed by the concrete shear at the maximum force of 364 kN with a corresponding slip of 0.53 mm. The load bearing capacity decreased by 16 percent, compared to the reference case. When no shear reinforcement was placed inside the notched connector, the concrete damage started earlier, at a load level of approximately 300 kN as shown in force-slip curve (see Figure 14). At the maximum load, the upper notched connector failed first and was followed by the lower one. For the CLT panel, the highest rolling shear resistance obtained was approximately 1.43 MPa (see Figure 17).



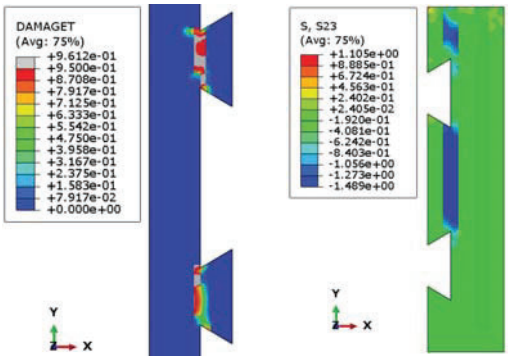
(a) Tensile damage *(b) Rolling shear stress*

Figure 17: *Tensile damage in concrete and rolling shear stress of the CLT at the maximum load in Case C6-1*

In Case C6-2, the failure was initiated by concrete shear failure of the notched connector. The maximum load was obtained at 427 kN with a corresponding slip of 0.75 mm, when the upper notched connector failed. At this point, a high rolling shear stress was obtained in the cross-layer of the CLT panel.

The V-shape rebars were subjected to a tensile stress of 478 MPa at the maximum load and experienced the yield stress shortly after when the concrete of the upper notched connector failed. The tensile damage of the concrete and the rolling shear stress of the CLT panel can be visualized in Figure 18.

In terms of stiffness, the studied parameters have minimal influence, except for the Case C4-1, in which the stiffness decreased more than half compared to the reference case. However, the notched connector in Case C4-1 can be still considered as stiff, as its stiffness is higher than the suggested value of the design slip modulus of 1.00×10^6 N/mm/m proposed in the recommendations for the design of TCC beams with notched connectors given in BNTEC [17].



(a) Tensile damage *(b) Rolling shear stress*

Figure 18: *Tensile damage in concrete and rolling shear stress of the CLT at the maximum load in case C6-2*

Regarding the ductility, no improvement was obtained by changing the values of the parameters in the second group, except for Cases C6-2 and C4-1 where ultimate slips of around 1.5 mm and 4.2 mm, respectively, were obtained.

4 CONCLUSION

This paper presents the experimental and numerical investigations on a novel notched connector for CLT-concrete composite floor systems. The pushout tests showed high shear resistance and stiffness of the connector, but low ductility, as the failure was governed by rolling shear failure of the cross-layer of the CLT panel. In addition, a full FE model of the pushout tests using ABAQUS/Explicit was established and validated against the experimental results. The simulation was capable of reproducing the failure mode of the experimental tests and giving a good agreement of force-slip curve with the results from pushout tests. The validated model was then used for a parametric study to investigate the influence of various parameters of the geometries and the materials. The following results are obtained from the parametric study:

- If not changing the notch dimensions, the strength and the thickness of the concrete panel had no significant influence on the strength, as it was governed by the rolling shear failure in cross-layer of the CLT panel. However, they had a slight effect on the stiffness of the connector, as earlier damage in the concrete notches was obtained in these cases.

- An increase of the heel length led to a larger cross-layer area of the CLT panel, and the failure was then governed by concrete shear of the notched connector. A small improvement of the post-peak behaviour was obtained. An estimation of the load provoking the concrete failure in shear was obtained. It was 22 percent larger than the mean of the experimental results.
- Decreasing the notch length from 90 mm to 40 mm was able to provoke a concrete shear failure, resulting in the improvement of the ductility of the system. Lower stiffness was found when adopting a notch length of 40 mm, but it was larger than the value suggested in BNTEC [17] for notched connections.
- A reduction of the notch depth to a value smaller than the thickness of the first longitudinal layer of the CLT panel increased the cross-section of the rolling shear of the CLT panel. This led to a higher strength and stiffness. However, low ductility was still observed.
- A higher amount of V-shape rebars increased the strength and stiffness of the notched connection.

In conclusion, based on the numerical results, it is possible to improve the ductility of the present notched connection by prioritizing the shear concrete failure of the notch, if a sufficient number of V-shape rebars are placed inside the notch. This prioritization can be obtained by increasing the spacing between the connectors, in order to increase the rolling shear resistance. The concrete failure should happen for a load 22 percent larger than the experimental resistance obtained by pushout tests. However, these conclusions need to be confirmed by additional experimental investigations.

A 3D DUCTILE-NOTCHED CONNECTION FOR TIMBER-CONCRETE COMPOSITE BEAM : EXPERIMENTAL INVESTIGATION

Adham Al Rahim[1], Piseth Heng[2], Clemence Lepourry[3], Hugues Somja[4], Franck Palas[5]

ABSTRACT: A 3D ductile-notched connection for timber concrete composite beams is proposed in this study. The innovation of the proposed connector is the particular geometry of the notch. This configuration on one hand generates three shear planes instead of one as typical notched connection and on the other hand provides a mechanical locking to limit the uplift without the need for metallic screws. This paper presents an experimental investigation on the behaviour of the newly proposed notched connector. Three pushout tests were performed. The results show high strength and stiffness as well as ductility, as the failure mode was governed by local crashing of the timber. In addition, one flexural test was carried out on the beam specimen. The mode of failure was governed by flexural failure of the timber beam. The analysis of the slip and the uplift demonstrated the effectiveness of the connectors.

KEYWORDS: 3d ductile-notched connection, Timber-concrete composite beam, Pushout tests, Inversed flexural tests

1 INTRODUCTION

The new environmental regulations such as the RE2020 [1] in France stimulate the interest of using structural timbers in the construction within the last few years. However, timber slabs fulfil hardly all the criteria for serviceability. In this case, timber-concrete composite members represent a great compromise by associating timber with concrete. This association can improve the flexural strength and stiffness of the members as well as the sound insulation, the vibration performance, and the thermal insulation properties [2]. Several configurations of shear connectors have been proposed for timber-concrete composite members [3]. For instance, ordinary smooth nails of 70 mm with a diameter of 3.4 mm, arranged in pair, have been used as timber-concrete connectors [4]. 12 mm and 16 mm lag screws have been employed for their hybrid failure mode related to the steel's plastic deformation [5]. The first research on tooth plates was conducted in 1984. This technology was used in the construction of timber-concrete composite wall in Sweden [6]. The use of adhesive and epoxy resin within the connection system has been also investigated [7]. Although notched connections perform well in term of strength and stiffness, poor ductility is obtained when the failure is governed by shear rupture of the concrete notch [8]. Steel screws placed inside the concrete notches are sometimes added to improve the post-peak behaviour [9], but the installation of these steel fasteners increases the construction cost. In this context, a novel composite floor technology, called Bobé, is proposed (see Figure 1a). It combines a reinforced concrete slab and an inverted T-shaped wooden beam, which are joined by means of 3D notch connectors with three shear planes. The particular shape of the notch provides a geometrical locking for limiting the uplift, and the rebars (Figure 1b) improve the post-peak behaviour of the connection.

This paper presents an experimental study on the behaviour of the proposed notched connectors for timber-concrete composite beams. In this study, a series of three symmetrical pushout tests were performed in order to determine the strength, stiffness, ductility and failure of the connection system. In addition, a six-point bending test has been made to verify the effectiveness of the notched connection for timber-concrete composite beams.

2 PUSHOUT TESTS

2.1 SPECIMENS AND TEST SETUP

The pushout test program included three identical specimens, noted by S1, S2 and S3. The specimens are made of two glued timber panels of solid pine (Spruce) with a grade of C24, measuring 1020 mm in height, 360 mm in width, and 70 mm in thickness, embedded between two concrete slabs (see Figure 2a). The compressive strength of timber, has been tested on 10 compressive pieces, parallel to the grain, with a cross section of 75 x 200 mm and length of 450 mm, according to EN 408 guideline [10]. An average resistance of 34.30 MPa, with a standard deviation of 3.19 MPa, was obtained. The average moisture content was found to be 13.05%, with a standard deviation of 1.27%.

Regarding the pushout specimens, two shear connectors, with a spacing of 326 mm, are made on each timber panel, as illustrated in Figure 2b. The concrete slabs were 450 mm in width, 1120 mm in length, and 80 mm in thickness (Figure 2c). The concrete strength grade was C25/30. The real average strength, obtained from compressive tests on cylindrical specimens, with a diameter of 110 mm and a length of 220 mm, was 27.7 MPa, with a standard deviation of 1.58 MPa. In turn, the notches are reinforced with B500B grade U-shaped rebars, with a diameter of 6 mm.

In order to reduce the friction, and to ensure a smooth contact between the materials, the timber panels were painted before concrete casting. For all specimens, the first of the two concrete slabs were cast on the same day in a horizontal position. Two days after, the specimens were lifted and turned over for the second casting. The timber panel and concrete slabs had an offset of 100 mm in length.

The test setup is described in Figure 3a. The compression load is imparted on the wooden panel by means of a hydraulic jack with 1000 kN capacity and a stroke length of 200 mm, and transferred to the concrete slabs through the connectors. Subsequently, the load is counterbalanced by the reaction forces provided by the rigid supporting system.

The monotonic loading protocol, derived from EN 26891, started with an initial ramp up to 40% of the estimated failure load, followed by a discharge and then a steady increase up to failure. The estimated capacity (F_{est}) of the specimen, with four connectors, was estimated to be 188 kN referring to the BNTEC guidelines [12]. The loading is sustained until the specimen failure is reached.

The measurement devices for the push out tests are illustrated in Figure 3b. The relative slip and uplift between timber and concrete were recorded by linear variable displacement transducers (LVDTs). On each side of the specimen, four uplift LVDTs with a stroke length of 2.5 mm and 6 mm, and four slip LVDTs with a stroke length of 25 mm, were attached.

2.2 RESULTS

Figure 4a and Figure 4b exhibit the evolution of the applied force as a function of the mean slip and the mean uplift, respectively. A high ductility of the connection was obtained, as the failure mode in the three tests was governed by the local crushing of the timber. The specimens were cut after tests to allow for an assessment of large compressive deformation of timber at the position of the notch connections (Figure 5). The maximum forces (F_{max}) obtained are 206.8 kN, 170.1 kN, and 198.5 kN for tests S1, S2 and S3, respectively. Adopting the method proposed by Ceccotti [13], the mean stiffness at serviceability limit state (K_s) and at ultimate limit state (K_u) are 184.8 kN/mm with a standard deviation of 19.3 kN/mm and 167.3 kN/mm with a standard deviation of 15.5 KN/mm, respectively.

3 SIX-POINT BENDING TEST

3.1 SPECIMENS AND TEST SETUP

This test aims at studying the flexural behaviour of the timbre-concrete floor system.

Three specimens of the timber concrete composite beam, noted F_1, F_2, and F_3, were designed and fabricated. Each specimen was made of two identical T-shape wooden beams connected to a concrete slab using 14-notched connectors, with a spacing of 426 mm (Figure 7a). The T beam, had a cross section of 175 x 68 mm (height x width) for the web and 58 x 145 mm (height x width) for the flange (Figure 7b). For reducing friction between materials and ensure a smooth interface, the timber beams were coated with paint before concrete casting. The average moisture content in timber beams of the specimens was measured before flexural tests of F_1, F_2, and F_3, at 8%, 9%, and 8%, respectively.

To determine the mechanical properties of the timber beams, ten wooden pieces, with a mean cross section of 68 x 173 mm and a mean length of 397 mm, were tested for their compressive strength parallel to the grain. The average compressive modulus of elasticity (MOE) was 5297 MPa, with a standard deviation of 834 MPa. The flexural modulus of elasticity, tested on ten timber beams at the measured moisture content, was 11166 MPa with a standard deviation of 1445 MPa [14].

The timber beams were embedded in the concrete slab with an insertion depth of 20 mm. The concrete slab was designed with dimensions of 6845 x 920 x 80 mm (length x width x thickness) (see Figure 7b). The concrete slab was reinforced with a rebar mesh ST10 with a rebar diameter of 6 mm and a spacing of 200 mm. The actual average concrete strength was determined on cylindrical samples of 110 x 220 mm (diameter x length), on the same day of each flexural test. The results were 25.26 MPa (27 days age), 47.81 MPa (43 days age), and 23.26 MPa (92 days age), with a standard deviation of 0.124 MPa, 3.25 MPa, and 2.92 MPa, for F_1, F_2, and F_3, respectively.

The test setup consisted of a 1500 kN capacity hydraulic jack, a guidance system for a vertical loading only, two supporting systems, and a spreading system to transfer the applied load to the specimen through four points (Figure 7c).

The flexural performances were investigated via a reversed six-point bending test. In such a configuration, the specimen is invertedly mounted on the testing device, and a vertical pull is exerted by the hydraulic jack (Figure 7a). This specific setup has been developed in order to obtain measurements for loads lower than the weight of the specimen.

For all three specimens, the same loading protocol was respected. It consists of five consecutive phases (Figure 7b): 1. Lifting of the specimen upon contact with the supports, 2. Assembly of the lag screws between the supporting system and the specimen, 3. Quasi-permanent service limit state (SLS) cycling (five to seven cycles), 4. Ultimate limit state (ULS) cycling (one cycle), and 5. Loading to the failure. Service and ultimate limit states correspond to the loads of use category A (floors) in Eurocode 1 [15].

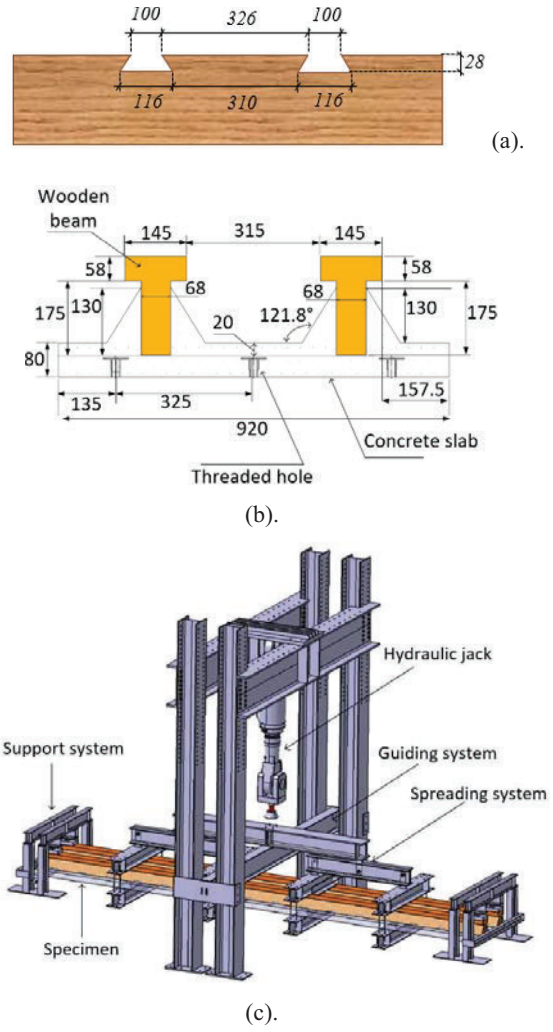

Figure 6: *(a) Notch connectors geometry and spacing. (b) Cross section dimensions of timber concrete floor. (c) 3D test setup. Dimensions in mm.*

Before the test began, the specimen was lifted slowly to make contact with the supports. During this phase, the accuracy of the instrument's operation and data acquisition was checked. Once contact was achieved, the test officially started. A displacement control was adopted, with a speed of 3 mm/min.

To measure the interface slips between the timber and concrete, eighteen linear variable differential transducers (LVDTs) were fixed horizontally on the timber beams with nine being located on front side and nine on the back side of the specimen. For the uplift, ten LVDTs were attached vertically on the timber beams. Five LVDTs were affixed to the front side of the specimen and another five were fixed on the back of the specimen. For both measurements, the pushrod of LVDT was set in contact with a steel plate that was glued on the concrete side. Additionally, five LVDTs are employed to quantify the vertical deflection of the specimen (Figure 8).

3.2 TEST RESULTS

3.2.1 Load capacity and failure mode

In the initial period of loading, at the service limit state compaction, there was no visible cracks in timber beams or concrete slab of the specimens F_1 and F_2, while, some cracks were observed on the concrete drop in the specimen F_3 (see Figure 10a). At the ultimate limit state, as the load was on the increase, invisible fibre breakage of wood were heard and fractures appeared on the concrete drop of F_1, F_2, and F_3. During the loading process to the total collapse, failure occurred at mid-span due to the combination of bending and tensile fractures in the flange of the timber beam. The collapse of F_1, F_2, and F_3 was governed by the rupture of the timber beam (see Figure 10b, Figure 10c, and Figure 10d). The maximum loads reached were 130.2 kN, 123.5 kN, and 128 kN, applied on F_1, F_2 and F_3, respectively. The corresponding mid-span deflection was 61 mm, 47.2 mm, and 68.6 mm, respectively (Figure 9).

However, the examination after collapse uncovered the absence of shear failure at the locations of timber-concrete connectors for all specimens tested. In addition, the uplifts between the concrete and the timber were limited, demonstrating the excellent shear resistance exhibited by the selected connectors.

3.2.2 Experimental bending stiffness

Figure 9 displays the force vs mid-span deflection curves for all the specimens. The experimental bending stiffness was calculated by Eq. (1) based on the elementary beam theory.

$$EI_{exp} = \frac{F}{4w}\left[\frac{1}{2}(2a+b)\left(a+\frac{3}{2}b\right)^2\right] \quad (1)$$

In such expression, a is the distance from the loading point to the support, a = 1235 mm; b is the distance between two loading points, b = 1360 mm; F is the maximum force applied by the hydraulic jack to the specimen during the compaction cycle; w is the corresponding mid-span deflection.

The results of the three tests are collected in the Table *1*.

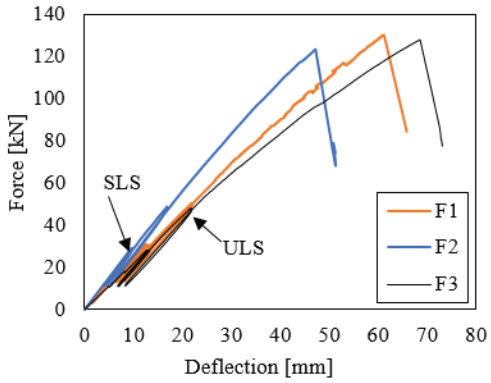

Figure 9: *Load-deflection curves at mid-span of all specimens.*

Figure 10: *(a). Cracks in concrete drop. (b). Failure of F_1. (c). Failure of F_2. (d). Failure of F_3.*

Table 1 Flexural rigidity of the test specimens.

Specimen	$\mathbf{EI_{1-SLS}}$ (10^{13}) Nmm^2	$\mathbf{EI_{ULS}}$ (10^{13}) Nmm^2
F_1	1.22	1.15
F_2	1.57	1.49
F_3	1.14	1.13

Where, EI_{1-SLS} is the flexural rigidity at the 1st cycle of the service limit state, and EI_{ULS} is the flexural rigidity at the ultimate limit state. It can be observed that the flexural stiffness of specimens F_1 and F_3 exhibit a comparable level, while that of the specimen F_2 is relatively higher. The higher concrete strength measured in the F_2 test might be a contributing factor.

3.2.3 Relative slip

The relative slips along the composite beam span were depicted in Figure 11 at different load levels. The three cases have shown the higher relative slips occurred at the both ends of the beam. The maximum relative slips were 0.72 mm, 0.92 mm, and 1.98 mm, recorded for F_1, F_2, and F_3, respectively. However, the relative slips obtained from the bending test do not exceed the plastic resistance of the connector obtained in push-out tests (see Figure 4a).

3.2.4 Interface uplift

Figure 12 shows the distribution of uplift at the interface between timber and concrete layers. It can be noticed that the uplift at the mid-span were much higher than that at the both ends of the specimen. The maximum timber-concrete uplifts were 0.29 mm, 0.5 mm, and 0.55 mm, recorded for F_1, F_2, and F_3, respectively. The test results showed that the geometrical locking of the connector offered an effective resistance to uplift between concrete and timber layers.

3.2.5 Analytical evaluation according to Eurocode 5

According to Annex B of the Eurocode 5 guidelines [16], the ϒ-method was employed to assess the flexural performance of the timber-concrete beam. The general effective bending stiffness is expressed as:

$$EI_{eff} = E_1I_1 + E_2I_2 + \gamma_1E_1A_1a_1^2 + \gamma_2E_2A_2a_2^2 \quad (2)$$

For the tested specimens, the Eq.(2) becomes:

$$EI_{eff} = 2(E_1I_1 + E_2I_2 + \gamma_1E_1A_1a_1^2 + \gamma_2E_2A_2a_2^2) \quad (3)$$

In such formula, E_i (MPa), I_i (mm^4), and A_i (mm^2) denote the elastic modulus, the second moment of area, and the cross section of the concrete slab ($i = 1$), and timber beam ($i = 2$), respectively; a_i (mm) represents the distance between the centroid of the component (i) to the overall neutral axis of the composite cross section, given in Eq.(4):

$$a_1 = \frac{\gamma_2E_2A_2}{\sum\gamma_iE_iA_i}d_{1-2}$$

$$a_2 = \frac{\gamma_1E_1A_1}{\sum\gamma_iE_iA_i}d_{1-2} \quad (4)$$

Where, d_{1-2} (mm) is the distance between the centroides of the two components.

Timber was taken as a reference (γ_2=1) and the γ_1 parameter of the shear connector can be written as:

$$\gamma_1 = \frac{1}{1 + \frac{\pi^2A_1E_1s}{KL^2}} \quad (5)$$

Where, K (N/mm) and s (mm) are the stiffness and spacing of shear connectors, respectively, and L (mm) is the beam span.

For the present analytical calculation, the effect of the cracking of concrete is approximated by neglecting the contribution of the concrete drops, except the steel rebars (HA8), while the concrete drops are not taken into account (see Figure 13).

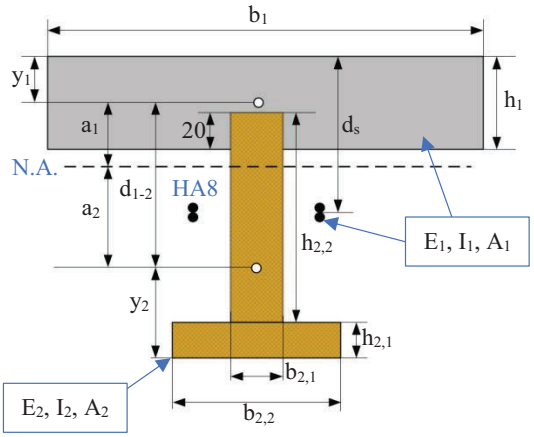

Figure 13: *Composite beam cross section.*

N.A. and d_s denote the overall composite neutral axis and the distance between the steel rebars to the upper slab surface, respectively; and y_i represents the position of the centroid of the element (i).

The geometrical parameters indicated on the Figure 13 were measured and represented in Table 2. While, the

parameters of the analytical method were calculated and provided in Table 3.

Table 2 Dimensions of timber-concrete cross section.

	Parameter	F_1	F_2	F_3
Concrete slab	h_1[mm]	76	83.5	79.5
	b_1[mm]	458.75	457.5	460
	y_1[mm]	41.5	44.1	43.2
	A_1[mm^2]	34875	37982	36614
	I_1[mm^4]	33992832	36126620	37700607
	d_s[mm]	155	159	159.5
Timber beam	$h_{2,1}$[mm]	57.5	59	54.5
	$b_{2,1}$[mm]	68	67.5	68
	$h_{2,2}$[mm]	179	175.5	180
	$b_{2,2}$[mm]	142	140.5	140.5
	y_2[mm]	99.5	98.5	99.4
	A_2[mm^2]	20337	20136	19897
	I_2[mm^4]	103000000	99900000	99700000
	$d_{2,1}$[mm]	151.5	155.4	151.4

Table 3 Effective bending stiffness of test specimens.

	Parameter	F_1	F_2	F_3
	E_1[MPa]	29050	35178	28340
	E_2[MPa]		11166	
	L[mm]		6550	
ELS	K_s[kN/mm]		184.8	
	γ_1	0.65	0.58	0.64
	γ_2		1	
	a_1[mm]	38.8	34.7	37.7
	a_2[mm]	112.7	120.7	113.7
	EI_{eff}[10^{13}Nmm^2]	1.20	1.32	1.20
	EI_{exp}[10^{13}Nmm^2]	1.22	1.57	1.14
	Error (%)	1.6	15.9	5
ELU	K_u[kN/mm]		167.3	
	γ_1	0.63	0.56	0.62
	γ_2		1	
	a_1[mm]	39.9	35.8	38.8
	a_2[mm]	111.6	119.5	112.6
	EI_{eff}[10^{13}Nmm^2]	1.19	1.3	1.19
	EI_{exp}[10^{13}Nmm^2]	1.15	1.49	1.13
	Error (%)	3.3	12.7	5

According to the comparaison results, represented in Table 3, a good accuracy between the analytical and experimental results can be noticed for the specimens F_1 and F_3. Whereas, in case of F_2, the test results were underestimated, at both service and ultimate limit states with an error of 15.9% and 12.7%, respectively.
This approach exhibits an inadequate consideration of concrete cracking, thereby neglecting the beneficial effect of the higher concrete strength in F_2 test on the crack formation.

4 CONCLUSIONS

This paper presents an experimental study on a newly proposed notched connection for timber-concrete composite beams. Three pushout tests were made. The results showed high strength and stiffness of the connector. The high ductility of the connector was obtained as the failure was governed by local crashing of the timber in compression. In order to assess the failure mode, flexural capacity, slip, and uplift of the beam specimens, 6-point bending tests were performed on three timber-concrete specimens. The failure mode was governed by a brittle tensile-flexural rupture of the flange of the timber beam. It must be noted, that after collapse, no failure was observed in either the concrete slab or the notch connectors. The analysis of slips and uplifts revealed the effectiveness of the shear connection without the need of any mechanical elements.
Moreover, the analytical method, proposed in Eurocode 5 guidelines, is used to calculate the effective bending stiffness of the composite beams, with a simple hypothesis to account the concrete cracking. An acceptable accuracy, compared with the experimental results, is reached.
A new methodology, is currently being developed to refine the representation of the concrete cracking in the analytical calculation with the aim of reducing the discrepancy between analytical and test results.

HIGH CAPACITY SHEAR CONNECTORS AND APPLICATION FOR TIMBER-CONCRETE BRIDGES

Raitis Lacis[1], Maris Karlsons[2]

ABSTRACT: This paper describes the experimental study of a new hybrid type shear connector for timber-concrete composite systems. The main emphasis of the study is the development and testing of high capacity shear connectors and their use in timber-concrete systems associated with high structural demand for composite interaction such as vehicular and pedestrian bridge structures. Experimental pushout test data of a hybrid shear connector is presented along with the full-scale bridge design and testing using this shear connection system. Shear connection consists of two main parts welded together: a circular hollow section (CHS) and a common steel nail plate. The first part is considered a rigid dowel, but the addition of the nail plate considerably improves the redistribution of the shear forces to a larger area of the timber body, thus minimizing the risks of high concentration shear-induced damage locally if only dowel is used. Based on the test results, a single span timber-concrete vehicular bridge design and load-proof aspects are briefly discussed, including factors of different loading effects and construction methods.

KEYWORDS: Bridge, Timber-concrete composite, Shear connection, Circular hollow section, Nail plate

1 INTRODUCTION

Appropriate choice of the shear connector configuration is crucial in order to provide effective degree of composite action between timber and concrete structural parts such as beams and slabs. Vehicular bridges have to sustain relatively high concentrated loads both in the ultimate state as well as at the service level. As a result, timber-concrete systems require special attention to the shear connection used because of it directly depends the vertical deformations and overall stress state of timber/concrete components.

In order to level up the ability of timber-concrete systems to compete with other structural formulas, it requires to develop shear connectors, that both have high stiffness and high strength so that they not limit the overall design of the structure.

Many types of timber-concrete shear connectors have been tested during the last two decades [1]. These include different combinations of notched, screwed, dowel-type and adhesion based connections generally subtyped as continuous or discrete shear connectors [2]. The purpose of this paper is to present a hybrid type of connection, that employs two of the aforementioned principles by using a large diameter dowel in the form of a circular hollow section (CHS) filled with concrete [3] in combination with a widely known industrial product, punched nail plate (see Figure 1 and 3) representing the semi-continuous part of the connector.

The proposed connector's experimental push-out testing results are presented, including shear stiffness, ultimate strength, failure character, and specific sample preparation aspects that were taken into account to achieve failure, particularly in the shear mode along the wood grain. Particular investigation results were directly used in the design, construction and proof loading of a single span vehicular timber-concrete bridge. A quantitative discussion is given to demonstrate the importance of chosen construction method for the timber-concrete composite bridge, which is already at the design stage. For instance, temporary construction propping or no propping affect the magnitude of shear forces in the connectors, the permanent self weight induced stresses of beams/slabs and overall structural stiffness.

2 MATERIALS AND TEST SETUP

2.1 CONFIGURATION OF THE CONNECTOR

Hybrid connector consists of the steel nail plate and circular hollow section (steel CHS), which are welded together in 90° configuration (Figure 1). Connector is pressed into the predrilled slot of the timber beam and hollow section is consequently filled with the concrete during the deck construction process in such a manner that no steel parts are exposed to the direct environmental impacts. Timber and concrete penetrating part of CHS dowel serves well for the transfer of shear force in the concrete deck and provides stiffness due to its volume and relatively large contact area, but the nail plate effectively distributes these forces in the timber with the help of many small sized but high number of nails. Besides, as the steel CHS element extends also in the timber then it functions as a circular notch and thus providing extra stiffness. (Figure 2b).

Figure 2: *a) single connector; b) predrilled slots in the timber; c) timber beams with pressed-in shear connectors*

For less demanding shear systems a variation presented in Figure 2 appears to be more practical due to its simpler application, however, research of this layout is outside the scope of this publication and is reserved for future investigations [3].

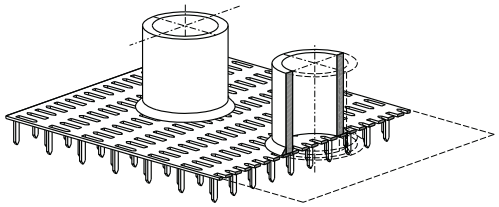

Figure 3: *Variation of shear connector without CHS extension to the wood*

2.2 PREPARATION OF THE SAMPLES AND TESTING PROCEDURE

Samples for the laboratory push-out testing in shear were prepared using symmetrical test layout depicted in Figure 4 and 5. This employs two identical slip surfaces constituting two shear planes each of which characterizes individual shear connector. Shear connectors and sample dimensions were chosen to represent the design of full-scale bridge, which was intended following the current research.

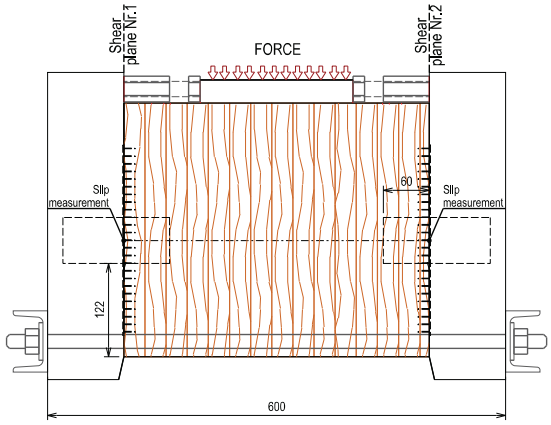

Figure 4: *Layout of the sample*

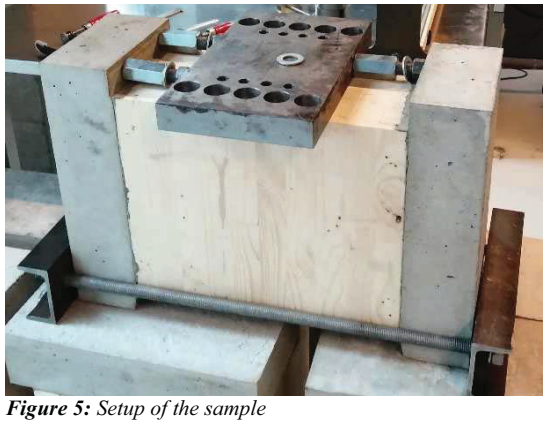

Figure 5: *Setup of the sample*

General characteristics of the materials used:
Timber class GL24h according to [5], moisture content 8-11%;
Concrete class C35/45 [6];
Steel class of circular hollow section S355, diameter 60mm, wall thickness=3mm;
Nail plate Wolf 15N [7], steel class S280, size 175×250mm.
The test timeline and loading schedule followed the routine of EN 26891 [8], see time-load history in Figure 6. Loading machine Zwick/Roell Z600.
Number of specimens: seven (one of which were predamaged).

https://doi.org/10.52202/069179-0436

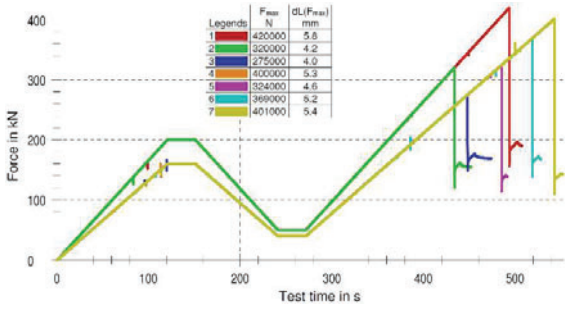

Figure 5: *Time-load history of the samples tested*

Special attention was paid in the sample preparation process in order to avoid unnecessary mechanical restraining effects during the loading. When applying vertical force to the timber upper face, horizontal reactions at the top and bottom of the sample develops, which tend to split the sample at the bottom and push it together at the upper part. As a result, compression fixings were used at the top level and tension rods at the bottom. Steel plate for the force distribution at the top was chosen such that expected failure of the shear plane is not crossed over and failure in pure shear could be objectively expected.

