World Conference on Timber Engineering Oslo 2023

A comparative study of design standards for assessment of long-span steel-timber composite floors under human-induced vibration

Sardar Malek[1], Najmeh Cheraghi-Shirazi[2], Keith Crews[3], Roger Parra[4], Ariel Creagh[5], Parham Khoshkbari[6]

ABSTRACT: Steel-timber composite (STC) floors are gaining popularity for residential and commercial buildings worldwide. Adding steel joists to wood-based panels is an attractive option for some designers to increase the span of timber floors. However, there is often a serviceability (vibration) concern with timber composite floors. It is well-known from the literature that human comfort due to vibration is subjective, and people's perception of comfort varies. Nevertheless, structural engineers still need to consider vibration in designing composite timber floors according to various standards and guidelines, especially when comparing two alternative designs. This study investigates the vibration behavior of STC floors under footfall force using a numerical model validated by experimental data. Transient finite element (FE) analysis is conducted to simulate human walking on the floor. The study also discusses acceptability of STC floors according to guidelines and building codes (e.g., AISC Design Guide 11, ATC, CLT Handbook, Eurocode 5). Lastly, the effects of various design parameters, such as CLT thickness, damping ratio, and CLT-to-CLT connection, on the vibration behavior of the composite timber floor are assessed.

KEYWORDS: Finite element analysis (FEA), Timber, Steel, Vibration, Standards, Mass timber buildings

1 INTRODUCTION

Over the past 20 years, significant research has been conducted on the vibration behavior of timber and timber-concrete composite (TCC) structures [1–6]. However, limited studies have been done on steel-timber composite (STC) systems [7]. STC flooring systems consist of steel joists and wood-based flooring panels such as cross-laminated timber (CLT) panels and oriented strand boards (OSB). Steel sections provide longer floor spans due to steel's high strength and stiffness. However, human comfort is increasingly considered a vital serviceability requirement for STC floors.

There are different criteria in standards and guidelines to investigate floor vibration based on various parameters, such as frequency, deflection, acceleration and velocity. A finite element (FE) model can accurately determine such parameters. Basaglia et al. [8] employed a numerical model in ANSYS to simulate walking on timber floors. They also used analytical equations in AISC Design Guide 11 [9], CCIP-016 [10], and SCI P354 [11] to find floor responses due to walking. Experimental results showed that the numerical model accurately predicted floor response (RMS acceleration) with an error of less than 3%. Chiniforush et al. [12] and Hassanieh et al. [7] studied the numerical modelling of STC floors under human-induced vibration. Their numerical model was calibrated using 22 variables (i.e., E, G, μ, k) with ABAQUS software [13]. The calibrated model was used for parametric studies to determine influential parameters on the vibration performance of STC floors. Huang et al. [14] generated a numerical model in OPENSEES to simulate running on STC floors. Elastic beam-column elements and springs were used to model CLT panels. All connections were modelled with extremely high stiffness values. Wang et al. [15] used the same numerical model to simulate walking on another steel-timber floor. A review of previous studies suggests more research is needed to create a numerical model for STC floors using characteristic (not calibrated) values of parameters. Moreover, engineers need the ability to model timber composite floors numerically without relying on springs or beam-column members for CLT panels. Further parametric studies are necessary, especially for parameters not studied by researchers, like footfall load functions, damping ratios, CLT panel connections, and loadings.

This study uses numerical modelling to examine the vibration performance of STC floors under footfall forces according to different standards. Similar to Basaglia et al. [8], transient analysis is performed to determine floor velocity and acceleration due to walking. The numerical (FE) model results are compared with estimates from the simplified equation in AISC Design Guide 11 [9] and with limits provided in various standards. Finally, the effect of important design parameters on floor vibration is analyzed.

2 VIBRATION CRITERA

Generally, guidelines and standards use different approaches to assess floor vibration. The behavior of floors under human-induced force may be examined based on simple parameters such as deflection and frequency [16–18]. More complicated parameters, such as Vibration Dose Value (VDV), peak (or RMS) acceleration, or peak velocity, can be used to assess floor vibration according to ISO [19,20], BS 6472-1 [21], CCIP-016 [10], and the AISC Design Guide 11 [9]. Some standards use a combination of two criteria. For example, Eurocode 5 [22] considers deflection and the limit for maximum impulse velocity. All these standards and guidelines may be used for timber composite floors. However, the different results from various references make it challenging for structural engineers to decide whether a floor has adequate serviceability. To showcase the challenge faced by practitioners, the vibration performance of two STC floors is assessed based on design guides such as the AISC Design Guide 11 [9], ATC [23], as well as timber-specific standards like Eurocode 5 [22] and CSA Standard O86-19 [24].

3 NUMERICAL MODELLING

3.1 Geometry

A finite element (FE) model in ETABS software [25] has been developed to understand floor performance. Under static and dynamic loads, the model was employed to inspect floor response, such as the floor mid-span deflection, velocity, or acceleration. The floor geometry and input properties were selected based on the previous work of Wang et al. [15], as shown in Figure 1. The simply supported floor comprised two steel joists (HN 450×200 mm) and five CLT panels (1.2×6×0.105 m) placed on top of the joists. The properties of CLT layers are provided in Table 1. As Wang et al. provided E1 and E2, other parameters have been taken from Hassanieh et al. [7]. A layered shell and beam elements were used in ETABS software [25] to simulate the three layers of CLT panels (with a thickness of 105 mm) and steel beams, respectively.

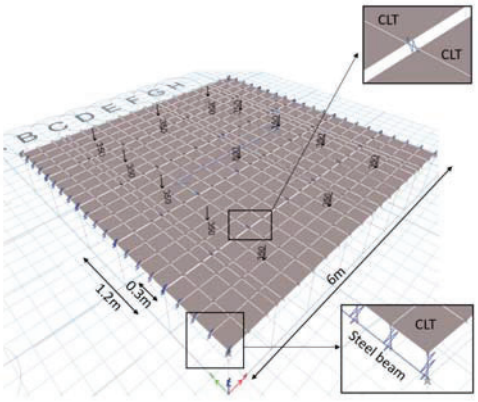

Figure 1: *STC floor considered in Wang et al.* [15] *and selected for this study*

Table 1: *Mechanical properties (MPa) of CLT panels obtained from literature [7, 15]*

Wang et al. [15]		Hassanieh et al. [7]						
E_1	E_2	E_3	G_{12}	G_{13}	G_{23}	υ_{12}	υ_{13}	υ_{23}
10767	979	530	610	860	120	0.59	0.57	0.24

3.2 Connections

As shown in Figure 1, there are six connections between adjacent CLT panels. In the numerical model, the value of 900 N/mm was selected for the shear stiffness of half-lapped connections perpendicular and parallel to CLT panels, according to Ussher et al. [26]. Furthermore, the CLT panels were connected to steel beams at a spacing of 0.3 m. The connection shear stiffness was selected based on the values provided in Hassanieh et al. [7] for Coach Screw 12, Coach Screw 16, and BGP 12 connections. The results varied by less than 3%, and the stiffness of Coach Screw 16 was selected for the results presented in this paper.

3.3 Loading

To define the floor's maximum deflection, a 1 kN static load was applied. For the maximum acceleration of the floor, a walking simulation was conducted according to the experimental study of Wang et al. [15]. In the ETABS software, a 75 kg human walking at 0.789 s/step was considered. Also, concentrated loads (according to the experiment) equal to a constant load of 0.15 kN/m2 were applied on the floor. Figure 2 shows the function employed to model the footfall force according to the experimental data. A transient modal analysis was performed to define the maximum acceleration of the middle point of the floor with a damping ratio of 2% and 3% under the human-induced force.

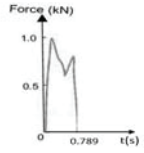

Figure 2: *The single footfall function considered to simulate walking on the floor in Wang et al. [15]*

According to Eurocode 5 [22], an impulsive force of 1 Ns was employed to investigate the velocity of the floor caused by walking. To simulate the impulsive force, the function recommended by Ohlsson [18] and presented in Hassanieh et al. [7] was used, as shown in Figure 3.

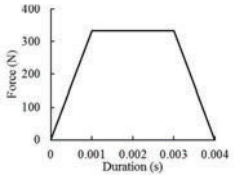

Figure 3: *The force function to simulate the impulsive force of 1 Ns according to Eurocode 5* [22]*, obtained from Hassanieh et al.* [7]

https://doi.org/10.52202/069179-0256

3.4 Convergence study

Mesh convergence was conducted to determine the suitable mesh size. The acceleration and frequency of the floor remained constant with a finer mesh size of 16 cm. Hence, 16 cm mesh size was used in the study.

4 Validation

The current numerical model was validated using the experimental results of Wang et al. [15] in terms of frequency and acceleration. Table 2 shows the comparison of predicted and measured floor frequencies, with a difference less than 3%. Figure 4 compares the measured acceleration and the current model's predictions of the acceleration at the middle of the STC floor, considering two damping assumptions of 2% and 3%. The results demonstrate that the STC floor is a low-frequency floor (frequency below 9 Hz and 10.5 Hz per AISC Design Guide 11 [9] and CCIP-016 [10], respectively) with a resonant response to walking. The figure depicts a good agreement between the results, displaying a similar trend of changing acceleration over time for all cases.

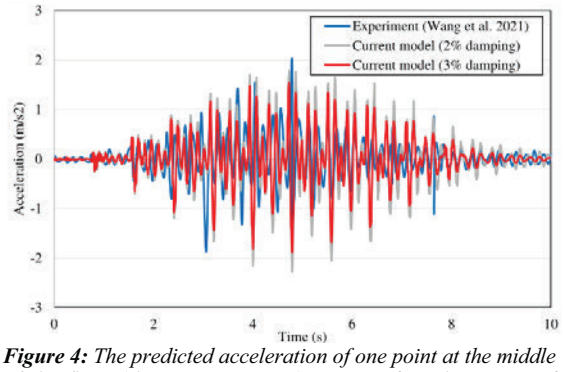

Figure 4: *The predicted acceleration of one point at the middle of the floor (shown in Figure 1) compared to the measured acceleration*

Table 2: *The predicted and measured frequency (Hz) of the STC floor (see Figure 1 for details of the floor)*

Measured frequency (Hz)	Predicted frequency (Hz)

5.21	5.16	5.15

5 VIBRATION PERFORMANCE

Wang et al. [15] calculated VDV for the floor depicted in Figure 1. The study found that the floor's VDV was about 0.8 m/s$^{1.75}$ with poor vibration performance (likely to receive an adverse comment) as per BS 6472-1 [21] (refer to Table 3). In the current study, the floor vibration is assessed according to other standards and guidelines, such as AISC Design Guide 11 [9], Eurocode 5 [22], ATC [23], and the Canadian CLT Handbook [27].

Table 3: *The VDV values range presented in BS 6472-1* [21]

Place and Time	Low Probability of Adverse Comment (m/s$^{-1.75}$)	Adverse Comment Possible (m/s$^{-1.75}$)	Adverse Comment Probable (m/s$^{-1.75}$)
Residential buildings (16 h daytime)	0.2 to 0.4	0.4 to 0.8	0.8 to 1.6
Residential buildings (8 h night)	0.1 to 0.2	0.2 to 0.4	0.4 to 0.8

5.1 AISC DESIGN GUIDE 11

According to AISC Design Guide 11 [9], the simplified design criterion based on peak acceleration for low-frequency (< 9 Hz) floors is defined by:

$$\frac{a_p}{g} = \frac{P_o e^{-0.35 f_n}}{\beta W} \leq \frac{a_o}{g} \quad (1)$$

where P_o is the constant force (65 lb), W is the effective weight of the floor (lb), β is the damping ratio, a_o is the vibration tolerance acceleration limit according to Figure 5, and a_p is the peak acceleration of the floor.

For high-frequency (>9 Hz) floors, the equivalent sinusoidal peak acceleration (a_{ESPA}) is calculated and compared to the acceleration limit. a_{ESPA} is defined using a calibration factor to adjust the prediction to match the measured data, as:

$$\frac{a_{ESPA}}{g} = \left(\frac{154}{W}\right)\left(\frac{f_{step}^{1.43}}{f_n^{0.3}}\right)\sqrt{\frac{1-e^{-4\pi h\beta}}{h\pi\beta}} \leq \frac{a_o}{g} \quad (2)$$

where W is the effective weight of the floor (lb), f_n is the fundamental natural frequency (Hz), and f_{step} is the step frequency (Hz) while $f_n = hf_{step}$. h is the step frequency harmonic that matches the natural frequency (see Table 4). a_o is the tolerance acceleration limit, according to Figure 5.

Table 4: *Step frequency harmonics matching the natural frequency of high-frequency (>9 Hz) floors adopted from AISC design guide 11* [9]

f_n (Hz)	h
9–11	5
11–13.2	6
13.2–15.4	7

The frequency of the floor presented in Figure 1 was below 9 Hz, making it a low-frequency floor according to AISC design guide 11 [9]. The calculated a_p (from Equation (1)) for the STC floor was around 6.7% g, exceeding the limit shown in Figure 5 for offices and residences.

According to modelling results, the maximum acceleration was 19% g, which exceeds the limit provided in Figure 5 for offices and residences. Therefore, the floor vibration is unacceptable according to AISC Design Guide 11 [9]. It should be noted that there is a considerable discrepancy between the results from Equation (1) and the numerical model for the maximum acceleration of the floor (see the blue and red points in Figure 5). More research is needed to investigate the

accuracy of existing design equations for timber composite floors.