3 RESULTS OF PUSH-OUT TESTS

3.1 Ultimate shear capacity and stiffness

Values of ultimate shear capacity varied from 275kN to 420kN (see Table 1). The lowest value 275kN represents the sample Nr.3, which was predamaged, but still tested for the sake of interest. All of the seven samples failed in a brittle manner (Figure 6).

Table 1: *Shear capacity, slip and stiffness results of push-out tests*

#	F_{max} * [kN]	Slip at $0,6F_{max}$ [mm]	Slip at $0,8F_{max}$ [mm]	Stiffness at $0,6F_{max}$ [kN/mm]	Stiffness at $0,8F_{max}$ [kN/mm]
1	419,8	0,9	1,4	134,7	117,8
2	319,6	0,8	1,1	125,7	119,4
3	274,9	0,6	0,9	134,1	125,5
4	400,0	1,1	1,4	114,3	111,1
5	324,3	0,7	1,1	130,1	115,8
6	369,1	0,8	1,2	138,4	127,3
7	401,0	0,9	1,3	133,7	122,4

*F_{max} results are presented for the symmetric sample layout (two connectors per sample)
**Slip and stiffness values calculated as an average from two of the connectors forming one test sample. In all tests only one side failed

For each sample, the slip values between timber and concrete were measured during the loading. Due to the minor geometrical and material variation the slip values always differed for the two shear connectors of the sample (example in the Figure 6), therefore for all the samples a complete failure only occurred in one of the shear plane, the other in all cases remained intact.

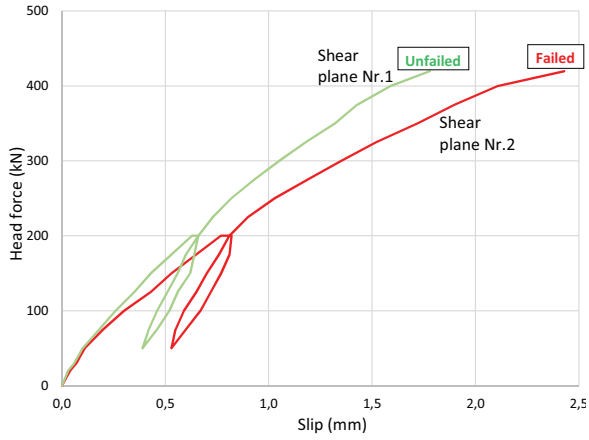

Figure 6: *Slip - load values (example of one sample)*

Failure mechanism observed was in pure shear by the block shear failure in wood depicted in Figure 7 and 8. Extension of the CHS element in the wood demonstrates provision of extra stiffness and strength as the line of the failure copies CHS profile in all of the samples. Physical deconstruction (Figure 9 and 10) of the failed sample indicates some plastic deformation in front of the CHS profile (compression perpendicular to the grain) before wood failure in shear along and mostly between the annual rings takes place. Notably that CHS element is relatively intact and only outer nails of the plate are visibly deformed after the ultimate slip of the shear surface in the wood.

4 APPLICATION OF TEST RESULTS IN THE DESIGN OF TIMBER-CONCRETE BRIDGE

Laboratory tests of the shear connectors were preliminary part of the timber-concrete bridge design process during which all of the necessary data in terms of connectors stiffness and strength were acquired. Once these were established a design of the the full-scale bridge could be carried out. Structural model was build using 2D beam elements following the grillage modelling principles. Timber and concrete cross sectional parts were placed by appropriate eccentricities and interconnected with spring elements [12] characterised by the stiffness values established from the connector's push-out tests.

Figure 11: *Jecupe bridge in a construction stage and in a finished state*

The bridge consists of ten individual laterally braced glulam beams (GL28h 750×220mm) and cast-in situ concrete deck (C35/45). Length of theoretical span is 12,80m (Figure 11, 12); minimal design load is heavy-duty forestry vehicles up to 60t. Concreting of the deck was done using temporary propping beneath the glulam beams. Bridge is named after the river it is crossing (*Jecupe bridge*) - it was successfully built and load-proofed in 2020, location Nica parish, Latvia) proving to a client (Latvia's State Forests) that rationally approached timber-concrete systems can be a competitive option for the bridge inventory.

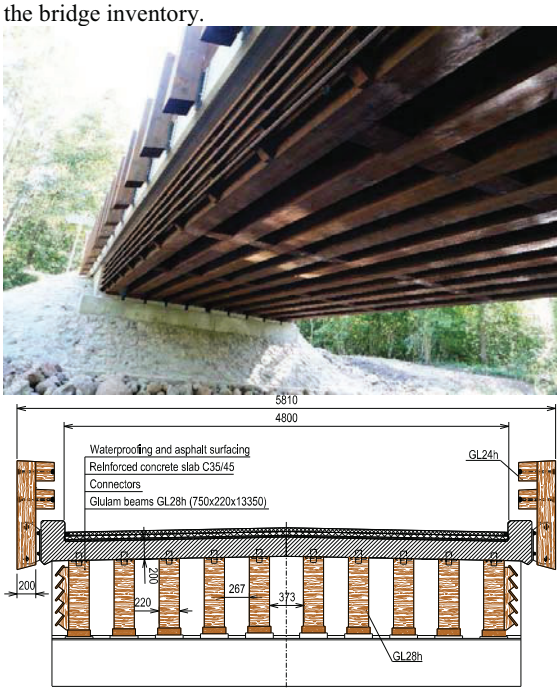

Figure 12: *Cross section of the bridge*

Load-proofing procedure included symmetrical and asymmetrical quasi-static load schemes using 40t five axle vehicle. Load effects were controlled by vertical

https://doi.org/10.52202/069179-0436

deformation measurements and strain gage system installed on the lower face of the timber beams at midspan. Beam stresses were calculated based on the continuous strain measurements (Figure 13), which approved satisfactory load distribution and stiffness across the beams.

Figure 7: *Load-proof with 40t vehicle*

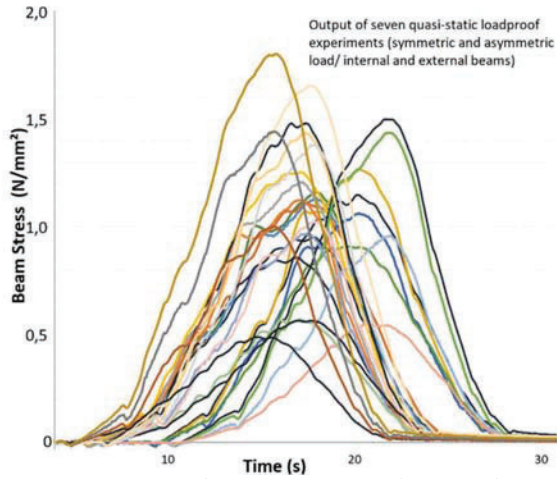

Figure 13: *Calculated beam stresses (based on recordings of strain gages)*

Figures 14, 15, 16, 17 summarises main load effects for different design and load-proof situations. Main differentiation is made between different construction methods (temporary propping and no propping) and different load models including Load model 1 (α=0,8). Also load effects of theoretical non-composite situation is given in order to emphasize the importance of shear connectors in timber-concrete composite systems.

Maximum shear (Figure 14) force in the connectors according to the design model were purposefully kept low due to the brittle character of the connection region as established in the laboratory tests. For instance, maximum value of Eurocode ultimate limit state shear force in the connectors zone using Load model 1 (α=0,8; γ_{LM1}=1,5) did not exceed 56 kN. However, at everyday service levels (60t wood harvester and 40t five axis vehicle) as demonstrated in the calculations and load-proof situation the total self weight and live load connectors shear force maximal range is 14 kN to 28kN depending on the vehicle and live load placement relatively to the longitudinal axis. Highest beam stresses registered in asymmetric load-proofing did not exceed 1,8 MPa. According to the design model stresses of similar category are in the range of 2 MPa.

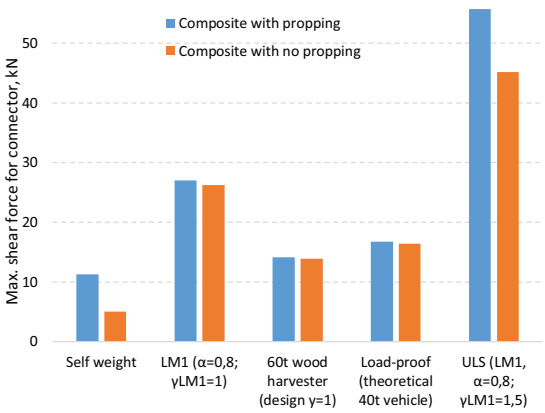

Figure 13: *Comparison of maximal shear forces of connectors*

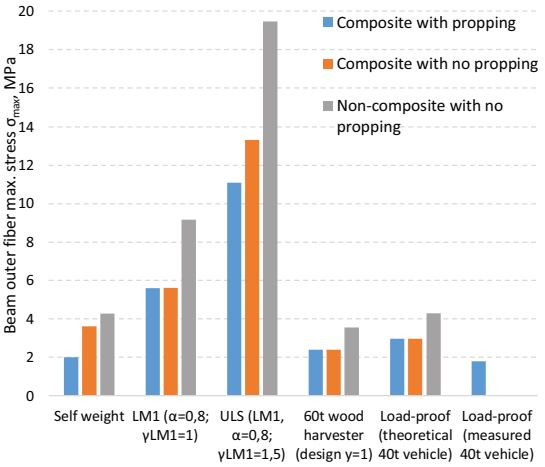

Figure 14: *Maximal beam bending+tension stresses*

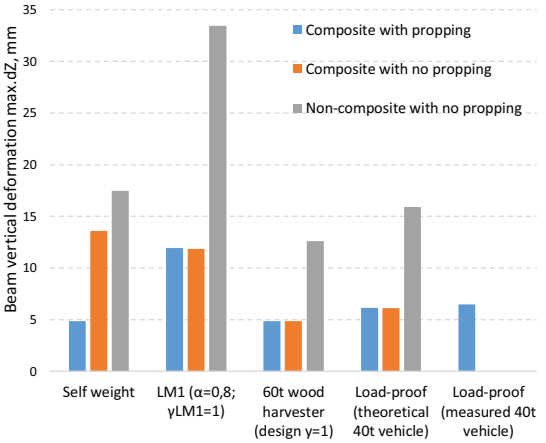

Figure 15: *Comparison of vertical deformations*

https://doi.org/10.52202/069179-0436

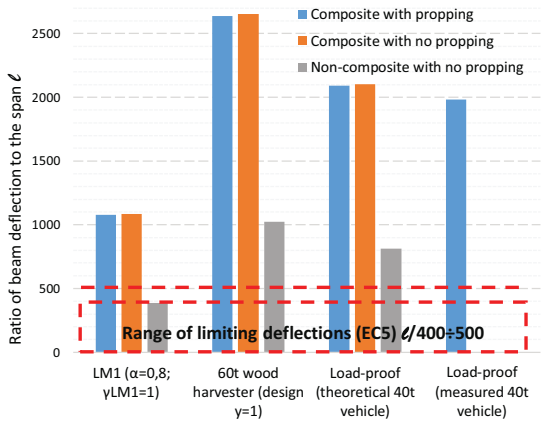

Figure 16: *Serviceability criteria of vertical deformations*

As for the deflection category, the lowest vertical deformations (Figure 15) are achievable using temporary propping construction method naturally on the expense of increased shear forces. Figure 16 represents levels of serviceability for different live load situations. For this shear connection and bridge design a deflection criteria of EC5 serviceability is fully satisfied ranging from 1/1080 for the LM1 and 1/1983 for the load-proof 40t vehicle (Figure 16).

5 CONCLUSIONS

Experimental testing demonstrated high strength and stiffness of the proposed hybrid shear connectors. Their applicability to the road bridges with design loads of up to the Load Model 1 (α=0,8) has been presented. Different construction methods and impact on the shear connectors utilisation and general stress state of the timber-concrete bridge was quantitatively discussed acknowledging potential use of the hybrid shear connectors in other bridge design situations.

DEVELOPMENT OF LVL-CONCRETE COMPOSITE FLOOR SYSTEMS

Alireza Fadai[1], Johann Scheibenreiter[2], Alex Müllner[3], Marie Theres Brunauer[4]

ABSTRACT: The growing enormous number of mid-rise timber buildings in European metropolitan areas leads to the investigation of a possible optimization potential in the use of timber in combination with other building materials. Various timber-based composite floor systems, in particular the combination of laminated veneer lumber products and other conventional building materials, such as conventional or steel fiber reinforced concrete coupled by various sorts of dowel-type or notched connections, are studied. In regard to structural, economical and resource efficiency on overall component level, the extent of interrelationships in the development of multifaceted optimized system solutions can be shown.

This paper shows the results of the feasibility studies and the conceptional design. The objective of the studies is to develop application-optimized multi-layered structural composite floor systems with a special focus on the joint design of the various thereby used connection types between the coupled composite layers. The conceptual feasibility studies illustrate the capabilities in the application of laminated veneer lumber products in composite floor systems. Consequently, the presented results enable engineers, as well as builders and planners, to further strengthen the implementation of timber-based composites within modern building applications. A construction-optimized design with increased resource efficiency can be achieved.

1 INTRODUCTION

In Austria, timber construction has increasingly gained market share over the last twenty-five years. Based on the total constructed usable volume in the building sector, it has increased from 14 up to 24% between 1998 and 2018 [1].
In 2018 (24%) the timber-based building material proportion in housing construction is distributed to 53% (newly built single and multi-family houses as well as extensions and conversions) and 47% in non-residential construction (public, commercial and industrial buildings as well as agricultural buildings). At the residential segment, the proportion of timber-based construction has risen particularly strong with an increase from 10 up to 23% in the mentioned period [1].
Further increases are to be expected, especially for large-volume buildings as residential and public buildings.
The city of Vienna continues to grow and an increasing population means that more living space must be made available. Since land is not available in unlimited quantities and there are some old buildings in Vienna without roof extensions, there is the possibility of extending them and thus creating new living space. As of 2018, it is estimated that approximately 9,300 expandable roofs are available in Vienna [2].
Often, the top floor is designed as a reinforced concrete structure with or without a connect to an existing wooden floor. If steel fiber concrete is used instead of conventional reinforcement concrete, this could lead to a more economical construction method. Thus, with the help of steel fiber concrete and an existing wooden floor, a composite roof can be created in old buildings, which, for example, can be erected economically and increase the structural safety.

Within the framework of the research project the Department of Structural Design and Timber Engineering (ITI) at the Vienna University of Technology (TU Wien) in cooperation with Schmid Schrauben Hainfeld Ltd. developed a multi-layer floor system, composed of concrete connected to timber sections and use advantages of each used building material. Timber-hybrid elements meet modern architecture´s demands and can help to increase the use of timber as building material.

2 EXPERIMENTAL TEST EXECUTION

The research project includes design concepts, feasibility studies and performance assessments of the components in order to improve the overall performance. In addition, the development includes experimental investigations of the components in order to improve the overall performance.

2.1 STEEL FIBER CONCRETE

In Austria and Germany guidelines on the use of fiber-reinforced concrete are available. In Austria, this is the "Fiber-reinforced concrete" guideline published by the Austrian Construction Engineering Association (ÖBV) [3] and in Germany the "Steel-reinforced concrete" guideline published by the German Committee for Reinforced Concrete (DAfStb) [4]. These guidelines, which have been introduced by the building authorities, also permit the use of fiber-reinforced concrete. For the connection of wooden beams and fiber-reinforced concrete, fasteners are used, especially in old buildings in the form of self-tapping screws. For the use of these screws, European Technical Assessments (ETA) are required [5]. In previous investigations [6, 7], compression-shear tests were carried out to show the equivalence of fiber-reinforced concrete to normally reinforced concrete. It was confirmed that the investigated lanyards in fiber-reinforced concrete give equivalent results in terms of load-bearing capacity and serviceability. These tests were carried out for steel fiber reinforced concrete, which was qualified according to the Austrian guideline.

2.1.1 Experimental investigations according to the guidelines for fiber-reinforced concrete

In this chapter, the tests carried out according to the Austrian [3] and German guidelines [4] are described and evaluated. The aim of the tests is to show the difference between the two guidelines using the same fiber-reinforced concrete with 25kg/m³ steel fibers and to find a possible correlation between the test results in order to save multiple tests in the future. The background to this is that fiber-reinforced concrete tests are relatively expensive and time-consuming, one test of a concrete-beam takes about 60 minutes and at least six tests are prescribed to state performance [8].

The 4-point bending test itself lasted 20 min per fiber-reinforced concrete bar (Figure 1). This time results from the deformation rates of 0.1mm/min up to 0.75mm and 0.25mm/min up to 4mm deflection. For a better comparison, all specimens are tested up to 4 mm deflection and then the test is terminated. After that, the specimens are "manually" broken in the middle to count and evaluate the number of fibers in the fracture surface.

In addition to the post-cracking tensile strength in the bending tension zone, the compressive strength is also determined using four cube specimens with an edge length of 15cm.

Figure 1: *Completed fiber-reinforced concrete testing according to DAfStb guideline*

For each specimen, the deflection wis measured using two probes, the applied force and the test time. The bending tests start loading the beams according to the ÖBV guideline [3]. In the first two tests, the measuring frequency is 10Hz, then increased to 20Hz. During the first test, the aluminum angles, which served as stops for the measuring probes, were glued on with a 2-component adhesive. However, one angle came off after the initial cracking, so that control via the displacement transducers was no longer possible and the test had to be aborted. As a result, the aluminum angles are screwed to the bending beams with a 5x30mm dowel in all further tests. Furthermore, in the fifth test according to the ÖBV guideline [3], the test also failed because it was not possible to create a complete force-deflection diagram. In this test, there is a sudden drop in the force after the initial crack and the test is terminated prematurely. For these reasons, only ten complete test results exist carried out according to the ÖBV guideline [3]; for the tests according to the DAfStb guideline [4], all twelve tests are successful. The tests according to the ÖBV guideline [3] are labeled and numbered as sample K1-12 and those according to the DAfStb guideline [4] as sample G1-12.

In general, it can be said that oscillations after the initial crack and the force drop can be observed in the force-deflection diagrams. Figure 2 shows an example of a diagram in which the deviations can be seen.

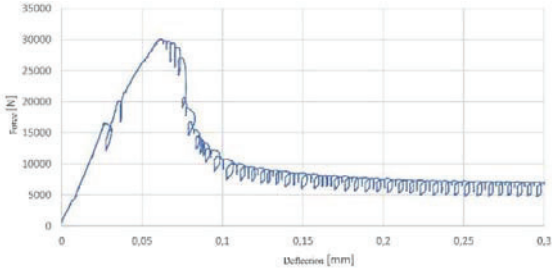

Figure 2: *Evaluation of the force-deflection diagram specimen K8 [8]*

https://doi.org/10.52202/069179-0437

It can be seen that in a range of 0.005 mm the deflection increases very quickly, although the force is slightly reduced. This is a deformation-controlled test with a deformation rate of 0.10 mm/min and it can be seen from the measured data, that within 50 milliseconds the deflection increases by 0.0037 mm and the force decreases by 40.95 N. Therefore, the deformation speed in this range is 4.40 mm/min.
Subsequently, the force is decreased and the deflection consequently becomes less. After that the force is increased again and in a certain range, there is again a sudden increase in the deflection.
This effect occurs in almost all the specimens tested, both the shorter (ÖBV) and the longer (DAfStb) ones. The reason for this effect is the control behavior of the machine. [8].

Based on the tests carried out, the fiber concrete C25/30 XC2 GK8 F52 ZG1 with a steel fiber content of 25kg/m³ corresponds to classes T2 and G1 according to the Austrian ÖBV guideline [3] and L1-0.6 and L2-0.9 according to the German DAfStb guideline [4]. Based on these classifications, the German guideline results in lower design values. Thus, if a fiber-reinforced concrete is classified with classes T2 and G1 according to the Austrian guideline and designed with classes L1-0.6 and L2-0.9 according to the German guideline, sufficient safety is provided. However, this does not apply in the opposite sense, since the design values of the German guideline are significantly lower.
In summary, it can be said that significantly different design values according to German and Austrian guidelines can be expected for the same fiber-reinforced concrete. For both serviceability and ultimate limit state, the characteristic post-cracking tensile strengths differ, in some cases considerably. Therefore, when converting these values into the design values of the post-cracking tensile strengths, the formulas of the guidelines are adapted to the respective test. The evaluation of a test series according to the respective other guideline makes little sense, since the characteristic values of the post-cracking tensile strengths are almost identical, but the design value, which is decisive, is different. Furthermore, the values of the individual tests scatter very strongly, which makes a general correlation of the two guidelines difficult.
In general, the test results of the DAfStb guideline "Steel fiber reinforced concrete" [4] is more conservative than the Austrian guideline [3].

2.2 CONFIGURATION OF THE JOINTS

The load-bearing behavior of the floor element is not only dependent on the properties of the single composite materials, but also on the configuration of the joints between the timber and concrete-based composite layers. This is the subject of numerous experimental Push-Out tests.
Load-bearing capacity of structures can be increased significantly by the usage of semi-rigid or rigid shear connections (e.g. dowel-type or notched connections) between the timber and concrete composites. By the optimized use of composite materials on joint level as well as on overall component level, not only structural performance can be increased, but also resource efficiency.
For this reason, resource-conserving load-bearing composite structures consisting of various types of laminated veneer lumber (LVL), such as spruce or beech LVL, in combination with different types of concrete toppings, such as conventional reinforced concrete (RC) or steel fiber concrete (SFC), coupled by various types of joints (dowel-type fasteners, notches) are being investigated (Figure 3).
The experimental performance assessments are executed by means of small-scaled Push-Out tests. Due to technical and geometrical aspects, the various test series partially differ in terms of the number of shear transmission points per shear joint as well as in terms of the number of shear joints (symmetric assemblies with one shear joint respectively double symmetric assemblies with two shear joints). In order to ensure the comparability of the individual test series, all experimental results are related to a single shear transmission point. Thus, not only conclusions about the various joint typologies become possible, but also values for further structural computations can be gained (Figure 3).

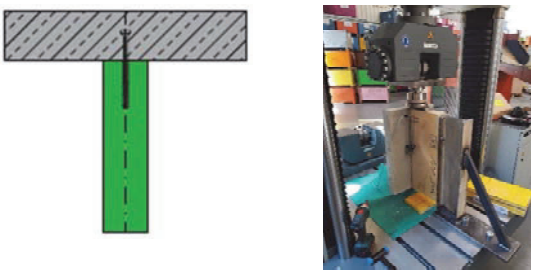

Figure 3: *Examined composite assemblies*

2.2.1 Discussion of experimental test results

Assessing the gained test results with focus on the spruce LVL assemblies' significant diversities, but also similarities within the individual test series can be identified.
Concerning the application of beech LVL assemblies coherent test results in conjunction with the spruce LVL assemblies can be observed. With the initial objective to evaluate the general suitability of hardwood LVL (beech) in comparison to softwood LVL (spruce), the conducted test series are carried out with a smaller amount of respective specimen (3 specimen in each case). As a consequence of this, the gained test results are likely to be less statistically significant and are accompanied by a simultaneously increased scattering compared to the spruce LVL assemblies, but also show the quantitative promising trends as to be expected. The increased material stiffness of hardwood beech LVL further leads to increased mechanical properties of the examined assemblies.

https://doi.org/10.52202/069179-0437

With respect to the application of crossed screw typologies a reduced increase of the load-bearing capacity in comparison to not crossed screw typologies can be observed. In conclusion, the doubling of screws per shear transmission point only leads to a 33% higher maximum load $F_{max,k}$. So, the application of screw typologies with a pure tensile load transfer can be described as the more efficient variation compared to the application of screw typologies with a combined tensile/compressive load transfer.
By the application of notch typologies, the maximum loads $F_{max,k}$ as well as the slip moduli $K_{ser,mean}$ can be increased noticeably. A significant influence of the notch depth cannot be observed thereby.

3 CONCEPTUAL FEASIBILITY STUDIES

Technically, the ribbed timber-concrete composite floor is planned as a prefabricated component. These elements can be installed completely on the construction site or subsequently assembled and concreted on site.
The structural design idea of timber-based composite constructions is founded on the utilization of joints between the single composite layers to reach an optimized application of each used composite material.

The research project includes design concepts, feasibility studies and performance assessments of the components in order to improve the overall performance. Based on the results of the performance assessments and on accompanying computation approaches (shear analogy method according to DIN EN 1995-1-1/NA [9] respectively gamma-method according to ÖNORM EN 1995-1-1 [10]) different types of composite floors are developed and compared with each other.

A comparative parameter study is done with the aim of finding a resource-efficient solution for a single-span floor system with a total length up to 12 meters (between 8m, 10m and 12m) considering fire resistance R90 (see Figure 4 as an example for a span of 8.00m).

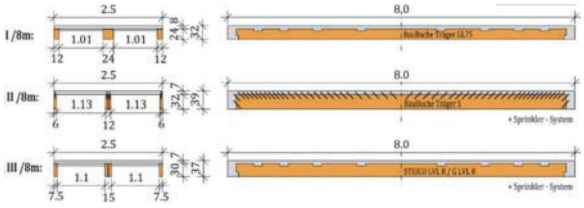

Figure 4: *Optimized LVL-RC composite floor structures for 8m with various connection notches and screws [6]*

The resource efficiency is investigated in terms of the cross-sectional dimensions, the constellation of the materials and the kind of connections including form-fitting notches and fasteners, which can be fixed mechanically [6].

Type I is a floor system without sprinkler, Type II is a system with sprinkler and mechanical fasteners - by hand inserted screwed connection (about 13 pc. /m^2) and type III is a system with sprinkler as well as reduced timber square sections and with notches as very strong and stiff connectors between timber and concrete - notches cut in the timber and filled with concrete.
A significant part in the optimization of the floor systems is using the cost-efficient quantity of timber. This means Beech-LVL ribs instead of the massive cross-laminated timber (CLT) elements. This offers advantages especially in terms of reduced resource consumption.

With regard to the material cost calculation, it should be mentioned that only the material prices are actually calculated. It makes sense to carry out a material cost calculation. The decisive factor here is that only the material costs are evaluated in monetary terms and this is not a detailed cost calculation. Furthermore, the relationship between resource efficiency and cost efficiency for the ranges investigated becomes apparent.
For this purpose, reference values for cubic meter prices of LVL and reinforced concrete are obtained.
With the help of the already determined amount of resources per floor element, it is possible to make a rough cost calculation for a floor element or to roughly determine a price per square meter for a LVL-concrete composite floor of the respective span. It should be noted that additionally required materials after the installation of the individual ceiling elements are not taken into account depending on the constructive system.
Additionally, the material costs for the different solution variants are determined, the most cost-efficient solution can be determined.
Moreover, costs for an active fire protection system (sprinkler system) are included in the calculation, if this is necessary to be able to comply with the fire protection requirements. In this case, the sprinkler system is purely an acquisition cost without the maintenance costs. Although these costs are not directly material costs, they must be taken into account so that all solutions can be considered equal and thus remain comparable with each other [6].
By including a sprinkler system, the amount of timber can be reduced to a minimum, so that just the verifications of the design for the normal state ("cold-state design") are fulfilled. This optimization of the timber cross-section results in the use of narrow but high ribs. However, if the joint between timber and concrete is to be achieved via shear notches, a minimum width of the LVL ribs is required, otherwise the notch verifications according to [11] cannot be fulfilled. Notches are basically suitable for new buildings and an efficient composite variant. No additional resources are required, production is simple and cost efficient, only a small number of notches is needed and no additional personnel is required in the manufacturing process. In the case of screws, the rib width can be further reduced to 60mm if the verification permits. According to the approval, an edge distance of 30mm is required. In the case of fasteners, a large number are

https://doi.org/10.52202/069179-0437

required and the manpower required for setting the screws should not be underestimated either. However, as already mentioned, this is not taken into account in the material cost calculation. But due to the fact that the costs for the LVL ribs make up the main part of the material costs of the floor element and that minimum timber cross-sections are possible due to the joint via screws, a resource- as well as cost-efficient solution is also possible with screws for new buildings (see Figure 5; Solution II/8m). However, it should be mentioned here again that by minimizing the timber cross-section, an extinguishing system is mandatory to meet the fire protection requirements. And the installation of an extinguishing system is, of course, inevitably associated with an expenditure of resources, but it is often a basic requirement in high-rise construction. Comparing the concrete slab, it results for 12m to 10m span-width a reduced thickness of the slab by 3cm (from 11cm to 8cm), comparing a span of 8m, hardly no further reduction is possible. The reason for this is either the minimum thickness of 7cm specified in the approval, as well as the vibration verification according to Eurocode 5 [10] which is no longer fulfilled with a further reduction.

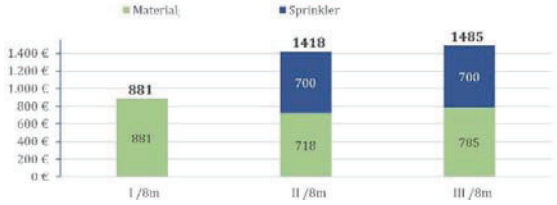

Figure 5: *Comparison of material cost calculation for 8m with various connection notches and screws [6]*

3.1 TIMBER-STEEL FIBER CONCRETE-COMPOSITE

In addition to the studies presented above, the verifications of the load-bearing capacity and serviceability are carried out on modelling bending beam floor [8]. The dimensions are chosen in such a way that the verifications of the load-bearing capacity and serviceability go out with the tests carried out. A brief overview of the most important data for this study of the timber-fiber-reinforced concrete beam floor is below mentioned:

Dimensions of the wooden beams C24: width 16cm, height 26cm, span of the beams: 6m
Height of the concrete layer C25/30: 7cm
Residential building; service class 1
Fasteners Composite screws ACC 8.0 x 165 screwed at an angle of 45°, 3 rows of screws per timber beam, screw-in depth in the timber: 7.1cm
Thickness of the formwork: 2.5cm
The cross-section is shown below, the beam spacing is 65cm, therefore all verifications are carried out for a 65cm wide cross-section.

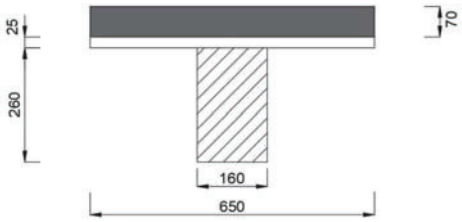

Figure 6: *Composite floor structures connection with screws [8]*

Based on the results, it can be seen that the fiber-reinforced concrete is the most stressed cross-section. Therefore, it is important to ensure that the bending moment in the fiber-reinforced concrete cross-section is reduced to a minimum, if possible, while at the same time increasing the normal force.

In the present example, the verifications of load-bearing capacity (ULS) and serviceability (SLS) are fulfilled for a fiber-reinforced concrete T2 according to the ÖBV guideline [3] and L1-0.6/ L2-0.9.

Finally, different classes of fiber-reinforced concrete will be compared and the effects on utilization or the number of fasteners will be presented. The aim of the study is to keep the number of fasteners as low as possible while maintaining an economical fiber-reinforced concrete class.

First, a reduction of the fiber-reinforced concrete layer thickness of 6cm is investigated. The fastener spacing is 25cm minimum and 80cm maximum. This results in 70 screws, which corresponds to a reduction of 40 screws per meter of slab strip. At the same time, the utilization is 92% according to the German guideline [4], which is authoritative.

In a further step, a fiber-reinforced concrete of class T3 according to the Austrian guideline [3] is considered in more detail. Here, a 7cm thick fiber-reinforced concrete layer is again assumed and a screw spacing of 15cm in the minimum and 60cm in the midspan. The only change compared to the original configuration is the design value of the post-cracking tensile strength of 0.31N/mm². Thus, the use of screws results in a utilization of 84% compared to 86%. A fiber-reinforced concrete of class T4 would produce a utilization of 81%. Thus, the difference in design is not too great when changing the fiber-reinforced concrete class alone.

If the minimum lanyard spacing is increased to 25cm and the maximum to 80cm as well as using a fiber concrete class T4 and increasing the tensile strain in the cross section from 0.9 to 1.5‰, an equilibrium condition with utilization of 98% is obtained. This means that with a fiber concrete two classes higher and a higher utilization, fasteners can be saved, in this case 40 pieces.

As a final optimization step, an increase of the fiber concrete class from L1-0.6 or L2-0.9 to L1-0.9 or L2-1.2 is also investigated when considering the German guideline [4]. Here, the utilization in the fiber-reinforced concrete cross-section also changes from 89 to 87%. Under the same boundary conditions, a saving in

https://doi.org/10.52202/069179-0437

connection material would only be possible with a fiber-reinforced concrete class three classes higher.

Table 1 summarizes the decisive results of the different optimization variants. It should be noted, however, that these results only refer to the example given here.

In summary, increasing the fiber-reinforced concrete class has very little effect on the load-bearing capacity of the fiber-reinforced concrete cross-section. A more effective way to save fasteners, especially screws, is to reduce or optimize the thickness of the fiber-reinforced concrete layer. However, when the concrete thickness is reduced, the compressive stresses are increased. Thus, depending on the application and the given boundary conditions, it must be decided which variant, fiber-reinforced concrete or reinforced concrete, is to be used.

Table 1: *Overview of optimization*

Optimization variant	Number of screws	Change in utilization
Reference example T2 or L1-0.6, L2-0.9	110	0%
Thickness of the fiber concrete layer 6cm	70	+3%
Fiber concrete T3	110	-2%
Fiber concrete T4	70	+12%
Fiber concrete L1-0.9 or L2-1.2	110	-2%

In this study, only a fiber concrete with 25kg/m³ steel fibers is considered. Subsequently, the question is how big the differences are between the two guidelines with a fiber content of 20 or 30kg/m³. Further research questions on this topic would be how the combination of plastic fibers with steel fibers affects the load-bearing capacity and shrinkage behavior. The use of steel fibers in lightweight concrete would also be a useful option when used in timber-fiber-reinforced concrete composite structures in order to reduce the deadweight of the floor. In order to verify the calculations of timber-fiber-reinforced concrete composite floors, both fiber-reinforced concrete tests and tests on timber-fiber-reinforced concrete composite floors with the same fiber-reinforced concrete would be useful in a further step. Thus, a classification of the fiber-reinforced concrete according to Austrian and German guidelines would be available and the effects in the ultimate load of the composite floor would be visible.

4 CONCLUSIONS

The experimental performance assessments of spruce LVL assemblies as well as of beech LVL assemblies generally show promising results for an application of LVL products in composite floor systems. Also concerning the substitution of conventional reinforced concrete (RC) through steel fiber concrete (SFC), a general suitability can be observed.
The conceptual feasibility studies, based on the results of the performance assessments and on accompanying computation approaches, show the capabilities in the application of LVL products in composite floor systems. Consequently, the presented results enable engineers, as well as builders and planners, to further strengthen the implementation of timber-based composites within modern building applications.
A significant part in the optimization of the floor systems is using the cost-efficient quantity of timber. This means Beech-LVL ribs instead of the massive cross-laminated timber (CLT) elements. This offers advantages especially in terms of reduced resource consumption.

ACKNOWLEDGEMENT

The research project is a collaborative effort of the ITI/TU Wien and the Schmid Schrauben Hainfeld Ltd. The authors gratefully acknowledge the support of the Schmid Schrauben Hainfeld Ltd. and the TU Wien, Austria.

ANALYTICAL AND EXPERIMENTAL STUDY ON REVERSIBLE STEEL-TIMBER COMPOSITE CONNECTION SYSTEMS

Fabiana Yukiko Moritani[1], Pedro Santos [2], Luís Jorge [3], Alfredo Dias [4]

ABSTRACT: This paper presents a study on the structural behavior of steel-timber composite (STC) with a special focus on reversible connection systems. Particularly, it addresses the research of composite structure floors comprising cold-formed steel (CFS) beams and cross-laminated timber (CLT) panels that allow a highly industrialized and reversible construction as well as high mechanical efficient since it overcomes the inherent limitations of each component. The analysis is based on an experimental campaign carried out to assess the mechanical behavior of the proposed connection systems in terms of stiffness and strength as well as relevant failure modes. A series of new bolted connection systems are proposed and push-out tests on five types of CFS-CLT composite connections were performed to obtain the load-slip curves and failure modes. The test results were compared with those provided by EN 1995-1-1 analytical models. The results showed that bolted joints using special types of nut obtained higher load bearing capacity and slip modulus than screwed joints of similar diameter. The failure modes were, mostly, simultaneous occurrence of embedding strength failure on CLT and slight developing of plastic hinges on connectors.

KEYWORDS: Steel-Timber Composite, Cross-Laminated Timber, Cold-Formed Steel, Connections

1 INTRODUCTION

Composite structures have been used as an effective solution for modern buildings combining the benefits of dissimilar materials to overcome their individual limitations and improve the structural system performance [1-2]. Besides the structural efficiency due to the composite action, the application of steel-timber composite (STC) structures allows to use prefabricated elements and, in some cases, a fully reversible construction system. STC applications for buildings presents many advantages proving their suitability as a structural solution, for instance: lightness, structural in-plan stability, low environmental impact, as well as the possibility of recycling and replace the degraded elements [3].

The engineered wood products with high mechanical performance such as Laminated Veneer Lumber (LVL), Glued Laminated Timber (Glulam) and Cross-Laminated Timber (CLT) are prefabricated structural elements of timber whose use have increased significantly in the construction industry due to lower carbon footprint, relatively high mechanical performance and lower self-weight in comparison with other traditional solutions [4-5]. The association of steel profiles and CLT slabs allows highly industrialized construction, as the elements are connected quickly, precisely, and using full-dry mechanical devices [3]. Comparatively to traditional lightweight timber structures, CLT panels are higher strength-to-weight ratio, and due to its crossed-layers and massive nature, the structural capacity and fire resistance are improved, making it possible to design and build large timber structures that are competitive against steel and reinforced concrete but significantly more sustainable [6-9]. The CFS profiles are attractive options in commercial and residential buildings due to high structural performance, lightweight, ease of prefabrication and quick assembly on site [10-12]. The increasing application of CFS in the construction industry has brought researches to overcome the safety issues and to

https://doi.org/10.52202/069179-0438

improve the use of CFS elements as primary structures [13].

Therefore, the association of CFS beams and CLT panels can also satisfy requirements in terms of lightweight, prefabrication, modularity, sustainability, on-site installation, and relative manufacturing costs [1]. Navaratnam *et al.* (2021) [14] investigated the structural performance through FEM model of CLT-CFS composite beam for the flooring system. Karki *et al.* (2022) [15] carried out push-out tests of CFS-plywood connections with screws and bolts, as well as the influence of adhesives at the shear interface. Based on the results, the authors recommended using self-drilling screws, M8 nuts and bolts for CFS-timber composite flooring systems. Vella *et al.* (2020) [16] performed experimental tests of CFS and timber panel (*i.e.* plywood and particleboard) connections with inclined screws. This study evaluated the influence of type of timber panel, type and inclination of connector, and the thickness of CFS. The authors showed that the CFS thickness influences significantly the resistance to thread withdrawal failure and degree of rotational restraint of the fastener head.

In this paper, novel connection systems for CFS-CLT composites are presented in order to achieve an efficient mechanical behavior, allowing a simple and quick assembly/disassembly process, requiring fewer connectors, and thus, globally, turning the composite system into a more economical and efficient solution than the current ones found for CFS-CLT composites.

2 CONNECTIONS FOR CFS-CLT COMPOSITE STRUCTURES

The connector types used in this study comprise self-drilling screws and bolts, with 60 mm length and 8 mm diameter. More details are given in Table 1 and Figure 2.

Table 1 - Parameter of connections

ID	Connector	Description
S1	Screw	Self-drilling screws, 8 mm diameter, $f_{y,k}$ = 1000 N/mm²
B1	Bolt + washer + nut	Bolt, 8 mm diameter, grade 8.8, with washer (24 mm external diameter) and nut
B2	Bolt + T-nut	Bolt, 8 mm diameter, grade 8.8, with T-nut for wood (11 mm height, 9 mm external diameter and 22 mm outer diameter)
B3	Bolt + threaded insert	Bolt, 8 mm diameter, grade 8.8, with threaded insert (19 mm height and 12 mm external diameter)
B4	Bolt + threaded insert + T-nut	Bolt, 8 mm diameter, grade 8.8, with threaded insert (same as in B2 connection) and T-nut (same as in B3 connection)

Figure 1 – Connection components (a) Screw; (b) Bolt; (c) Washer and nut; (d) T-nut for wood and, (e) Threaded insert for wood

Connections S1 and B1 ("S" stands for screw and "B" for bolt) are commonly used in timber structures and those were considered as reference connectors to the new solutions B2 (using a T-nut), B3 (using a threaded insert) and B4 (a combination of concepts of connections B2 and B3. Bolted connection systems are considered due to easiness for quick assemble and disassemble (presumably and assuming normal conditions of the use of the structure, i.e., service limit states) as well the possibility of pre-fabrication on factory. Threaded inserts and T-nut were used to provide stiffness to the bolted connections (i.e. to reduce the stiffness lose effect due to the hole clearance) and at the same time keeping the disassemble advantages of the bolted solution. In the bolted connections, 8 mm diameter holes were predrilled and at one of the surfaces of the CLT (solutions B1, B2 and B4), a 28 mm diameter hole was drilled insertion of washer/nuts and avoided the protruding from the outer surface of the CLT panel.

3 EN 1995-1-1 DESIGN RULES FOR CFS-CLT DOWEL-TYPE CONNECTIONS

The design rules for dowel-type that are recommended in EN 1995-1-1 [17] are based on the Johansen's Theory [18]. The method establishes the limit equilibrium equations for timber-to-timber and steel-to-timber connections, assuming the rigid-plastic behavior of the connectors and the timber subjected to crushing by the rigid connector. Two concepts that translate these hypotheses into the calculation are the localized crushing resistance of the timber and the plastic moment of the connector. Depending on the mechanical and geometric characteristics of the elements involved in the connection, the failure can take different forms; however, the friction forces between the connected elements and the withdrawal strength of the fasteners are ignored in Johansen's model [19-20]. The failure modes always imply the localized crushing of the timber, combined or not with plastic hinges in the connector [21].

The characteristic load-carrying capacity of the dowelled connections depends on the yield strength, the embedment strength, and the withdrawal strength of the fastener. EN 1995-1-1 [17] provides equations to determine the load-

https://doi.org/10.52202/069179-0438

carrying capacity of single- and double-shear plane in different connection types [19].

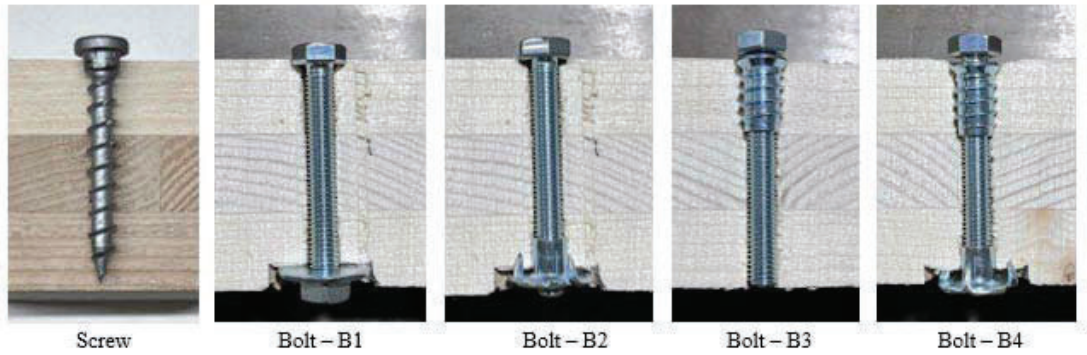

Figure 2 – Types of tested connection systems.

For a thin steel plate in single-shear, the characteristic load-carrying for screws per shear plane per fastener $F_{v,Rk}$, is taken as the minimum value found from Equation (1a):

$$F_{v,Rk} = min\begin{cases} 0.4\, f_{h,k}\, t_1\, d & \text{(1a)} \\ 1.15\sqrt{2\, M_{y,Rk}\, f_{h,k}\, d} + \frac{F_{ax,Rk}}{4} & \text{(1b)} \end{cases}$$

Where, $f_{h,k}$ is the characteristic embedment strength in the timber member; t_1 is the thickness of the timber member or the penetration depth; d is the screw diameter; $M_{y,Rk}$ is the characteristic fastener yield moment; $F_{ax,Rk}$ is the characteristic withdrawal capacity of the screw.

For cold-formed steel profiles, thin-walled sheets are usually considered since their thickness is generally less than half the fastener diameter. In Figure 3, two failure modes are presented for thin steel-timber connection that represent, respectively, the embedment of timber member obtained from Equation (1a) and the same failure plus the plastic moment of the connector from Equation (1b).

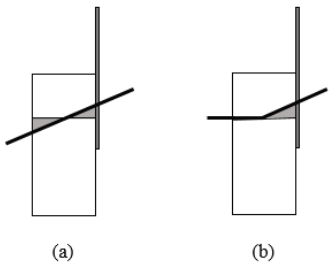

Figure 3 - Failure modes for thin steel-timber connection; (a) embedment of timber member; (b) embedment of timber member plus plastic moment of the connector

Models for determination of the embedment strength in CLT connections were developed in several studies [19-22] and an empirical model for the load-slip behavior of steel-CLT composite connections was proposed by Hassanieh *et al.* (2017) [23].

The value of the characteristic embedment strength in the timber member with pre-drilled is given in EN 1995-1-1 [17] by Equation (2):

$$f_{h,k} = 0.082\,(1 - 0.01\, d)\, \rho_k \qquad (2)$$

Where, d is the screw diameter and ρ_k is the characteristic density of wood.

The characteristic fastener yield moment ($M_{y,Rk}$), according to EN 1995-1-1 [17], is calculated from Equation (3):

$$M_{y,Rk} = 0.3\, f_{u,k}\, d^{2.6} \qquad (3)$$

Where, $f_{u,k}$ is the material characteristic tensile strength.

For bolted connections, according to EN 1995-1-1 [17], the characteristic withdrawal capacity is given by the minimum of the following possible failure mechanisms: maximum bolt tensile capacity ($F_{R,t,k}$), punching of the washer in the timber ($F_{ax,Rk,\ bearing}$) or punching of the bolt in steel plates ($B_{p,Rk}$), as shown in Equation (4).

$$F_{ax,Rk} = min\begin{cases} F_{\mathrm{R,t,k}} \\ F_{ax,Rk,bearing} \\ B_{p,Rk} \end{cases} \qquad (4)$$

The bearing capacity of steel plate should not exceed that an equivalent washer, whose external diameter corresponds to a minimum between *12t* and *4d*.

The slip modulus per shear plane per fastener under service load (K_{ser}) for screws or bolts are given by the Equations (5):

$$K_{ser} = {\rho_m}^{1.5}\, d/23 \qquad (5)$$

For steel-to-timber connections, K_{ser} should be based on ρ_m for timber member and could be multiplied by 2.0.

https://doi.org/10.52202/069179-0438

4 EXPERIMENTAL PROGRAM

Experimental characterization of the developed CFS-CLT composite connections is carried out through push-out tests according to EN 26891 [27]. In total, five types of CFS-CLT connections systems were tested to characterize the shear-slip behavior of the proposed connections.

As result of tests, load-slip curves of CFS-CLT composite connections were obtained to determine the ultimate load capacity and slip modulus.

4.1 MATERIALS

The timber elements used in this study were a CLT panel made from 3-layered of Spruce lamellae of strength class C24 (Table 2). The panel was cut in 350 mm wide x 400 mm long stripes. In the push-out test the CLT panel was loaded in the direction parallel to the external layers' grain. The cold-formed steel profile used was an Omega profile S350GD whose properties are given in Table 3.

Table 2 - Properties of CLT panel

Parameter	
Modulus of elasticity (MPa)	11000
Compressive strength (MPa)	24
Density (kg/m³)	420
Thickness (mm)	3 x 20

Table 3 - Properties of CFS profile

Parameter	
Modulus of elasticity (MPa)	210000
Yield strength (MPa)	350
Ultimate strength (MPa)	420
Thickness (mm)	2.5
Height (mm)	250
Length (mm)	400

4.2 FABRICATION OF SPECIMENS

Five types of CFS-CLT connection (Figure 2) in a total of eighteen specimens (six for S1 and three for each bolted solution) were produced (Table 1). Each specimen was composed of a CLT panel connected to the flanges of two CFS profiles (each with two connectors per shear plane) using a symmetric layout, resulting in two independent shear planes, as shown in Figure 4.

4.3 LAYOUT AND CONFIGURATION OF PUSH-OUT TESTS

The specimens were placed in the testing rig as shown in Figure 5. Four linear variable differential transformers (LVDTs) were used to measure the relative displacement (or slip) between the CLT panel and CFS profile.

The loading procedure was carried out as specified in EN 26891 [27]. The test stop conditions were failure of the specimen, 15 mm of slip or 900 s of test, whatever occurred first. The loading procedure was updated with respect to the ultimate load obtained in the first specimen tested within each solution (pre-test).

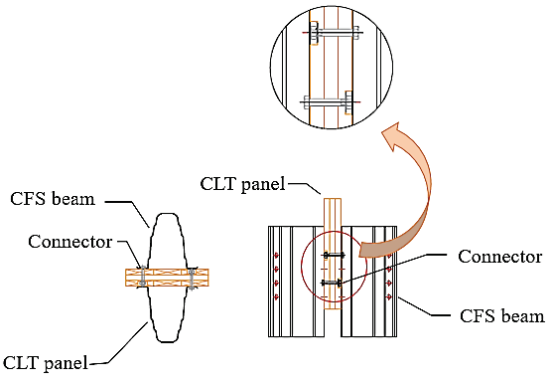

Figure 4 – Scheme of connection tests

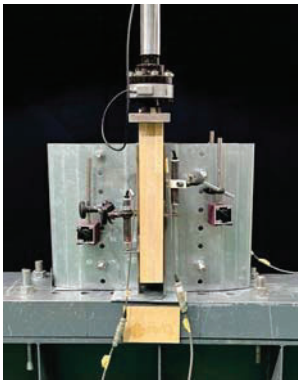

Figure 5 - Layout of push-out test

5 RESULTS AND ANALYSES

5.1 LOAD-SLIP CURVES

The load-slip curves of the CFS-CLT connections with screws and bolted connectors obtained per specimen and per solution are shown in Figures Figure 6 to Figure 10.

With regard to the ultimate load capacity (F_{ult}) of the composite connections it can be observed that the bolted solutions present higher values than joints with screws. Although the solutions B3 and B4 were pre-drilled, the bolts were connected with a nut at the top of the hole, which provided higher initial slip modulus than solutions B1 and B2. Although screwed connection had on average higher stiffness than solutions B1 and B2, the screwed joint showed rapid loss of stiffness with increase on load. All load-slip curves demonstrated ductile behavior. Similar to the results shown in Hassanieh *et al.* (2016) [4], the load-slip curves of the joint solutions with screws (Figure 6) showed close to elastic-perfectly plastic behavior, while the bolted solutions presented some hardening characteristics.

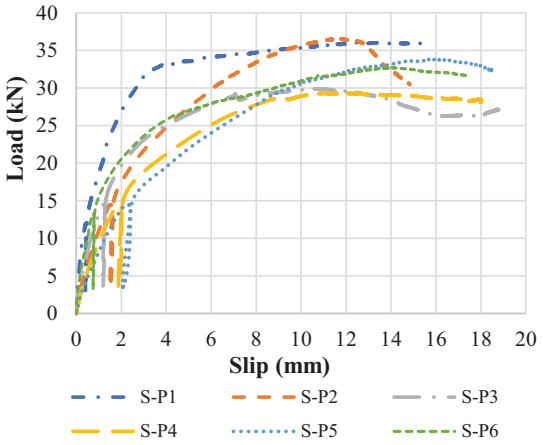

Figure 6 – Screw load-slip curve

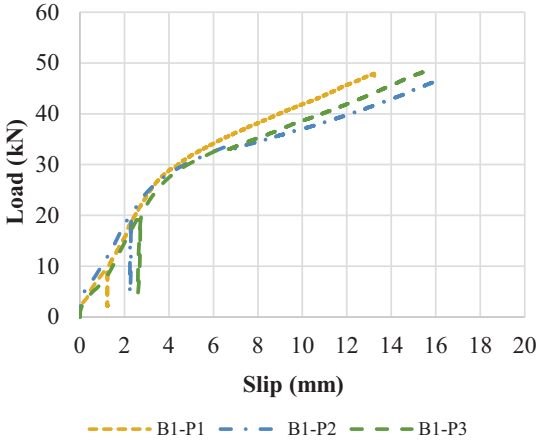

Figure 7 – Bolt-B1 load-slip curve

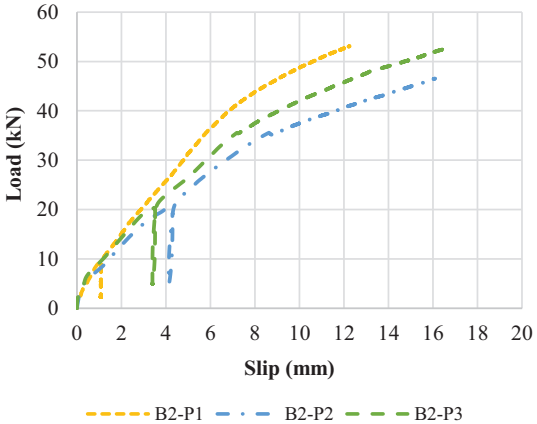

Figure 8 – Bolt-B2 load-slip curve

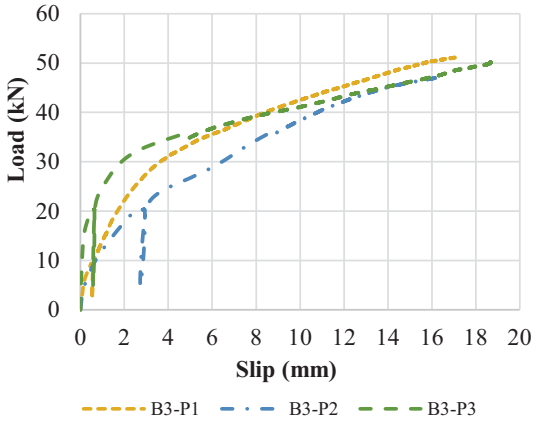

Figure 9 – Bolt-B3 load-slip curve

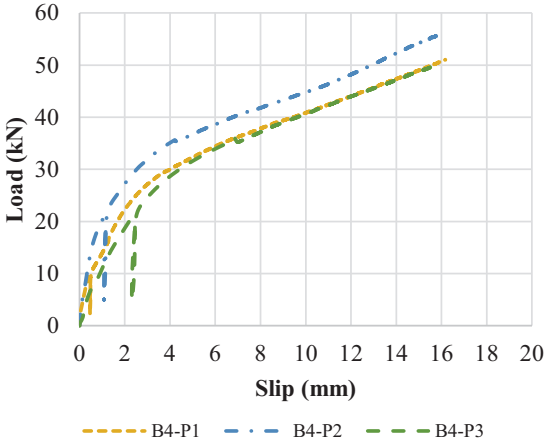

Figure 10 – Bolt-B4 load-slip curve

5.2 TEST RESULTS

The mean values obtained in the tests for the ultimate load capacity (F_{ult}) and slip modulus (k_s) - defined according to EN 26891 [27] - are presented in Table 4, as well the characteristic values calculated according to EN 14358 [28]. The mean ultimate load capacity for the screwed connections was 8.3 kN while for the bolted solutions, in descending order, was: 13.1 kN (B4), 12.7 kN (B2), 12.4 kN (B3) and 11.9 kN (B1). Regarding the mean slip modulus, for screws a value of 2773 N/mm was achieved while for the bolted solutions, in descending order, was: 4413 N/mm (B3), 3604 N/mm (B4), 1737 N/mm (B1) and 1543 N/mm (B2). Overall, the ultimate load capacity of the different bolted connections was quite similar (maximum difference around 1.2 kN). Both B2 and B3 connections presented similar load capacity, however B2 presented the lowest stiffness while B3 the highest. On the other hand, B4 connection (which was a combination of concepts of connections B2 and B3) resulted in a solution with the second highest slip modulus (3604 N/mm) and the highest ultimate load capacity of all solutions (13.1 kN).

Note: CoV: Coefficient of variation; Ch. Value – Characteristic value calculated according to EN 14358 [28]; *Ultimate load capacity equally distributed on four connectors.

In general, B1 solution compared poorly against the other bolted ones regarding stiffness and strength. Comparing the bolted solutions with the screwed one, it is found that the firsts performed better in terms of strength while in terms of stiffness only B3 and B4 solutions superseded the S1 connection.

Table 4 shows a comparison of the ultimate load capacity and slip modulus between push-out test results and those estimated according to EN 1995-1-1 [17]. According to the predictions, the characteristic load-carrying capacity per connector and per shear plane was $F_{v,k}$ = 7.5 kN and $F_{v,k}$ = 5.8 kN for the screwed and bolted connections, respectively. The slip modulus under service was K_{ser} = 5988 N/mm for both screws and bolts.

The estimated ultimate load capacity was mostly lower than the value obtained in tests, with a test-to-estimated ratio between 0.5 and 0.6 for bolts. In terms of the estimated slip modulus, the results showed that those were significantly higher than the test values - the mean ratio was 2.2 for the screwed connection and between 1.4 and 3.9 for the bolted connections.

It should be noticed that the coefficient of variation of the results was noticeable (67.0% for screwed joints and between 6.8% and 68.9%), and this may be the reason for the discrepancy found. Likewise, Vella *et al.* (2021) [29] presented the same analysis for CFS and plywood composite connections and reported that the estimated load capacity was significantly lower than that measured from the tests, with a mean test-to-estimated ratio $F_{v,EN}/F_{v,k}$ of 0.55 and even higher ratios of K_{ser}/k_s (around 6.20) on their connections.

Overall, from the novel connections proposed and assessed in this study, solutions B3 and B4 presented the highest and more balanced performance, and thus showing a significant potential to be used in CFS-CLT structures.

5.3 FAILURE MODES

According to EN 1995-1-1 [17], two failure modes are possible for steel-to-timber composite connection with thin steel plate in single shear – (a) embedment of timber and connector rotation; (b) connector bending and plastic hinge.

Figure 11 shows slight developed plastic hinges on a bolt and on a screw (less pronounced in the last). Figure 12 and 16 show local deformations around the CFS holes and rotation of the screws and bolts head at the end of the tests, being more evident in the bolt connections because those were subject to higher loads. Figures 13 to 15 shows the crushing of timber and the embedding of the bolts. In the present study, the CFS sheet of the specimens was unable to significantly restrict the rotation of the connectors, which created a localized deformation around the CFS hole, a large rotation of the connector and excessive crushing in the CLT panel. Therefore, the failure modes obtained in the tests were much closer to mode (a) presented in Figure 3.

6 CONCLUSIONS

This study presented novel proposed types of connection for CFS-CLT composite solutions and their mechanical behavior. Those solutions include self-drilling screw S1 and bolt B1, which are commonly used in timber structures. In addition, new bolted solutions were proposed, *i.e.* B2 (using a T-nut), B3 (using a threaded insert) and B4 (a combination of concepts of connections B2 and B3.

Push-out tests on CFS-CLT connections were carried out according to EN 26891 [27]. The load-slip curves and failure modes revealed ductile behavior, with failure occurred after a large post-peak branch in the load-slip curve. It can be seen the failure modes were simultaneous occurrence of the embedding strength failure of CLT and slight developing plastic hinges in both connectors, as well as local deformations around the CFS holes and rotations of the screws and bolts.

Overall, the bolted connection solutions B3 and B4 obtained the highest ultimate load capacity and slip modulus, and thus showing a significant potential to be used in CFS-CLT structures.

Experimental and Numerical Investigations on the Usage of CLT Panels to Form Timber-Steel Composite Floor Systems

Hugh Merryday[1], Megan Potuzak[2], David Roueche[3], Kadir Sener[4]

ABSTRACT: This paper presents experimental and numerical results from an ongoing investigation to evaluate the performance of steel-timber composite floor systems. A composite floor system comprised of cross-laminated timber (CLT) made from Southern Yellow Pine species was fastened to a hot-rolled wide flange steel beam using self-tapping wood screws. Experimental evaluations included pushout tests for mechanical fastener characterization and a beam test that was monotonically tested under a four-point bending setup. Beam test results were compared against a steel-timber fiber model, existing equations adapted from steel-concrete composite design, and experimental steel-CLT load-slip response from the pushout testing. Near full-composite behavior was observed in the beam prior to connection slip but reduced to partial-composite behavior as screws began to deform. A substantial increase in strength and stiffness was observed for the composite beam from the non-composite (hybrid) case which was nearly equal to the level of composite action achieved during the test. Both the section fiber model and adapted steel-concrete composite design equations estimated the steel-CLT beam behavior with reasonable accuracy compared to the experimental test.

KEYWORDS: Mass timber, steel-CLT composite beam, self-tapping screws

INTRODUCTION

The recent popularity of mass timber construction as an alternative to traditional materials such as steel, concrete and masonry can be credited to its designation as a renewable resource. Also, mass timber, such as cross-laminated timber (CLT), can improve construction times as modular elements are manufactured off-site and installed with minimal site work. However, due to limitations stemming from strength and serviceability, mass timber elements are not efficient for high-rise construction since deep glue-laminated beams are often required for large spans. Accordingly, Figure 1 depicts a popular design practice to address this challenge in which hybrid construction systems involve the use of mass timber floor panels as decking elements in steel-frame structures. Utilizing this system will enable smaller steel beams and girder sections while maintaining a CLT deck comparable to the more well-established steel-concrete construction. However, unlike steel-concrete construction, there is little to no guidance on the design of steel-timber composite construction. Thus, engineers must oversize steel members to work as floor members alone, ignoring any strength contribution provided by the CLT deck.

This paper presents ongoing experimental and numerical studies to evaluate the performance of steel-CLT composite beams using large diameter self-tapping screws as shear connectors. Previous experimental studies have been conducted on steel-CLT composite beams with the use of heavy-duty wood screws and bolted connections [1]; whereas in the US, self-tapping screws are a preferred choice in the mass-timber industry over other types of connection for their speed of installation (Figure 1). Static pushout tests have been conducted to evaluate the connection strength and to identify possible failure modes associated with three self-tapping screw types used in steel-timber composite construction [2]. This study also presents preliminary results from a large-scale beam test, informed by the pushout test results, conducted to investigate the flexural strength performance of steel-CLT composite using one of the self-tapping screw types. A section fiber model has been developed to predict the flexural behavior of steel-timber beams, accounting for partial composite action at the steel-timber interface. The model obtains both section-level and member-level behavior to provide a holistic summary of the beam's response. Finally, model results are compared with experimental data.

2 METHODOLOGY

2.1 MATERIALS

CLT used in this study was manufactured from southern yellow pine at a nearby CLT production facility. According to manufacturer specifications, the alternating 5-ply layup consisted of visually graded No. 2 or better lumber in the outermost and middle layers and No. 3 or better in the remaining transverse layers in accordance with the National Design Specification (NDS) for Wood Construction [3]. The specific gravity and moisture content were measured in accordance with ASTM D2395 [4]. The moisture content was measured to be 10.2% and the specific gravity was measured to be 0.46±0.07 (mean and standard deviation) for 20 samples. Steel sections used for pushout and beam testing consisted of hot-rolled W16 x 31 (American designation) made from A992 steel with a measured yield strength of 385 MPa and ultimate strength 495 MPa as provided from the mill test report. Self-tapping screws used to attach CLT to steel are shown in Figure 2 and their geometric and material properties are shown in Table 1. The fastener bending yield strength, F_{yb}, was determined in accordance with ASTM F1575 [5]. In Table 1, L is the screw length, D_n is the nominal diameter, D_s is the shank diameter, and D_r is the root diameter.