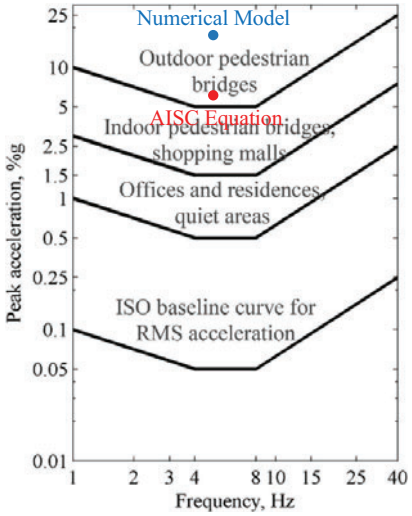

Figure 5: *Vibration performance of the floor showed in Figure 1 according to AISC Design Guide 11* [9]. *Red and blue points highlight the maximum acceleration of the floor estimated from the AISC simplified equation and the numerical model, respectively*

5.2 EUROCODE 5

Eurocode 5 [22] presents simplified equations to evaluate the vibration performance of timber floors with a frequency above 8Hz. This standard limits vertical deflection and unit impulse velocity response (due to an impulsive force of 1Ns) based on the following equations:

$$\frac{w}{F} \leq a \tag{3}$$

$$v \leq b^{(f_1\zeta-1)} \tag{4}$$

where w is the floor maximum instantaneous deflection (mm) under a point load F (kN), v is the unit impulse velocity response (m/(Ns^2)), and ζ is the modal damping ratio. Two constant floor vibration parameters, a and b, and the relation between them are obtained from a graph in Eurocode 5. Their relationship can be formulated [28] as follows:

$$b = 180 - 60a \qquad a \leq 1\ mm \tag{5.a}$$

$$b = 160 - 40a \qquad a > 1\ mm \tag{5.b}$$

According to the UK National Annex (UKNA) to Eurocode 5 [29], the floor deflection, a (mm), due to 1 kN force, should meet the following requirements [28]:

$$a \leq 1.8\ (\text{mm}) \quad ; \quad L \leq 4000\ mm \tag{6.a}$$

$$a \leq 16{,}500/L^{1.1}\ (\text{mm}) \; ; \quad L > 4000\ mm \tag{6.b}$$

where L is the floor span length (mm).
In ETABS software, an impulsive force of 1 Ns was modelled using the function recommended by Ohlsson [18], as presented in Figure 3.

Figure 6 presents the floor velocity diagram due to the impulsive force. Results showed that the maximum velocity of the floor is approximately 5.5 mm/s, which is below the allowable velocity of 18 mm/s. The maximum deflection of the floor under 1kN is 1.5 mm, while the allowable deflection is 1.15 mm. As noted in previous research [30], deflection is a more decisive criterion than velocity. However, the floor does not meet the frequency limit of 8 Hz. Hence, evaluating the floor according to Eurocode 5 may not be appropriate [22].

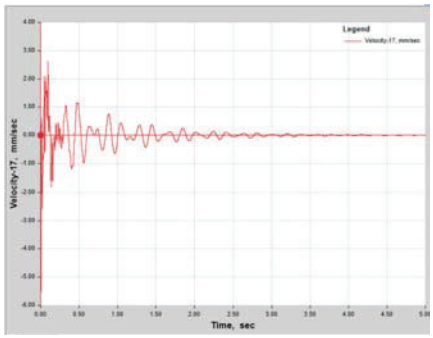

Figure 6: *Floor velocity diagram due to the impulsive force of 1 Ns using the function recommended by Ohlsson [18]*

5.3 ATC DESIGN GUIDE

ATC [23] defines a relation for light-frame floors with a fundamental frequency of more than 8 Hz to limit the maximum floor deflection under a 1 kN load applied at the mid-span. This criterion is defined based on Equation (7):

$$\Delta_p \leq 0.61 + 2.54e^{-0.59(L-1.95)} \leq 2.0\ mm \tag{7}$$

where Δ_p is the maximum floor deflection (mm) and L is the span length (m). Equation (1) is also used by ATC [23] as a resonance criterion. Modelling results showed a maximum floor deflection of 1.5 mm, which is exceeding the allowable deflection of 0.84 mm. Therefore, the vibration performance of the floor is unacceptable according to ATC [23].

5.4 CLT HANDBOOK

The Canadian CLT Handbook [27] presents the following equation to define the deflection of a CLT floor under the uniformly distributed load.

$$\Delta = \frac{5wL^4}{384(EI)_{eff}} + \frac{wL^2}{8(GA)_{eff}} \tag{8}$$

where $(EI)_{eff}$ is the floor's effective bending stiffness (N-mm^2), $(GA)_{eff}$ is the effective shear rigidity (N/mm), L is the span length (mm), and w is the distributed load (N/mm). The FE model predicted the deflection of the floor within 5% of the result of Equation (8). The maximum deflection of the floor under a distributed load of 0.15 kN/m^2 was 2.6 mm, while the result of Equation (8) was around 2.5 mm. According to the Canadian CLT Handbook [27] and the CSA Standard [24], the vibration-

https://doi.org/10.52202/069179-0256

controlled span (m) for a CLT floor (simply supported) can be obtained from the following equation:

$$L \leq 0.11 \frac{\left(\frac{(EI)_{eff}}{10^6}\right)^{0.29}}{m^{0.12}} \quad (9)$$

here m is the mass of CLT for a 1-meter width (kg/m), and $(EI)_{eff}$ is the floor's effective bending stiffness (N-mm^2). The vibration performance of the considered floor (Figure 1) with a span length below 3 m is satisfactory using Equation (9). Hence, the floor with a span length of 6 m as in (Figure 1) is unacceptable according to the CLT Handbook.

In summary, the floor with the configuration presented in Figure 1 showed unsatisfactory vibration performance per AISC Design Guide 11 [9], ATC [23], and Canadian CLT Handbook [27]. The ratio of floor deflection to allowable deflection in Eurocode 5 [22] seems to be very low. Hence, lowering span length or using thicker CLT panels will increase floor frequency and decrease the deflection. Accordingly, the floor can be acceptable according to Eurocode 5, but still unacceptable according to AISC Design Guide 11 [9], ATC [23], and Canadian CLT Handbook [27]. Hence, it might be helpful to look at another example that illustrates the discrepancy between the results of different standards and guidelines, namely the STC floor studied by Hassanieh et al. [7].

Using the data provided by Hassanieh et al. [7], Table 5 presents the vibration performance of the floor according to different standards and guidelines. The maximum acceleration of the floor exceeded the limit provided in Figure 5 (with a ratio of 1.16). Furthermore, the maximum deflection of the floor (0.72 mm) is more than the allowable deflection according to ATC [23] (0.68 mm) and less than that allowed by Eurocode 5 [22] (0.84 mm). In addition, as a result of Equation (9), the floor (with a span length of less than 10 m) was acceptable according to the CLT Handbook [27]. As mentioned before, AISC Design Guide 11 [9] and ATC [23] were more conservative than others.

Table 5: *Acceptability of STC floors according to different standards and guidelines*

6 Parametric studies

Different design parameters can affect the acceleration of the floor due to walking. This study focuses on previously understudied parameters such as force function used to simulate walking. Further research is needed to investigate the effect of various footfall force functions and step frequencies on floor vibrations. Additionally, adding secondary steel beams to CLT panels can change the behavior of the floor from resonant to transient, resulting in a significant reduction of floor acceleration. This study quantifies the impact of CLT thickness, damping ratio, and CLT-to-CLT connections on the acceleration of the floor under footfall force over time, and demonstrates that increasing CLT thickness and damping ratio, as well as improving CLT-to-CLT connections, can effectively decrease floor acceleration.

6.1 CLT thickness

Different thicknesses of CLT panels (105, 160, and 180 mm) with layers at different thicknesses (20, 30, 35, and 40 mm) were used to investigate the effects of the CLT thickness on the acceleration of one point at the middle of the floor. Figure 7 shows that the maximum acceleration of the floor was reduced by almost 65% when the thickness of the CLT panels increased from 105 mm to 180 mm. All models utilized a 3% damping ratio for the floor, with six connections between adjacent CLT panels.

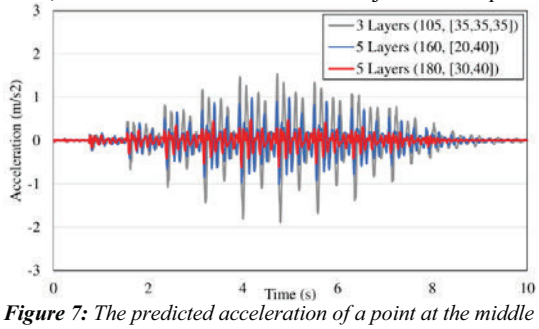

Figure 7: *The predicted acceleration of a point at the middle of the floor (see Figure 1) for different CLT thicknesses*

6.2 Damping ratio

The damping ratio of floors is influenced by multiple factors, such as the floor type and non-structural elements. Figure 8 illustrates that increasing the floor's damping from 1% to 3% reduces the maximum acceleration by approximately 35%. However, further increases in damping have a negligible effect on the floor's maximum acceleration. Despite 3% being suggested as the damping ratio in various sources, further research is needed to assess its impact on the vibration performance of different STC floor types. All models in Figure 8 utilized 105mm thick CLT panels with six connections between them.

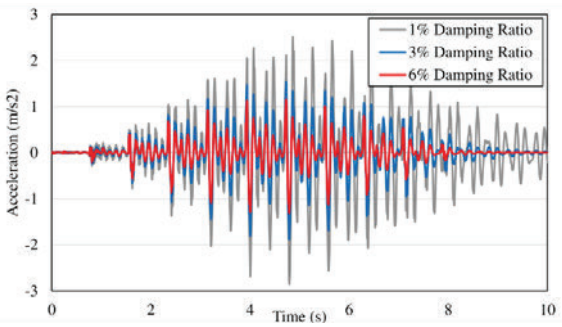

Figure 8: *The predicted acceleration of a point at the middle of the floor (see Figure 1) for different damping ratios*

6.3 CLT-to-CLT connections

Internal spline, single-spline, double-spline, and half-lapped are different methods of connecting adjacent CLT panels. This study used half-lapped connections as described in Section 3.2. To investigate the effect of the number of connections on the acceleration of the floor due to walking, a numerical model was employed using six connections, no connections, and fully bonded connections. The results indicated that increasing the number of connections from 0 to 6 reduced the maximum acceleration by approximately 35% (see Figure 9). However, further increasing connections to fully bond the adjacent CLT panels had little impact on the results. All models utilized a 3% damping ratio for the floor, with 105mm thick CLT panels. The type of CLT-to-CLT connections did not appear to have a significant effect on the floor acceleration under footfall forces. Further research with more detailed information is necessary to validate this finding.

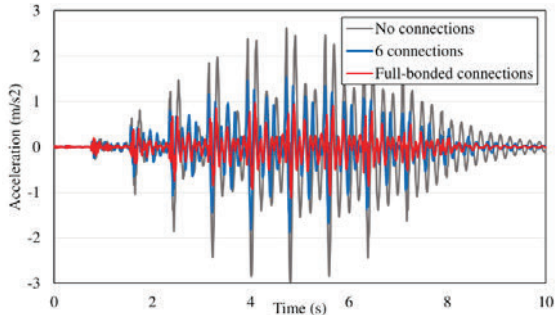

Figure 9: *Predicted acceleration at the mid-floor point (see Figure 1) for different CLT-to-CLT connections*

7 CONCLUSION

The findings of this paper indicate:

- There are various standards and guidelines that may seem applicable to STC floors.
- Different standards may lead to contradictory results based on floor dimensions.
- The AISC Design Guide 11 [9] has an appropriate criterion if the floor's acceleration is predicted accurately.
- The simplified equations in the AISC did not accurately predict the peak acceleration of the floor as compared to the results from the numerical model. Further research is necessary to determine the accuracy of these simplified equations for both high-frequency and low-frequency timber and timber composite floors.
- The deflection limit was found to be a more important criterion than velocity in the Eurocode 5 assessment of floor performance.
- The use of a detailed FE model will enable structural engineers to optimize the design of STC floors according to various standards and assess the impact of different design parameters, such as floor span, damping, and panel-to-beam and panel-to-panel connection systems, on floor vibration.
- Human tests may be necessary to determine the most appropriate standard or guideline for evaluating the vibration performance of composite timber floors.
- Design parameters such as CLT thickness, damping ratio, and CLT-to-CLT connections can affect the maximum acceleration of the floor significantly.

This research suggests the need for further studies to investigate the impact of various single footfall forces with different step frequencies on the acceleration of the composite timber floor. Further research is needed to validate the relevance of the developed numerical model for a real building, taking into account all details including column-to-beam connections, beam-to-beam connections, internal and external walls, and openings.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to Katie Boisseree and Kyle Steuck of Degenkolb Engineers for valuable technical discussions. They also acknowledge the financial supports received from the University of Victoria (through FGS award) and the Charles S. Humphrey Graduate Student award.

ASSESSING THE EFFECTS OF BOUNDARY CONDITIONS ON THE VIBRATIONAL COMFORT OF ON-SITE TIMBER-CONCRETE COMPOSITE FLOORS

Francesca Lanata[1], Clement Boudaud[2]

ABSTRACT: The design of timber-concrete composite structures (TCC) is usually governed by the serviceability rather than the strength, particularly for medium to long span floors. In terms of users' comfort, issues can come from vibrations of TCC floors. Indeed, discrepancies are usually observed between the calculations at the design stage and the on-site measurements, due to the gap between design assumptions and in service conditions (boundary conditions, partition walls, floor finishing…). This paper focuses on the comparison between analytical, experimental (on-site and laboratory) and numerical approaches in the assessment of vibration performance of a TCC floor to obtain the frequencies corresponding to different boundary conditions. Results show unexpected differences between analytical models and laboratory experimental measurements for simple boundary conditions. A new equation is being developed to adapt the design of the TCC floors of the full-scale building under study, which presents the specificity of a TCC floor with overhang. A FEM model is developed to assess the validity of the proposed analytical equation.

KEYWORDS: timber-concrete floor, overhang, vibration assessment, multi-approach analysis

1 INTRODUCTION

TCC is known for improving the vibrational comfort for users compared to a timber floor. Nevertheless SLS (vibration) is still a dimensional criterion. The next version of EC5 should include a new design method, modifying both the assessment of the fundamental frequency (proposing an equation for semi-rigid support for example) and the limit criteria ($4 \cdot f_w$, 7 or 8Hz depending on the required performance level) [1]. Yet literature suggests that while analytical models and laboratory experiments fit well together (on dynamical properties), they are too conservative compared to the dynamic properties observed in real buildings [2, 3], and therefore force oversized designs to meet the SLS criteria.