2.2 MONOTONIC PUSHOUT TESTS

Pushout tests were conducted using a symmetrical test setup, with two CLT panels fastened to each flange of the steel section with two rows of screws. CLT panels had dimensions of 457 mm wide by 610 mm tall with varying thickness depending on the number of laminations (35 mm per lamination). Steel sections measured 610 mm tall with adequate offset from the end of CLT panels to accommodate displacement. The standard test specimen is shown in Figure 3, with a typical layout of 8 screws. 12.7 mm holes were punched in the steel flange using a hydraulic punch to replicate field conditions. The transverse hole spacing was 102 mm leaving a 19 mm center-to-edge distance on the steel flange. To ensure screws were installed straight, a 6 mm pilot hole was provided, and the self-tapping screws were torqued to 54 N-m in accordance with manufacturers' recommended torque limits. Four potentiometers, one at each specimen corner, were used to measure the relative slip between the steel and CLT panels during testing. The load regime was adapted from ASTM D5652 [6], where load was applied under displacement control at a rate of 2.54 mm/min to reach the maximum load in approximately 10 minutes. Tests were stopped either when screw failure occurred, or 80 percent of the post-peak load was reached. Further details of the pushout tests are available in [2].

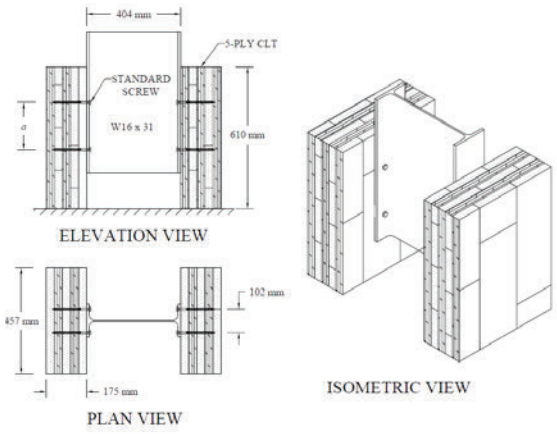

Figure 3: *Standard pushout test specimen.*

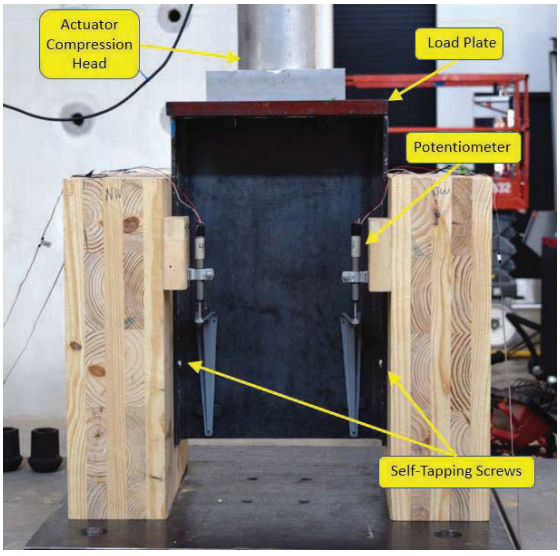

Figure 4: *Pushout test setup.*

2.3 LARGE-SCALE BEAM TEST

The beam test was conducted using a four-point bending test setup as shown in Figures 5 and 6, with a continuous 5-ply CLT panel fastened to a 9.14-meter long W16 x 31 steel member. The CLT deck measured 483 mm wide and was oriented so that the major strength direction was parallel to the length of the beam. Screws were installed at 305 mm spacing using methods outlined for pushout testing, without the use of pilot holes to mimic field application. Six string potentiometers were used to monitor and record vertical displacement at midspan, load points, and at the mid-shear spans. Four inclinometers were placed at mid-height of the steel section at each load point to measure rotation. Eight 25 mm slip sensors were used to measure the relative slip between the steel and CLT along the length of the beam. Strain gauges were attached to the steel and CLT within the constant moment region to capture the strain profile of the cross-section. Figure 7 illustrates the steel and wood strain gauge arrangement at midspan. Load was monotonically applied through a transfer beam under displacement control at a rate of 1.27 mm/min and was increased to 2.54 mm/min in the post-yield region. The test was stopped when the actuator stroke limit was reached. To limit out of plan deflection, Teflon plated bracing was provided at midspan with 3 mm of clearance as shown in Figure 8.

2.4 NUMERICAL MODEL

A 2D section fiber model was developed to analyze the flexural behavior of steel-timber beams, accounting for the degree of partial composite action between the steel and timber, cross-sectional dimensions, mechanical properties, and timber orientation. The model discretizes the cross-section into small horizontal layers, which are assigned with uniaxial material properties and dimensions corresponding to each layer. In steel-CLT beams, different material properties were assigned to each layer of timber based on its orientation. Using fundamental constitutive relationships between stress and strain of each material and establishing force equilibrium, the cross-sectional stress and strain profiles were obtained at increasing curvatures. The percentage composite action incorporated into the strain calculation was obtained through calibration of slip strain measurement from testing, as provided in Equation (1).

$$CA_{strain} = (1 - \varepsilon_{slip_test} \,/\, \varepsilon_{slip_non-comp})\% \qquad (1)$$

https://doi.org/10.52202/069179-0439

In Equation (1), CA_{strain} = percentage composite action determined from slip strain, ε_{slip_test} = slip strain measured at curvature φ obtained from experimental test, and $\varepsilon_{slip_non\text{-}comp}$ = slip strain under non-composite (0% composite) condition at curvature φ obtained from fiber model. The percentage composite action was assumed to be constant throughout the analysis that resulted in a linear relationship between slip strain and curvature.

The section moment was calculated for incrementally increasing curvature levels to develop the moment-curvature response of the cross-section, where equal curvature was assumed for steel and timber elements at the same cross-section. The numerical model steps to achieve the moment-curvature relationship are summarized in Figure 9. Once the moment-curvature relationship was obtained for the section, this response was integrated along the beam length to obtain member-level responses including mid-span deflection, interfacial slip at beam ends, and support rotation. The fiber analysis results were validated against a database of steel-timber beam tests, and the comparisons are discussed in detail elsewhere [7].

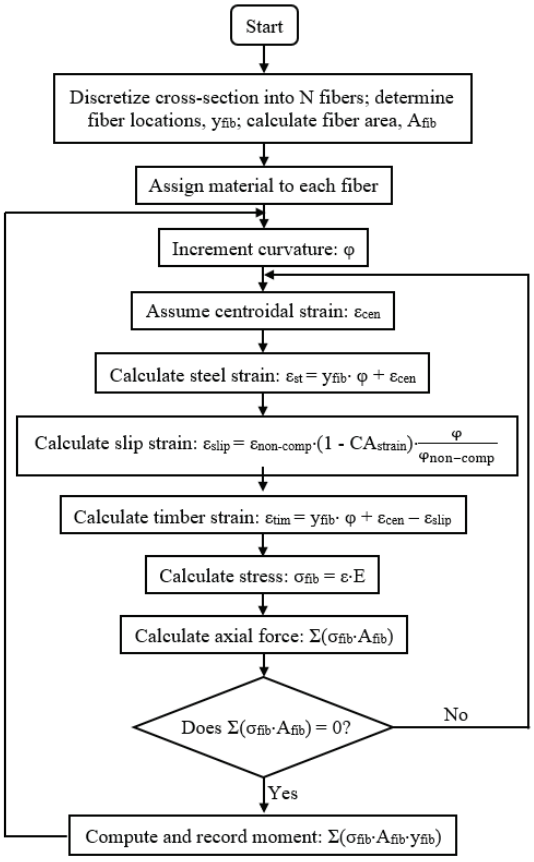

Figure 9: *Flowchart summarizing section fiber analysis model.*

2.5 STRENGTH AND STIFFNESS PREDICTIONS BASED ON AISC APPROACH

Since steel-concrete composite floors are a common structural system, extensive research has been performed to establish design equations to calculate beam stiffness and flexural capacity for these composite systems. Steel-timber composite flooring systems resemble steel-concrete composite systems in that they both pair low-tensile strength materials with structural steel members. Therefore, the applicability of typical steel-concrete composite design equations on steel-timber systems were evaluated. Understanding the correlation between these two structural systems as it pertains to partial composite action would accelerate the adoption of steel-timber composite structures into design provisions.

The design equations analyzed were adopted from the American Institute of Steel Construction (AISC) Specification [8]. The Specification provisions in Chapter I characterize composite action between structural steel members and concrete slabs as a fraction of the combined shear strength of the shear connectors within the shear span of the beam to the minimum strength contribution between the steel and concrete elements. Similarly, Equation (2) emulates the AISC steel-concrete composite system equation by replacing concrete compressive strength and shear stud strength with timber compressive strength and mechanical connector (self-tapping screw) shear strength:

$$CA_{strength} = \frac{\Sigma Q_n}{\min\left(A_s f_y, \Sigma f_{c,tim} A_{tim}\right)} \qquad (2)$$

where $CA_{strength}$ = percentage composite action based on strength, ΣQ_n = total shear strength of mechanical connectors located within the shear span, A_s = cross-sectional area of steel, f_y = steel yield strength, $f_{c,tim}$ = timber compressive yield strength, and A_{tim} = cross-sectional area of timber.

Once the partial composite action percentage is determined from Equation (2), the effective stiffness of each beam is calculated in accordance with the Specification Equation C-I3-3, as shown in Equation (3):

$$EI_{equiv} = E_s * \left[I_s + \sqrt{CA_{strength}}\left(I_{tr} - I_s\right)\right] \qquad (3)$$

where EI_{equiv} = equivalent flexural stiffness of steel-timber composite member, E_s = elastic modulus of steel, I_s = moment of inertia of steel, and I_{tr} = transformed moment of inertia of the steel-timber cross section.

Additionally, the plastic moment capacity was calculated for each steel-timber beam to compare the accuracy of experimental results, as outlined in Section I2a of the Specification. These calculations performed in accordance with the AISC Specification are compared to experimental data to draw conclusions about their applicability to steel-timber composite flooring systems.

https://doi.org/10.52202/069179-0439

3 EXPERIMENTAL RESULTS

3.1 PUSHOUT TESTS

Results of pushout testing for the screws used in this beam test have been previously presented in detail elsewhere, [2], but will be briefly summarized for the type of screw used in the beam testing.

Typical failure of the screws used for beam testing was associated with the formation of a single plastic hinge within the CLT accompanied by a brittle shear/tensile failure at the steel-CLT interface. The cross-section of a typical pushout test specimen with screws spaced at 203 mm is shown in Figure 10. This study concluded that the abrupt transition of the screw geometry between the head and shank disrupted the full development of a double plastic hinge. The representative load-slip response of the screws shown in Figure 11 demonstrated that the screws have an average strength of 29.8 kN/screw corresponding to an average maximum slip of 17.3 mm. The connection was also observed to experience a region of no slip due to torquing during initial parts of the loading, as highlighted in Figure 11.

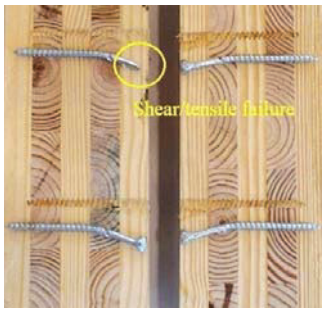

Figure 10: *Failure mode of self-tapping screws loaded parallel to outer lamination in steel-timber pushout setup.*

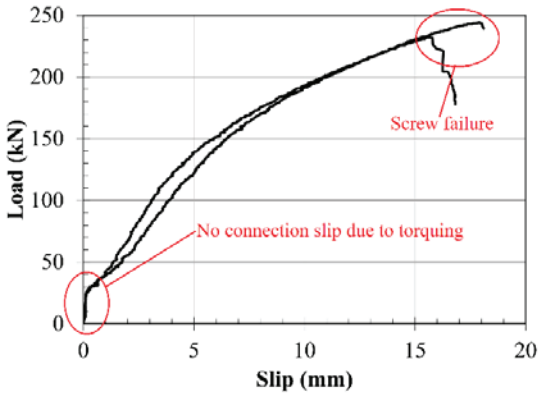

Figure 11: *Load-slip response of steel-CLT connection comprised of eight self-tapping screws.*

3.2 BEAM TEST

No distinct failure mode was observed as the test was stopped due to the constraints of the actuator stroke as shown in Figure 12. Though not a limiting factor for strength, Figure 13 depicts initiation of crushing of timber at a finger joint location on the top surface near midspan. It should also be noted that the beam experienced two instances of support settlement, where the roller/pin setup adjusted to accommodate large rotations.

The load vs. midspan displacement, load vs. support rotation, and load vs. average relative slip between the steel and CLT at the supports are presented in Figures 14, 15, and 16, respectively. The load vs. displacement plot indicated a stiff response until relative slip initiated at the steel-timber interface. The reduced stiffness response was linear until yielding initiated in the steel member at around 150 kN. The load gradually increased in a nonlinear fashion until the actuator stroke limit was achieved (250 mm), and the specimen was unloaded. The load vs. rotation and load vs. slip plots were observed to follow a similar response to the load-displacement, where a reduced stiffness response was followed by a post-yield nonlinear response until stoppage. However, the load slip response depicts a region of no slip between the steel and CLT at the support up to a load of 25 kN when slip initiated. A linear slip response was observed until steel yielding, at which a nonlinear response occurred.

The relative slip between the steel and CLT along the beam corresponding to various load levels is shown in Figure 17. The slip is observed to increase with distance away from load points and indicated a nearly symmetric slip-response in each shear span. The section strain profiles at the initiation of yielding and at ultimate loading conditions is shown in Figure 18, indicating the shifting in each neutral axes observed in CLT and steel with nearly identical curvature in both members. The variation in wood strains across the width of the CLT top surface is shown in Figure 19. The compressive strains in the wood members were observed to be uniform until nearing the ultimate load, where one side experienced more strain.

The service-level stiffness (EI_{eff}), support rotation, and beam end slip corresponding to the ultimate load are provided in Table 2. The service-level stiffness was calculated as the tangent slope of moment-curvature responses between moments corresponding to 80 and 120 kN-m. The yield and ultimate displacements are provided in Table 3, where yielding is defined as the initiation of yielding based on steel tension strain measurements.

4 DISCUSSION OF BEAM TEST RESULTS

The results demonstrate that the steel-CLT beam constructed with self-tapping screws exhibited partial-composite behavior based on the measured slip strain at the steel-CLT interface. However, prior to the initiation of slip, the beam exhibited near full-composite action as indicated by strain continuity at 25 kN shown in Figure 20. Using Equation (1), the composite action was determined to be 91.4% at 25 kN. After overcoming the initial friction provided by screw torquing, it is observed that the strain continuity at the interface was lost, and the slip strain increased with increasing loading as shown in Figure 21. Consequently, the composite action was calculated to be 46.0% and 37.9% at 75 kN and 147 kN, respectively. The increase in slip strain results from the relative slip between the steel and CLT, as pictured in Figure 22, since the self-tapping screws are deforming due to the shear flow occurring at the interface. Thus, it was observed that the composite action between the steel CLT reduces as the load-slip response increases.

The test also produced some notable results that are useful for design purposes. Firstly, it was observed that the CLT was under uniform compression across the width until reaching large displacements, suggesting that there was no major shear lag observed in the CLT deck. This means that the entire width of the CLT can be accounted for in the calculations. Additionally, it was observed that the CLT deck provided adequate support of the steel compression flange against lateral torsional buckling. Since this beam test configuration does not mimic a real floor system application where a much wider panel would typically be used, it is useful to know that the CLT can be relied upon to provide continuous bracing against lateral-torsional buckling even at a relatively narrow slab width.

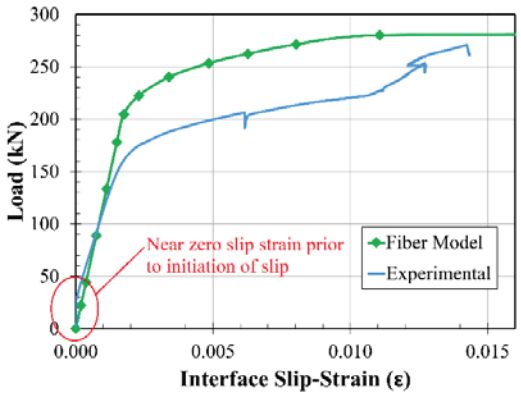

Figure 21: *Experimental slip strain at midspan between the steel flange and CLT slab*

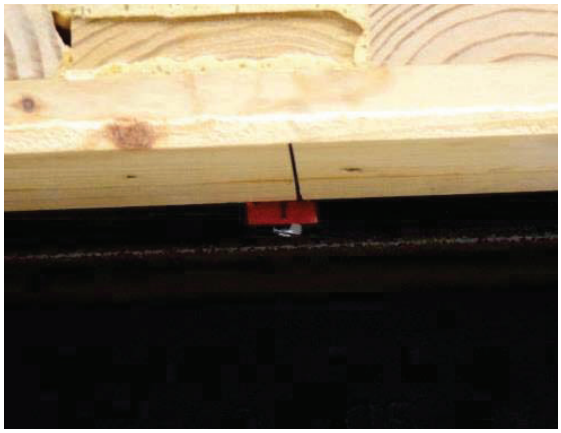

Figure 22: *Relative slip between the steel flange and CLT deck at support location*

Overall, the 2D fiber model predicted the beam behavior with reasonable accuracy compared to the experimental steel-CLT beam, considering the simplicity of the model and various underlying assumptions. From the fiber analysis, the percentage composite action at the steel-CLT interface was determined to be 41 percent at 111.2 kN. This percentage composite action was assumed constant throughout the fiber model analysis. The fiber analysis results yielded accurate ultimate strength, maximum rotation, and strain profiles through the section (Figures 20 and 21). Compared to the experimental steel-CLT behavior, the fiber analysis results predicted the ultimate strength to be 3% greater and the maximum rotation to be 5% lower. However, the fiber analysis results overestimated the maximum slip and initial stiffness by approximately 32% and 20%, respectively. Several limitations exist within the model due to assuming elastic-perfectly plastic behavior of the steel and CLT and assuming constant percentage composite action throughout the analysis.

Furthermore, the AISC calculations adapted from steel-concrete composite beam design predicted the ultimate capacity of the beam within 4 percent accuracy, but overestimated the initial stiffness by about 47 percent, as reported in Table 2 and Figure 23.

Finally, the experimentally obtained moment curvature response is provided in Figure 23 by taking the derivative of measured rotation at load points, and compared against AISC capacity and stiffness, fiber analysis, and 0% composite action (hybrid case). The experimental moment curvature is observed to closely align with the AISC stiffness until initiation of yielding. By accounting for the contribution of composite behavior, the flexural stiffness and moment capacity increased by nearly 40%, from the hybrid case.

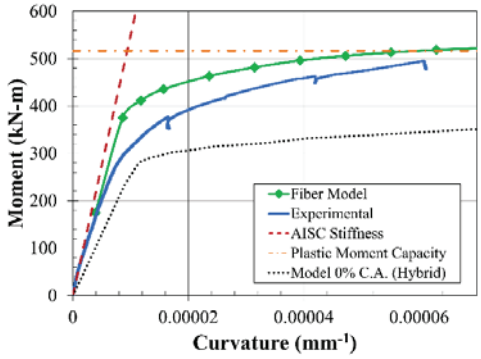

Figure 23: *Moment-curvature relationships for experimental steel-CLT beam and fiber model compared against AISC stiffness and plastic moment capacity.*

5 CONCLUSIONS

As demand increases for mass timber in high-rise construction, there exists a need for design guidance for efficient structural systems such as steel-CLT floor systems. A steel-CLT composite beam constructed with self-tapping wood screws was monotonically tested under a four-point bending setup and compared with analysis results obtained from a fiber model. Test results demonstrate almost full-composite (greater than 90%) behavior prior to connection slip but reducing to partial composite (about 40% prior to steel yielding) behavior with increasing load due to screw deformation. For design purposes, it was observed that the CLT deck was under near uniform compression and the deck provided continuous bracing for the steel against lateral torsional buckling. The fiber analysis model predicted the steel-CLT flexural response with reasonable accuracy, including the ultimate strength, maximum rotation, and strain profiles, but has limitations due to its assumptions and simplicity. Calculations adapted from steel-concrete composite design proved to be accurate for calculating the plastic moment capacity of the beam but overestimated its flexural stiffness.

6 FUTURE RESEARCH

Additional testing will be completed utilizing self-tapping screws in steel-CLT composite beams with the aim to develop a design guide for practicing engineers.

https://doi.org/10.52202/069179-0439

Parameters that will be investigated will include increasing CLT width, adjusting screw spacings, minor strength CLT bending (perpendicular orientation), and the contribution of concrete topping. Furthermore, the steel-CLT beams will be modelled in finite element analysis software to gain a deeper understanding of steel-timber flexural behavior.

EXPERIMENTAL TESTING OF SMALL-SCALE TIMBER-CONCRETE COMPOSITE BEAMS UTILIZING ADHESIVE SHEAR CONNECTIONS

Adam Petrycki[1], Osama (Sam) Salem[2], Matthew Leitch[3]

ABSTRACT: Timber-concrete composite (TCC) structural elements have shown desirable mechanical characteristics for use in the structural design of mass timber buildings. Most shear connections used in TCC elements are not perfectly rigid. However, a nearly full composite behaviour can be achieved in TCC sections that utilize adhesive for their shear connections, which significantly increases the stiffness and strength of the resulting sections. Due to the costs and logistics of large-scale studies, an experimental program was conducted to test small-scale TCC beams from a black spruce glulam section. Modulus of Elasticity (MOE), Modulus of Rupture (MOR) and compression tests were conducted on two groups of samples. The first group was for small-size beams with no concrete layer on top, that were taken from a glulam beam section, and consisted of three sub-groups: Group A for beams with no glue line present; Group B for beams with one horizontal glue line at mid-depth between two lamellae; and Group C for beams with one vertical glue line at the beam midspan. The second group was for small-size TCC beams that utilized adhesive for their shear connections and consisted of three sub-groups: Group D for TCC beams with 28-day concrete age that utilized wet-on-dry adhesion process; Group E for TCC beams with 7-day concrete age that utilized wet-on-wet adhesion process; and Group F for TCC beams with 28-day concrete age that utilized wet-on-wet adhesion process. Each sub-group consisted of 10 samples for determining the MOE and MOR and another 10 samples for the compression tests. Additionally, Scanning Electron Microscope images were taken for the adhesive lines between the wood lamellae highlighting how a perfectly rigid connection can be developed using adhesive. The results for the glulam beam specimens were found to have a low coefficient of variability and are close to the results published in the available literature. This suggests similar characteristics of glulam made from small diameter trees on both small and large scales. In contrast, the results of the TCC beam specimens were more variable due to the application of two different adhesion methods (i.e., wet-on-wet, and dry-on-wet methods). Also, all test specimens experienced brittle failures.

KEYWORDS: Timber-concrete composite (TCC) sections, Glulam, Adhesive shear connections, Composite action

1 INTRODUCTION

Timber-concrete composite (TCC) systems have been proven to provide many benefits over conventional timber or reinforced-concrete floor systems [1]. TCC systems have seen increased use in new construction and the rehabilitation of existing timber structures. Such composite systems rely on various shear connectors to develop the composite action between the timber element carrying the tensile forces and the concrete topping layer having the compressive forces. Brittle failure can occur in the timber element and the concrete layer. The type and mechanical characteristics of the utilized shear connectors can influence the failure mode (i.e., brittle, or ductile) of a TCC system [2]. While mechanical shear connectors, such as screws and steel plates, are approved for specific composite systems in the EU, none of these connectors guarantee perfectly rigid composite action. Therefore, initial stiffness for a TCC section is reduced when calculated using the gamma method. TCC systems with adhesive shear connections can achieve perfectly rigid behaviour in both small [3] and large-scale tests [4]. Adhesives connections can be applied either in a dry-on-wet method between a timber element and a cured concrete section or in wet-on-wet method, where a mass timber element has adhesive applied to it and fresh concrete is poured on top before the adhesive sets.

Full-size tests of TCC elements can be costly and time consuming, and storage constraints can limit the number of samples produced in an experimental setting. Small-scale tests can be more cost effective, and the smaller size of elements can allow for a greater number of samples to be produced. A greater number of specimens can increase confidence in the test results and be used as a cost-effective pilot project before committing resources to a large-scale testing program. However, mass timber elements can be difficult to scale down proportionally while maintaining their mechanical properties. For example, glued-laminated timber (glulam) and cross-laminated timber (CLT) elements are stronger than their individual lamina, so using clear samples of the wood

https://doi.org/10.52202/069179-0440

species in the lamina would not provide the same results as a proportionally scaled down mass timber element. Before committing to a large-scale experimental program on TCC floor slabs with an adhesive connector and in accordance with ASTM-143-14 [5] standard requirements, this study investigated:

- the effect of the adhesive bond line between small-diameter, black spruce glulam wood elements themselves;
- whether these glulam elements could be used to represent the behaviour of a mass timber floor element in a TCC flexure beam, with a perfectly rigid adhesive connection;
- the difference on results between the wet-on-wet and dry-on-wet application process; and
- whether the strength of a small-scale TCCs concrete element was more accurately reflected through conventional sized testing cylinders or compression columns sized to ASTM-143-14.

2 EXPERIMENTAL PROGRAM

2.1 SPECIMENS DETAILS

In accordance with ASTM-143-14 standard, specimens tested for determining the MOE and MOR measured 300 mm in length and 20 x 20 mm cross-sectional dimensions. Whereas the specimens tested in compression had a height of 60 mm and 20 x 20 mm cross-sectional dimensions. Black spruce of 24F-ES stress grade was used from a glulam beam section for the timber elements. The glulam beam was composed of finger-jointed lamina with cross-sectional dimensions of 25 mm x 50 mm made from small diameter black spruce harvested between 80 and 120 years of age. The relevant mechanical properties are summarized in Table 1.

Table 1: *Mechanical properties of black spruce glulam [6]*

Product name	Nordic Lam
Stress grade	24F-ES/NPG
Comp. parallel to grain	33.0 MPa
Tension parallel to grain	20.4 MPa
Modulus of elasticity	13100 MPa

The compressive strength values of the two concrete batches used in the MOE/MOR specimens and compression specimens are summarized in Table 2. Due to the small size of the samples, a regular concrete mixture could not be used, as the maximum aggregate size is typically not greater than 1/3 the depth of the concrete layer so a number 6 sieve, with an opening of 3.35 mm was used to sieve the materials, resulting in a reduced concrete strength, based on the assumption of the concrete element having a slab thickness of 10 mm.

Table 2: *Average compressive strengths of concrete cylinders (MPa)*

Batch No.	1 (dry-on-wet)	2 (wet-on-wet)
7-day concrete age	15.8	15.4
28-day concrete age	19.74	20.1

To cast a TCC element in a wet-on-wet process, mimicking the process of casting a TCC section in place instead of prefabricating it, required the specification of a moisture insensitive adhesive capable of bonding wet concrete to timber. Sikadur®35 Hi-Mod [7] was selected. It is classified as a moisture insensitive, two-component structural epoxy with a 14-day shear strength of 41.0 MPa and a pot life of 30-38 mins. To ensure a proper bond, after the adhesive is applied, the concrete must be poured on top and packed into the form (without disturbing the adhesive) within 30 minutes.

Specimens for flexure bending tests had three different material cross sections: clear black spruce from a glulam beam, two black spruce laminae with an adhesive connection passing through the cross-sections centroid either vertically or horizontally aligned to the load as seen in Figure 1, and TCC elements with equal depths of concrete and black spruce with the concrete element oriented towards the load as seen in Figure 2.

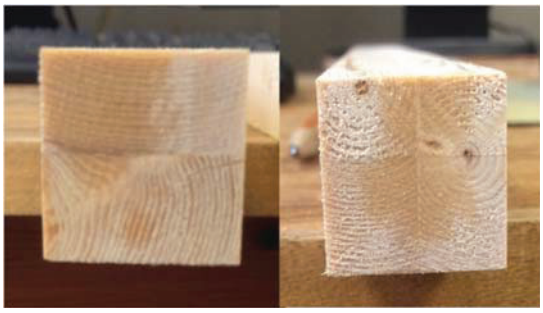

Figure 1: *Sample glue line orientation for MOE and MOR samples, mid-depth (left) and perpendicular to mid-depth (right)*

Figure 2: *TCC flexure specimens*

https://doi.org/10.52202/069179-0440

2.2 SPECIMENS PREPERATION

Pieces of wood were cut from a glulam beam section and sized to be either 10 mm or 20 mm (deep) by 20 mm (wide) and 355 mm long for the bending tests and 60 mm tall for the compression tests. Samples were placed in a conditioning chamber at 20 ˚C and 65% relative humidity for a week, to bring their moisture content to 12% as required by ASTM D4933-16 [8].

For TCC elements, Sikadur®35 Hi-Mod was applied to the 10 mm deep glulam elements and either topped with concrete in a wet-on-wet process and allowed to cure for 7 or 28 days in forms before testing, or applied to previously cast, 10 mm deep, 20 mm wide, 355 long concrete elements in a dry-on-wet process and tested at 28 days. All concrete elements were lightly vibrated, covered with plastic to retain moisture, and lightly misted for the first seven days.

2.3 TEST SETUP

The test program consisted of 60 three-point flexure bending specimens and 70 compression samples, consisting of 10 samples in each of Group A to F and A to G, respectively. The respective test variables of the specimens are summarized in Table 3 for the three-point flexure bending tests and in Table 4 for the compression tests.

The MOE is a measurement of the stress-strain relationship within a material and describes the stiffness of a material with respect to the allowable amount of elastic deformation before full recovery is no longer possible. The MOR is a measurement of the maximum bending capacity of a sample before failure occurs.

Table 3: *MOE and MOR test matrix*

Group	Material (cure time)	Glue line location	Concrete batch No.
A	Glulam	Perp. to mid-depth	N/A
B	Glulam	Mid-depth	N/A
C	Glulam	N/A	N/A
D	TCC (28-day)	Mid-depth	1
E	TCC (7-day)	Mid-depth	2
F	TCC (28-day)	Mid-depth	2

The compression resistance parallel to wood grain was tested as this type of load occurs in both axially loaded columns, as well as the top fibres of beams undergoing flexure bending. Compression tests were done on small-size columns of concrete as well as glulam and TCC sections as the compressive strength of a concrete sample scaled to ASTM-143-14 would more accurately reflect the compressive strength of the concrete element in the TCC sections as opposed to the results of a full-size test cylinder.

TCC elements undergoing three-point flexure bending in groups E and F made with a wet-on-wet process were tested at 7 days in addition to 28 days as in-situ where a wet-on-wet process could be used with a mass timber elements acting as the formwork for the concrete, as the TCC element could reasonably be expected to take some loading at 7 days. Samples in Group D made with the dry-on-wet process reflect a prefabricated TCC section which would not be loaded until the concrete had cured for 28 days or much longer before being bonded to a mass timber element at a factory or on site.

Table 4: *Compression tests matrix*

Group	Material	Concrete batch No.	No of days
A	Glulam	N/A	N/A
B	Glulam	N/A	N/A
C	Glulam	N/A	N/A
D	TCC	1	28
E	Concrete	2	7
F	Concrete	2	28
G	Concrete	1	28

The MOE and MOR tests were conducted using the three-point Tinius Olson H10KT testing machine (Figure 3); while for the compression tests, the Tinius Olsen Universal Testing Machine H50KT was utilized in accordance with ASTM-143-14 testing standard.

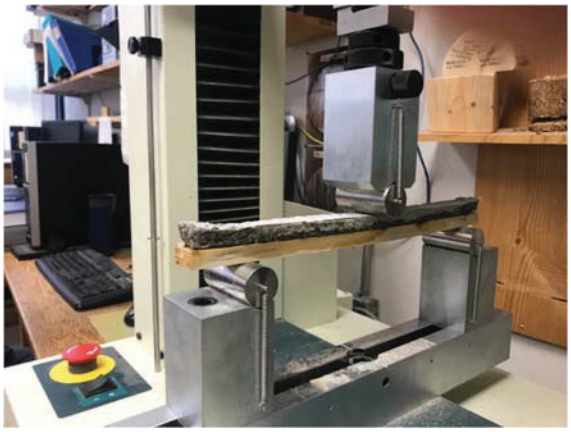

Figure 3: *Three-point flexure bending test with computer registered failure*

Samples were loaded until the machine detected a failure, as shown in Figure 4, during a compression test of a TCC column.