The objective of this work is to assess the influence of boundary conditions (support conditions, overhang, partition walls and floor finishing), by combining modelling (analytical and numerical) and experimentation (laboratory and on-site) on a case study presenting particularities about overhangs. Indeed, TCC floors in the building under study (ESB) have one overhang, and they are supported by a truss structure with an overhang portion itself. The laboratory tests are conducted on two TCC specimens that are as identical as possible as those in the full-scale building (where on-site measurements were conducted in the past [4]). Yet, as dimensions and materials could not be exactly the same, direct comparisons between on-site and laboratory results are not possible. Moreover, due to current limitation in the numerical model (only rigid timber/concrete interface), it cannot be directly compared to laboratory and on-site measurements. For these reasons, and because an evolution of an analytical equation is proposed in this paper, analytical calculations serve as the reference to which numerical, laboratory and on-site are successively compared. In the following, once the case study is described (§2), analytical state of the art and proposed evolution necessary for the case study (overhang combined with 2D behaviour) are detailed in §3. Experimental (§4) and numerical (§5) works are then explained.

2 DESCRIPTION OF STUDIED TCC FLOORS

The case study introduced in this paper is the large-span TCC floor of the ESB building, built in 2011 and presenting some interesting features for the aim of this work. Several experimental campaigns have been performed on the on-site building and parallel laboratory tests have been conducted to better understand the structural response of the floor and propose an analytical and numerical approach to better design such a TCC floor. Two TCC specimens have been built at a smaller scale but as identical as possible as the floors of the full-scale building. The characteristics of both building and specimens are detailed in the following.

2.1 ON-SITE BUILDING

The expansion of the ESB building is constituted by three floors, realized with two parallel trusses in glue-laminated timber (Figure 1). The trusses are around 45m long and 13m height with a one-side overhang of about 9 to 10m. The architectural design of both trusses is the same, but timber cross-sections are different because of the slightly different supported loads.

Figure 2 shows that each truss is simply supported in three points (one is V-shaped): the part between the two vertical columns (Section C) is linked to the existing concrete building, the part with the overhang (Sections A and B) is more flexible because of the lack of a closed ground floor. Some partition walls have a structural function to assure the wind bracing resistance.

Figure 1: *3D representation of the ESB expansion building (overhang on the right)*

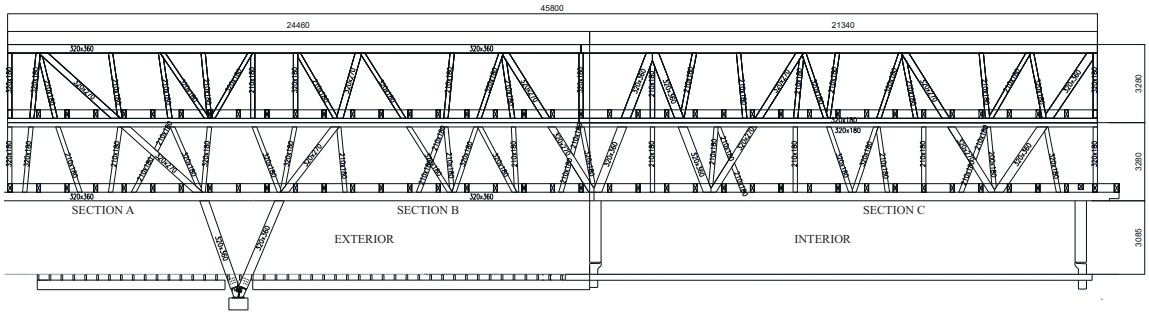

Figure 2: *Geometry of the South truss (overhang on the left side), with the biggest cross-sections and loads*

The South and North trusses are linked together through TCC floors object of the study. The total span of the floor is 9.6m, including a walkway of 2.0m, forming an overhang (Figure 3), also visible in Figure 1.

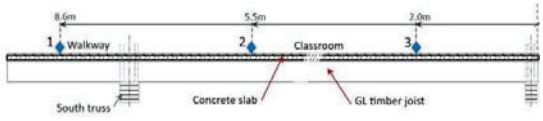

Figure 3: *Geometry of the TCC floor. The two supporting trusses with different cross-sections are visible. 1, 2 and 3 are the sensors positions (§4.2)*

The cross section of the TCC floor is represented in Figure 4 and the main characteristics are detailed in Table 1.

2.2 LABORATORY SPECIMENS

The laboratory tests have been performed on two specimens as similar as possible as the on-site TCC (§2.1). The dimensions of the TCC specimens are represented in Figure 5.

Before assembly, the mass, density, moisture content and longitudinal Young modulus (through vibration method) of each glulam beams have been measured. A 20µm polyethylene protective film between the concrete slab and the timber (beam and plywood) was used to avoid excessive humidification.

Figure 5: *Geometry of the two laboratory TCC specimens*

The mechanical characteristics of the specimens are detailed in Table 2. For the Young's modulus of timber and its density, the mean values from the four timber joists are given.

Table 2: *Geometric and mechanical properties of materials used for the laboratory specimens*

Element	Material properties	Symbol	Value
GL24h timber joists	Width	b_2	80mm
	Height	h_2	220mm
	Effective width	b_{eff}	540mm
	Total span	L_{tot}	6.0m
	Overhang span	L_f	1.0m and 2.0m

Non-structural elements	Floor finishing and partition wall	m	30kg

3 ANALYTICAL APPROACH

3.1 EQUATIONS STATE-OF-THE-ART

The current version of EC5-1-1 [5] suggests to assess the vibrational comfort of a floor following three steps:

1. Calculation of the fundamental frequency f_1 (Hz);
2. Calculation of the maximum deflection w_{1kN} (mm) due to a vertical static point-load F=1kN;
3. Calculation of the velocity v (m/N s²) as a structural response due to a unit impact force

The paper will be only focused on the calculation of the fundamental frequency. The proposed calculation of this parameter is given from Equation (1):

$$f_1 = \frac{\pi}{2L^2}\sqrt{\frac{(EI)_L}{m}} \quad (1)$$

where L is the floor span, in m, $(EI)_L$ is the bending stiffness along the floor span par meter width, in Nm²/m, and m is the floor mass per unit area, in kg/m².

The velocity criterion is used for single span floors having a fundamental frequency exceeding 8Hz, that are approximatively rectangular in plan and are supported by rigid supports [6]. Equation (1) is a simplified version of the flexural behaviour of a rectangular orthotropic plate (LxB) on supported edges, whose equation takes into account the elastic constant D in both directions, along and transverse to the floor span (Equation (2)) [7].

$$f_{m,n} = \frac{\pi}{2L^2\sqrt{\rho}}\sqrt{D_x m^4 + 2D_{xy}m^2n^2\left(\frac{L}{B}\right)^2 + D_y n^4\left(\frac{L}{B}\right)^4} \quad (2)$$

Even if EC5-1-1 does not specify this, Equation (1) can only be used when the transversal bending stiffness $(EI)_B$ is not exceeding 1% of the longitudinal bending stiffness $(EI)_L$. This means that the approximated value of the fundamental frequency from Equation (1) is given for a one-way spanning floor (1D behaviour), having a negligible effect of transversal bending stiffness (low $(EI)_B$ and/or large floor width B). The EC5 National Annex of Finland [8] suggests using the complete equation to better assess the fundamental frequency of a two-way spanning floor (2D behaviour) on supported edges (Equation (3)).

$$f_1 = \frac{\pi}{2L^2}\sqrt{\frac{(EI)_L}{m}}\sqrt{1 + \left[2\left(\frac{L}{B}\right)^2 + \left(\frac{L}{B}\right)^4\right]\frac{(EI)_B}{(EI)_L}} \quad (3)$$

As Equation (1) is based on some strict assumptions and validated on floors having a span not exceeding 4.5m, the calculation of fundamental frequency is usually quite far from the real measured one from experimental results [2, 3]. The provisional version of the future EC5 [1] includes lots of improvements to adapt and generalize Equation (1), as indicated in Equation (4).

https://doi.org/10.52202/069179-0257

$$f_1 = k_{e,1} k_{e,2} \frac{\pi}{2L^2} \sqrt{\frac{(EI)_L}{m}} \quad (4)$$

First of all, the consideration of the two-way spanning (2D) behaviour of a floor to consider the effect of the transverse floor stiffness has been added, through the factor $k_{e,2}$, given in Equation (5).

$$k_{e,2} = \sqrt{1 + \left(\frac{L}{B}\right)^4 \frac{(EI)_B}{(EI)_L}} \quad (5)$$

The equation given for $k_{e,2}$ is a simplification of Equation (3), neglecting the $(L/B)^2$ term. This is similar to the current approach used into the National Annex of Austria [9], to be used when the ratio between transversal and longitudinal bending stiffnesses is higher than 5%. Nevertheless, no specification concerning this ratio is given in the future version of EC5. The presence of a double span floor is also considered in prEN EC5-1-1 [1] through the factor $k_{e,1}$. The Annex K has to be considered if the floor configuration is more complex. Finally, the stiffness of the supports has been introduced to include floors supported by elastic beams. The suggested equation in prEN EC5-1-1 (Equation (6)) is adapted from [10].

$$\frac{1}{{f_1}^2} = \frac{1}{f_{1,rigid}^2} + \frac{1}{f_{1,beam1}^2} + \frac{1}{f_{1,beam2}^2} \quad (6)$$

Considering the boundary conditions, neither the current version of EC5 [5] nor the provisional version of the future EC5 [1], mention the possibility to have other supports than the isostatic ones (pin/roller). In the literature, some coefficients have been proposed to consider the fixed/pinned, the fixed/fixed, the fixed/free (cantilever) conditions [11, 12, 9]. In Equation (1) the coefficient $\pi/2$ is substituted by $\lambda^2/2\pi$, also called C_B. The same approach is suggested into the National Annex of Austria, by multiplying Equation (1) by a coefficient $k_{e,1}$, different from the $k_{e,1}$ of the future EC5.

Table 3: *Comparison between coefficients proposed to adapt Eq. (1) to different ends conditions*

Ends conditions	λ [11]	C_B [12]	$k_{e,1}$ [9]
Pin-roller	π	1.57	1
Fix-pin	3.927	2.45	1.562
Fix-fix	4.730	3.56	2.268
Fix-free	1.875	0.56	0.356

However, the studied boundary conditions do not cover the case of overhangs, as in the case of ESB building. To adapt the fundamental frequency equations to the full-scale ESB floor, an approximated equation proposed by [13] and adapted by [14] from a FEM analysis has been used. Equation (7) is defined for a simply supported beam with one-side overhang of an arbitrary length. The coefficient K_1 is given graphically as a function of the ratio between the span without overhang and the total length of the beam (Figure 6).

$$f_1 = \sqrt{K_1 \frac{(EI)_L}{\rho A L^2}} \quad (7)$$

The calculation of the equivalent bending stiffness $(EI)_{ef}$ for a composite floor is unchanged (EC5 Annex B).

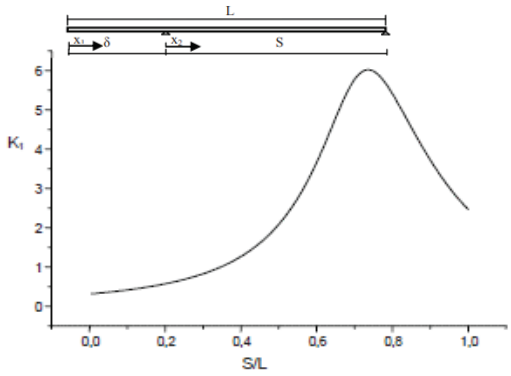

Figure 6: *Representation of the variation of K_1 as a function of the S/L ratio [14]*

3.2 ANALYTICAL RESULTS FOR ON-SITE BUILDING

To assess the fundamental frequency of the ESB floor, Equation (7) has firstly been applied to catch the overhang behaviour. A coefficient K_1 equal to 5.55 has been assessed from Figure 6 entering with the ratio $(L_{tot}-L_f)/L_{tot} = 0.79$. The longitudinal bending stiffness $(EI)_L$ has been computed from the Annex B of EC5. The value for the ESB floor is $2.34 \times 10^7 Nm^2/m$. The floor mass has been computed as the sum of self-weight loads, including supported and suspended layers, but not partition walls. The numerical value of m for the ESB floor is $238 kg/m^2$. L is the total length of the joists L_{tot} (Table 1). A fundamental frequency of 8.09Hz has been determined from Equation (7).

Equation (7) has also been studied with pinned-clamped ends restraints [14]. These conditions approach much more the on-site conditions because of the stiffness of the supporting walls. The fundamental frequency increases to 11.97Hz in this case. However, it seems difficult to justify such a configuration for the ESB floors, as the two supports conditions are very similar.

The current version of EC5 (Equation (1)) has been used for the original design computation of the floor, without considering the overhang and using a span of 9.6m (L_{tot}). A fundamental frequency of 5.39Hz is computed with these assumptions. When the overhang if fully neglected, considering a span of 7.6m, a frequency of 8.62Hz is retrieved (Table 4). It seems therefore very important to consider the presence of the overhang for a better assessment of the fundamental frequency.

https://doi.org/10.52202/069179-0257

In all cases, the 2D behaviour of the floor is not considered yet. The ratio between transversal and longitudinal bending stiffnesses for the ESB floor has been assessed to check if the 2D behaviour is really negligible. The obtained ratio is around 5%, showing the important 2D behaviour of this TCC floor, mainly due to the connected concrete slab. With this assumption, Equation (3) and its simplified version from the National Annex of Austria seems to be more precise in assessing the fundamental frequency of the floor. The results give 5.47Hz and 5.76Hz respectively. A floor width B of 12m (10x1.2m) has been considered for the computation, according to the slab discontinuity joints at each partition wall with wind bracing functions. Indeed, no specification is given in EC5 to clarify the definition of the floor width to consider. Finally, it has to be underlined that the future EC5 approach (Equation (4)) is the same as the Austrian equation, with $k_{e,1} = 1$ for the ESB case. Table 4 summarizes the results when applying the explained equations.

Table 4: *Results of fundamental frequencies f_1 for ESB floor from current available equations*

Configuration	2D floor	f_1 (Hz)	Source
	-	8.09	Eq. (7)
	-	11.97	Eq. (7)
	-	5.39	Eq. (1)
	-	8.62	Eq. (1)
	yes	5.44	Eq. (4)(5)
	yes	5.59	Eq. (3)

The last parameter to consider is the elastic supports. As a matter of fact, the ESB floor is supported by two timber trusses, that cannot be considered as rigid supports. Equation (6) has thus to be used and the natural frequencies of supporting trusses (beams) assessed. For this purpose, a numerical model has been realized for both trusses. The models are slightly different due to the cross-sections and loads, but the truss design is the same. As the stiffness of the truss itself is affected by the overhang, the modal shapes have been observed to retrieve the fundamental frequency for the overhang and the one for the part between the V-shaped column and the first vertical column (Section A and Section B respectively, Figure 2). It has to be underlined that the analysis only focuses on the less stiff part of the trusses (the exterior part, Sections A and B). The results for the fundamental frequencies of the trusses are summarized in Table 5. The difference between South and North trusses can be considered as negligible.

Table 5: *Fundamental frequencies f_1 of the supporting trusses*

Truss	f_1 (Hz) Section A	f_1 (Hz) Section B
South	5.82	8.40
North	5.84	8.42

Equation (6) has been applied to the results of Table 4 (except for the clamped case), giving a frequency value for Section A and another one for Section B (Table 6).

Table 6: *Results for the ESB floor on elastic supports*

Configuration	f_1 (Hz) Section A	f_1 (Hz) Section B
	3.67	4.79
	3.27	4.00
	3.72	4.90
	3.29	4.01
	3.32	4.07

Taking into account the elastic supporting beams have a very strong impact on fundamental frequency, especially for the overhang part, as it will be demonstrated in §4.2.

Existing equations are not fully adapted to such a complex configuration. The authors have decided to combine the different equations to better catch the real structural dynamic response of the ESB floor. The suggested equations from the future version of EC5 (Equations (4), (5) and (6)) have been adapted considering the coefficient K_1 taking into account the overhang configuration. The 2D behaviour is considered too, giving finally Equation (8).

$$f_1 = \sqrt{K_1 \frac{(EI)_L}{m}} \sqrt{1 + \left[2\left(\frac{L}{B}\right)^2 + \left(\frac{L}{B}\right)^4\right] \frac{(EI)_B}{(EI)_L}} \qquad (8)$$

A different width B has been considered for Section A and Section B to take into account the discontinuity joints cutting the concrete slab where the partition walls are (across the V-shaped column). For the overhang (Section A) it has been assumed B = 8.4m (7x1.2m) and for Section B the floor width is assumed as 12m. The results are summarized in Table 7. The results from Equation (3) have also been added for comparison purposes (in italic).

Table 7: *Results of f_1 for the ESB floor with two-way spanning and elastic supports (values from complete equation in italic)*

f_1 (Hz) rigid	f_1 (Hz) Section A	f_1 (Hz) Section B
8.39 (*8.83*) (B = 8.4m)	3.70 (*3.74*)	-
8.16 (*8.61*) (B = 12m)	-	4.81 (*4.89*)

3.3 ANALYTICAL RESULTS FOR LABORATORY SPECIMENS

The analytical equations described in §3 are used to estimate the fundamental frequency of some of the configurations tested in laboratory. The TCC tested are

https://doi.org/10.52202/069179-0257

described in §2.2, calculations are based on the geometry and the material properties given in Table 2. Additional information about these tests (configurations, protocol) can be found in §4.3. Table 8 presents the equation used for each configuration, the value of the coefficient (either λ from Table 3 or K_1) and the fundamental frequency f_1. As the specimens are only 1080mm wide and not supported on their sides, 1D equations (only based on $(EI)_L$) are used. It should be noted that the results for configurations including a fixed support are expected to be quite far from experimental results, as laboratory means were not adapted to generate such a perfect mechanical linkage.

Table 8: *Fundamental frequencies f_1 according to analytical equations for the TCC tested in laboratory*

Configuration	Equation	f_1 (Hz)
	Eq. (1) $\lambda = \pi$	10.04
	Eq. (1) $\lambda = 3.927$	15.68
	Eq. (1) $\lambda = 4.730$	22.75
	Eq. (7) $K_1 = 5.0$	14.29
	Eq. (7) $K_1 = 4.8$	14.00

4 EXPERIMENTAL APPROACH

4.1 EXPERIMENTAL SET-UP

Measurement protocol has been defined according EN 16929 [15], which specifies test methods for the determination of natural frequencies, damping, unit point load deflection and acceleration of floors composed of sawn timber, engineered wood products, mass timber beams or slabs, with or without concrete screeds, as well as for timber-concrete composite floors. Data acquisition was performed with a NI measurement device and a LabVIEW interface, with a packager for accelerometers (8µg resolution, sensitivity 10V/g (± 5%) and a frequency range of 0.15 to 1000Hz (± 5%)). A total of 9 accelerometers was available for the experimental set-up. Double face tape (on-site measurements) and metal plates (laboratory tests) were used to fix the accelerometers to the floor (Figure 7).

Figure 7: *Accelerometers floors fixation for on-site (left) and laboratory (right) measurements*

The approach used for all performed tests was to have an output-only signal, without measuring force. Different excitation sources have been used: weight drop, walking, running, ambient vibrations. The registered signals are accelerations at the measurement points.

Different acquisition frequencies have been tested, assuming finally that 100-150Hz is enough to capture the relevant frequencies of these systems. The acquisition length for each measurement was between 10 to 90 seconds, depending on the time necessary to reach the static equilibrium.

The modal analysis technique used to get the structural response in terms of natural frequencies and modal shapes is the Frequency Domain Decomposition [16].

4.2 EXPERIMENTAL MEASUREMENTS FOR ON-SITE BUILDING

Measurements took place at first and second floor, focusing on the external part only (Sections A and B). Two positions have been tested, one in Section A and the other in Section B. For each position 3 accelerometers have been installed parallel to the joists, at half distance between joists (points 1, 2 and 3 in Figure 3). The building was empty during measurements.

Different types of loading were tested: 5kg weight drop (sandbag) from 80cm height (using a small crane or manually), normal and fast walk, and ambient vibrations. Impact tests and walking are performed in different locations of the floors. For each position, at least 3 measurements have been performed to manage repeatability.

Table 9 presents the results of the fundamental frequency at different measurements points and floor positions. Only the results at 2nd floor are presented, the 1st floor gives globally the same frequencies. The results show that the elastic supports have a strong impact. The fundamental frequency of Section A decreases of about 40% compared to Section B because of the overhang flexibility. Compared to the analytic results based on Equation (8), which is the most complete available (overhang, 2D and elastic supports), experimental measurements show quite different and greater values of f_1. The differences between analytical and on-site frequencies observed by [2, 3] on single span floors are therefore observed again in the case of overhang floors on elastic supports.

Table 9: *Analytical and on-site experimental results for the ESB floor (2nd floor)*

Section	Pos.	Analytic	Exp.	Δ^* (%)
	1		4.33	
A	2	3.70	4.40	18.1
	3		4.37	
	1		7.03	
B	2	4.81	7.00	46.1
	3		7.05	

**Δ is the difference (in %) of the experimental result relatively to the analytical one*

https://doi.org/10.52202/069179-0257

4.3 EXPERIMENTAL MEASUREMENTS ON LABORATORY SPECIMENS

The aim of the laboratory experiments was to measure the dynamic properties for different ends conditions and finishing: roller, pinned or fixed supports, with or without overhang, with or without floor finishing and with partition walls at different locations on the floor. Different preliminary tests have been performed to verify the reliability of the measurements protocol:

- The calibration of the load drop height to assure that accelerometers are not overloaded. A drop height of 50mm has been chosen.
- Checking that the energy given to the floor is enough to induce vibration on the whole specimen: two accelerometers were fixed on the concrete slab and under the joist to ensure having the same response in terms of frequency and damping ratio.
- The fixation of accelerometers to the rough concrete slab: a three-point metal plate has shown to be more adapted to the irregular surface than double face tape, to avoid surface sanding.
- The number of measurements repetitions to have a coefficient of variation lower than 0.5%: 4 measurements prove to get the purpose.
- The definition of measurement positions to catch as much as possible the modal shapes for all boundary conditions: all configurations have been numerically modelled to define the maximum displacement for each modal shape. A set-up of 6 accelerometers has shown to be the better configuration to get all the modal shapes with a good accuracy.
- The specimens were put on small pieces of wood directly on the ground: by applying Equation (6) it has been shown that such supports can be considered as rigid supports.

A sandbag (mass 4636g) was dropped at different locations to excite the TCC. The impact force was applied for all boundary conditions on the top of TCC at mid and third span to excite the first three flexural modes.

Firstly, the geometrical ends conditions presented in Table 8 were tested for both specimens: Pin-roller, Fix-pin, Fix-fix and Pin-roller with one-side overhang of 1 and 2 m (Figure 8, right). The pinned configuration resists both vertical and horizontal movements but not bending moment; as specimens have a huge masse (1076kg), there was no need to put anything to restrain the horizontal and vertical movements. The roller configuration, allowing the horizontal movement, was realized by putting a steel rod under the specimens (Figure 8, left). Finally, the fixed configuration was achieved by putting a concrete block (600 kg) on edges, applying its weight on the slab trough a surface of approximately 30x80cm (Figure 8, middle).

Figure 8: *Tested boundary conditions (roller, fixed, overhang)*

Results are summarized in Table 10 for both specimens. Second and third frequencies and damping ratios have also been assessed through laboratory measurements, but not presented in this paper. The differences between the two specimens are negligible.

Table 10: *Experimental fundamental frequency f_1 (Hz) for laboratory specimens under different ends conditions*

Ends condition	Specimen 1	Specimen 2
	8.33	8.37
	9.05	9.10
	9.24	9.29
1m	11.26	11.28
2m	11.46	11.40

Table 11 presents a comparison between these experimental results and the analytical prediction. The biggest differences appear for fixed configurations, which can be explained by the fact that the experimental means of realizing a fixed support do not increase the rigidity enough. Nevertheless, better fit was expected for isostatic supports, as differences are high (between 9.0 and 13.7%). The assumed values of some material properties might be the cause: compression tests on concrete could not be performed to assess its Young's modulus, data for moisture content of wood were lost for some stages of the whole study, timber properties are the mean values from the two specimens, even if experimentally values from both specimens are very close (Table 10).

Table 11: *Analytical and experimental results for laboratory specimens*

Ends condition	Ana.	Exp.	Δ^*(%)
	9.18	8.35	-9.0
	14.34	9.08	-36.7
	20.80	9.27	-55.4
1m	13.06	11.27	-13.7
2m	12.80	11.43	-10.7

**Δ is the difference (in %) of the experimental result relatively to the analytical one*

Other tests have been realized to consider the effect of finishing and partition walls. The ends conditions are the isostatic ones for all these tests. Only the specimen 2 has been selected for the further measurements. The configuration without any finishing has been tested

https://doi.org/10.52202/069179-0257

again, to have a reference value. Previous tests have been performed during summertime, this second measurement campaign was performed during winter, in a heated building, leading to dryer moisture content of wood. A parquet floor has been put in place over a fibrewood undercoat 5mm thin (Figure 9, left). Frequencies decrease compared to the floor without finishing (Table 12). Finally, the presence of partition walls has been investigated. The wall provides an additional mass of 27kg to the floor. Six configurations have been tested: two positions of the wall perpendicular to the joists (at 2/5 and 3/5 of the span), two positions of the wall parallel to the joists (at 2/5 of the span and at mid-span), one position with two partition walls parallel to the joists and one position with a T-section wall approximatively at mid-span (Figure 9, middle and right).

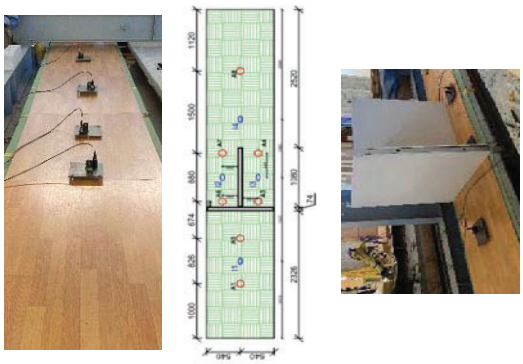

Figure 9: *Tested specimen with finishes (left) and partition walls (T-section)*

Results for this second measurement campaign are summarized in Table 12. Adding a partition wall at mid-span has a negative impact on fundamental frequency, as expected, because in this situation the wall is not connected to other elements of the building, therefore its weight is obviously added to the floor, while the possible increasing floor stiffness is not adequately represented with this setup. The orientation of the wall has a relatively small impact on the structural response. Adding twice the partition wall mass, the frequency decreases, mainly when the wall is positioned near to the mid-span.

Table 12: *Experimental results for laboratory specimen under various finishing (floor and partition walls) conditions*

Finishing condition	f_1 (Hz)
Without finishing	9.63
Parquet floor	9.47
Perpendicular wall at 2/5 span	9.22
Perpendicular wall at 3/5 span	9.25
Parallel wall at 2/5 span	9.33
Parallel wall at mid-span	9.22
Two parallel walls	9.15
T-section wall	9.03

5 NUMERICAL MODEL

The long-term objective of the finite elements model is to predict the rigidity and the modal parameters of TCC for different boundary conditions. In this paper, the focus is to corroborate the analytical equations used in §3, especially the one combining the 2D behaviour with an overhang (Equation (8)). The rest of the numerical study being too extensive and not totally finalized yet, it will be the focus of a future publication.

5.1 COMPARISON TO AVAILABLE ANALYTICAL EQUATIONS

The case study for analytical and numerical comparisons is the geometry and materials described in §2.2. The 6m long floor (L_{tot}) includes two joists and one concrete slab. For the sake of comparing the different analytical equations to FEM results, the aim is not the determination of the equivalent stiffness of the composite section $(EI)_{ef}$, but the effect of boundary conditions on the fundamental frequency. Therefore, the model introduced in this paper uses a perfectly rigid interface between timber and concrete.

Concrete is modelled as an isotropic material and timber as an orthotropic one. The values for modules of rigidity and densities are given in Table 2, except for the timber shear modulus. Indeed, the low G values for timber induce deflections that are significant compared to bending deflections. As this shear deflection is not modelled analytically, it was artificially removed from the model by implementing values ten times greater than normal (G = 6GPa).