Once loading of a test specimen stopped, failure modes were observed and recorded. Based on the registered load and corresponding deflection, the MOE, MOR, and the compression resistance parallel to wood grain were all determined. Each group had 10 samples to ensure

reasonable consistency and thus, the co-efficient of variation (CV) was calculated to determine the relative consistency of the results.

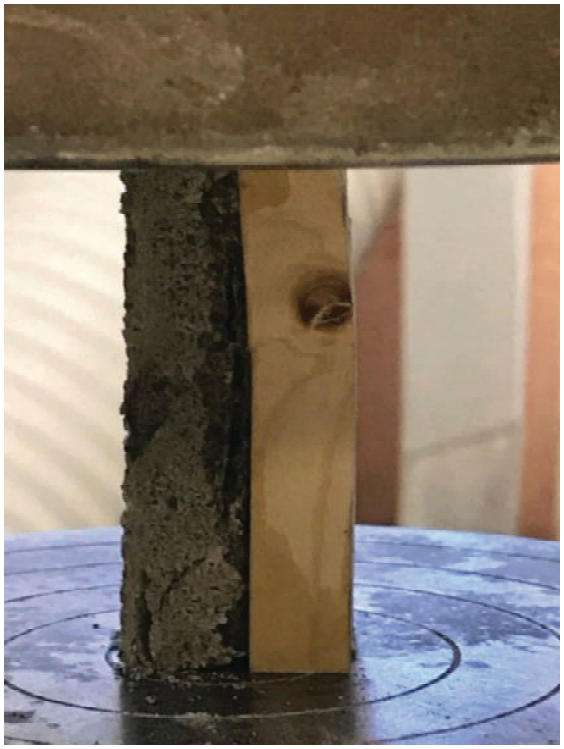

Figure 4: *Computer registered failure of a TCC column under compression*

2.4 MICROSCOPIC STUDY

In addition to the mechanical properties testing, a microscopic study was undertaken to observe the adhesive interface between black spruce lamina from the glulam section and to visually highlight its effectiveness. A Scanning Electron Microscope (SEM) provides high resolution images by using electrons to bombard a sample and interpret the measured results into a digital image. The Hitachi Su-70 Schottky Field Emission SEM used in this study is in the Wood Science and Testing Facility at Lakehead University. Small cubes measuring 1 mm on all sides were cut from the pieces that were used for sectioning with the microtone. The electrical nature of this type of microscope requires biological samples to be coated in gold before being placed in the machine.

Detailed features seen in the cross-sectional plane from the SEM imagery include resin canals, early wood, and latewood tracheid (the latewood cells being particularly small and dense), and the wood-glue-wood interface between laminates is seen in Figure 5.

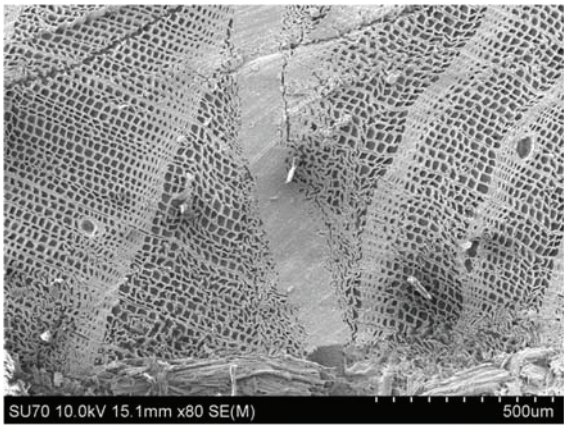

Figure 5: *Glulam SEM cross-section overview*

The SEM microscopy showed that many of the longitudinal tracheid are crushed and broken during the lamination process as can been seen in the cell walls near the glue line and within the glue, as shown in Figures 6 and 7.

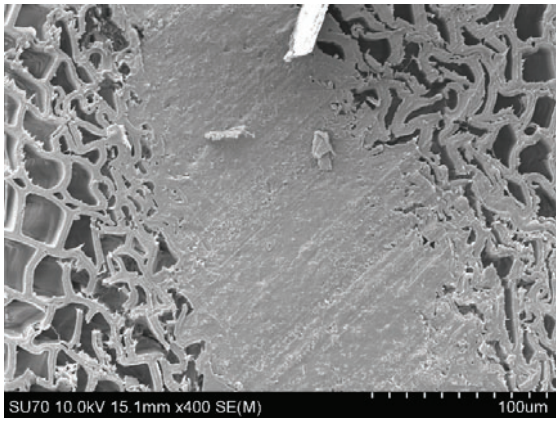

Figure 6: *Glulam SEM cross-section with glue line details*

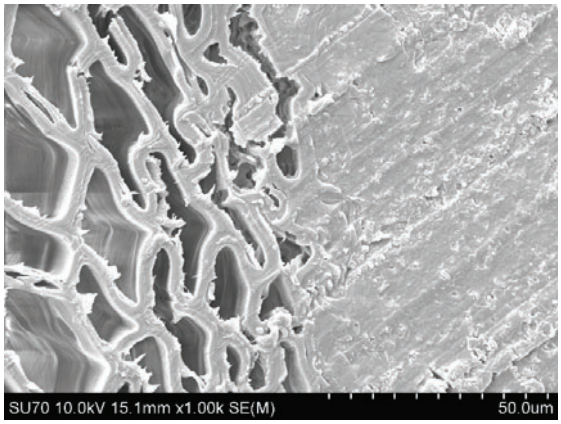

Figure 7: *Glulam SEM cross-section, glue-wood line detail*

The completeness of the wood-glue bond can be seen in Figure 8, where the glue is shown to seamlessly be bonded along the longitudinal tracheid cell walls both between the laminates and away from the glue line.

https://doi.org/10.52202/069179-0440

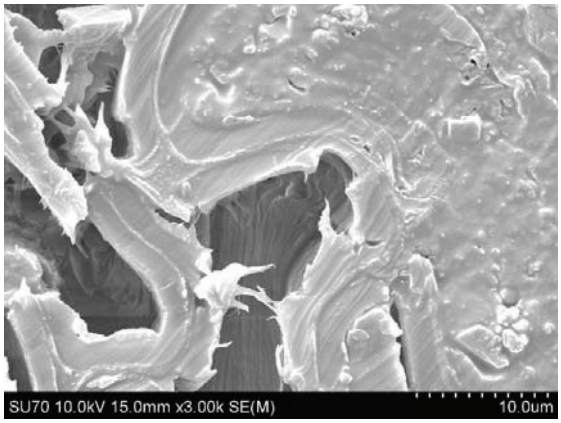

Figure 8: *Glulam SEM cross-section, showing glue-wood bond detail*

3 RESULTS

3.1 MECHANICAL

The MOE and MOR test results are summarized in Table 5; whereas Table 6 shows the compression test results. Test specimens in Group D from Table 5 used concrete from batch No. 1 and specimens in Groups E and F used concrete from batch No. 2.

Table 5: *MOE and MOR test results*

Group ID.	MOE		MOR	
	Value (MPa)	CV (%)	Value (MPa)	CV (%)
A (glulam)	19,990	9.6	95.3	10.6
B (glulam)	17,566	20.7	88.0	19.8
C (glulam)	10,957	12.7	85.8	9.8
D (TCC-dry, 28-day)	8,646	15.7	50.4	28.6
E (TCC-wet, 7-day)	6,327	21.8	31.7	13.4
F (TCC-wet, 28-day)	6,629	28.7	38.7	24.0

Table 6: *Compression column test results*

Group ID.	Value (MPa)	CV (%)
A (glulam)	48.6	5.3
B (glulam)	49.7	11.1
C (glulam)	46.0	9.8
D (TCC, 28-day)	27.2	22.5
E (concrete, 7-day)	7.64	26
F (concrete, batch 2, 28-day)	13.71	19.6
G (concrete, batch 1, 28-day)	20.4	18.7

The compression columns, from Table 6, tested in Groups D and G were made using concrete from batch No. 1, and concrete compression columns in Groups E and F were made using concrete from batch No. 2.

3.2 FAILURE MODES

3.2.1 Three-point flexure bending

In the three-point flexure bending tests, samples from Groups A, B and C all experienced brittle tensile failure in the wood, as shown in Figure 9. Group A had different break patterns than those of Groups B and C. Group A specimens would often see a tensile break across the bottom of only one lamina (half the width of the cross section due to the vertically oriented glue line). Failure in Groups B and C was characterized by a break across the width of the entire singular lamina (Figure 9). Typically, all failures occurred around a defect in the wood, such as a knot or a finger joint.

Figure 9: *Typical tensile failure mode in glulam samples*

Failure in the TCC beams almost always occurred in the concrete and was characterized by very sudden and brittle failure. Occasionally, some of the concrete at the adhesive bond would shear off after vertical or diagonal cracking appeared at the midspan, resulting in a section of the concrete flying away as the wood beam rebounded due to the load being removed by the machine after it detected the failure in the concrete, as shown in Figure 10.

https://doi.org/10.52202/069179-0440

Figure 10: *Sudden and brittle shear failure near the adhesive interface*

Other observed failures modes include local crushing in the top concrete layer near the point load (Figure 11), diagonal shear cracks in the concrete (Figure 12) or vertical separation above the adhesive interface indicating a reduced area of effective adhesive (Figure 13).

Figure 11: *Local crushing from compression near the applied load*

Figure 12: *Diagonal shear crack at failure*

Figure 13: *Shear along adhesive interface (indicative of epoxy quality control) with some shear failure in concrete*

A small number of TCC samples appeared to have failed due to tensile failure in the wood as seen in Figure 14.

Figure 14: *Tensile failure in wood component*

However closer inspection of these samples often showed small cracks in the concrete as seen in Figure 15, suggesting the concrete had failed and transferred the load to the wood, resulting in a tensile splitting failure.

Figure 15: *Shear crack visible in concrete close to tensile failure zone in timber*

https://doi.org/10.52202/069179-0440

3.2.2 Compression

For Groups A, B and C, the wood samples experienced typical compressive failure modes in the wood fibres as shown in Figure 16.

Figure 16: *Compression specimens from Groups A, B and C*

Failure in Group D, the TCC columns, was typically observed in the wood, after some cracking in the concrete, as shown in Figure 17.

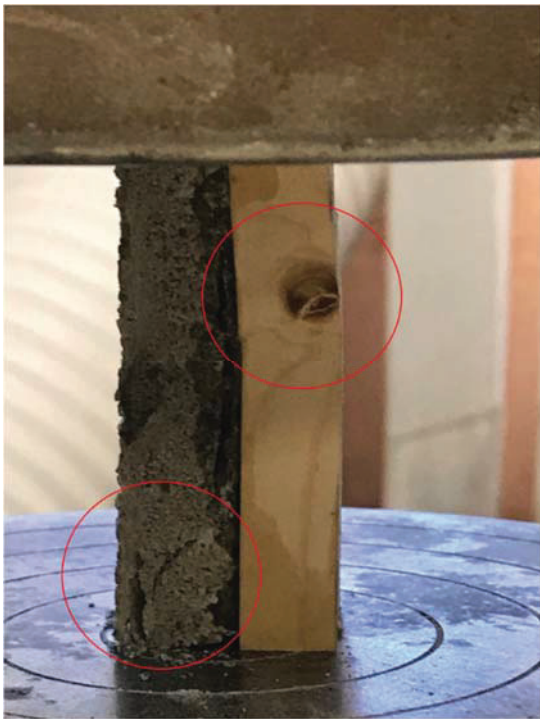

Figure 17: *Failure in timber and concrete in the composite column compression test*

This suggests that the failure of the timber after the concrete stopped contributing to the load-carrying capacity and thus, the load path progressed through the timber element only. The damage in the timber is around the circled knot, a stress concentration area, and the damage in the concrete is at the base, suggesting a bearing failure that crushed the concrete locally.

The small-scale concrete columns, typically failed without cone development and thus, failure predominantly followed vertical lines. This may have been due to the square shapes of the columns and their small size. In some cases, the column crumbled to very small parts as seen in Figure 18. The compressive strength of the small-size compression samples (Figure 18) was a more accurate representation of the concrete's compressive strength in the TCC flexure beams than the strength of the full-size compression test cylinders.

Figure 18: *Failure in timber and concrete in the composite column compression test*

4 DISCUSSION AND RECOMMENDATIONS

From the flexure bending tests results, specimens in Groups A and B had significantly higher MOE values than those in Group C, by a factor of 1.8 and 1.6, respectively. This suggests that adhesive bond between the lamina and orientation of the growth rings allowed for loading to be better distributed around defects in the lamina compared to the specimens in Group C which came from the same glulam section but were clear wood samples. The MOE, MOR, and compression resistance values for the clear black spruce samples in Group C were in line with the values found in literature for the same species of tree and harvest region [9]. The modulus of rupture in all three glulam groups was similar with an increase of 5% and 10% in MOR for Groups B and A, respectively. From the MOE and MOR results from Group A and B, it is shown that the presence of glue lines increased the MOE but not the MOR compared to the clear wood specimens in Group C, suggesting that small diameter black spruce elements glued together and tested at the small scale can model the increased stiffness of built-up timber sections used in full-scale testing.

https://doi.org/10.52202/069179-0440

The timber elements were moisture conditioned prior to application of the adhesive and bonding with fresh or dry concrete in line with previous experimental work on TCC elements [10]. Extensive shear tests have shown that in typical applications, failure will occur in either the timber or concrete elements before the adhesive if enough surface area is covered [11]. From the tests of the present study, it was seen that in all TCC bending tests the concrete elements failed. This was expected as the timber and concrete elements had equal cross-sectional areas under bending; however, the compressive strength of the concrete was appreciably lower than either the tensile or bending strength of the timber elements in the small-scale TCC beams.

While hundreds of samples at the small scale have been tested for shear strength in push-out tests, most large-scale tests of adhesively bonded TCC beams and slabs have a limited number of samples [12-15]. For the TTC elements, the MOE for specimens made with the wet-on-wet process at 7-days (Group E, Figure 19) and 28-day (Group F, Figure 20) were very close, and both values were significantly lower than the MOE for Group D with the dry-on-wet application method (Figure 21). However, the application method most likely did not reduce the MOE of these samples, rather the reduction in strength came from the difference in the concrete batches.

As seen in Figure 19, the samples at 7-days with the lowest strength of concrete, suffered significantly more damage to the concrete layer, with many of the sections separating. Of the 10 samples, 5 failed due to shear cracks in the concrete, followed by local shear failure in the concrete at the bond line, and the other 5 samples failed due to local crushing failure in the concrete.

In Group F (Figure 20), 1 of the 28-day wet-on-wet, specimens exhibited a severe shear crack followed by failure in the concrete at the glue line upon rebound of the wood sample. The 9 other samples failed with minor cracks in the concrete element or due to local crushing. Conversely, in the 28-day, dry-on-wet specimens, 3 exhibited a severe shear crack followed by failure in the concrete at the glue line upon rebound of the wood sample. The 7 other samples failed with minor cracks in the concrete and no local crushing failure in the concrete was seen. This suggests that at the small scale, a better bond was formed with the fresh concrete than the previously cast small-scale strips. As the compressive strength of the batch used in the wet-on-wet specimens was lower than in the dry-on-wet specimens, local crushing in the concrete was an observed failure mode in the former group and not in the latter group which all failed due to shear in the concrete element.

Figure 19: *7-day wet-on-wet MOE-MOR TCC beam specimen*

Figure 20: *28-day, wet-on-wet MOE-MOR TCC beam specimen*

https://doi.org/10.52202/069179-0440

Figure 21: *28-day, dry-on-wet MOE-MOR TCC beam specimens*

In compression tests, the samples with two laminae in the cross-section had an average increase in strength of 5%. The TCC columns had a compressive strength of 27.2 MPa, which was between the 46-49.7 MPa of the glulam groups and the 20.4 MPa of the concrete compression column from batch No. 1. This suggests that the adhesive bond with the wood element, with its higher compressive strength, increased the capacity of the column overall, in comparison to pure concrete columns made from the same batches of concrete. TCC compression samples consistently failed in the concrete elements as seen in Figure 22. The results show that there could be some potential in future programs studying the behaviour of prefabricated TCC wall panels.

Due to the potential for variability between wood elements, large numbers of specimens are required to increase the confidence in results, small scale testing if shown to be accurate with respect to full scale applications can allow for pilot studies to be conducted before a more expansive full scale testing program is designed.

Despite batch No. 1 and 2 of the concrete having similar compressive strength values with standard test size cylinders, the compressive strength values for batch No. 1 and 2 with small-scale compression specimens were 20.4 and 13.7 MPa, respectively. This can explain the reduction in the MOE and MOR values between the 28-day wet-on-wet specimens and the 28-day dry-on-wet specimens. To reduce the CV of the results and increase confidence of these observations, a greater number of samples are required.

Figure 22: *28-day, dry-on-wet compression specimens*

5 CONCLUSIONS

Adhesive can be used to develop a perfectly rigid (full composite action) TCC structural elements. However, quality control during the adhesion application process can be an issue. Also, brittle failure modes exhibited by TCC elements that utilized adhesive for shear connections are not desirable. Using small-diameter wood species and bonding them together with an adhesive can provide mechanical properties in accurate proportion to full-size mass timber elements which have greater mechanical properties than clear wood specimens. Small scale testing of adhesively bonded TCC elements can provide informative data before large scale testing at a reduced resource cost. Small scale concrete compression tests provide a more accurate picture of the compressive behaviour of the concrete in small-scale TCC flexure beams than the results obtained from a standard size concrete tests cylinder. The quality control of the dry-on-wet application method is better due to some potential displacement of adhesive, especially at the small scale, when placing fresh concrete on top of the epoxy.

EFFECT OF DIFFERENT TESTING METHODS ON THE STRUCTURAL PERFORMANCE OF WOODEN SHEAR WALLS

Yua Kosuge[1], Satoshi Onishi[2], Hideyuki Nasu[3]

ABSTRACT: The purpose of this study was to verify the effect of different testing methods on structural performance evaluation in in-plane shear tests with high-strength bearing walls. The results obtained from tie-rod type tests were used to verify the effects of axial force and placement of tie-rod on the performance evaluation of bearing walls. As a result, it was verified that axial force has almost no effect on the performance evaluation of bearing walls in general strength bearing walls. In the future, we will verify the effects of axial force and placement of tie-rod on the performance evaluation of bearing walls by changing the test specimen specifications.

KEYWORDS: Shear wall test, Column-base fixed type, Tie-rod type, Placement of tie-rod, Axial force of tie-rod

1 INTRODUCTION

In Japan, performance evaluation of bearing walls in wooden buildings is based on in-plane shear tests. There are two types of test methods: column-base fixed type and tie-rod type.

The column-base fixed type is a method of restraining lifting by attaching hold-down hardware to the legs of a bearing wall (Fig.1.1). This is currently the most used test method. However, when used for high-strength bearing walls, there is concern that the column-leg joints may fail prior to the end state of the bearing wall.

The tie-rod type is a method of restraining the lifting of bearing wall legs by using tie-rods (steel rods) (Fig.1.2). This test method is suitable for evaluating the performance of the bearing wall itself. This test method is often used for high-strength bearing walls.

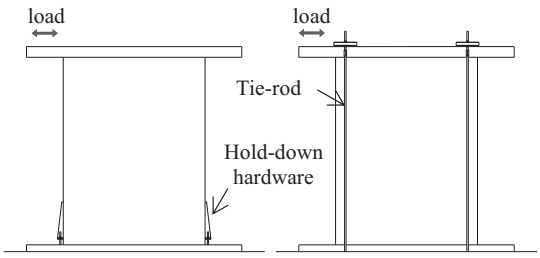

Fig 1.1: *Column-base fixed*

Fig 1.2: *Tie-rod type*

In recent years, high-strength bearing walls have been developed to promote the use of medium to large scale wooden buildings. Accordingly, the tie-rod type is increasingly used. However, it is not clear how different testing methods affect the performance evaluation of such high-strength bearing walls. The purpose of this study was to compare the results of tests conducted with column-base fixed type and tie-rod type, and to determine the effect of the different test methods on performance evaluation.

In the tie-rod type test method, it is common knowledge the restraint by the tie rods is such that no load is applied. The tie rods are often placed along the column core, but this depends on the test equipment and the test specimen specifications. It was thought that different axial forces and placements would affect the performance evaluation, but it was not clear how much they would affect it. Therefore, in the tie-rod type, the effects of tie-rod axial force and placement on performance evaluation were also examined.

2 SUMMARY OF RESEARCH

The purpose of this study was to verify the effect of different testing methods on structural performance evaluation in in-plane shear tests with high-strength bearing walls. In terms of the effect of restraint force on performance evaluation, differences in restraint force and left-right differences in restraint force have a slight effect on structural performance but almost no effect. Controlling the restraining force through torque management or other means would have less effect on performance evaluation. In terms of the effect of the different placements on the performance evaluation, the structural performance of the specimens with 200 mm different tie-rod placements was compared, and the results were almost the same, so there was no effect with differences in placement. In terms of the effect of the different test methods on the performance evaluation, the determinants of allowable shear strength were different, but the values were the same, so there was no effect of the final evaluation on the wall strength.

3 EFFECT OF AXIAL FORCE ON THE STRUCTURAL PERFORMANCE

3.1 VERIFICATION WITH GENERAL STRENGTH BEARING WALLS

First, the effect of the axial force of the tie rods on the performance evaluation of the bearing walls was verified. The specimens were compression braced load-bearing walls (Fig. 3.1,3.2). A total of four tie rods were placed along the column cores. The left front and left back tie rods restrained the uplift of the left leg, and the right front and right back tie rods restrained the uplift of the right leg. Initially, to understand the relationship between the tightening angle and the axial force of the tie rods, the axial force was measured when the nuts of the tie rods were tightened by hand and when they were tightened half a turn each using a tool. The results are shown in Fig. 3.3 and Table 3.1. The total axial force for both the left and right sides was less than 1kN when hand tightened. At 1260- degree, the left axial force was about 36kN and the right axial force was about 44kN, with the right axial force tending to be higher. This is considered due to the distortion of the specimen and the order of tightening.

Next, in-plane shear tests were performed with the tie-rods tightened to the limit (1260-degree). The test results are shown in Table 3.2. While the wall magnification was equivalent to 2.5, the result was 2.8. Considering that a total axial force of about 80kN was applied, the axial force has almost no effect on the performance evaluation of bearing walls.

3.2 VERIFICATION WITH HIGH-STRENGTH BEARING WALLS

The test specimens were two specifications. One is framework construction method bearing walls and the other is framed wall construction method bearing walls (Fig.3.4,3.5). Three specimens were used for each.

For the framework construction method bearing walls, 9mm plywood (JAS A class 2) was attached using CN50 nails at a pitch of 150mm in the middle passage and 75mm in the perimeter. For the framed wall construction method bearing walls, 9mm plywood (JAS A class 2) was attached using CN50 nails at a pitch of 200mm in the middle passage and 50mm in the perimeter.

https://doi.org/10.52202/069179-0441

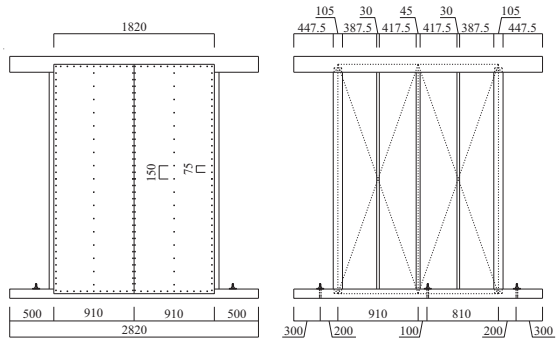

Fig 3.4: *Framework construction method bearing wall*

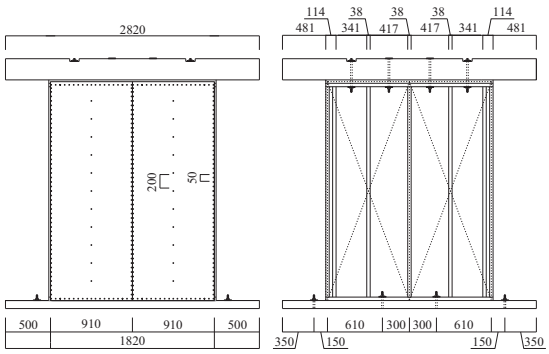

Fig 3.5: *Framed wall construction method bearing wall*

Table 3.3: *Measured results of restrained axial force*

		Left axial force [kN]	Right axial force [kN]	Left-Right differences [kN]
Framework construction	1. Hand-tightened	3.63	3.74	0.11
	2. Half-turn	14.80	16.86	2.06
	3. Axial force 20kN	20.91	20.61	0.30
Framed wall construction	1. Hand-tightened	3.19	2.59	0.60
	2. Half-turn	17.86	12.83	5.03
	3. Axial force 20kN	22.51	21.62	0.89

Installation for tie rod type is shown in Fig.3.6,7. There are three test conditions. One is when the tie rods are hand-tightened, another is when they are hand-tightened and then tightened a half-turn using a tool, and the third is when they are tightened until the axial force per column reaches 20 kN (the long-term design axial force for a typical Japanese house). Table 3.3. shows the measured results of the restrained axial force at each condition.

The tie rod type in-plane shear test was performed using a load frame tester in Nippon Institute of Technology (Fig.3.6,7). The loading method is repeated three times in alternating positive and negative, and the loading cycle is apparent shear deformation angle 1/600, 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50, 1 / 30 rad. (Only 1/30 rad was repeated once). The tie rod test was repeated when the true shear deformation angle, which is the apparent shear deformation angle minus the deformation angle due to the rotation of the leg, reached each specific deformation angle.

Fig 3.6: *Framework construction method bearing wall*

Fig 3.7: *Framed wall construction method bearing wall*

Table 3.4,3.5 and Fig 3.8,3.9 shows the test results for each specification.

The load-displacement curve for the three conditions for the framework construction method bearing wall were almost identical. All allowable shear strengths (Pa) were determined by Pu (0.2/Ds). Compare the hand-tightening case with the half-turn and 20 kN cases. Compared the allowable shear strengths (Pa), the hand-tightening with half-turn and 20 kN cases. The value was 20% lower in the hand-tightening case. This is because Pu had the highest value, but Ds had unfavorable values. Compared to the fracture properties, the plywood peeling was total for the half-turn and 20 kN cases, whereas it was partial for the hand-tightened case. Compared the allowable shear strengths (Pa), the half-turn and 20 kN cases. The values were equivalent. The fracture properties were both plywood peeling, and the degree of plywood peeling was similar. Compared with hand-tightening and half-turn, 20 kN cases shows that the difference in initial restraint force affects the performance evaluation. Although there was a difference of approximately 10 kN in the restraint force between the half-turn and 20 kN, the allowable shear capacity was equivalent. Therefore, we believe that above a certain level of restraint force, there is no significant difference in performance.

https://doi.org/10.52202/069179-0441

The load-displacement curves for the framed wall construction method bearing walls were almost identical for the hand-tightened and 20 kN cases but differed for the half-turn case. All allowable shear strengths (Pa) were determined by Pu (0.2/Ds). In the case of half-turn, both Pu and Ds showed unfavorable values, resulting in lower values of allowable shear strengths (Pa) than during the other conditions. In the half-turn case, there was nail penetration but little damage to the plywood. In the case of hand-tightened and 20 kN, nail pull out and punching out occurred, and damage to the plywood was significant. The reason why the half-turn case resulted differently from the other conditions was due to the balance between the left and right restraining axial forces. In the case of half-turn, there was a relatively large left-right difference in restraint force, with a lower value for the right restraint force, which affects the time of final failure. The load-bearing wall tended to lift during other conditions, and the load-bearing wall rotated as one piece. Therefore, the allowable shear capacity showed low values due to low initial stiffness and unfavorable toughness.

4 EFFECT OF TIE-ROD PLACEMENT

4.1 TEST OVERVIEW

The effect of the placement of the tie rods on the performance evaluation of the bearing walls was verified. In-plane shear tests had different tie-rods placement. The test results of the previous research were compared again,

https://doi.org/10.52202/069179-0441

and a new perspective on the effect of the placement of the tie rods on the performance evaluation of the bearing walls was verified.

4.2 TEST SPECIMENS AND TEST METHODS

The tie rod type in-plane shear test was performed using a load frame tester in Nippon Institute of Technology (Fig.4.1,4.2). The loading method is repeated three times in alternating positive and negative, and the loading cycle is apparent shear deformation angle 1/600, 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50. The tie rod test was repeated when the true shear deformation angle, which is the apparent shear deformation angle minus the deformation angle due to the rotation of the leg, reached each specific deformation angle.

Fig 4.1: *Placement of tie rod (First and second specimens)*

Fig 4.2: *Placement of tie rod (Third specimens)*

4.3 TEST RESULTS

Table 4.1 shows the test results and Figure 4.3 shows the load-displacement curves. The allowable shear strengths (Pa) were determined by the yield strength, Py, for the first specimen, and by the toughness value, Pu (0.2/Ds), for the second and third specimens. The load-deformation angle curves at ultimate failure were different for the first, second, and third specimens. These differences were due to different factors of fracture properties. Since the results of the first specimen were different from those of the other specimens, a comparison of the second and third specimens was conducted to verify the effect of the different placements on the performance evaluation. The load-displacement curves were almost identical. The allowable shear strengths (Pa) showed 11.6 for the second and 10.2 for the third, a difference of about 10%. The left and right restraints at 1/600 rad. were generally in agreement. The left restraint force at 1/50 rad. was generally consistent. The right restraining force showed approximately 167 kN for the second body and 212 kN for the third body, a difference of about 20%. However, the differences in determinants and allowable shear strengths (Pa) were all about 10%, and the load-displacement curves and fracture characteristics were almost identical, suggesting that the differences in tie-rod placements had little effect on the performance evaluation of the bearing walls.

Table 4.1: *Test results*

	First	Second	Third
K [kN/rad.]	13084.3	12331.8	12972.2
Pmax [kN]	87.9326	83.58	82.24

5 EFFECTS OF DIFFERENT TEST METHODS

5.1 TEST SUMARY

The effects of different testing methods for in-plane shear tests on the performance evaluation of load-bearing walls. The influence of the different test methods is verified by comparing the results of in-plane shear tests using the fixed column leg and tie-rod methods.

https://doi.org/10.52202/069179-0441

5.2 TEST METHODS

The tie rod type in-plane shear test was performed using a load frame tester in Nippon Institute of Technology (Fig.5.1,5.2). The loading method is repeated three times in alternating positive and negative, and the loading cycle is apparent shear deformation angle 1/600, 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50. The tie rod test was repeated when the true shear deformation angle, which is the apparent shear deformation angle minus the deformation angle due to the rotation of the leg, reached each specific deformation angle.

Fig 5.1: *Specimen installation state (Column-base fixed type)*

Fig 5.2: *Specimen installation state (Tie-rod type)*

5.3 TEST RESULTS

The load-displacement curves are shown in Figure 5.3 and the test results are in Table 5.1,5.2. The allowable shear strengths (Pa) were 10.21 kN and 10.47 kN for the column-base fixed type and tie-rod type, respectively, with the tie-rod type showing a slightly higher value. The allowable shear strengths (Pa) were determined by 0.2Pu $\sqrt{(2\mu-1)}$ for the fixed column leg method and Py for the tie-rod method, and the determining factors differed depending on the test method. Comparing the determinants, only 0.2Pu$\sqrt{(2\mu-1)}$ is higher for the tie-rod type. The other determinants were higher for the column-base fixed type. Since the column-base fixed type showed more favorable performance in terms of bearing capacity and the tie-rod type showed more favorable performance in terms of toughness, the different test methods are considered to have an influence on the performance evaluation. However, since the allowable shear strengths (Pa) values were comparable, we believe that the different testing methods have little effect on the final evaluation.

Table 5.1: *Test results*

	Column-base fixed type	Tie-rod type
K [kN/rad.]	1395.30	1696.49
Pmax [kN]	17.37	16.02
Pu [kN]	16.05	14.55
δv [rad.]	0.011	0.008
δu [rad.]	0.063	0.062
Ds	0.314	0.270

Table 5.2: *Determinants of allowable shear strengths*

	Column-base fixed type	Tie-rod type
Py	11.20	10.47
Pu*(0.2/Ds)	10.21	10.75
2/3Pmax	11.58	10.68
Pγ	11.42	11.01
Pa (kN)	10.21	10.47

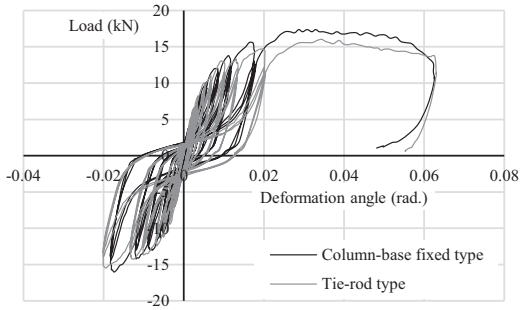

Fig 5.3: *Load-displacement curve*

5.4 SUMMARY

Although the determinants were different, the allowable shear strengths (Pa) were almost identical. Therefore, the differences in test methods affect the performance evaluation but have little effect on the final allowable shear strengths (Pa) evaluation.