The different modelled boundary conditions are: single span floor on isostatic supports, with an embedded support on one and on both ends, a one-side overhang floor on isostatic supports with 1 and 2m overhang, and finally a one-side overhang floor embedded at one end with a 1 and 2m overhang (Table 13). Supports are modelled by defining a surface of 75mm x b_2 (joists width) beneath the joists, where either the 3 translations or just the vertical one are fixed. For embedded supports, the surfaces of the section on the end are fixed.

The meshing is generated using Hex20 50mm length side volumetric meshes. A modal analysis is performed on the aforementioned models, modal shapes are observed (*e.g.* Figure 10) and the fundamental frequencies are extracted (Table 13). These models and calculations are achieved using the software Ansys Mechanical 2023 Release 1.

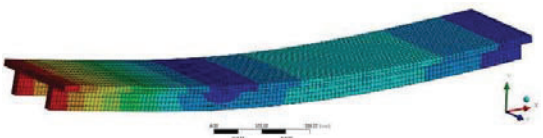

Figure 10: *Modal shape (f_1 = 15.81 Hz) for an isostatic floor with 2m overhang*

Table 13 includes also the analytical fundamental frequencies corresponding to each numerical model.

https://doi.org/10.52202/069179-0257

The difference (Δ) is calculated as a percentage of the analytical value. It can be observed a relatively good accordance between analytical and numerical values with a difference up to 7.3%.

Table 13: *Analytical and numerical comparison of the fundamental frequency (Hz) for different boundary conditions*

Configuration	Analytical	Numerical	Δ^* (%)
	11.84	11.65	-1.6
	18.50	17.97	-2.9
	26.84	25.51	-5.0
1m	16.42	16.08	-2.1
2m	16.59	15.82	-4.6
1m	25.73	24.71	-4.0
2m	19.53	18.11	-7.3

**Δ is the difference (in %) of the numerical result relatively to the analytical one.*

5.2 COMPARISON TO PROPOSED ANALYTICAL EQUATION

As previously showed (§5.1), the numerical model predicts quite well the analytical results of available equations (Equations (1) and (7)). The numerical model can now be used to assess the validity of the proposed Equation (8), the one combining the K_1 factor for overhang configurations and $(EI)_B$ on $(EI)_L$ ratio to include the 2D behaviour. The modelling approach is similar for materials, meshing and boundary conditions. In the longitudinal direction, three configurations are used: single span floor on isostatic supports, 1 and 2m overhang on isostatic supports. In the transversal direction, widths of 1.2, 2.4, 4.8 and 9.6m (Figure 11) are modelled, and a blocked vertical displacement is imposed to the ends of the concrete slabs, therefore modelling the 2D effect on the floor.

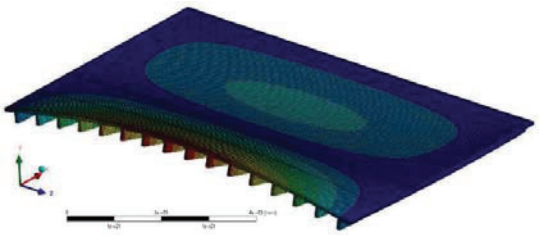

Figure 11: *Modal shape (f_1 = 16.43 Hz) for an isostatic floor with 2m overhang (width B = 9.6m) supported on its longitudinal sides*

Table 14 shows that the numerical model predicts accurately the results of Equation (3) for a single span floor on isostatic supports (Δ_{max} is 5.7%). It should be noted that analytical calculations using the proposed equations of the future EC5 (Equations (4) and (5)), without the $(L/B)^2$ term, provide less satisfactory results, with Δ values between 8 and 19.5%. The equation proposed in this paper (Equation (8)) fits relatively well (Δ_{max} = 4.2%) for lower values of the ratio L/B (B equal to 4.8 and 9.6m), but is much less precise for bigger values of L/B (Δ_{max} = 23.9%) for 1.2 and 2.4m. Additional calculations should be performed to assess more precisely the L/B ratio over which the analytical equation fits. As bigger values of L/B are not very representative of real floors, it is hoped that Equation (8) could be validated for realistic L/B ratios.

Table 14: *Analytical and numerical comparison of the fundamental frequency (Hz) for different widths of floor supported on their longitudinal sides (2D effect)*

Model		1.2m	2.4m	4.8m	9.6m

**Δ is the difference (in %) of the numerical result relatively to the analytical one.*

6 CONCLUSIONS

The first main conclusion of the work presented in this paper is that analytical calculation of the fundamental frequency of a floor is possible via several equations, yet none was strictly adapted to the specific case of TCC floors with overhang. Equations exist to take into account its longitudinal and transversal stiffness and the elasticity of its supports, other ones to take into account an overhang. In this study these equations have been combined to compare the analytical results to on-site measurements. It is observed that same conclusions as in [2, 3] (made for single span floors) can be drown also in the presented case study with overhang. Nevertheless, the validity of the proposed equation is still to be fully justified, a FEM model tends to show that for realistic L/B ratios (when B is greater than 1 or 2m) the proposed equations fits well.

The analytical approach has been used as a reference to compare experimental and numerical results, because experimental on-site and laboratory measurements cannot be directly compared (scaled specimens).

The important differences between analytical and experimental laboratory results are quite surprising, especially for simple boundary conditions. More detailed investigations will be necessary, nevertheless some variations can be already explained by the possibly different moisture content of the specimens during the experimental campaigns. Materials properties (timber and concrete) are also assumed as mean values from both specimens, the analytical approach should add a sensitivity analysis based on varying materials properties. Expected analytical results have to show a

https://doi.org/10.52202/069179-0257

confidence interval to catch the variability from experimental results.

The experimental on-site analyses present a higher stiffness of the ESB floor, even considering the overhang and the elastic supports. The analytical calculations are more conservative because they do not consider the stiffness contribution of secondary elements and partition walls. This means that current equations, including the ones proposed into the future EC5, tend to underassess the fundamental frequency of TCC floors.

The numerical approach has to be fully validated for a rigid connection between timber and concrete. Nevertheless, it allows some interesting comparisons with analytical equations, showing that the two-way spanning behavior cannot be neglected into design.

Further steps of the work should allow the development of a more reliable numerical model, taking into account the real stiffness of the interface. A comparison between on-site and laboratory experiments will finally be possible through the numerical model.

LOCAL DAMAGE ASSESSMENT STRATEGY OF A TWO-STORY CLT WALL THROUGH VIBRATION-BASED NON-DESTRUCTIVE TECHNIQUES

Alexander Opazo-Vega[1], Franco Benedetti[2], Alan Jara-Cisterna[3], Peter Dechent[4]

ABSTRACT: This paper presents a methodology to evaluate the damage in CLT walls by applying non-destructive vibration-based methods. The main contribution is that the methodology allows locating the damage and estimating the severity of damage in the different wall joints, going beyond the typical global damage detections. One of the relevant aspects was the novel combination of Operational Modal Analysis, Finite Element Model Updating, and Regional Sensitivity Analysis. The methodology was successfully applied to a 2-story CLT module built in the laboratory and instrumented with accelerometers. The wall was evaluated in 11 different damage scenarios induced by incremental pseudo-static lateral loads. The results obtained correlated reasonably well with the visually observed damage, so it is estimated that this methodology could be extended to more complex CLT wall configurations.

KEYWORDS: Massive timber, CLT joint damage, Operational Modal Analysis, Model Updating, Sensitivity Analysis.

1 INTRODUCTION

Previous research has shown that earthquake-induced damage tends to be concentrated in the joints of CLT walls [1]. Therefore, it is desirable to assess the condition of these joints after seismic events. However, such an assessment cannot always be made visually because the joints are usually hidden behind non-structural elements.

To face the difficulties mentioned above, some researchers have preferred to instrument this type of buildings with sensors that measure the structural dynamic response induced by ambient or forced vibrations [2-5]. In this way, any relevant change in the measured dynamic properties can be an indicator of damage in its joints and thus justify a complete inspection. The dynamic properties most used as an indicator of damage in CLT buildings have been the natural vibration frequencies. For example, previous investigations have shown that the lateral frequencies can decrease between 15% and 36% depending on the level of lateral solicitation [6-10]. However, these investigations have only focused on detecting global damage without providing information about the localization of the damage in the joints or the associated level of local damage severity.

This work aims to propose a methodology to detect, locate, and evaluate the severity of damage in CLT wall joints. The methodology mentioned above combines Operational Modal Analysis (OMA), Finite Element Model Updating (FEMUP), and Regional Sensitivity Analysis (RSA), applied to a two-story CLT wall of cross-section H. The results obtained are expected to contribute to structural health monitoring of two-story CLT dwellings in developing countries.

2 MATERIAL AND METHODS

2.1 DESCRIPTION OF THE CLT WALL

One 2.6-m-long, 1.2-m-wide, and 4.2-m-high CLT wall was built from the assembly of eight wall panels (2.0-m-high, 1.2-m-wide) and two slab panels (2.6-m-long, 1.2-m-wide) (Figure 1). All CLT panels had a thickness of 100 mm consisting of three layers of C16 Radiata Pine timber bonded with bi-component polyurethane.

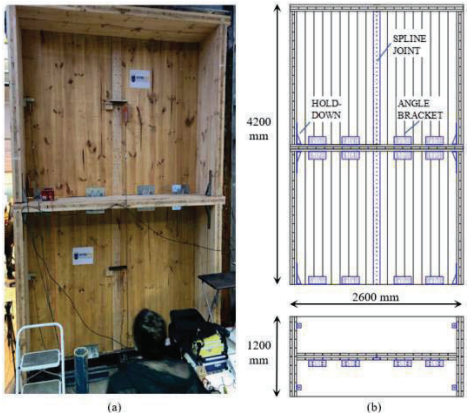

Figure 1: *(a)Laboratory assembly, (b)Dimensions and joints.*

The CLT panels were joined together through metal hardware, screws, and nails. To prevent the panels from uplifting, metal hardware of the hold-down type (model HTT4) was used. On the other hand, metal hardware of the angle brackets type (model ABR255) was used to avoid the relative horizontal sliding of the panels. Furthermore, the hold-down and angle brackets used ring-shank nails (CNA 4x60mm) and bolts (diameter 13mm) to connect to the different panels. Finally, to avoid relative vertical slippage between panels, spline-type joints were used, with pieces of wood screwed to the panels (2 DSVT3R screws spaced every 100mm). All the connector models mentioned above are shown in Figure 2, while their quantity and distribution are shown in Table 1.

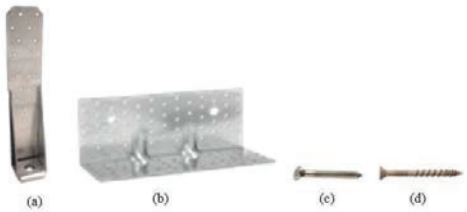

Figure 2:*(a) HTT4 hold-down, (b) ABR255 angle bracket, (c) CNA 4.0x60 nail (HTT4, ABR255), (d) DSVT3R screw (spline joints)*

Table 1: *Quantity and distribution of connectors*

Item	Story 1	Story 2
Number of hold-downs (number of nails)	8(18)	4(9)
Number of angle brackets (number of nails)	8(40)	4(35)
Number of screws in vertical spline joints	2@100mm	2@100mm

2.2 METHODOLOGY FOR ESTIMATING DAMAGE LOCATION AND SEVERITY

The proposed methodology has four stages: 1) induction of initial global damage, 2) measurement of dynamic properties, 3) numerical model simulations, and 4) regional sensitivity analysis.

2.2.1 Induction of initial global damage

In the first stage, initial damage is induced in the structure by applying a pseudo-static lateral load on the second story. The load is applied in the longitudinal direction X, parallel to the web panels, as shown in Figure 3. After maintaining the load for a few minutes, the wall is completely unloaded. This first stage was carried out 11 times with different levels of initial loads to generate different levels of damage to the walls. The first time this stage was performed, a minimal lateral load was applied, close to 0 kN, to adjust the measurement systems. On the other hand, in the following ten times, the lateral loads were increased every 10 kN until reaching 100 kN.

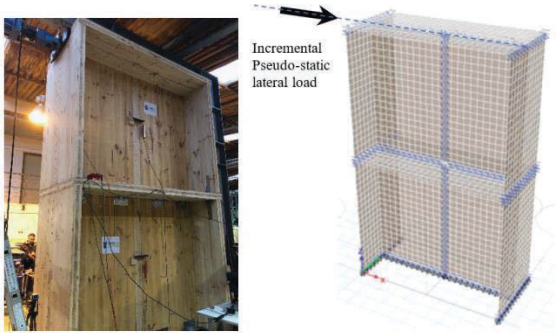

Figure 3: *Incremental pseudo-static test.*

2.2.2 Measurement of dynamic properties

Then, in the second stage, the dynamic properties of the wall (frequencies and modal shapes) are measured using OMA techniques (EFDD and SSI methods) [11]. The wall is excited through a series of low-energy impacts in the X direction. The impacts are applied at the intersection between the left flange panel and the web wall panel but at different heights. On the other hand, the lateral dynamic response is recorded in the right flange panel through six uniaxial accelerometers oriented in the X direction. With this information, it is possible to identify the first two frequencies and modal shapes in the X direction of the wall. It is important to note that this stage is also performed 11 times immediately following each load-unload level applied in the first stage. The experimental setup mentioned above is shown in Figure 4.

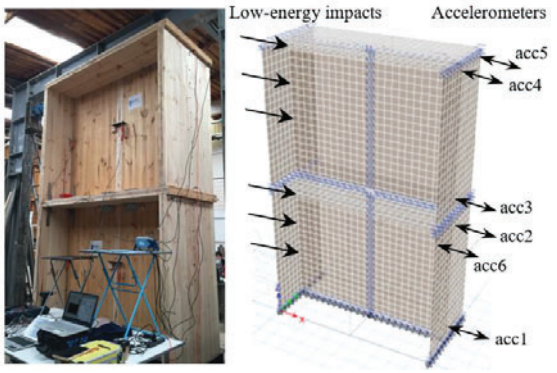

Figure 4: *Dynamic impact testing.*

2.2.3 Numerical model simulations

Next, in the third stage, a 3D finite element model of the wall is generated in the ETABS software to calculate its dynamic properties numerically. The CLT panels were modeled with four-node linear-elastic orthotropic shell elements. Their elastic properties were obtained from previous investigations [12]. On the other hand, the most relevant connections were modeled through link-type elements with uniaxial multilinear-elastic properties, as

https://doi.org/10.52202/069179-0258

shown in Figure 5. In the numerical model, it was assumed that the hold-down connectors only restrict displacements in the vertical direction to avoid the uplift of the wall panels (HD_1 to HD_4). On the other hand, for the angle-bracket connectors, it was assumed that they could restrain both vertical (AB_{t1} to AB_{t8}) and horizontal (AB_{s1} to AB_{s8}) displacements, but in an uncoupled manner. Finally, for the spline connectors, it was assumed that they could only restrain relative vertical displacements between the central wall panels. Therefore, the model considered 22 link-type elements to incorporate the relevant degrees of freedom of the connectors.