6 CONCLUSION

In terms the effect of restraint force on performance evaluation, differences in restraint force and left-right differences in restraint force have a slight effect on structural performance but almost no effect. Controlling the restraining force through torque management or other means would have less effect on performance evaluation. In terms of the effect of the different placement on the performance evaluation, the structural performance of the specimens with 200 mm different tie-rod arrangements was compared, and the results were almost the same, so there was no effect with differences in placement. In terms of the effect of the different test methods on the performance evaluation, the determinants of allowable shear strength were different, but the values were the same, so there was no effect of the final evaluation on the wall strength.

DEVELOPMENT OF HIGH STRENGTH BEARING WALLS FOR FRAMEWORK CONSTRUCTION METHOD USING 2X4 LUMBER AND PLYWOOD MADE OF JAPANESE TIMBER

Hideyuki Nasu[1], Kenji Aoki[2], Hiro Kawahara[3]

ABSTRACT: The purpose of this research is to develop a high strength bearing wall for the framework construction method using Japanese frame material and Japanese plywood. To achieve this, it is necessary to consider the combination, or balance, of plywood thickness, wood species, frame materials and type of nails. At first, single shear tests were performed on the nail joints, then the optimum combination was determined by modelling. After that, the performance of the walls was verified with in-plane shear tests using full-scale bearing walls. It was found that when the wall legs are joined to the ground with metal joints, a brittle fracture has occurred at the metal joint. Therefore, by changing the test method from the column fixed type to the tie rod type without using metal joints, column base breakage was prevented and the high strength performance of the shear wall itself was confirmed.

KEYWORDS: Framework construction method, Single shear tests, In-plane shear tests, Fixed column base, Tie rod

1 INTRODUCTION

Wooden public buildings are increasing popularity. In public buildings, a large space is often required, and research on load-bearing walls using structural plywood that can produce a high-strength load-bearing walls with easy construction has been promoted. At present, a lot of Japanese timber is being harvested and it is thought that effective utilization of this timber and the additional higher value will stabilize Japan's supply and demand of timber and stimulate forestry. However, most of the frame materials are imported materials, such as SPF, and domestic materials are rarely used. Therefore, one of the effective uses for domestic large-diameter materials is the use of the frame wall construction method for frame materials.

2 SUMMARY OF RESEARCH

We intend to develop a type of high strength frame wall construction bearing wall using domestic frame material and domestic plywood for public buildings. In order to realize this, it is necessary to consider the plywood thickness, the combination of the tree species, the frame material, and the type of nails. Therefore, after examining the optimum combination for the bearing walls from single shear tests with nail joints, in-plane shear tests (column base fixed type and tie rod type) were conducted on the actual bearing walls. The target performance is 10 times the wall strength ratio of the Japanese building code regulations, 1.96 kN/m horizontal allowable load/length of wall performance.

3 SINGLE SHEAR TESTS

3.1 SUMMARY OF EXPERIMENTS

Test bodies were made using 2×6 cedar as the center materials and plywood as the side materials (Fig. 1). The number of test specimens were 54 in total, 6 in each of 9 specifications with varying plywood thickness and tree species. Three types of plywood were selected: cedar (C), larch (L), and cedar-larch mixed plywood (M). The combination of plywood and nails were CN50 nails for 12 mm thick, CN65 nails for 15 mm thick, and CN75 nails for 24 mm thick for the purpose of exhibiting excellent one-side shear performance. The tests were performed monotonically using a 50 kN universal testing machine at Nippon Institute of Technology. The loading time was such that the time to reach the maximum load was 5 minutes ± 2 minutes. The displacement was determined by measuring the relative displacement between the frame material and the both side of plywood for recording the average.

3.2 EXPERIMENTAL RESULTS

Table 1 shows the average and standard deviation of the experimental results of each specification, and Fig. 2 to 4 show graphs of the experimental results. Note that the test results are values for one nail. For the cedar plywood and the mixed plywood, the average value of maximum loads and allowable test stress were increased in proportion to the thickness of plywood (Table 1). The results were as follow. With larch plywood the test specimen with 15 mm thickness had similar load and maximum stress to the specimen with 24 mm thickness. In the case of cedar and composite plywood, there were many indentations and punching out of nail heads (Fig. 5 and 6). In larch plywood, bending deformation of nails was common (Fig. 7).

4 MODELING BEARING WALLS

Assuming a wall panel with a width of 1820 mm and a height of 2460 mm, the calculation was performed assuming that the nail distance of the face material was 50 mm and 75 mm. The yield strength of one nail was determined from the test average value obtained in the experiment in 3 SINGLE SHEAR TESTS, and the allowable shear strength as a load-bearing wall was determined therefrom (Fig. 8 and 9). The wall magnification is obtained by multiplying the allowable shear strength of the load-bearing wall by the reduction factor due to toughness as the short-term allowable shear strength. Among these, the C-24, L-15, L-24, and M-24 specifications with each nail distance of 50 mm and the L-24, M-24 specifications with each nail distance of 75 mm are predicted to be high strength bearing walls (Table 2).

5 COLUMN BASE FIXED TYPE IN－PLANE SHEAR TESTS

5.1 OUTLINE OF TEST SPECIMEN

The dimensions of the test specimen were 1820 mm (2P) in wall length and 2400 mm in wall height for wooden surface materials (Fig. 10). The framing material used was 204 cedar wood (JAS A class 2). Normally, there is only one vertical frame between panels, but with high strength load-bearing walls, the spacing between nails for holding plywood is narrow, and the vertical frame may be damaged. Therefore, the vertical frames between the panels were joined together and fastened with CN75 nails in a 300 mm distance staggered arrangement. In the same way, the orientation of the torso was changed to horizontal use to make it harder to break. The specifications of the bearing wall are 3 of C-24 specification using cedar 24 mm plywood material, L-15 specification using larch 15 mm plywood material, and L-24 specification using 24 mm larch plywood material. In the L-15 and L-24 specifications, the each nail distance for securing the vertical frames were changed to double-rows with CN75 nails 100 mm distance. For the joint connectors, HD metal joints with the short-term reference strength of 60 kN were used for the column pedestal, and HD metal joints with the short-term reference strength of 40 kN were used for the column base fixed type tests.

https://doi.org/10.52202/069179-0442

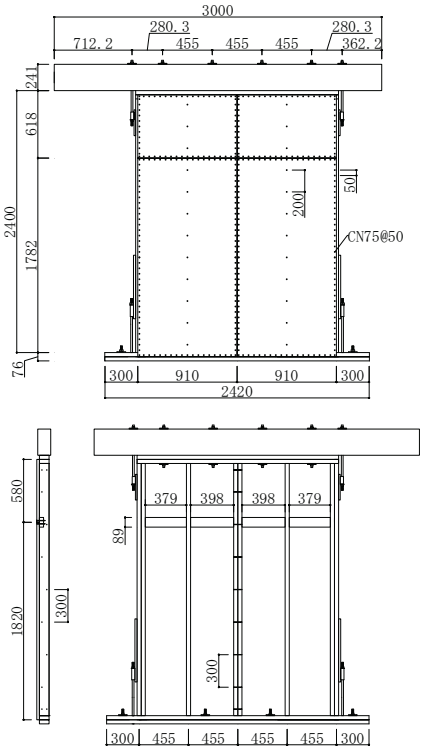

Fig. 10 *C-24 specification test body*

5.2 TESTS METHOD

The column-base fixed type in-plane shear tests were performed using a load frame tester in Nippon Institute of Technology (Fig. 11). The loading method was repeated three times in alternating positive and negative, and the loading cycle was apparent shear deformation angle 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50, 1 / 30 rad. (only 1/30 rad. was repeated one time).

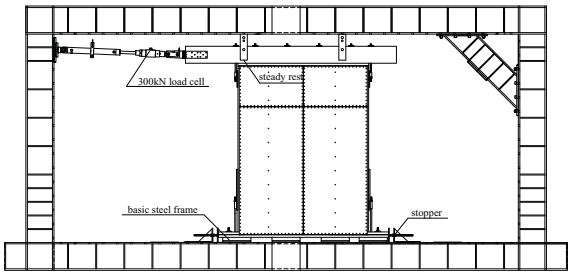

Fig. 11 *Specimen installation state*

5.3 EXPERIMENTAL RESULTS

Tables 3 and 4 show the experimental results for each specification, and Fig. 12 shows a graph of the test results. Comparing the structural performance of the three specifications, the initial stiffness and maximum load were in the order of L-15, L-24, and C-24. However, when compared by wall magnification, the C-24 specification, L-15 specification, and L-24 specification were in descending order. In the case of the C-24 specification, in which the nails of the vertical frame were placed as usual, the vertical frame between the panels was greatly displaced, and the outer vertical frame caused bending failure at the time of tearing (Fig. 13, 14). In L-15 and L-24, because the number of nails between panels was increased, the displacement of the vertical frame was suppressed, but aggregated shear failure of the vertical frame was induced at the wall legs (Fig. 15, 16).

5.4 COMPARISON OF TEST RESULTS AND MODELING

A comparison of the modeling and test results showed that all specifications were below the wall magnification of the modeling (Table 5). It is considered that the wall magnification of the test was lower than the estimated value due to the occurrence of brittle collective failure and the sinking at the upper and lower ends of the vertical frame, which was ignored in the calculation. In addition, in the modeling, it is assumed that the joint is destroyed, but in the experiment assuming high magnification, such as in this study, the frame material was destroyed.

https://doi.org/10.52202/069179-0442

Therefore, when the wall magnification was calculated from the yield load that was not affected by the fracture and compared with the estimated results, the results were almost similar.

Table 5 *Comparison of wall magnification*

Specimen name	C-24	L-15	L-24

Wall magnification calculated from Py	9.11	10.25	9.03

5.5 SUMMARY OF COLUMN BASE FIXED TYPE IN-PLANE SHEAR TESTS

When more nails were struck into two vertical frames, the force concentrated on the metal joint, causing collective destruction of the metal joint. In order to achieve a wall magnification of 10 times, it is necessary to consider the number of nails that hold the panels together and the metal joint that suppresses collective destruction.

6 TIE ROD TYPE IN-PLANE SHEAR TESTS

6.1 SUMMARY OF EXPERIMENTS

When the degree of fixation of the vertical frame increased from the destructive properties in Fig.16, collective destruction of the outer vertical frame occurred. It is considered that the stress is concentrated on the wall bases due to the increased wall strength. The performance of the bearing wall itself could not be verified with the fixed column base, and there was concern that the wall strength would be determined by the performance of the metal joint. In order to grasp the performance of the load-bearing wall itself, it is necessary to conduct an experiment that does not break the column base metal joints before the wall itself. Therefore, a tie rod type in-plane shear test was carried out in which the lifting of the load bearing wall legs was suppressed with a tie rod. The tie rod type in-plane shear test is suitable for evaluating the shear performance of the load-bearing wall.

6.2 OUTLINE OF TEST SPECIMEN

From the modeling of wall magnification in 4 MODELING BEARING WALLS, tie rod type tests were performed with C-24 specification, L-15 specification and L-24 specification. In the case of the tie rod type, it is described as TC-24 specification, TL-15 specification, TL-24 specification, and the number of test specimens was one each.

6.3 TEST METHOD

The tie rod type in-plane shear test was performed using a load frame tester in Nippon Institute of Technology (Fig. 17). The loading method was repeated three times in alternating positive and negative, and the loading cycle is apparent shear deformation angle 1/600, 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50, 1 / 30 rad. (only 1/30 rad. was repeated one time). The tie rod test was repeated when the true shear deformation angle, which is the apparent shear deformation angle minus the deformation angle due to the rotation of the leg, reached each specific deformation angle.

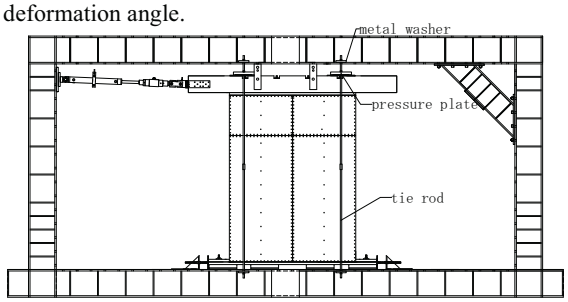

Fig. 17 *Specimen installation state*

6.4 EXPERIMENTAL RESULTS

Tables 6, 7 show the experimental results for each specification, and Fig. 18 shows a graph of the test results. In the TC-24 and TL-15 specifications, measurement was not possible until the end due to measurement failure. In TL-24, the wall magnification was determined by Py, and the value was 8.61 times. Comparing the TL-24 with the other two specifications, the one with the highest rigidity and maximum load was the TL-24 specification, so it is considered that the other two specifications will not perform any better. When confirming the fracture properties, the entire bearing wall showed rocking behaviour, cracks occurred in the lower frame from deformation after 1/50 rad. (Fig. 19, 20). In all specifications, cracks were caused by nails hit into the lower frame at the final failure. This failure could reduce the ultimate performance of the walls.

6.5 OVERVIEW OF ADDITIONAL TEST

An additional test was performed to find a specification that can exceed the wall magnification by 10 times, because the target specification did not exceed the target wall magnification of 10 times. The nails were placed in one low frame material, thus the nail interval became shorter, then frame material was broken. Therefore, it was thought that cracking of the framed material could be prevented by staggering the nails between the vertical frames. In addition, since the frame material can be connected not only with nails but also with plywood, it is considered that rigidity and strength can be improved. We set the TL-24W specification (Fig. 21). The TL-24W specification uses a zigzag arrangement of 75 mm nails to hold the plywood, so that more nails can be hit than a 50 mm distance single row arrangement, while keeping the gaps between nails and preventing the nail spacing from becoming shorter. Since there were originally two vertical frames between panels, nails were struck in one vertical frame in a staggered arrangement. As a result of estimating the wall magnification by the method described in 4 MODELING BEARING WALLS before starting the final version of test, wall magnification was estimated 19.33 times. The test method was the same as in Section 6.3.

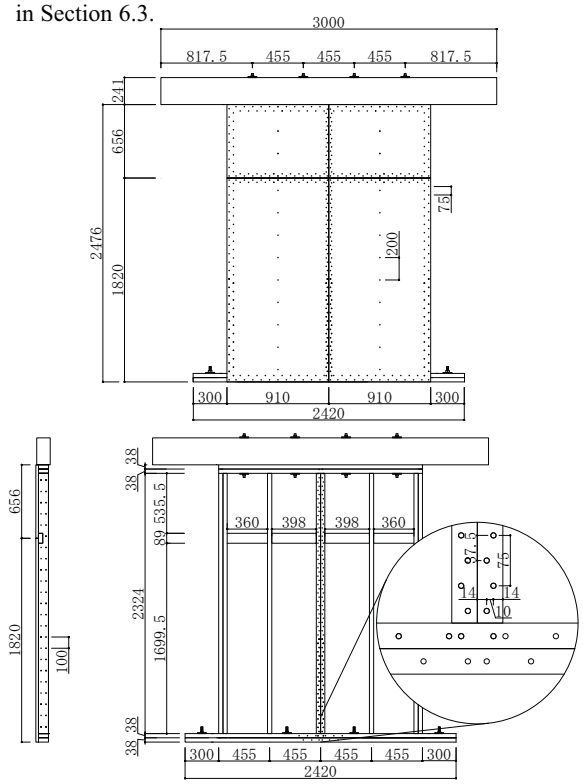

Fig. 21 *TL-24W specification test body*

6.6 ADDITIONAL TEST RESULTS

Tables 8, 9 show the experimental results for each specification, and Fig. 22 shows a graph of the test results. The TL-24W specification showed higher structural performance than the TL-24 specification from the beginning of deformation. This is considered to be due not only to an increase in the number of nails, but also to an increase in rigidity caused by connecting the frame members with plywood. When the fracture properties were confirmed, the vertical frame protruded from the minute deformation (1/450 rad.) because the bearing wall exhibited rocking behavior (Fig. 23). This is probably because the rigidity of the wall itself has increased and the legs have been rotated without deforming the wall. When the interlaminar deformation angle reached 1/50 rad., cracks occurred in the lower frame, although slightly less than before (Fig. 24). It is considered that the reason why the wall magnification of the experiment was lower than that of the modeling is that the deviation between the vertical frames from the initial stage of deformation is more remarkable than before, even though the vertical frame sinks (Fig. 25 and 26). However, the structural performance reached 12.39 times, exceeding the target wall magnification of 10 times.

6.7 SUMMARY OF TIE ROD TYPE IN-PLANE SHEAR TESTS

Even in the case of a shear wall test with a wall magnification of about 10 times, which was the target in this study, the performance of the shear wall itself could be evaluated by changing the test method to a tie rod type. In actual design, it is conceivable to prevent breakage in the vertical frame by increasing the number of vertical frames according to the pulling force acting on the vertical frame and installing appropriate HD metal joints.

7 CONCLUSION

Through this research, it was possible to realize a high-strength framework construction method wall (equivalent to a wall magnification of 10 times the wall strength ratio of the Japanese building code) using domestic Japanese cedar framing materials and Japanese plywood that are commercially available, without using special tools or special materials. Also, within the scope of this research, to make higher structural or fully effective performance of the surface material, two vertical frames between the panels were joined, nailing to the head joint and base through plywood, it is necessary to increase the degree of fixing between the vertical frames between panels. The tie rod type test method is better than the column base fixed type test method for verifying higher performance wall, such as 10 times the wall strength ratio of the Japanese building code regulations using Japanese timber.

ACKNOWLEDGEMENT

This research was carried out by the “Innovative Technology Creation Promotion Project in JAPAN through Field for Knowledge Integration and Innovation”. These experiments were conducted by Mr. Daiki Kato, a master's course student at Nippon Institute of Technology. We would like to thank all those involved.

IMPACT OF EXTERIOR SIDING WALLS AND THE CONNECTING METHODS IN WOODEN HOUSES: COMPARATIVE VERIFICATION FOR STRUCTURAL PERFORMANCE WITH DIFFERENT CONNECTION METHODS OF WALL SIDINGS

Kouta Matsumoto [1], Kiyotaka Terui [2], Hideyuki Nasu [3]

ABSTRACT: In recent years, siding has been widely used for the exterior walls of Japanese houses. There are two methods of installation: nailing (hereinafter referred to as "nailed SD") and hooking with metal fittings (hereinafter referred to as "hooked SD"). Previous research [2] shows that nailing bears about 10% of the external force, but it is not clear how much external force is borne by the hooked SD. In this study, we will examine the extent to which a hooked SD bears the external force in terms of wall magnification. The objective was also to elucidate the contribution of the SD itself to the wall magnification. The specimens were subjected to static force tests to extract the structural performance of each load-bearing element. Static force tests revealed the following results compared to the nailed SD, which was the mainstream method at the time. The present mainstream hooked SD was found to have reduced bearing capacity.

KEYWORDS: Wooden Houses, Exterior Materials, Sidings, Static Force Tests, Non-structural Members

1 INTRODUCTION

There are two methods of finishing the exterior walls of wooden houses: wet methods, such as mortar exterior walls, and dry methods, such as siding (hereinafter referred to as "SD"). Wet methods have been commonly used in the past, but in recent years, dry methods have been widely used in order to shorten the construction period and to address the shortage of skilled workers. There are two types of installation methods for ceramic-SD: Nailed SD (Figure 1) and Hooked SD (Figure 2).

In the past, nailed SD was the most common method, but cracks and defects occur around the nails due to inter-story deformation caused by external forces such as earthquakes. However, since hooked SD does not cause major visible damage such as cracks and defects like nailed SD, hooked SD is currently the most common type of SD. However, since hooked SD is a method in which the SD is hooked to the joints, it is considered to have almost no ability to restrain the interstory deformation of the frame against external forces such as seismic forces, and there is concern that the actual bearing capacity may be reduced.

The Architechal Institute of Japan [1] states that 2/3 of external forces such as seismic forces are borne by bearing walls and 1/3 by non-bearing walls such as SD. The same style for [2] states that nailed SDs bear about 10% of the external force. The same style for [3] and other full-scale experiments have also been conducted, but it has not been clarified how much external force is borne by hooked SDs.

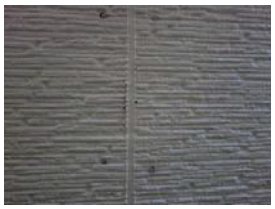

Figure 1: *Nailed SD*

Figure 2: *Hooked SD*

2 OBJECTIVE

The purpose of this study is to determine how much external force is borne by a hooked SD in terms of wall modulus by subtracting the structural performance of the bearing wall itself from the structural performance of the bearing wall to which the SD has been applied. The purpose of this study is to clarify the contribution of the SD itself to the wall ratio.

3 SUMMARY OF RESEARCH

3.1 TEST SPECIMEN SUMMARY

In order to extract the structural performance of each load-bearing element, the test specimens were constructed using the Single-sided fascia (Figure 3) and Single-sided plywood (Figure 4) specifications as load-bearing walls, as well as the Nailed SD (Figure 5) and Hooked SD (Figure 6) specifications with the SD fastened to the frame to grasp the structural performance of the different

https://doi.org/10.52202/069179-0443

fastening methods for ceramic SD, a dry construction method.

In addition, in order to understand the bearing capacity of the SD when installed in a load-bearing wall, tests were conducted using six specifications: a Single-sided fascia specification with SD fastened to the Single-sided fascia specification and a Single-sided fascia + nailed SD specification (Figure 7), and a Single-sided fascia specification with SD fastened to the Single-sided fascia + hooked SD specification (Figure 8). The test specimens were conventional wooden walls with a core width of 3640 mm for columns and a core distance of 2730 mm for transverse members, with 105 mm square cross sections for columns and foundations, 105 mm x 30 mm for studs, 180 mm x 105 mm for beams, and 90 mm x 45 mm for braces. In order to suppress bending deformation of the beams and pull out of the columns due to up thrusting of the braces, which bear the compressive force, yamagata plates were attached to the top and bottom ends of the middle columns that are connected to the transverse members on the back of the specimens.

The thickness of SDs was 14 mm for nailed SDs and 15 mm for hooked SDs, and joints were made with joints dedicated to each SD (Figures 9 and 10).

3.2 EXPERIMENTAL SUMMARY

The static in-plane shear static force test was conducted using a force frame tester at the POLUS R&D Center of Life Style with a fixed leg using three repetitive positive-negative alternating cycles of force as described in The same style for [4] (Figure. 11 and 12). The applied force was controlled by displacement, and three push-pull cycles of 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, and 1/50 rad. were performed, and only those that could be applied up to 1/30 rad. were pushed and pulled once. Thereafter, pull-destruction was performed with a target of 1/15 rad. The deformation for each interlaminar deformation angle that was repeated is shown in Table 1.

Table 1: *Deformation for each interlaminar deformation angle*

Interstitial deformation angle (rad.)	1/450	1/300	1/200	1/150
Amount of deformation (㎜)	6.06	9.10	13.65	18.20
Interstitial deformation angle (rad.)	1/100	1/75	1/50	1/30
Amount of deformation (㎜)	27.30	36.40	54.60	91.00

3.3 EVALUATION METHOD

The SD contribution ratio is calculated by dividing the wall ratio of the wall with SD installed by the wall ratio of the single-sided fascia bearing wall specification; the SD contribution ratio is calculated by dividing the wall ratio of the single-sided fascia bearing wall specification with SD installed by the wall ratio of the single-sided fascia bearing wall specification. The burden ratio was calculated by dividing the contribution ratio by the wall ratio of the single-sided fascia bearing wall specification with SD installed.

4 EXPERIMENTAL RESULTS

The relationship between load and horizontal displacement for each specification is shown in Figures 13~16, and the Pa determinants and calculated wall factors for each specification are shown in Table 2. The wall magnification of the Single-sided fascia specification was 2.18 times compared to the assumed wall magnification (2.00 times), which is almost equivalent. The wall factors for walls with SDs constructed using different fastening methods were 1.14 times for the Nailed SD specification and 0.28 times for the Hooked SD specification. In addition, the wall-to-wall ratio of the Single-sided fascia + nailed SD specification, in which SD was fastened to the Single-sided fascia wall, was 4.08x, which was much higher than the value obtained by adding the wall-to-wall ratios of the Single-sided fascia and nailed SD specifications (3.32x). The value of 2.39 times for the Single-sided fascia + hooked SD specification was almost equal to 2.46 times, which is the value obtained by adding the wall factors for the one-sided rebar and hooked SD specifications. The single-sided plywood specification showed a wall factor of 2.50 times, the same as the assumed wall factor.

The nailing SD itself was converted to a wall factor of 1.90 times and the burden ratio was 46.5%, while the hooking SD itself was converted to a wall factor of 0.21 times and the burden ratio was 8.7%.

5 COMPARISON AND DISCUSSION

5.1 SINGLE-SIDED FASCIA SPECIFICATION AND SINGLE-SIDED FASCIA + NAILED SD SPECIFICATION

The load-horizontal curves are shown in Figure 17 and a comparison of test results in Table 3. The Single-sided fascia + nailed SD specification improved the overall structural performance compared to the Single-sided fascia specification. The yield load and ultimate bearing capacity increased by about 80%, and the maximum bearing capacity and toughness values increased by about 90%. The reason for this improvement is thought to be that nailing the SDs restrained the entire wall, as if it were a face plate load-bearing wall. The nailed SDs were also

https://doi.org/10.52202/069179-0443

considered to be a factor in the increase in the overall restraint of the wall due to the use of the furring strips for ventilation as joints. These factors are thought to have increased the bearing capacity by suppressing bending deformation of the beams and pulling out (Figure 18 and Figure 19) of the columns due to the beams pushing up against the fascia, which bears the compressive force.

5.2 SINGLE-SIDED FASCIA SPECIFICATION AND SINGLE-SIDED FASCIA + HOOKED SD SPECIFICATION

A comparison of test results is shown in Table 4 and Figure 20. The Single-sided fascia + hooked SD specification showed a slight improvement in structural performance, except for initial stiffness, compared to the Single-sided fascia specification, but only the initial stiffness was almost the same. From this, we consider that the influence of the hooked SD is almost negligible until 0.4Pmax, when the value of the initial stiffness is determined. The yield load increased by about 30%, and the maximum and ultimate bearing capacity increased by about 20%. The damage check revealed that the joints had scratches where the metal fittings interfered with each other (Figure 21 and 22). This caused a restraining force on the SD, and the resistance force of the SD was transmitted to the frame via the metal fittings.

5.3 SINGLE-SIDED FASCIA + NAILED SD SPECIFICATION AND SINGLE-SIDED FASCIA + HOOKED SD SPECIFICATION

A comparison of the Single-sided fascia + nailed SD specification and the Single-sided fascia + hooked SD specification is shown in Table 5 and Figure 23. The structural performance of the Single-sided fascia + nailed SD specification was higher than that of the Single-sided fascia + hooked SD specification. A performance difference of about 70% was observed for the wall ratio. Yield load, maximum bearing capacity, and ultimate

https://doi.org/10.52202/069179-0443

bearing capacity increased by approximately 60%. This is due to the fact that the Single-sided fascia + nailed SD specification with nailed SD and nailed furring strips restrained the entire wall like a plywood bearing wall, which suppressed deformation such as the lifting of columns, and thus increased the bearing capacity. The most significant difference in the values was in the amount of energy absorption, which increased by approximately 2.2 times. We believe that the difference in initial stiffness and the difference in the number of joints per SD caused the difference in the ability to distribute the force to the entire wall.

5.4 SINGLE-SIDED FASCIA + NAILED SD SPECIFICATION AND ADDITIVE VALUE OF SINGLE-SIDED FASCIA SPECIFICATION AND NAILED SD SPECIFICATION

Figure 24 shows a comparison of the load-horizontal curves of the measured values (hereafter referred to as "measured values") and the added values (hereafter referred to as "added values") of the Single-sided fascia + nailed SD specification and the Single-sided fascia specification + nailed SD specification. The measured values showed an increase in structural performance compared to the added values. The difference between the measured values and the additive law is considered to be due to the difference in stress transfer to the frame. Looking at the fracture behavior of the nailed SD and Single-sided fascia + nailed SD specifications, both specifications showed cracking of the SD and fracture of the furring strips (Figures 25 and 26), and the damage to the SD was almost the same. However, looking at the backside of the specimens, the Single-sided fascia + nailed SD specification showed greater damage to the frame due to the dislodging of the studs, the penetration of the foundation by the fascia, and the pulling out of the columns due to the rupture of the pile plate (Figs. 27 and 28). No damage to the frame occurred in the nailed SD and Single-sided fascia specifications. The installation of the nailed SDs caused the entire wall to deform as a single unit, which transmitted sufficient force to the fascia and increased the stress transmitted to the frame, resulting in damage to the frame, such as column pull out. This suggests that the difference between the measured and added values was caused by the increase in the maximum bearing capacity.

5.5 SINGLE-SIDED FASCIA + HOOKED SD SPECIFICATION AND ADDITIVE VALUE OF SINGLE-SIDED FASCIA SPECIFICATION AND HOOKED SD SPECIFICATION

A comparison of the Single-sided fascia + hooked SD specification (hereafter referred to as "measured value") and the additive value of the Single-sided fascia

https://doi.org/10.52202/069179-0443

specification + hooked SD specification (hereafter referred to as "additive value") is shown in Figure 29. There is almost no difference between the measured values and the additive values, indicating that the additive law is valid. This is due to the fact that the SDs hardly bear the load-bearing capacity and depend on the load-bearing capacity of the structural members, which is why there is no difference. Also, there is a difference in final failure between the measured value and the added value. In the case of the measured value, the strength was reduced due to the pull out of screws attached to the fascia plate (Figure 30), whereas in the case of the added value, the strength was reduced due to the buckling failure of the fascia (Figure 31), resulting in the difference in the graphs near the endpoint.

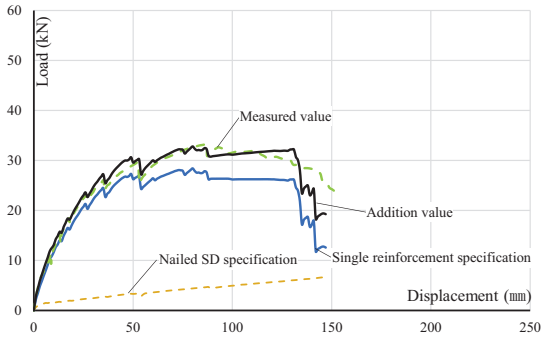

Figure 29: *Relationship between load and horizontal displacement for the added values of single-sided fascia + hooked SD specification and single-sided fascia + hooked SD specification*

Figure 30: *Fascia plate screws missing*

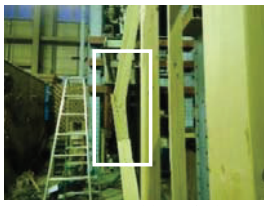

Figure 31: *Buckling failure of Fascia*

6 CONCLUSION

The burden ratio was 46.5% for nailed SD and 8.7% for hooked SD. Although SD exterior walls are not included in the structural design as load-bearing walls, it was found that the wall ratio of the current mainstream "hooked SD" was about 70% lower than that of the nailing SD, which was the mainstream at that time.

STUDY ON THE EVALUATION OF THE RESTORING FORCE CHARACTERISTICS OF FLOOR OF TRADITIONAL WOODEN BUILDING IN KYOTO

Rongji Fu[1], Mina Sugino[2], Yasuhiro Hayashi[3]

ABSTRACT: The vibration characteristics and seismic performance of traditional wooden buildings are heavily influenced by the restoring force characteristics of the floor. In this paper, we perform static loading tests on floors of traditional wooden buildings in Kyoto to understand the restoring force characteristics of floors of various specifications (Non-joist floor/ Joist floor). Then, Degrading Slip models (DS models) are used to develop highly accurate restoring force characteristics models of tested floors. In order to build restoring force characteristics models of floors with other specifications, a predictive formula for skeleton curves of floors is established. In addition, to calculate the skeleton curves of floors by using the formula, shear force-deformation models of a single nail are constructed by conducting the loading tests of floorboard-beam joints. The results indicated that 1) There are significant differences in restoring force characteristics of two different floors. 2) DS models can accurately represent the restoring force characteristics of the experiments. 3) Established predictive formula can simulate the skeleton curve of Non-joist floor with the shear force-deformation models of a single nail.

KEYWORDS: Traditional wooden building, Floor, Restoring force characteristics, Static loading test

1 INTRODUCTION

Since the 1995 Southern Hyogo Prefecture Earthquake, Japan has entered a period of seismic activity, and the risk of damaging earthquakes in various regions is increasing. And with the imminent occurrence of the giant Nankai Trough earthquake, inland crustal earthquakes are also said to occur frequently around that time. Meanwhile, there are many traditional wooden buildings in Japan. The promotion of seismic resistance reinforcement of these traditional wooden buildings is an urgent issue. Response obtained from time history response analysis can provide important information and basis for seismic resistance reinforcement.

To evaluate the response of the traditional wooden buildings against ground motions accurately, many static loading tests of structural components have been conducted to develop the analysis models. In this paper, we focused on the restoring force characteristics of floors, which affect the vibration characteristics of traditional wooden buildings.

The floors of Japanese traditional wooden buildings are usually consisted of wooden floorboards and steal nails. These floors have lower initial stiffness and bearing capacity than the floors of plywood is used due to sliding deformation between floorboards. But previous studies have shown that during large deformation angles, friction occurs between the floorboards, resulting in greater shear force [1-3]. Therefore, in this paper, we perform static loading tests on floors of traditional wooden buildings in Kyoto to understand the restoring force characteristics of floors of various specifications (Non-joist floor/ Joist floor) and to develop restoring force characteristics models. The models are aimed to describe the hysteresis characteristics with high accuracy to improve the accuracy of time history response analysis results. Then, to build restoring force characteristics models of floors with other specifications, a predictive formula for skeleton curves of floors is established. In addition, to calculate the skeleton curves of floors by using the formula, shear force-deformation models of a single nail are constructed by conducting the loading tests of floorboard-beam joints.

2 STATIC LOADING TEST

2.1 FLOOR SPECIMENS

The four specimens shown in Figure 1 and 2 are 1910 mm in the beam direction and 2865 mm in the girder direction, corresponding to half of a six-tatami room. The beams (270x120x2870 mm), girders (270x120x2910 mm), and small beams (180x120x1955 mm) of the specimens were all made of Oregon Pine (scientific name: *Pseudotsuga menziesii*). Dovetail joints were used to connect the beams and girders. Dovetail-dado joints were used between the girders and small beams. There were two types of non-joist floor specimens and joist floor specimens: those

without floorboards (TS, TJ) and those with floorboards (FS, FJ). The floorboards of the Non-joist floor specimen FS were 30 mm thick cedar (scientific name: *Cryptomeria japonica*) boards, and two N90 (which means the length of the nail is 90 mm) nails were utilized to fix the floorboards to the beams. Joists (105x45x899 mm) were installed between each beam in joist floor specimens (TJ, FJ). Dado joints were used to connect joists and beams. And at the joint, the joist was fixed to the beam with N75 nails, one on each side. The joist floor specimen FJ was covered with 15 mm thick cedar boards, and floorboards were fixed to the beams with two N45 nails. The nailing interval for both specimens was 110 mm. Details of the floorboard-beam joint are shown in Figure 3.

2.2 LOADING METHOD

The loading system is depicted in Figure 4. The load was applied to the top of the specimens. To prevent the overall rotation of the specimens, a pantograph was used to keep the beam horizontal. The vertical displacement of the top beam of the specimens was not constrained. Two cycles of positive and negative alternating cyclic loading were used for the static loading test. The target displacement of the specimens took the deformation angle R = 1/450, 1/300, 1/150, 1/120, 1/100, 1/75, 1/50, 1/30, 1/20, 1/15, 1/10 and 0.15 rad. Figure 5 shows the specimen FJ under load.

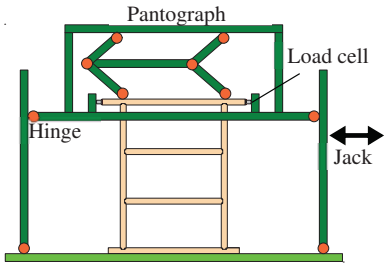

Figure 4: *Loading system of floor specimens*

Figure 5: *Specimen FJ under load (R = 0.15 rad)*

2.3 RESULTS

The restoring force characteristics of the floor specimens are shown in Figure 6. For all the specimens, the additional shear force due to the P-Δ effect was excluded using the method described in Ref [4].

At a target deformation angle R of 1/30 rad, the maximum load of TS and TJ was approximately 2 kN. Subsequently, as shown in Figure 7, the cracking of the dovetail joint developed, and the overall specimen load of the entire specimen decreased. Specimen TJ had slightly higher load at large deformation than Specimen TS due to the bending resistance of the joist.

For the Non-joist floor specimen FS, the load visibly increased about R = 1/15 rad. By R = 0.15 rad, no nail damage was observed.

Specimen FJ produced a shear force of 5.5 kN at 1/30 rad, and the load increased from 1/15 rad. The initial stiffness of specimen FJ was relatively high and the load gradually increased as the target deformation angle progressed. When the target deformation angle was small, the load at 0 rad was relatively high, but the load at 0 rad decreased with the applied load. During the large deformation, the nails of the upper and lower outer edge floorboards were pulled out from the girders as shown in Figure 8.

3 RESTORING FORCE CHARACTERISTICS MODELS

In this paper, the DS model developed by J.Nezaki et al. [5] was used to model the restoring force characteristics of the floor specimens. Degrading Slip model (DS model)

https://doi.org/10.52202/069179-0444

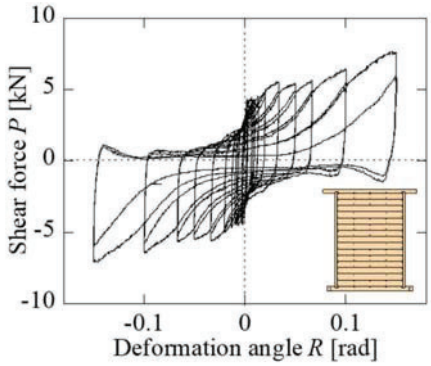
(c) *Specimen TJ*



(d) *Specimen FJ*

Figure 6: *Restoring force characteristics*

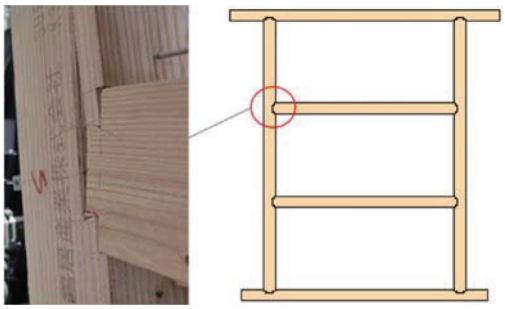


Figure 7: *The crack of the dovetail joint*

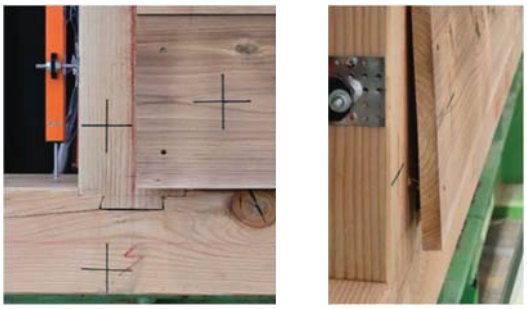

Figure 8: *Pulled out nail*

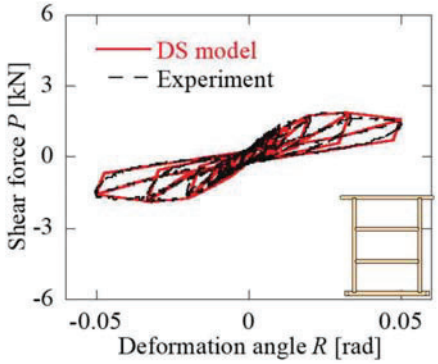
can describe the lowering slip stiffness around zero deformation angle as the maximum experienced deformation angle increases.

Figure 9 shows a comparison between the experimental data with the DS models. The figure illustrates that the DS models accurately represented the restoring force characteristics of the experiments. The initial stiffness of the TS, TJ specimens differed insignificantly. When the boards were applied, the initial stiffness of the Non-Joist floor increased by a factor of two, while that of the joist floor increased by a factor of eight. Furthermore, for specimen TS and FS the shear force Q_0 at the deformation angle of 0 rad of the hysteresis loop was 0.2-0.4 kN, which was not much different between the two specimens. While the shear force Q_0 at the deformation angle of 0 rad of FJ was much higher than Q_0 of TJ. Therefore, the area of the hysteresis loop of specimen FJ was larger than that of the TJ.

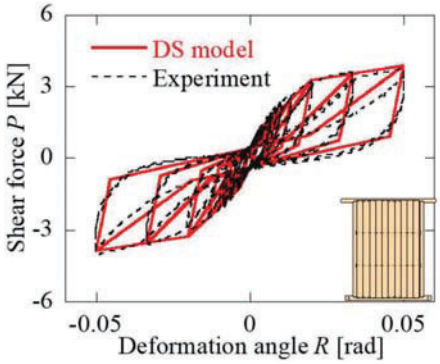
4 MECHANICAL MODEL

In Chapter 3, the restoring force characteristics models of the floor specimens were built. However, in actual traditional wooden buildings, the results obtained from experiments cannot be used directly in design because the specifications vary widely from building to building. Since the parameters of the DS models are mostly decided

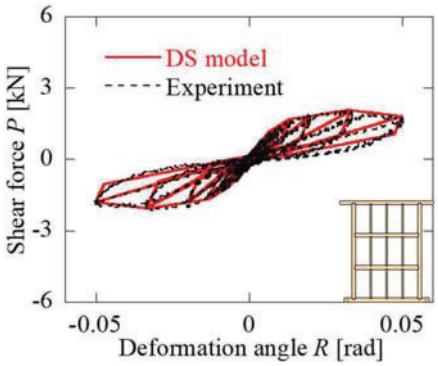
https://doi.org/10.52202/069179-0444



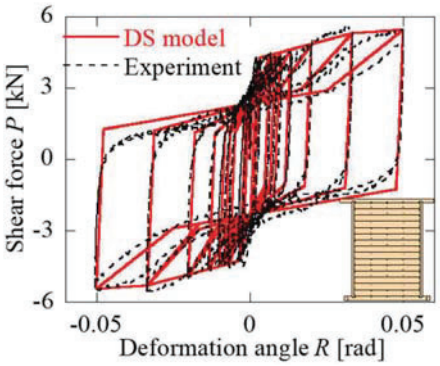
(a) *Specimen TS*



(b) *Specimen FS*



(c) Specimen TJ



(d) *Specimen FJ*

Figure 9: *Restoring force characteristics models*

according to the skeleton curve of floors, it is necessary to estimate the skeleton curve in developing restoring force characteristics models for floors with varying specifications, such as the number of nails and floorboard orientation. In this chapter, we started by building a shear force-deformation models for a single nail joint. The shear force-deformation models were then used to create a prediction formula that can simulate the skeleton curve of the entire floor.

4.1 SHEAR FORCE-DEFORMATION MODELS OF NAIL JOINT

Figure 10 shows the specimens simulating the floorboard-beam joint. At the floorboard-beam joint, the boards' movement causes the nails to bend in the same direction. The direction of movement of the boards is random because of the seismic load. Therefore, the effect of the direction of movement of the board on the nails' resistance characteristics needs to be confirmed by experimentation. As shown in Figure 10, there were 3 types (PV, PP, VP) of floorboard-beam joint. The fiber orientations of the floorboard and beam were different for each of the 3 types of floorboard-beam joint. To correspond to the floor specimens FS and FJ described in the Chapter 2, each type of floorboard-beam joint had two specimens with the same length of nails (N45 and N90) and thickness of the floorboard (15 mm and 30 mm) as specimens FS and FJ.

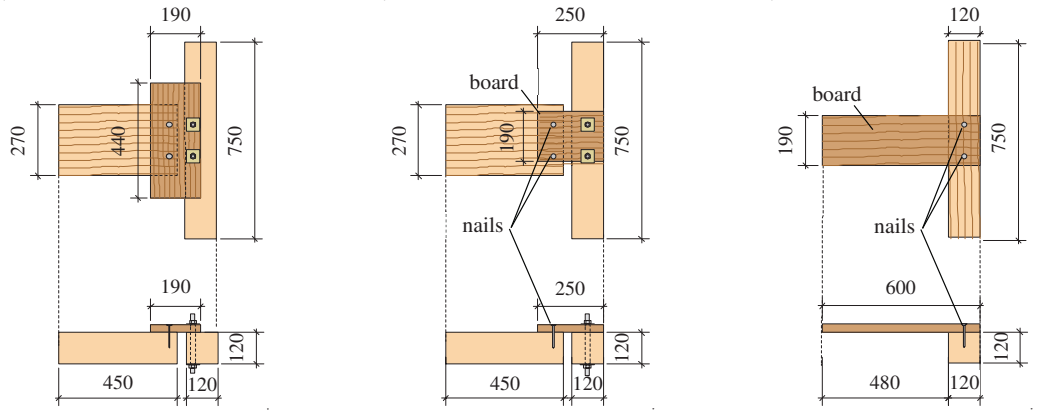
The loading systems are shown in Figure 11. The beam was fixed and positive and negative cyclic forces were applied to the floorboard side. The target displacement δ of the nails were 1, 2, 4, 6, 8, 10, 15, 20, 25 mm.

The skeleton curves of shear force-deformation characteristics of a single nail are shown in Figure 12. The figure shows that the maximum load of the single N90 nail in PV specimen was about 15% lower than that of the single nail of other specimens. On the other hand, the single N45 nail in PV specimen had a higher maximum load than the single nail in the other specimens. The differences between specimens with nails of the same length were likely due to specimen variability rather than fiber direction effects. Since no significant fiber direction effects were identified, the average of the results from the three types of specimens was used to model the shear force-deformation relationship for a single nail. The results are shown in Figure 13.

4.2 PREDICTIVE FORMULA FOR SKELETON CURVES

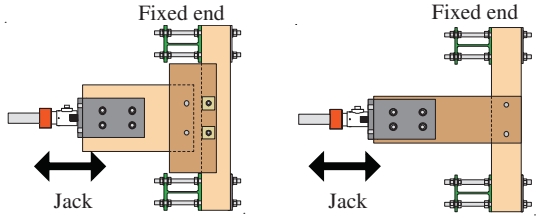
In the formula, the floor shear force was divided into three sections: the shear force of the floor frame P_b; the shear force P_n caused by nails; and the shear force P_f due to friction. The skeleton curve of the DS model of the TS, TJ specimens were used to represent the floor frame shear force P_b. The force P_n and P_f were calculated by the formula suggested in Ref [3]. Taking the specimen FJ as an example, the formula is explained as follows.

https://doi.org/10.52202/069179-0444



(a) *Specimen PV* (b) *Specimen PP* (c) *Specimen VP*

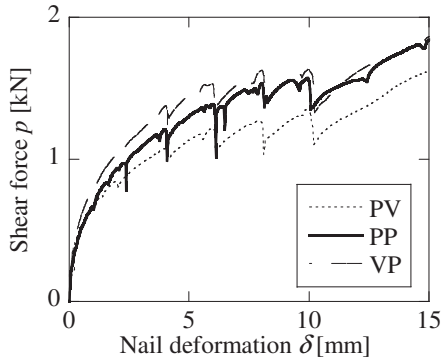
Figure 10: *Floorboard-beam joint type*



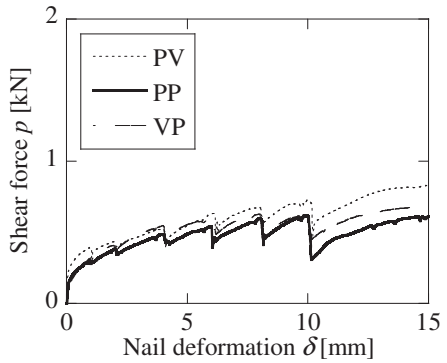
(a) *PV, PP* (b) *VP*

Figure 11: *Loading systems of joint specimens*

The height of floor specimens is H, the deformation angle is R and the number of floorboards is N. As shown in Figure 15 the deformation caused by the rotation of the floorboards δ_x is calculated from Equation (1). When the rotation angle of the specimen occurs, the height of the specimen will shrink relative to the height of all the floorboards. The amount of shrinkage must be symmetrically distributed from the centre of the specimen. Therefore, as shown in Figure 14, when the centre of the girder is considered as the centre of rotation, the shrinkage $\delta_y(i)$ corresponding to the distance $h(i)$ from the centre of

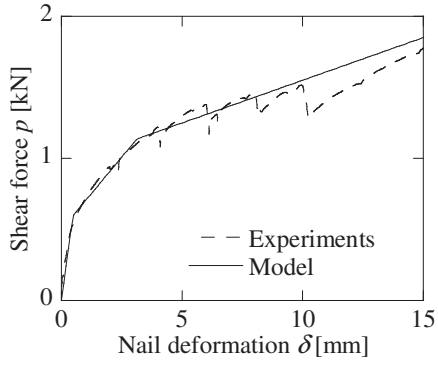


(a) *N90 nail*

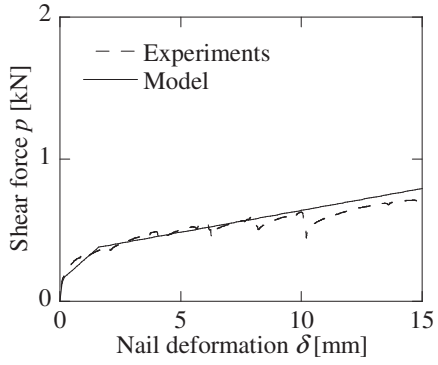


(b) *N45 nail*

Figure 12: *The skeleton curves for a single nail*



(a) *N90 nail*



(b) *N45 nail*

Figure 13: *The shear force-deformation relationship for a single nail*

each floorboard to the centre of the specimen can be calculated from Equation (2). The symbol (*i*) represents the *i*-th board. The shrinkage $\delta_y(i)$ can be seen as the y-axis deformation of nails in the i-th floorboard. So, the total deformation δ can be calculated from Equation (3). Substituting the total deformation δ of the nail (*i*) into the nail shear force-deformation relationship constructed in Chapter 4.1, the total shear force of the nail $p_{45}(i)$ can be obtained. The x-axis and y-axis shear force $p_x(i)$ and $p_y(i)$ can be calculated from Equation (4) as shown in Figure 16. Then, the resistance moment M_n of the whole specimen can be obtained from Equation (5). Here, *m* is the number of nail joints per board (*m* = 5 for joist floor specimen FJ). The friction force between the boards is then calculated from the y-component $p_y(i)$ (Equation (4)) and the coefficient of friction. The frictional force $p_f(i)$ acting on the *i*-th plate, as shown in Figure 17, can be obtained from the difference between the upper and lower plate frictional forces from Equation (6). The resisting moment M_f can be obtained from the frictional force $p_f(i)$ and the distance $h(i)$ from the centre of the floor specimen (Equation (7)). The resisting moments M_n and M_f divided by the height of specimen *H* are the resisting forces P_n and P_f (Equation (8)).

The simulation results for a friction coefficient μ of 0.3 are shown in Figure 18. The shear force P_b of the floor frame was the skeleton curve of the restoring force characteristics model of the floor flame specimen TS and TJ built in Chapter 3; the shear force $P_{(model)}$ of the floor specimen was calculated by adding P_b, P_n and P_f.

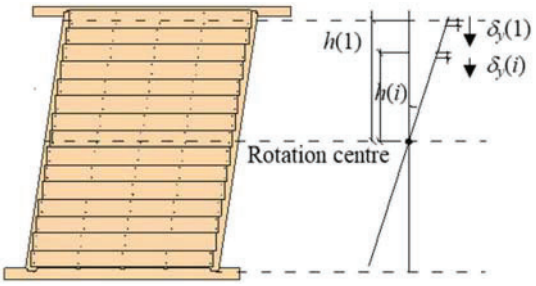


Figure 14: *y-axis deformation*

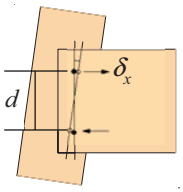

Figure 15: *x-axis deformation*

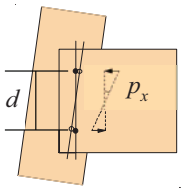

Figure 16: *x-axis force*

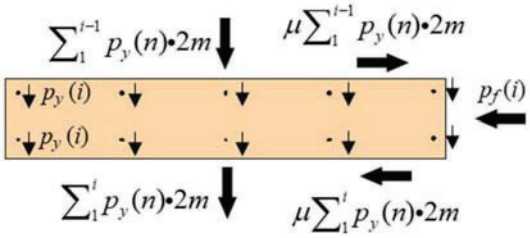

Figure 17: *Friction force caused by y-axis force $p_y(i)$*

$$\delta_x = \frac{d}{2}\sin R \tag{1}$$

$$\delta_y(i) = h(i)\ (1-\cos R) \tag{2}$$

$$\delta(i) = \sqrt{(\delta_y(i))^2 + (\delta_x)^2} \tag{3}$$

$$p_x(i) = p_{45}(i)\ \frac{\delta_x}{\delta(i)} \quad p_y(i) = p_{45}(i)\ \frac{\delta_y(i)}{\delta(i)} \tag{4}$$

$$M_n = m\ \sum_{i=1}^{N} p_x(i)\ \frac{d}{2} \tag{5}$$

$$p_f(i) = 2m \cdot p_y(i)\ \mu \tag{6}$$

$$M_f = \sum_{i=1}^{N} p_f(i)\ h(i) \tag{7}$$

$$P_n = M_n / H \qquad P_f = M_f / H \tag{8}$$

The shear force $P_{(exp)}$ was the skeleton curve of the restoring force characteristics model built in Chapter 3. The figure shows that $P_{(model)}$ and $P_{(exp)}$ of the FS specimen corresponded approximately. The load was carried by the floor flame during micro-deformation. The frictional force P_f increased gradually with increasing deformation angle. From *R* = 1/30 rad, the shear force of the floor flame decreased due to cracks in the dovetail joints, so the shear force of the floor specimens was borne by the nails and frictional forces.

On the other hand, for the specimen FJ, the difference between the model and the experimental result for the initial stiffness was significant. Predictive formula for skeleton curves of Joist floor should take further consideration.

5 CONCLUSIONS

In this research, we have used static loading tests on traditional wooden buildings floors to develop highly accurate models of restoring force characteristics for two types of floors. In addition, the shear force-deformation models of a single nail has been used to build a mechanical model that can estimate the skeleton curve of the floor. The results indicated that

1) There are significant differences in restoring force characteristics of two different floors.
2) DS models can accurately represent the restoring force characteristics of the experiments.
3) Established predictive formula can simulate the skeleton curve of Non-joist floor with the shear force-deformation models of a single nail.

INFLUENCE OF PLASTERBOARD ON THE STRUCTURAL PERFORMANCE OF TIMBER-FRAMED SHEAR WALLS

Craig J.L. Cowled[1], Tom P. Slattery[2], Keith Crews[3], Harrison Brooke[4]

ABSTRACT: Timber-framed shear walls are commonly used in residential buildings to provide lateral strength and stiffness against wind and earthquake loads. Wood-based panel products, such as plywood and oriented strand board, are typically fixed to timber framing with nails or screws to provide the necessary racking resistance of a shear wall. Plasterboard is a panel product used on walls to achieve a smooth finished surface. Plasterboard provides some strength and stiffness to the wall even though its primary function is architectural; however, most shear wall tests ignore the influence of plasterboard. The aim of this study is to quantify the influence of plasterboard on the structural performance of timber-framed shear walls. To achieve this aim, six (6) timber-framed shear walls (groups P1 and P2) were fabricated with 7mm F8 plywood sheathing on one side and 10mm plasterboard on the other side and tested under a monotonic loading protocol. Results were then compared with previous test results of three (3) similar timber-framed shear walls (group M1) without plasterboard. Results show that plasterboard improved the ultimate racking strength of these shear walls by up to 53%, a statistically significant result. Shear wall stiffness and failure modes were not affected by adding plasterboard.

KEYWORDS: Shear wall; Plasterboard; Monotonic loading

1 INTRODUCTION

Timber-framed shear walls do the important work of resisting racking forces from wind and earthquake that act on buildings. These shear wall systems usually comprise wood-based panel products, such as plywood or oriented strand board (OSB), nailed or screw-fixed to the structural timber framing. Shear wall systems then get tested in a laboratory to find their racking strength and stiffness and the data collected in these tests is used to justify their design rating. It is common practice to use only structural elements in a test panel, such as timber framing, sheathing, connectors, tiedowns and anchors. Plasterboard, also known as gypsum board or drywall, is rarely attached to laboratory test panels even though it is ubiquitous in residential construction and known to provide some strength and stiffness (*e.g.*, [1,2]).

Here, we report on our experimental test plan to quantify the influence of plasterboard on the structural performance of timber-framed shear walls. Following a brief literature review, the test method is described. Results are presented and compared to previous work [3] on timber-framed shear walls without plasterboard. Analysis and discussion highlights the additional capacity of timber-framed shear walls due to plasterboard.

2 LITERATURE REVIEW

The contribution of plasterboard to the racking resistance of residential buildings is formally recognised in the Australian Standard AS1684.2:2021 [4] where cl.8.3.6.2 allows for a design racking capacity of 0.45 kN/m if one side of the wall is sheeted and 0.75 kN/m if both sides of the wall are sheeted up to a maximum of 50% of the total racking resistance requirement for the building.

Wolfe [5] conducted an early comparison of walls with solid timber diagonal braces checked into studs. Wolfe found that gypsum wallboard improved the strength of these walls by as much as 300% and improved stiffness by as much as 400%.

Patton-Mallory *et al.* [1] tested several combinations of walls with plywood and gypsum board. They found that walls with plywood on one side and gypsum board on the other side outperformed walls with plywood only on one side by 30% – 40%. They did not report on stiffness.

Of note, both Wolfe [5] and Patton-Mallory *et al.* [1] found that the overall capacity of the shear walls could be predicted accurately by summing the capacity of the component parts of the system.

Liew *et al.* [2] found that walls with plasterboard fixed on one side of the shear wall using screws, but no adhesive, achieved ultimate capacities of 2.0 – 3.5 kN/m. This result is far better than the nominal design capacities in AS1684 [4].

https://doi.org/10.52202/069179-0445

Uang and Gatto [6] found that adding plasterboard to an OSB or plywood sheathed shear wall improved ultimate strength by 6% - 18% and improved stiffness by 30% - 90%. They also found that adding plasterboard altered the failure mode of the shear walls from the sheathing-to-timber connections to the framing timber itself.

Satheeskumar *et al.* [7] conducted simulated wind load tests on a full-size house building. The building was tested in two different conditions: 1) with structural elements only, and 2) with architectural claddings such as plasterboard and cornices. They found that plasterboard and cornices contributed about 40% of rigidity to the building.

This literature review shows that plasterboard does, in fact, contribute to the structural performance of timber-framed buildings; however, further work is needed to quantify the influence of plasterboard on typical shear wall systems that are in use in Australia.

3 DESCRIPTION OF TEST PANEL

Our standard test panel is 2700 (h) × 2400mm (l) with plywood sheathing fixed to one side of the panel and plasterboard fixed to the other side of the panel. Timber framing is kiln dried (KD) MGP10 *pinus radiata* with 90 × 35mm studs at 600mm spacings and 90 × 45mm top and bottom plates. Timber is sorted by density into four groups (*i.e.*, high, medium, low, and very low density). Timber framing for the three (3) P2 test panels is taken from sorted very low-density timber and is representative of the JD5 joint group. Timber framing for the three (3) P1 test panels is taken from sorted low, medium, and high-density timber to ensure that a broad range of densities are represented (nominally JD4 joint group). Joint groups for different species are defined in Australian standards for the purpose of joint design.

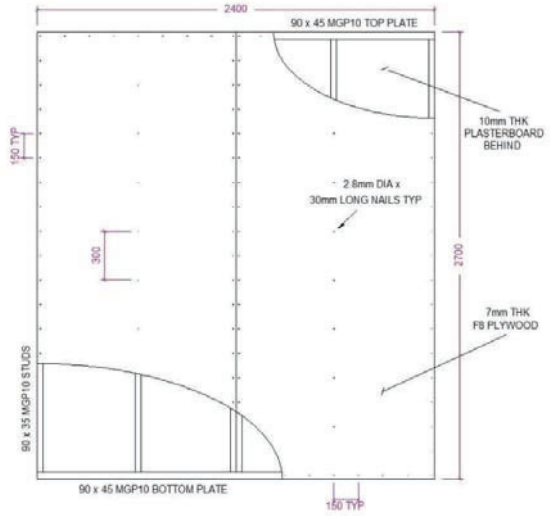

Figure 1: *Typical Test Panel (Plywood side).*

Plywood sheets are 2700 (h) × 1200mm (l) × 7mm thick F8 plywood sheathing consisting of three (3) veneers of radiata pine with a D grade face and back glued together with a phenolic A bond resin. The plywood sheets are connected to the timber framing with 2.8 (ϕ) × 30mm (l) galvanised clouts at 150mm spacings around the edges of the sheets and 300mm spacings at intermediate studs (Figure 1). The nail pattern precisely follows Detail (h) of Table 8.18 in AS1684.2 [4].

Plasterboard sheets are 1350 (h) × 2400mm (l) × 10mm thick randomly selected off the shelf from three (3) different Australian manufacturers. The plasterboard sheets are connected to the timber framing with 6g × 25mm (l) screws (*i.e.*, 3.5mm (ϕ)) at 270mm spacings and no adhesive (Figure 2).

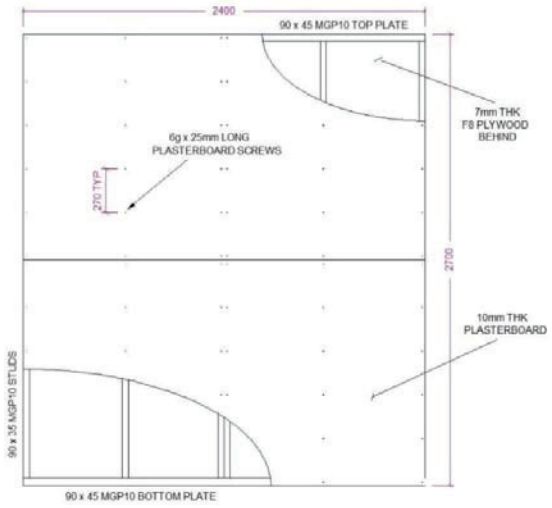

Figure 2: *Typical Test Panel (Plasterboard side).*

To resist sliding, the test panels were anchored to a steel floor beam with 3M12 bolts through the bottom plate at 1200mm spacings. To resist overturning the test panels were secured with an M12 tiedown rod from the top plate nearest the ram end. 50 × 3mm square washers were used with each bolt and tiedown rod.

The test panels in this study are almost identical to the test panels in the loading protocol study by Cowled, Crews, and Gover [3] with two exceptions: 1) plasterboard was not used in the previous study, and 2) the timber framing in the previous study was sourced from the Southern Queensland pine resource, which is either *pinus elliottii* var. *elliottii* (a.k.a. slash pine), *pinus caribaea* var. *hondurensis*, or a hybrid of the two species. Material properties of these species are comparable to those of radiata pine. These timber species have similar strength grades. Slash pine and Caribbean pine have a slightly higher density than radiata pine (*i.e.*, 650 kg/m^3 and 575 kg/m^3 respectively compared to 550 kg/m^3 for radiata pine). Slash pine has a better rated joint group (*i.e.*, nominally JD4 compared to nominally JD5 for radiata pine and Caribbean pine) [8]. All other aspects of the test setup, including tiedowns and anchors are identical to the test setup in [3]. The loading mechanism and loading protocol used in this study is identical to that used on test group M1 in [3].

https://doi.org/10.52202/069179-0445

4 TEST METHOD

Test panels P1.1 and P2.1 were tested with a simple displacement-controlled monotonically ramping load at 10 mm/min similar to the method outlined in EN 594 [9]. Results from testing of P1.1 and P2.1 were used to select a suitable design load of 7.2 kN/m and 6.9 kN/m respectively which were then used to test the remaining panels according to the load-controlled method described in [3] for test group M1, which is consistent with the prototype test method in Appendix D of AS1720.1 [10].

A 500kN MOOG hydraulic actuator was used to apply the load at the top plate. Three (3) linear variable displacement transducers were used to capture sliding at the toe of the wall (Δ_4) and overturning (Δ_2 and Δ_3). Two (2) laser sensors, mounted on an independent steel frame, were used to capture the horizontal displacement at the top of the wall (Δ_1). The test setup is shown in Figure 3.