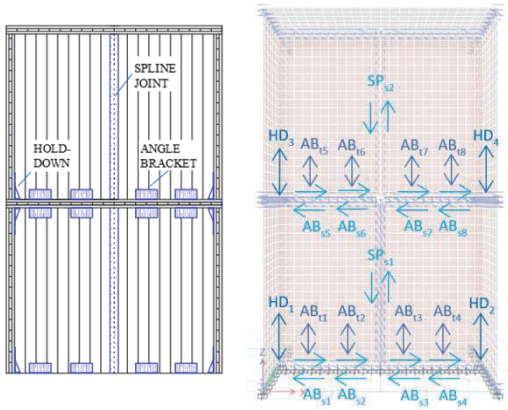

Figure 5: *Numerical model and input parameters.*

Each of the link-type elements of the model was assigned a multilinear-elastic force-deformation curve in their respective degrees of freedom. Specifically, a tri-linear axial force-deformation curve in tension and a linear force-deformation curve in compression were assigned to HD and AB's vertical degrees of freedom (see Figure 6a). These differences in the tensile and compressive behaviors are because these connectors are only susceptible to damage and stiffness degradation in the vertical direction when tensile. At the same time, when compressed, they maintain a high stiffness that is controlled by the crushing in the CLT panels. On the other hand, trilinear-elastic force-deformation curves were assigned to the ABs in the horizontal direction and to the SPs in the vertical direction because in those degrees of freedom, the aforementioned connectors work in shear (see Figure 6b).

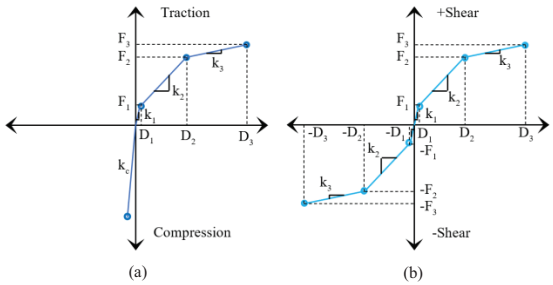

Figure 6: *Force-deformation curves: (a) tension, (b) shear.*

As can be seen in Figure 6, several input parameters are needed to define the force-deformation curves in multilinear-elastic link elements. However, several of these parameters were assumed as constants to simplify the model, considering results from previous experimental tests on similar connectors. For example, the first section of the tri-linear curves mainly represents the joints' friction mechanisms. In that section, the value of D_1 is small and quite close to 0.5 mm. Moreover, the stiffness k_1 of that section is generally very high and four times the stiffness of the second section k_2. The second section is one of the most important since it represents the elastic stiffness of the connectors, which the manufacturers generally report in their catalogs. Finally, the third section represents the degradation of the elastic stiffness of the connector, with deformation values ranging from D_2=4mm to D_3=15mm on average and a stiffness k_3 of the order of half of k_2. Therefore, given the importance of the parameter k_2, it will be assumed as the only input variable and indicator of the eventual damage to each of the connectors. The rest of the parameters will be assumed as constant or as a function of k_2 (D_1=0.5mm, D_2=4mm, D_3=15mm, k_1/k_2=4, k_3/k_2=0.5).

Once the finite element model is defined, running a series of numerical simulations is possible. Each numerical simulation has a different set of values of its 22 relevant input parameters, i.e., the k_2 elastic stiffnesses of the AB, HD, and SP connections. In this way, it is possible to calculate a set of dynamic properties of the wall in each numerical simulation through the solution of a finite element eigenvalue and eigenvector problem. These "simulated" dynamic properties of the wall correspond to the output parameters of the model.

It is essential to consider the possible combinations of the 22 input parameters of the model in the best way. For this purpose, a minimum and maximum value of k_2 must first be defined for each type of connector, representing different levels of damage, from severe to minor, respectively. The values considered are shown in Table 2 and were obtained from previous research [13]. Then, for each k_2 range, 2400 values are sampled with the Latin hypercube technique, assuming a uniform distribution and varying all input parameters at the same time. The execution of the numerical simulations was done by combining the API tools of the ETABS finite element software and the Python programming language.

Table 2: *Minimum and maximum values for k_2 joint stiffnesses.*

Item	Min (kN/mm)	Max (kN/mm)
HD_1 to HD_4	0.18	7.15
AB_{t1} to AB_{t8}	0.15	9.20
AB_{s1} to AB_{s8}	0.94	14.00
SP_{s1} to SP_{s2}	0.02	0.81

2.2.4 Regional sensitivity analysis

Finally, in the fourth stage, a regional sensitivity analysis (RSA) [14] is applied to each of the 11 damage levels induced to the wall in stage one. The objective of RSA is

https://doi.org/10.52202/069179-0258

to identify which joint stiffnesses (22 input parameters) are most influential on the dynamic properties of the wall and in what range of values these stiffnesses are most influential.

A necessary first step in applying RSA is to define an objective function (defined *Y*), which is an estimation of model performance calculated by comparison of measured and simulated variables. In the context of this work, it is convenient to choose the objective function as the differences between the dynamic properties measured in the wall (step two) and the dynamic properties simulated in the models (step three). Furthermore, as the simulated dynamic properties depend on the input parameters (stiffnesses of the joints stored in a vector *k*), the objective functions also depend on these input parameters ($Y_{(k)}$).

The dynamic properties are sometimes scalar (vibration frequencies) and sometimes vectors (modal shapes); therefore, it is advisable to use an objective function that includes both kinds of dynamic properties. Accordingly, Equation 1 shows the expression of $Y_{(k)}$.

$$Y_{(k)} = \alpha \cdot \frac{1}{n}\sum_{i=1}^{n}\left|\frac{\widetilde{f_i} - f_{i(k)}}{\widetilde{f_i}}\right| + \beta \cdot \frac{1}{n}\sum_{i=1}^{n} NMD\left(\widetilde{\phi_i}, \phi_{i(k)}\right) \quad (1)$$

where n is the number of identified dynamic properties (two in this case), $\widetilde{f_i}$ are the measured frequencies, $f_{i(k)}$ are the simulated frequencies, NMD is the normalized modal difference [11], $\widetilde{\phi_i}$ are the measured modal shape vectors, and $\phi_{i(k)}$ are the simulated modal shape vectors. The α and β constants take values between 0 and 1 depending on the relative importance to be given to the differences between frequencies concerning the differences between modal forms. In this case, both were assumed to be equal to 0.5.

After defining the objective functions, RSA requires that the models be separated into two groups. The first group corresponds to all models with objective function values below a specific acceptable threshold. These models are generally referred to as behavioral (B models) and, in this case, are characterized by generating simulated dynamic properties that differ very little from the measured dynamic properties. On the other hand, the rest of the models, which have objective function values higher than the threshold, are called non-behavioral models (NB models). Consequently, the acceptable threshold value was selected as 0.15 for the objective function $Y_{(k)}$.

Once it is known which models belong to groups B and NB, RSA requires the calculation of the cumulative density functions (CDF) of each input parameter for both B and NB models. That information makes it possible to rank which input parameters influence the objective functions most. For example, if, for an input parameter, the CDF of the B models is different from the CDF of the NB models, then that input parameter is very influential on the objective functions. However, this degree of influence is only sometimes possible to distinguish graphically; therefore, it is usual to resort to the Kolmogorov-Smirnov (K-S) statistical test to estimate the degree of influence of the input parameter. According to the suggestions of [13], an input parameter can be grouped into three possible sensitivity classes depending on the p-value obtained in the K-S test: critical (p-value < 0.01), important (0.01< p-value < 0.1), and negligible (p-value > 0.1). This kind of ranking of the influence of the input parameters helps estimate the location of the joints that could suffer more damage, given a variation in the global dynamic properties of the wall.

Finally, with the data associated with the B models, it is possible to know in what range of values the input parameters most influenced the objective functions. These ranges can be quickly visualized through box plots of the input parameters and further analyzed using the ANOVA statistical test. In this way, it is possible to evaluate the severity of the damage in the joints by studying the variation of their stiffnesses.

3 RESULTS AND DISCUSSION

3.1.1 Variation of the wall's dynamic properties

Figure 7 shows the variation of the first two vibration frequencies measured in the wall as the lateral load increased and, therefore, the level of damage. On the other hand, Figure 8 shows the modal shapes measured in the right-flange wall.

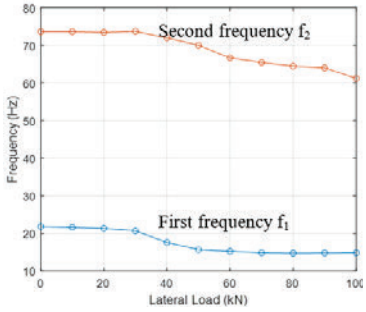

Figure 7: *Measured vibration frequencies.*

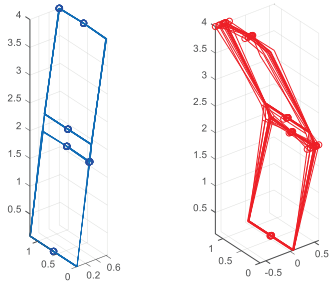

Figure 8: *Measured modal shapes: first vibration mode (left), second vibration mode (right).*

Figure 7 shows that the two vibration frequencies identified were decreasing as the damage caused by lateral loads increased. The decreases of the frequencies between

the undamaged and maximum damage states were 32% and 17% for f_1 and f_2, respectively. These decreases are the first global indicator of damage in the CLT wall joints; however, they do not indicate where the damage may be located or the severity of the joints' stiffness degradation. The measured modal shapes shown in Figure 8 suggest that the first vibration mode experienced almost no variation in the different levels of damage induced. However, the second mode of vibration showed more relevant variations as the lateral load on the wall increased.

3.1.2 Damage location and severity estimation.

The first relevant result of the RSA was ranking the most influential joint rigidities in the *Y* function. At each lateral load level, the value of *Y* was calculated for each simulated combination of input parameters and compared with the threshold value of 0.15. In this way, it was possible to separate the B models from the NB models and to visualize these results in scatter plots and CDF curves. Some examples of the graphs mentioned above are shown in Figures 9 to 12.

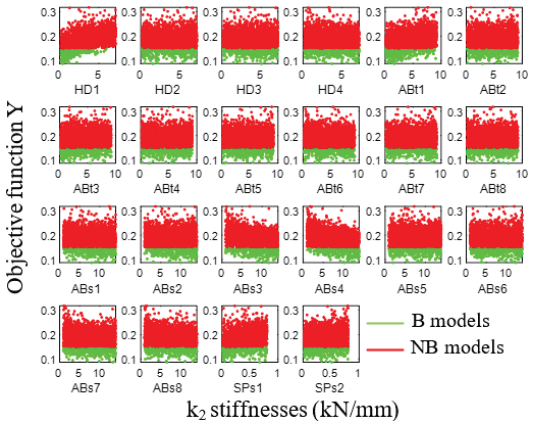

Figure 9: *Dispersion plots for k_2 stiffnesses, after 50kN lateral load.*

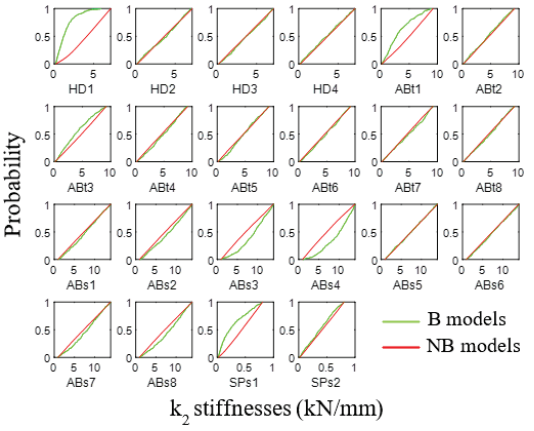

Figure 10: *CDF curves for k_2 stiffnesses, after 50kN lateral load.*

Then, applying the K-S test to the CDF curves, it was possible to obtain the ranking of the most influential stiffnesses of the connectors. Table 3 shows the top 5 ranking for each lateral load level.

Table 3: *Ranking of the most influential k_2 stiffnesses.*

Lateral Load (kN)	1st	2nd	3rd	4th	5th
0	AB_{s4}	AB_{s3}	HD_1	AB_{s8}	AB_{s7}
10	AB_{s4}	AB_{s3}	HD_1	AB_{s8}	AB_{s7}
20	AB_{s4}	AB_{s3}	HD_1	AB_{s8}	AB_{s7}
30	AB_{s4}	AB_{s3}	HD_1	AB_{s8}	AB_{s7}
40	AB_{s4}	AB_{s3}	HD_1	SP_{s1}	AB_{s2}
50	HD_1	AB_{t1}	SP_{s1}	AB_{s4}	AB_{s3}
60	HD_1	AB_{t1}	AB_{s3}	SP_{s1}	AB_{s4}
70	HD_1	AB_{t1}	SP_{s1}	AB_{s3}	SP_{s2}
80	HD_1	AB_{t1}	SP_{s1}	AB_{s4}	AB_{s3}
90	HD_1	AB_{t1}	SP_{s2}	SP_{s1}	AB_{s3}
100	HD_1	SP_{s2}	AB_{t1}	HD_3	SP_{s1}

From Table 3, up to the lateral load of 40kN, the most influential connectors were the angle brackets working in shear on the right side of the wall on the first and second floors (AB_{s4}, AB_{s3}, AB_{s8}, and AB_{s7}). Exceptionally, the tension stiffness of the hold-down on the left side of the first floor (HD_1) also appeared. These results are reasonable since there was practically no damage to the connectors for lateral loads less than 40kN, and most of the deformation was associated with the relative horizontal sliding of the wall panels. However, from a lateral load of 50kN onwards, the influence ranking of the connectors changed radically. The level of damage to the connectors increased, and the deformation mechanisms were those associated with wall rocking. Therefore, the tension stiffness of HD_1, the tension stiffness of AB_{t1}, and the vertical shear stiffness of SP_{s1} took an important role in the first story of the wall. This can also be seen in Figures 9 and 10. For a lateral load of 50kN, the B models tend to concentrate on the lower values of the stiffnesses of HD_1, AB_{t1}, and SP_{s1}, with more severe damage levels expected in these zones. The severity of damage in these connectors can be analyzed by studying the evolution of their stiffnesses in the B models for different lateral load levels. Figures 11 to 13 show this through box plots.

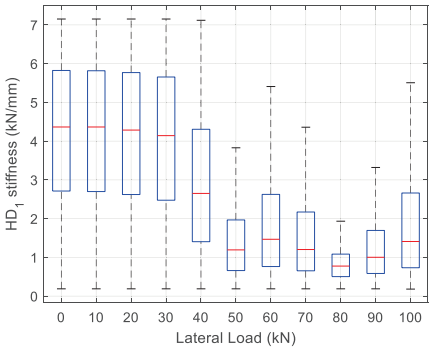

Figure 11: *Boxplot of k_2 stiffnesses for HD_1 connector.*

https://doi.org/10.52202/069179-0258

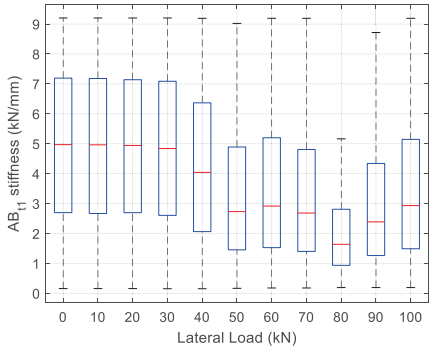

Figure 12: *Boxplot of k_2 stiffnesses for AB_{t1} connector.*

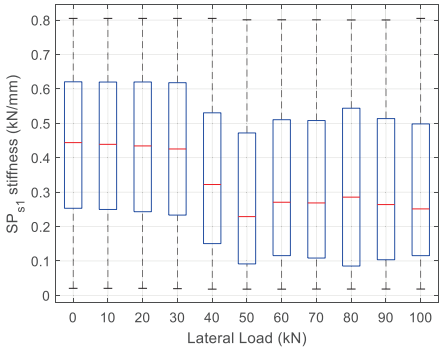

Figure 13: *Boxplot of k_2 stiffnesses for SP_{s1} connector.*

Figures 11 to 13 show that significant degradation of the stiffness of HD_1, AB_{t1}, and SP_{s1} connectors occurred as the lateral load increased. The initial stiffnesses of these connectors decreased by 63%, 36%, and 27%, respectively. These stiffness reductions obtained by the proposed vibration-based non-destructive method closely matched the real damage observed, as shown in Figures 14 to 16 [].

Figure 14: *Damage in HD_1 connector after 100kN lateral load.*

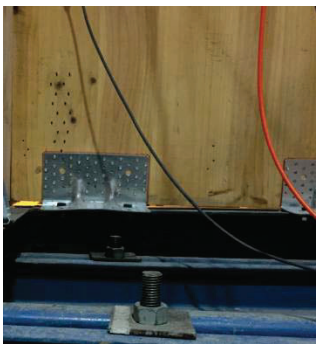

Figure 15: *Damage in AB_{t1} connector after 100kN lateral load.*

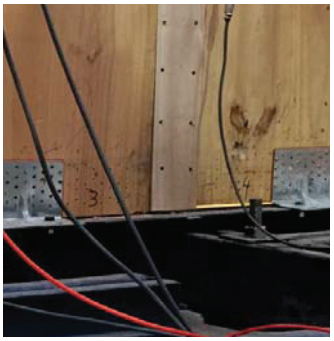

Figure 16: *Damage in SP_{s1} connector after 100kN lateral load.*

4 CONCLUSIONS

In this paper, we have described a new approach to estimate the location and severity of damage in CLT wall joints based on OMA, FEMUP and RSA techniques. We have obtained satisfactory results showing that this non-destructive methodology can be extended to more complicated structural configurations.

PREDICTION OF THE ACOUSTIC INSULATION OF A PREFABRICATED WOODEN-BASED SYSTEM FOR COLLECTIVE BUILDINGS

Marina Tenório[1], Sandra M. Silva[2], Jorge M. Branco[3]

ABSTRACT: Using wood, a renewable, carbon sink material with outstanding thermal properties associated with the prefabrication process and its benefits, a construction system for multi-storey multifamily buildings based on prefabricated wooden panels was developed to act as a tool for meeting the national carbon neutrality targets. It will contribute to the promotion of increasingly sustainable cities that optimise the use of materials and rely on highly energy-efficient buildings. This sustainable alternative to conventional construction materials was designed to comply with the Portuguese needs, regulations, and regulatory requirements regarding construction, structural, functional, and logistics demands. As the acoustic behaviour of wooden buildings is a sensitive subject due to the wood's lightweight and poor insulation performance for low-frequency sounds, this work aims to analyse the panels regarding their acoustic behaviour through INSUL software. The predictions showed favourable results for airborne insulation and partially favourable for impact sound insulation.

KEYWORDS: Wooden buildings, Acoustic, INSUL

1 INTRODUCTION

As a growth strategy for a competitive economy, efficient in the use of resources and, consequently, aligned with sustainable development, one of the European Union's priorities is to achieve carbon neutrality by 2050. As a result, Portugal has stipulated a reduction in greenhouse gas (GHG) emissions of between 85-90% [1].

In this context, reviewing the construction sector's conventional models becomes a priority given its impact: 40% of energy demand, 36% of GHG emissions, 40% of raw material consumption, and 33% of waste [2]. Materials processing holds the most significant share of energy consumption and GHG emissions [3], with cement and steel responsible for 4-7% [4] and 5% [5] of CO_2/year global emissions, respectively.

Wood re-emerges as a promising alternative due to its carbon storage capacity and lower embodied energy. Its processing/transport generally emits less carbon than that stored by wood, strengthening the carbon economy through local production. The buildings' operation phase, responsible for 45-80% of their carbon emission [6], benefits from the wood's high insulating capacity: 10 times higher than concrete and 400 than steel [2]. Also, at the end of its life, wood enables reuse to generate new products or energy [7].

Population and urban expansions (230bi m² of new constructions by 2060 [8]) dictate the need for increasingly denser forms and transform cities into opportunities for sustainable development, highlighting the wood sector's potential in offering carbon-neutral solutions for buildings. This modern application of wood was possible through the introduction of Engineered Wood Products, which optimised the timber structural capacity and overcame many of its limitations, reinventing the industry with competitive products to concrete and steel. Withal, the development of CAD/CAM technology, CNC equipment, and integrated design in BIM methodology has raised the degree of precision and quality of wood products that, produced in a factory, have the potential to reduce work times, site costs, noise, pollution, waste, accidents, and deterioration due to moisture exposure [9,10].

However, in the last decades, the diffusion of high-rise timber buildings, mainly in countries with cold climates, has promoted the development of knowledge and the proposal of solutions to this specific scenario, which does not apply to the Portuguese reality. Despite the rich history of using wood on floors and roofs, Portugal did not follow its transition to high performance, so the projects are few and conservative. It represents a missed opportunity for economic, social, and environmental gains, proving fundamental to developing specific knowledge of this typology application in the national context.

To make this typology compatible with the Portuguese context, a construction system for multi-storey buildings using prefabricated panels and 3D modules with a timber

structure is proposed, designed to meet local needs and act as a tool to fulfil the national objectives of carbon neutrality.

Besides contributing to the reduction of carbon emissions in the production and operation phases of the buildings from the renewable nature and carbon storage potential of the wood itself, it makes use of the prefabrication process that, optimized to its maximum, contributes to the rationalization of the construction, reducing waste and, consequently, the ecological footprint of the system, besides providing healthy interior environments from the precise and controlled production process.

Based on features designed and validated for successful application in the Portuguese context, the aim was to propose a solution with high replication and sustainable impact potential in Portuguese cities, besides promoting scientific enrichment in the use of wood in multi-storey buildings. The construction system was, then, idealized based on the rules and good practices of design for timber structures identified in the literature, considering the supply and consumption patterns of the national market (species, products, and prefabrication technologies of the sector), the conditions and restrictions of production, transport and construction phases, as well as the applicable normative requirements.

Acoustics is an important performance aspect of wood construction and a prerequisite for the acceptance of wood buildings by the construction industry, owners, and consumers.

The acoustic behaviour of wooden buildings, whether for airborne or impact sounds, differs from that observed in heavy constructions, such as those in concrete. It is because the construction weight is a decisive parameter for its acoustic performance, especially for the lower frequency range (generally 20 – 200 Hz). Therefore, wooden constructions are often associated with poor acoustic insulation, suffering significant vibrations and disturbances, especially in this frequency range [11].

In this context, prediction models become indispensable tools in the wooden structures' design, despite the existing methods being more suitable for predicting the acoustic insulation of heavy and homogeneous structures. Moreover, low-frequency results are often associated with prediction difficulties, which makes them even more uncertain.

The alternative of using a test building is common practice, although it is an expensive process and therefore puts wood at a disadvantage compared to other materials. Furthermore, the results obtained through measurements are mostly exclusive to those specific conditions, so they may not be useful for application in non-similar projects. The variations in sound insulation measurements often imply over-qualifying the construction elements through a high safety margin in the design phase to secure the fulfilment of the appropriate requirements [12].

Aiming at developing a system that provides acoustic comfort to the occupants and that is adequate to the regulatory requirements for building performance in Portugal, in this work, the construction system panels, composed of timber-frame walls and CLT panels floors, are evaluated aiming for its acoustic performance validation regarding their airborne and impact sound insulation.

2 THE CONSTRUCTION SYSTEM

The construction system was developed from the identification of design constraints and strategies, which range from the definition of the concept and design assumptions determining the system's applicability to the detailing of the layers, materials, joints, and finishes. Based on the design objectives, the premises of the system were established:

- Use of timber as the sole structural material, except for the foundation and connections associated with the timber elements (that are metallic);
- Definition of the basic structural unit in 2D panels, whether for walls, floors or roofs;
- Suitability for multifamily building structures;
- Compliance with the structural, functional and logistic requirements and conditions imposed by national regulations, valuing safety, durability, comfort and applicability;
- Maximisation of the prefabrication process and off-site operations;
- Use of complementary materials in line with national consumption and technical-financial accessibility standards to facilitate replication and acceptance of the system;
- High potential for adaptation to various projects due to architectural versatility (dimensions, combinations, and modularity) and the possibility of combining different aesthetic solutions;
- Simple, fast, and precise production, transport, assembly, and installation processes.

The development and application of the construction system (besides the definition of the concept that stipulates its essence and purposes) are also subject to predefinitions that typify and specify the panels and confer the ideal design conditions for the fulfilment of the system's structural and functional objectives. Therefore, it is determined that:

- The wall panels resistant to vertical loads are made of light timber-frame structure, except for the core wall panels, which enclose stairwells and lift shafts and which, due to their function as a central core, can be materialised by CLT or mixed panels (CLT + timber-frame) (Figures 1 a-c);
- The floor panels, in order to produce resistant diaphragms in the structure, are made of CLT panels (Figures 1 d-e);
- The foundation must be made of reinforced concrete.

Besides the structural definitions, the functional layers of the system play a decisive role in guaranteeing its adequate performance and have the potential to ensure, for instance, the durability of the construction, one of the topics of greatest distrust regarding the use of wood in buildings.

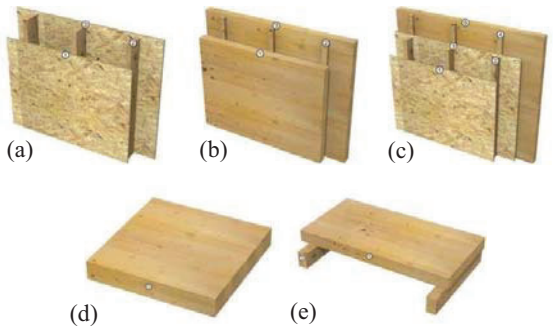

Figure 1: *Design strategies – Structural solutions. (a) Timber-frame; (b) CLT wall panels; (c) Mixed solutions with timber-frame and CLT; (d) CLT floor panels; (e) CLT floor panels with beams*

The critical functions to be performed and the functional layers that directly or indirectly contribute to this end were then identified (Figure 2). It was possible through an in-depth study of the literature, seeking to understand the behaviour of wooden structures and identify the traditional and innovative strategies/design practices specific to this construction typology and the existing solutions available on the market. In the scope of this work, the strategies pertinent to noise control stand out.

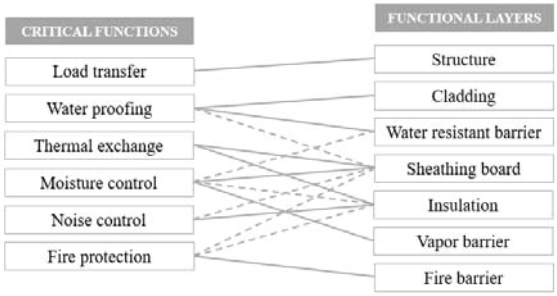

Figure 2: *Critical functions and the correspondent functional layers*

Thus, the noise control strategies adopted are (Figure 3):

- Use of rock wool as a thermal insulation layer and as an acoustic absorbing material to reduce the transmission of airborne sounds;
- Desolidarisation between rigid elements using resilient material layers or flexible connectors to reduce the transmission of impact-generated sounds;
- "Duplication" of elements, such as the construction of suspended ceilings, additional wall panels (such as a service layer, a layer originally conceived for MEP installations that can be filled with insulation to provide thermal and acoustic benefits) and floating floors, which are employed in association with resilient and absorbent materials;
- Double plasterboard internal lining and, for some panels, adoption of acoustic membranes. These solutions increase the system's mass and, consequently, the absorption of sound waves.