Figure 3: *Test Panel P2.1.*

Since the data from the laser sensors is not clean, the displacement used for plotting has been measured at the hydraulic actuator and adjusted to match the laser data using a nonlinear least squares optimisation algorithm. Adjusted displacement then is:

$$\Delta_{adj} = \alpha \cdot \Delta_1 \tag{1}$$

where α is the multiplier obtained from curve-fitting using the nonlinear least squares optimisation described above. Racking displacement can also be corrected to remove the sliding and overturning components to obtain the shear component of the displacement:

$$\Delta_s = \Delta_1 - \Delta_4 - (\Delta_2 - \Delta_3) \cdot \frac{h}{l} \tag{2}$$

where, h and l are the height and length of the test panel.

5 RESULTS

Load – adjusted displacement (Δ_{adj}) plots for the P1 (blue lines) and P2 (red lines) groups of test panels are presented in Figure 4 along with those of the M1 group of test panels from [3] (black lines).

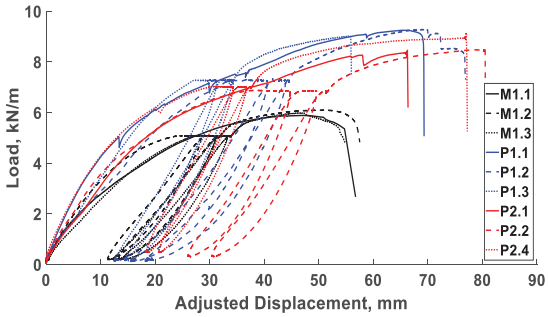

Figure 4: *Load – Adjusted Displacement Plots for Groups M1 (plywood only) [3], P1 (plywood & plasterboard), and P2 (as per P1 except with very low-density timber).*

The clearest observation from this plot is that plasterboard significantly improves the ultimate capacity of plywood braced shear walls. Initial stiffness also appears to be higher in the P1 and P2 groups compared to the M1 group; although, this relationship is not as clear when load is plotted against global displacement or corrected racking displacement.

Structural performance characteristics have been calculated in this paper in accordance with the methods outlined in ASTM E2126 [11]. The maximum load obtained is P_{ULT}. The global secant shear modulus is calculated at $0.4 \times P_{ULT}$:

$$G' = \frac{P}{\Delta_e} \times \frac{h}{l} \tag{3}$$

where P and Δ_e are the load in kN and displacement in mm at $0.4 \times P_{ULT}$ where global displacement is used (*i.e.*, including components of shear, overturning, and sliding). The internal secant shear modulus, calculated at $0.4 \times P_{ULT}$, uses the corrected shear displacement, Δ_s, from (2):

$$G_{int} = \frac{P}{\Delta_s} \times \frac{h}{l} \tag{4}$$

The yield load is found by deriving an equivalent energy elastic-plastic (EEEP) curve from the global load – displacement curve.

$$P_y = \left(\Delta_u - \sqrt{\Delta_u^2 - \frac{2A}{K_e}} \right) K_e \tag{5}$$

where, A is the area under the load – global displacement curve, Δ_u is the ultimate displacement (*i.e.*, corresponding to the last data point on the load – displacement curve where the absolute load is equal to or greater than $0.8 \times P_{ULT}$, K_e is the elastic shear stiffness equal to $(0.4 \times P_{ULT})/\Delta_e$.

https://doi.org/10.52202/069179-0445

The ductility ratio is:

$$D = \frac{\Delta_u}{\Delta_y} \quad (6)$$

where, Δ_y is the global displacement taken from the EEEP curve at P_y.

Structural performance characteristics for the P1 and M1 group of test panels are presented in Table 1 below.

The P1 group of test panels, which were fabricated with plywood on one side and plasterboard on the other side, achieved a mean ultimate strength of 9.18 kN/m and a tight variance (σ = 0.12 kN/m). The P2 group of test panels, which were identical to the P1 group except for having very low-density timber framing, achieved a mean ultimate strength of 8.72 kN/m (σ = 0.39 kN/m). Both results are significantly higher (53% & 46% respectively) than the mean ultimate strength of 5.99 kN/m for the M1 group of test panels in [3] (σ = 0.10 kN/m), which were fabricated without plasterboard and tested in the same laboratory with identical boundary conditions and the same loading protocol. The higher ultimate and yield strength of the P1 and P2 groups of test panels, as compared to the M1 group, is statistically significant with a *p*-value of 0.05 on a one-sided Wilcoxon ranksum test.

Table 1: *Results*

Test Panel	P_{ULT} (kN/m)	P_y (kN/m)	G' (kN/mm)	G_{int} (kN/mm)	D
M1.1	5.89	5.39	1.05	3.15	6.03
M1.2	6.09	5.47	1.01	1.55	3.90

μ	**8.72**	**7.39**	**1.12**	**1.99**	**4.35**
σ	0.39	0.34	0.24	1.24	1.14

* Data unavailable for test panel P2.3, so panel P2.4 was made.

Curiously, plasterboard did not improve the global and internal stiffness of the test panels in this study. This finding contradicts previous studies which found that plasterboard improved stiffness [5,6,7].

The in-group variance of ductility is high enough to make the higher ductility of the M1 group seem unremarkable.

Failure modes were similar between the test panels in this study and the M1 group of test panels. The primary mode of failure in all groups was nail pullout of the plywood-to-timber connection (see Figure 5). Two nail pull-through failures were observed in test panel M1.1 because this panel failed dramatically under load control. Timber fractures were observed in P1.1 (top of the end stud) and P1.2 (bottom plate near the heel of the wall, see Figure 6). Tearing of the plywood was observed at one nail in P1.2 and two nails in P2.4. The plasterboard in the P1 and P2 groups of test panels experienced localised crushing of the plasterboard at the screw holes, pull-through failures, and some tearing of the plasterboard at the corners (see Figure 7).

6 DISCUSSION OF LIMIT STATES

The shear wall system in this study is described as Method A of Detail (h), Table 8.1, AS1684.2 [4] and it has a published design capacity of 5.6 kN/m.

A similar shear wall system was originally tested in 1975 by Frodin and Ross [12], following a devastating cyclone in Darwin the previous year. Differences between test panel TP4 in [12] and the M1 group of test panels in [3] include the use of unseasoned hardwood timber framing instead of KD pine, 3.18mm (ϕ) clouts instead of 2.8mm (ϕ) clouts, studs at 450mm spacings instead of 600mm spacings, a panel height of 2.4m instead of 2.7m, a panel length of 2.7m instead of 2.4m, and the use of steel strapping at the corners of test panel. TP4 in [12] achieved an ultimate strength of 9.72 kN/m.

Several decades later, C.G. 'Mick' McDowall [13] tested panel TP2, which differed from the M1 group of test panels from [3] in only one respect; that is, TP2 in [13] was 2.4m high compared to the 2.7m high M1 group of test panels in [3]. TP2 in [13] achieved an ultimate strength of 8.21 kN/m.

It should also be noted that the loading protocols in [12] and [13] differed to the loading protocol used for the M1 group of test panels in [3] with design loads for TP4 in [12] being 2.07 kN/m (held for 5 min) and 2.87 kN/m (held for 5 min) and the design load for TP2 in [13] being 4 kN/m (held only once for 5 min); whereas, test panels M1.2 and M1.3 in [3] held a design load of 5 kN/m twice for 5 min. As argued in [3], the use of different loading protocols may have influenced results.

Adopting Mick McDowall's 2004 methodology [13] for determining limit state design values, also described in [3], the upper limit for the factored design strength of this wall system, based on TP2 from [13], would be:

$$Q^* = 0.8 \times 8.21 = 6.57\ kN/m \tag{7}$$

This result exceeds the design value of 5.6 kN/m in AS1684.2 [4] by 17%; however, the more recent work by Cowled, Crews, and Gover [3] raised concerns because it found that the factored design strength of this system, based on the M1 group of test panels, was 14% lower than the published design value:

$$Q^* = 0.8 \times \frac{5.89 + 6.09 + 5.98}{3} = 4.79\ kN/m \tag{8}$$

The work in the current study reassures us that, when architectural finishes such as plasterboard are considered, the design strength of this system does, in fact exceed the published design values. For this shear wall system an appropriate design load exceeds the published design load of 5.6 kN/m by 28%:

$$Q^* = 0.8 \times \frac{\begin{matrix}9.25 + 9.29 + 9.02 + \ldots \\ \ldots 8.46 + 8.52 + 9.16\end{matrix}}{6} = 7.16\ kN/m \tag{9}$$

7 CONCLUSIONS

We have presented here the findings of our study into the influence of plasterboard on the structural performance of timber-framed shear walls tested in accordance with the monotonic load-controlled test method outlined in AS1720.1 [10]. Test panels were 2700 (h) × 2400mm (l) using MGP10 framing and 7mm thick F8 radiata pine plywood sheathing fixed with 2.8 (ϕ) × 30mm (l) galvanised clouts at 150mm spacings around the edges of each panel and 300mm spacings along the intermediate stud. The P1 ($n = 3$) and P2 ($n = 3$) groups of test panels in this study also had 10mm thick plasterboard fixed to the other side with 6g × 25mm (l) plasterboard screws at 270mm spacings. The P2 group of test panels were fabricated with very low-density timber framing (nominally JD5 joint group) whereas the P1 group of test panels were fabricated with timber from a range of densities (nominally JD4 joint group). Results of this study were compared to the M1 group of test panels in a previous study [3] ($n = 3$) which did not have plasterboard attached. Test conditions, including tiedowns, anchors, and loading protocol, were identical for both the P1 and M1 group of test panels.

We found that plasterboard improves the ultimate and yield strength of timber-framed plywood-braced shear walls by 37% to 53%; however, stiffness and ductility are unaffected by the addition of plasterboard in this study.

Since the published capacities of timber-framed shear walls are primarily based on testing of panels without plasterboard cladding, as is the case for shear wall systems described in Table 8.1 of AS1684.2 [4], our findings provide the construction industry with confidence.

ACKNOWLEDGEMENT

The work presented here was supported by scholarships awarded to TS, including an Australian Government Research Training Program Scholarship and an industry top-up scholarship by Australian Panel Products, Engineered Wood Products Association of Australasia (EWPAA), Pryda Australia, and One Forty One.

Materials were kindly provided by One Forty One, Carter Holt Harvey, and an Advance Queensland A&TSI Research Fellowship awarded to CC, which was funded by the Queensland State Government, the EWPAA, and Queensland University of Technology (ATSIRF00817-18RD3). Test panels were fabricated by Bretts Timber & Hardware.

We also wish to thank the staff at QUT's Banyo Pilot Plant Precinct where the experimental work was done. Frank De Bruyne, Cameron Creevey, Barry Hume, Glenn Atlee, and Zeph Kadel have all made this project possible and their contribution is highly valued.

EXPERIMENTAL CHARACTERIZATION OF CLT SHEAR WALLS CONNECTED TO PERPENDICULAR WALLS

Elisabetta Maria Ruggeri[1], Giuseppe D'Arenzo[2], Denise Li Cavoli[3], Ignazio Casiraro[4], Marinella Fossetti[5]

ABSTRACT: "Box-type" CLT buildings are realized by connecting CLT panels through dowel-type fastener and mechanical anchor connections, which govern the lateral behaviour of these structures. However, while a lot of investigations in literature have been focused on the behaviour of connections placed at the base of CLT shear walls, typically hold downs and angle brackets, less studies have been focused on the behaviour of connections between perpendicular walls and how their affect the lateral response of CLT shear walls. This paper presents some results of a large experimental campaign aimed at investigating the effects of the interaction provided by perpendicular walls on the lateral behaviour of CLT shear walls. The findings of this experimental study showed that the structural interaction due to the presence of perpendicular wall significantly influence the lateral response of a CLT shear wall and increase its lateral performances, such as the lateral stiffness, the lateral capacity and the deformation capacity.

KEYWORDS: CLT shear wall, Perpendicular walls, Experimental tests, Lateral performance, Structural interaction.

1 INTRODUCTION

The Lateral Load Resisting System (LLRS) of Cross-Laminated Timber (CLT) buildings is composed of the CLT shear walls along with their base connections, which are typically realized using hold downs and angle brackets. Several testing programmes have been conducted to explore the lateral performance of CLT shear walls [1–3] and the results of these experimental investigations showed that the wall base connections govern the cyclic behaviour of a CLT shear wall system and provide the necessary ductility and energy dissipation. However, the lateral behaviour of a CLT shear wall is also influenced by other connections that can be found in the perimeter of the CLT panels. In particular, these connections vary depending on the type of construction. In this regard, CLT building construction typologies can be distinguished in "shear wall-type", in which the shear walls are not connected with the perpendicular walls in the corner of the building, and "box-type", in which the shear walls and the perpendicular walls are connected in the corner of the building by means of mechanical connections, see Figure 1.

The mechanical behaviour of CLT "box-type" buildings, especially those erected using the platform method, significantly depend on the effects of interactions between primary and secondary structural elements such as perpendicular walls, floor diaphragms, lintels and their mechanical connections, see for instance [4–9].

Concerning the "box-type" buildings, the influence of the perpendicular walls and the wall-to-wall connections is an issue of special interest. The effect of the interactions between the shear walls and the perpendicular walls on the lateral behaviour of CLT buildings was found in several numerical and experimental studies [10–13]. However, if from one side the effects of these interactions were found to be significative, from the other side no significant efforts were undertaken so far to investigate the effects of the interactions between CLT shear walls and perpendicular walls.

This paper presents an experimental campaign aimed at investigating the lateral response of CLT shear walls connected to perpendicular walls by means of typical screwed wall-to-wall connections. The main objective of this study is to quantify the increase of lateral performances of CLT shear walls as a result of their interactions with perpendicular walls.

2 EXPERIMENTAL TEST PROGRAM

2.1 MATERIALS AND CONFIGURATIONS

The experimental tests presented in this study were carried out at L.E.D.A. Research Centre of the University of Enna "Kore" (Italy). CLT panels used during the tests consisted of five-layered panels with a total thickness equal to 100 mm and layer thicknesses of **20**-20-**20**-20-**20** mm (in bold the thickness of the layers arranged in the vertical direction). Hold-downs (HDs) type WHT340 [14] were used to anchor the wall panels against rocking displacements. These connectors were fastened in the vertical flange by means of twelve annular ringed nails 4×60 mm [15] and anchored to the foundation through one M16 bolt strength class 8.8. Whereas, angle brackets (ABs) type WBR90110 [14] were used to anchor the shear wall against sliding displacements. These connectors were fastened in the vertical flange by means of thirteen annular ringed nails 4×60 mm [15] and anchored to the foundation by means of two M12 bolts strength class 8.8. Self-tapping screws HBS 10×200 mm [16] were used to join the perpendicular wall with the shear wall. These connections, which were positioned to span across at least two layers of the perpendicular wall panel, were installed with a spacing of 250 mm, resulting in a total number of wall-to-wall connections equal to ten. Hold-downs, angle brackets and self-tapping screws were produced by Rothoblaas. In Figure 2 the connections used for the experimental tests are shown.

Two CLT wall assembly configurations were considered to investigate the lateral performance of CLT shear walls connected to CLT perpendicular walls: single Shear Wall configuration (SW), see Figure 3 (a), which considers a single CLT shear wall subjected to lateral load, and Shear Wall connected to a Perpendicular Wall configuration (SW+PW), see Figure 3 (b), which considers the same CLT shear wall subjected to lateral load connected to a perpendicular wall positioned at the end of the shear wall. All shear wall specimens were made of monolithic wall panels with dimensions equal to 250×250 cm. Each shear wall was anchored at base with two hold-downs located at the extremities of the wall panels and four angle brackets distributed along the shear wall length, see Figure 3 (a) and (b). Whereas, specimens of perpendicular walls consisted of monolithic wall panels with dimensions equal to 50×250 cm, each of which was anchored at the base with one hold-down, see Figure 3 (b).

	1 Cyclic

2.2 LOAD PROTOCOLS AND TEST SET UP

Monotonic tests were performed in displacement control with the imposed displacement increasing at a constant rate of 0.10 mm/sec, see Figure 4 (a), according to the standard procedure EN594 [17]. The cyclic tests were also performed in displacement control with a rate between 0.05 and 0.25 mm/sec, depending on the displacement level, according to the standard procedure in EN12512 [18], see Figure 4 (b). In order to study the lateral behaviour of the shear wall-perpendicular wall systems using fewer parameters, all tests were performed by applying the horizontal load without applying any vertical load.

The monotonic and the hysteretic parameters of the shear wall tests were evaluated according to EN12512 [18]. The mechanical parameters evaluated from the load-displacement curves of the monotonic tests are the yielding load F_y, yield displacement V_y, maximum load F_{max}, maximum displacement V_{max}, ultimate load F_{ult}, ultimate displacement V_{ult}, ductility D, and elastic stiffness K_{el}, which was calculated as the slope between 10% and 40% of the maximum load. The same parameters were assessed for backbone curves obtained from the cyclic tests, for both positive and negative displacements. The hysteretic parameters evaluated from the cyclic tests are the dissipated energy E_d, the equivalent viscous damping v_{eq} and the normalised impairment of strength between the first and third cycles $\Delta F_{1\text{-}3}$.

Figure 5 (a) and (b) shows photos of the test set-up for both SW_2.50 and SW+PW_2.50 configurations. The lateral load was applied by means of a 300 kN hydraulic actuator. In particular, the lateral load was distributed on the shear wall panel by means of a steel beam IPE 160 type, properly drilled and fastened to the top of the shear wall panel with 24 10×200 mm self-tapping screws. The CLT walls were anchored, through the hold-downs and the angle brackets described in the previous section, to two steel beams HEB 220 type, properly drilled, used to simulate the foundation (see Figure 5). Linear variable displacement transducers (LVDTs) were used to measure vertical and horizontal displacements at different locations of the specimens. Three LVDTs for measuring uplifts of shear wall and perpendicular wall were placed in lower corners of both shear wall and perpendicular wall. One LVDT was placed in the lower corner of the shear wall for measuring the horizontal base displacement. The horizontal head displacement of the shear wall was measured with an LVDT placed on an external steel structure, while another LVDT was used to monitor the horizontal displacement of the steel beam representing the foundation (HEB 220).

The horizontal displacement at the top of the shear wall was obtained by subtracting the horizontal displacement of the steel beam representing the foundation (HEB 220) from the horizontal displacement measured by the LVDT placed on the shear wall head. In order to avoid the out-of-plane movements of the CLT panels, a steel frame system was used.

3 EXPERIMENTAL RESULTS

Figure 6 (a) and (b) show some photos of the specimens at the end of the tests, for the two configurations SW_2.50 and SW+PW_2.50, respectively.

During the tests, the top lateral displacement of the systems was mainly governed by a combination of sliding and rocking mechanism with a predominant rocking. In particular, CLT panels behaved almost as rigid bodies and the deformations occurred in the joint between CLT panel and wall base connections.

As shown in Figure 7, deformations were observed at the base of the hold-downs (HDs) with failure mechanisms associated with the embedment of the wooden panel and failure of the nails of the vertical flange, with formation of plastic hinges. Moreover, some nails failed due to tearing of the nail head. As a result, the nail shank remained embedded in the CLT panel. Angle brackets (ABs) were capable of bearing both shear and tensile loads, but failures were observed in some instances in the nails of the vertical flange, resulting in the formation of plastic hinges. In some cases, failures were observed in both nails and bolts, see Figure 7. No failure was observed in the screws of the wall-to-wall connections.

A comparison between the hysteresis loops acquired from the cyclic tests and the load-displacement curves obtained from the monotonic tests for two test configurations, SW_2.50 and SW+PW_2.50, is shown in Figure 8 (a) and (b), respectively. Figure 8 (a) and (b) depict graphs indicating that the outcomes obtained from the cyclic test align with those from monotonic tests. From this figure, it can be observed the typical symmetrical hysteresis loops for positive and negative displacements in case of single shear wall configuration (SW).

https://doi.org/10.52202/069179-0446

On the other hand, for the SW+PW configuration, asymmetric hysteresis loops describe a different behaviour of the system for positive and negative displacements. This asymmetric behaviour is due to the asymmetric distribution of the base connections, when the perpendicular wall is taken into account.
Table 2 presents the mechanical parameters evaluated for the load-displacement curves obtained from the monotonic tests, while the mechanical parameters evaluated from the backbone curves of the cyclic tests are shown in Table 3, for both range of positive and negative displacements.
The findings from both monotonic and cyclic tests indicate that the structural interactions due to perpendicular wall contributes to improve the lateral performance of the shear wall. In the next, the percentage of the increments are calculated, considering the average values between the results obtained from the load-displacement curves of the SW test (both monotonic and cyclic tests in the range of positive displacements) and the results obtained from the load-displacement curves of the SW+PW tests (both monotonic and cyclic tests in the range of positive displacements).Specifically, the average increases of the lateral stiffness (K_{el}) and the lateral capacity (F_{max}) of the SW+PW configuration respect to the case of SW configuration, are about 40% and 41%, respectively. Moreover, results show an increment of the deformation capacity (V_{ult}) in case of SW+PW configuration equal to 25%.
Figure 9 shows the displacement paths, evaluated for both monotonic and cyclic tests, of the hold-down placed at the base of the shear wall and of the hold-down placed at the base of the perpendicular wall. The graphs plotted in Figure 9 show that hold downs of shear wall and perpendicular wall are subjected to close vertical displacements, due to the effect of the interaction provided by the wall-to-wall connections. Figure 9 highlights therefore that perpendicular walls may act as a hold-down system and have a significant effect on the behaviour of the lateral load resisting system. This can also be seen from the photo in Figure 9, which shows the uplifts of both shear wall and perpendicular wall.
The outcomes in terms of hysteretic parameters are shown in Figure 10 (a) and (b). Results of the equivalent viscous damping v_{eq} and the normalised impairment of strength ΔF_{1-3} are plotted in graphs, which report in the horizontal axis the cycles and in the vertical axis the hysteretic parameters. The findings of cyclic tests show a maximum impairment of strength ΔF_{1-3} about 16.7% and 27.3% in case of SW and SW+PW configurations, respectively. Moreover, an average equivalent viscous damping v_{eq} of 7.2% and 9.2% was found for the SW and SW+PW configuration, respectively.
The comparison of the dissipated energy E_d between SW and SW+PW configurations, is presented in Figure 10 (c). In both configurations the dissipated energy follows a similar trend for all tests. The maximum values of dissipated energy E_d were equal to 25 and 42 kJ, in case of SW and SW+PW configuration, respectively.

4 CONCLUSIONS

This paper presented an experimental campaign aimed at investigating the lateral response of CLT shear walls connected to perpendicular walls by means of typical screwed wall-to-wall connections. The lateral performance of two configurations was investigated: SW, i.e. single shear wall, and SW+PW, i.e. shear wall connected to perpendicular wall.
The purpose was to compare the results obtained from these two configurations in order to evaluate the increases in lateral performances of the shear wall when the perpendicular wall is taken into account. The results of this study show that shear walls connected to perpendicular walls reach significative higher structural performance in terms of lateral stiffness, lateral capacity and deformation capacity than typical single shear walls.

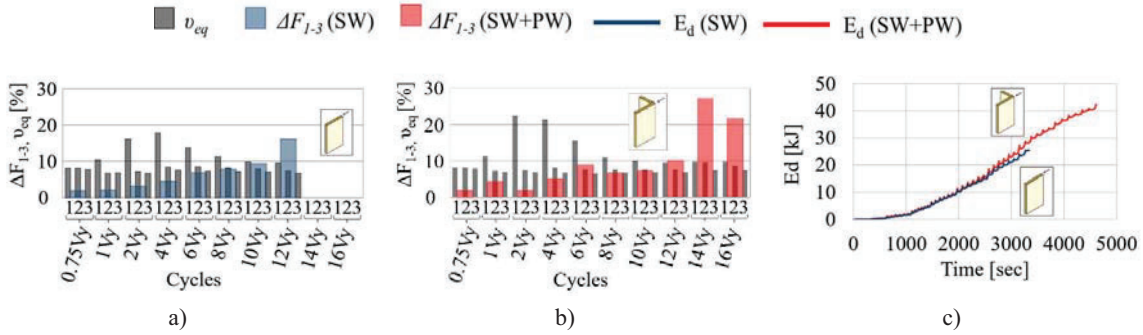

Figure 10: *a) Equivalent viscous damping v_{eq} and the impairment of strength ΔF_{1-3} in case of SW configuration, b) equivalent viscous damping v_{eq} and the impairment of strength ΔF_{1-3} in case of SW+PW configuration, c) comparison of dissipated energy E_d obtained from the cyclic tests of SW and SW+PW configurations.*

Increase of performances is governed by the properties of the wall-to-wall connections as well as the properties of the hold downs used in the perpendicular walls. In this study, in which the same hold downs were used for anchoring the shear wall and the perpendicular wall, increase of lateral stiffness and lateral capacity up to 40% and 41% were found, respectively. Moreover, experimental results show an increment of the deformation capacity in case of SW+PW configuration equal to 25%.

The findings of this experimental study showed that the presence of perpendicular walls provide significative interaction effects with the shear walls, and contribute to the so-called box behaviour of CLT buildings. The results presented in this study provides valuable insights into the interaction between shear walls and perpendicular walls in CLT platform-type buildings, demonstrating that these interactions can significantly modify the lateral response of CLT structures.

ACKNOWLEDGEMENT

FULL-SCALE LATERAL TESTING AND MODELLING OF INDUSTRIALIZED TIMBER DIAPHRAGMS INCLUDING ONLY FRAMING AND NON-STRUCTURAL SHEATHING

Fernando Véliz[1], Xavier Estrella[2], Pablo Guindos[3]

ABSTRACT: Over the last decade, industrialized mid-rise light-frame timber buildings have gained popularity in Chile due to their structural, manufacturing, and environmental advantages. However, structural design aspects and industrialization prescriptions are not thoroughly addressed by national design codes, highlighting the need for developing standards to regulate industrialized earthquake-resistant timber systems. Therefore, this paper presents the outcomes of a large national project aimed at characterizing the lateral performance of a series of full-scale industrialized timber diaphragms employing Chilean materials. Eight 3.6x2.4 m specimens were tested under in-plane lateral load, considering different detailings such as sheathing, nailing, and framing. Besides, bare slabs (no sheathing) were also studied in the campaign. Strength results proved to be consistent with those proposed by international regulations, while chord tensions exceeded 30% of those obtained by principles of engineering mechanics. Additionally, it was found that adding gypsum boards over plywood does not considerably improve the global stiffness, although it considerably increased the in-plane strength. Finally, a finite-element numerical model was developed for the slabs studied in this campaign, proving to be capable of capturing the nonlinear behavior of the specimens under large lateral displacements.

KEYWORDS: Diaphragms, timber buildings, gypsum, I-joist, in-plane testing, numerical modeling

1 INTRODUCTION

Since the 1950s, low-rise wood-frame structures have considerably increased across seismic regions, with recent data [1] showing a bright future for multi-story timber buildings in the years to come. Nevertheless, the lower stiffness of timber structures can produce a detrimental impact on their performance. Such an issue shows the fundamental role of diaphragms in the performance of buildings under seismic loads [2] or wind action, influenced by the local diaphragm's behavior, either rigid or flexible [3] as classified by [4]. Several experimental campaigns [5-10] have proven that both the shear capacity and stiffness of diaphragms are primarily dependent on the sheathing-to-framing connection [6].

Even though a large amount of research has been oriented to the traditional light-frame diaphragms, there is still a lack of studies focused on I-Joist diaphragms. For example, concerns about the validity of applying the same design provisions to conventional and I-joist diaphragms [11], have led designers to challenge such design methods, mainly due to the potential splitting of I-joist flanges, which was not addressed in those codes. Such concerns were partially addressed through I-joist diaphragm tests, such as those conducted by Weyerhaeuser, whose results have been reported by [12]. Among other outcomes, the researchers found that a lower shear strength improvement on I-joist diaphragms was reached when replacing 6d nails with 10d nails (+16% strength), compared to that improvement reached using sawn-lumber joists diaphragms and the same nails (+70% strength), attributable to flange splitting. Furthermore, other investigations such as the one conducted by [13], which considered eight 7.3x7.3 m I-joist diaphragms, proved that wooden I-joist diaphragms meet the design values specified in the Special Design Provisions for Wind and Seismic SDPWS standard [14], whose parameters were originally calibrated based on sawn lumber tests.

The new tendency of building higher timber buildings has raised concerns about the fire resistance of these structures. Such a concern is usually solved using gypsum boards. The structural contribution of gypsum panels has been experimentally assessed, however, putting the focus on gypsum sheathing over shear walls [15-17]. Some studies have tested gypsum sheathing attached to ceilings [18], which was supposed to improve their in-plane strength within the linear range. Such lack of data led authors [19-20] to study the contribution of gypsum sheathing in diaphragms. Then, an experimental campaign shown in [18] assessed the contribution of gypsum over ten full-scale (3.7 x 4.9 m) plywood roof

diaphragms, including both pitched and flat specimens. Such investigation focused on determining if the diaphragm strength or stiffness was increased by adding a 12 mm thick gypsum board, evaluating also the impact of employing different roof pitches. Tests confirmed that the increase in apparent stiffness for flat roofs is negligible; by contrast, gypsum increased the apparent stiffness of gable roofs by an average of 32% and hip roofs by 21%.

An important lack of houses has been noted in Chile the last decade, estimating a need of 650.000 units [21]. The main alternative chosen by the Housing Ministry to afford this lack is associated with industrialized construction, which can reduce manpower, time and overall cost, while better quality houses are obtained in contrast to using the traditional method [22]. Nowadays, guidelines such as the SDPWS [14] standard used to design timber structures in Chile, since no design recommendations are available in local regulations [21] to date. Therefore, the present investigation aims at contributing with scientific data for the inclusion and regulation of industrialized timber diaphragms in the Chilean code [21], including both experimental and numerical information of different typologies through an experimental campaign.

2 EXPERIMENTAL STUDY

As previously mentioned, this research is mainly focused in providing both experimental and numerical information for timber diaphragms, considering different typologies, including I-Joist framing as well as sawn-lumber framing, and non-structural ceiling panels over the diaphragms, so these contributions can be experimentally measured in terms of strength and stiffness. To address these issues, a set of 8 industrialized full-scale diaphragms 3.6 x 2.4 m were tested as part of the investigation presented in this paper according to ASTM E-455 loading protocol [23], considering a third-point load condition, and the results were used to validate the numerical models presented in a subsequent section of this document. The so-called numerical model was based on M-CASHEW software [24] and following the modeling guidelines proposed by [25].

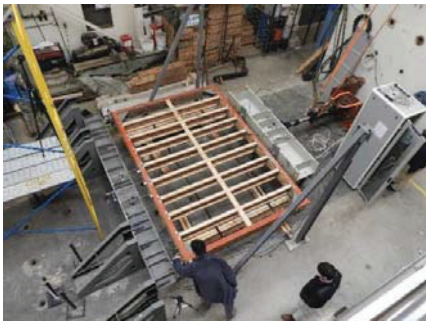

Figure 1: *Layout of the lateral testing of the specimens.*

2.1 DIAPHRAGM SPECIMENS

Different parameters were considered such as using sawn lumber joists as well as I-joists, assessing the contribution of gypsum panels over the structural sheathing and including different type of fasteners. Four diaphragms were constructed using 41 x 185 mm (2'' x 8'') sawn-lumber framing, graded as a C24 Chilean Radiata Pine [26]. The other four specimens were built using LSL as chord-and-end beams, while 241 mm deep LPI18 I-joists were used as interior beams, attached to LSL beams with ITS2.56/9.5 Hangers, and spaced at 407 mm on center.

Sawn-lumber (SL) specimens' chords were attached using Simpson Strong-Tie HRS416Z Straps, thus allowing to install strain gauges more easily, to experimentally obtain the chord tension. Every specimen was attached in their corners with four steel angles – attached by means of 8 shear bolts, 22 mm in diameter and 150 mm in length – to prevent early failures at the chord-to-end beam joint.

The first specimen of each configuration (sawn-lumber and I-joist), consisted of a bare slab, to measure the timber frame's stiffness, and then compared to the stiffness of the sheathed specimens. The sawn-lumber bare specimen was tested to failure, while, the I-joist specimen was tested only up to a design load, aiming at re-using it.

The second specimen of each configuration was designed with the same framing as the bare specimens. Nevertheless, these specimens were reinforced with an 11.1 mm thick APA rated OSB panel as sheathing on one side of the framing. The sawn-lumber diaphragm employed 2.9 x 65 mm smooth shank nails, spaced at 100 mm on center for the edge nailing, and 150 mm at adjoining panel edges parallel to the load direction. The I-joist diaphragms' panels were attached to the framing using 2.5 x 50 mm ring shank nails, spaced at 65 mm on center in the edge of the panels, and 100 mm at the adjoining panel edges parallel to the load direction. In all cases, field nailing was set to 300 mm on center . The third specimen of each configuration was similar to the second one, however, in this configuration the diaphragms were sheathed with a 15.1 mm thick plywood panel instead of 11.1 mm OSB, employing the same nails and nailing patterns for each case.