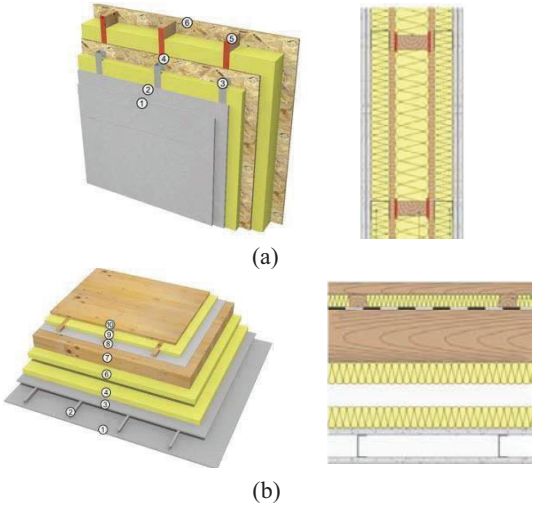

Figure 3: *Design strategies – Noise control. (a) Eg.: Internal walls (Par_Int_Nest_TF); (b) Eg.: Intermediate floors (Pav_Int_CLT)*

The panels developed for the various elements of the buildings, which make up the construction system, are shown in Figure 4. The construction details of each panel can be consulted at [13].

3 MATERIALS AND METHODS

The Portuguese Regulation on the Acoustic Requirements for Buildings (RRAE) (Decree-Law 129/2002, of 11 May 2002 [14]) regulates acoustic performance within the building regulations, contributing to improving the quality of the acoustic environment and the well-being and health of the population, in articulation with the Legal System on Environmental Noise. RRAE establishes minimum acoustic performance values for both new and existing buildings subject to reconstruction, extension, or alteration of the various building types, including multifamily buildings.

As the acoustic performance criteria are based on indexes dependent on the function of the element in the building (e.g. external wall, walls or floors between dwellings or dwellings and office spaces), the panels are assessed according to all their possible functions to consider the hypotheses that present the most rigorous criteria.

The determination of the sound reduction index for airborne and impact sounds to be compared with the maximum and minimum values established in the Portuguese Building Acoustic Regulation was obtained from the INSUL software [15], a tool for predicting the acoustic insulation in walls, floors, ceilings, and roofs. It models materials using well-known elastic plate theory, including allowances for thick panel effects, as stated by Ljunggren [16], Rindell [17] and others. More complex partitions are modelled using work by Sharp [18-20], Cremer [21,22] and others.

The software estimates transmission loss (TL) and sound insulation to impact sounds (L_n) in 1/3 octave bands. According to the concept of weighted value (single index) and from the comparison of the sound insulation curves with the reference curves contained in EN ISO 717-1 [23] and EN ISO 717-2 [24], it provides the sound reduction index (R_w) or sound insulation index to impact sounds ($L_{n,w}$).

The comparison between the curve described by the predicted values for TL and L_n, by frequency, with the conventional reference curve is performed by superimposing it so that the sum of the unfavourable deviations is as high as possible without exceeding 32 dB for 1/3 octave bands. Once this adjustment has been achieved, the value of R_w or $L_{n,w}$ corresponds to the value of the y-axis of the reference curve for the 500 Hz frequency.

As with any prediction tool, the INSUL software [15] is not a substitute for *in-situ* measurement. However, comparisons with test data indicate that it reliably predicts R_w values within 3 dB for most constructions [25].

As the objectives of the system design, which comprise the development only of the opaque panels and their suitability for various architectures, this study focuses on strategies detached from the architectural and location conditions. Therefore, for the acoustic analysis, aspects related to marginal transmission, interior acoustics, natural ventilation conditions in the façade or mechanical ventilation causing a break in acoustic insulation, and closure elements (such as doors, windows, and shutter boxes) will not be addressed.

4 RESULTS

The acoustic simulation produced in INSUL software [15] resulted in the sound insulation indexes to airborne and impact sounds (R_w and $L_{n,w}$) presented in Tables 1 and 2 for each of the construction elements developed. Tables 1 and 2 also present the minimum values for airborne sounds and the maximum values for impact sounds that each element must comply with, according to the RRAE. To specify these values, the supposed locations and functions that a given building element could assume in a building were considered, requiring the appropriate performance foreseen in the RRAE in terms of acoustic insulation.

It should be noted that the values obtained for the external walls through the simulation in the INSUL software correspond to panels without windows, while the values defined in the RRAE correspond to a wall with windows.

For all simulations, a fixed spacing between laths and studs of 300 mm was considered, although the system accepts spacings of 300 mm up to 600 mm because this represents the worst case since it increases the points of support between the different panels of the construction elements. The construction elements comprising CLT panels were analysed for 72 mm thickness when applied to walls and 120 mm when applied to floors.

Although the software is a practical option for acoustic insulation prediction, limitations were found. The software's student version does not allow the parameterization of new materials, limiting the analysis to the pre-existing materials in its database. Thus, it was necessary to assume materials with similar properties to the original ones. Also, the methods employed by the software support, at most, triple elements, which implies a limitation to the number of cavities between the element's panels (maximum of two). For the proper analysis of the elements presenting more than two cavities, considerations and adaptations were necessary to allow all the layers to be considered in the prediction of their acoustic performance.

The prediction of the acoustic insulation of the external wall panels (Par_Ext_TF) presented a sound reduction index of 55 dB (Figure 5a). Additionally, simulations were made to identify the contribution of each component in ensuring the required and desired acoustic insulation.

If the resilient material used between the rigid elements (studs and OSB) was dismissed, the anticipated sound reduction index would decrease by around 6 dB. In the same way, when considering a stiffer metallic support for the plasterboard than the one originally considered, with a thickness of 0.55 mm, lower insulation levels are achieved: 53 dB with 0.75 mm studs and 49 dB with studs between 1 mm and 1.6 mm.

https://doi.org/10.52202/069179-0259

Table 1: *Verification of the airborne sound reduction index according to RRAE*

Element	Sound emission space	RRAE $D_{2m,nT,w}$ or $D_{nT,w}$ (dB)	INSUL R_w (dB)
Par_Ext_TF	Exterior [1]	28 33	55
Par_Int_Est_TF	Common circulation area or a room [2]	48 50	63
Par_Int_Nest_TF	Common circulation area or a room [2]	48 50	63
Par_Int_Dupla_TF	Common circulation area or a room [2]	48 50	77
Par_Nuc_CLT	Vertical circulation [3]	40 48	63
Par_Nuc_CLT_TF	Vertical circulation [3]	40 48	65
Pav_Int_CLT	Garage or commercial or office areas [4]	50 58	61

[1] The standardised airborne sound insulation index measured two meters from the facade, $D_{2m,nT,w}$, between the outside of the building and bedrooms or living areas of dwellings shall be equal to or above 28 dB in sensitive areas (low noise neighbourhoods, mainly with residential buildings) and 33 dB in mixed areas (areas with residential and non-residential buildings).
[2] The standardised airborne sound insulation index, $D_{nT,w}$, between a room (emission) and bedrooms or living areas of another dwelling (reception) in a building shall be equal to or higher than 50 dB. When the emission comes from common circulation areas of the building, $D_{nT,w}$ should be equal to or higher than 48 dB in general conditions.
[3] The standardised airborne sound insulation index, $D_{nT,w}$, between a vertical circulation path (emission) of a building with lifts and bedrooms or living areas of dwellings (reception) shall be equal to or higher than 40 dB. When the building only has stairs, $D_{nT,w} \geq$ 48 dB applies, according to the previous item.
[4] The standardised airborne sound insulation index, $D_{nT,w}$, between a car parking garage (emission) and bedrooms or living areas of the dwellings (reception) should be equal to or higher than 50 dB. When considering the possibility of having a non-residential space on the ground floor of buildings, the acoustic insulation between commercial, industrial, offices or entertainment zones (emission), $D_{nT,w} \geq$ 58 dB applies.

Table 2: *Verification of the impact sound insulation according to RRAE*

Element	Sound emission space	RRAE $L'_{nT,w}$ (dB)	INSUL $L_{nT,w}$ (dB)
Pav_Int_CLT	Dwelling rooms or building common circulation areas	60	51
	Office spaces [1]	50	
Cob_CLT	Common circulation areas	60	64

[1] Inside the bedrooms or living areas of the dwellings (reception), the sound insulation index to impact sounds, $L'_{nT,w}$, from a standardised impact on floors of other dwellings or common circulation areas of the building (emission), should be equal to or less than 60 dB. When the emission occurs on the floors of the building with commerce, industry, offices or entertainment areas (emission), the sound insulation index to impact sounds, $L'_{nT,w}$, shall be equal to or less than 50 dB.

Instead of two layers of plasterboard, if only one layer is applied, a decrease of the sound reduction index to 52 dB and a worsening performance in low frequencies are observed. Still, when considering the exemption of the service layer keeping the two plasterboard finishing layers, an increase in the sound reduction index of 1 dB (56 dB) was observed. This fact can be justified by the lower stiffness of the gypsum plasterboard when supported on the rock wool compared to the case in which they are supported directly on the OSB, allowing greater oscillation of this layer and, consequently, the propagation of sound waves through its components. If the service layer is dismissed and the finishing is done with just one layer of plasterboard, the sound reduction index would be 52 dB.

Regardless of the variations imposed for simulation purposes, the opaque part of the external wall performs well. Its structural core (timber-frame with a cavity filled with rock wool and resilient material between the uprights and OSB) reaches a sound reduction of 46 dB itself. To meet the acoustic requirements, the external wall must have windows with high acoustic performance and adequate perimeter sealing.

Both interior walls, structural and non-structural timber-frame (Par_Int_Est_TF and Par_Int_Nest_TF), presented a sound reduction index of 63 dB, so the difference in thickness of the timber-frame and, consequently, of the acoustic absorbing material inside the cavities (140 mm and 90 mm, respectively) had no significant influence on the predicted performances. When the two service layers are removed, the sound insulation of both solutions decreases to 60 dB.

https://doi.org/10.52202/069179-0259

The results obtained for the different simulations developed for the external walls and structural and non-structural internal walls show that the greatest contribution to sound insulation comes from the double plasterboard finish, its support conditions in the adjacent layer, and the dissociation between the rigid elements of the panels.

By analysing the double-walled configuration (Par_Int_Dupla_TF), which presented sound insulation of 77 dB, it was possible to quantify the contribution of the acoustic membrane layers. Once removed, the Par_Int_Dupla_TF achieved a sound reduction of 76 dB, a result very close to the original configuration which, because it is so robust and with acoustic insulation significantly higher than the minimum limits defined in the legislation, makes the use of acoustic membranes in the promotion of acoustic comfort unnecessary. A less robust configuration of this wall solution, exempting the service layers, presented a noise insulation prediction of 74 dB.

The same was observed for the core walls, Par_Nuc_CLT and Par_Nuc_CLT_TF, which presented a decrease of 1 dB and 0 dB compared to the original configuration by removing the acoustic membrane. The acoustic membrane use had a more relevant impact on the panels' behaviour for the low-frequency sounds (lower than 125 Hz).

Considering the core wall panels' behaviour, when the remotion of the plasterboard layers was simulated to consider situations where the exposure of the CLT is wanted for aesthetic purposes, the sound reduction index decreased from 63 dB to 57 dB in the Par_Nuc_CLT and from 65 dB to 62 dB in the Par_Nuc_CLT_TF.

Associating the removal of the plasterboard layers on the CLT face with the removal of the service layer, some changes are observed only in the Par_Nuc_CLT, which reduces its sound insulation to 54 dB and significantly worsens the insulation level for the low-frequency range (more evident due to the removal of the service layer). The Par_Nuc_CLT_TF, with an absorbing material inside the timber-frame cavity, didn't present any change with the removal of the service layer, keeping the sound insulation of 62 dB and, in all its configurations (original and alternatives), presented insulation indexes in the low-frequencies higher and more stable than the results presented by Par_Nuc_CLT.

In terms of the airborne sound insulation of Pav_Int_CLT, the element fulfils the acoustic requirement when the emitting space is an office or a commercial area. Knowing that the prediction of acoustic insulation is based on a delicate analysis that can often lead to misunderstandings when compared to the actual acoustic insulation of the element, additional studies are needed to rigorously determine the performance of this element to ensure the minimum required behaviour. However, variations in the original configuration that may increase its acoustic performance were evaluated: the increase of the floating floor cavity to 100 mm and the adherence of continuous acoustic membranes over the CLT, both motivated by the need to include service installations.

For the isolated or associated application of both strategies, the same increase in sound reduction to 62 dB was obtained. It should be noted that this analysis considered spacings between slats and hangers of the suspended ceiling of 300 mm, so for any higher spacing, the acoustic insulation will be favoured. Also, as observed for the walls when simulating the removal of the service layers and, essentially, of its interior acoustic absorbing material, for Pav_Int_CLT it was noted that the adoption of one or two layers of acoustic absorbing material inside the suspended ceiling did not result in variations in the acoustic insulation. However, it was noted an expressive contribution of the acoustic suspended ceiling in the insulation to low-frequency sounds, mainly when in association with the increase of the floating floor cavity to 100 mm. When used over garages, whose requirement is lower, one can consider replacing the suspended ceiling with a 60 mm rock wool layer under the CLT, resulting in an acoustic insulation of 55 dB. This configuration can also be increased by using an acoustic membrane and enlarging the cavity of the floating floor, resulting in an acoustic insulation of 56 dB, although this measure is not necessary.

In terms of impact sound insulation, Pav_Int_CLT has a reasonable performance when it comes from impacts produced in residential or common circulation areas of the building (Figure 5b).

Compliance with the requirements is maintained even when the acoustic suspended ceiling is replaced by the slenderest option for the element, in which a 60 mm layer of rock wool is placed under the CLT and with a double plasterboard layer, with sound insulation to impact sounds of 56 dB. The same was not observed when the emission is from places in the building intended for commerce, industry, offices, or entertainment. However, this work aims essentially to the analysis of the developed construction system when applied in multi-family buildings, so the most stringent requirement ($L'_{nT,w} \leq 50$ dB) does not apply. The evaluation of the construction system for other building programs will be the object of future studies. However, seeking to identify the potential of the solution also for these cases, the application of resilient ceiling suspenders and more efficient damping systems for the floating floor was simulated, with the potential to achieve about 45 dB for the sound insulation to impact sounds.

Furthermore, assuming that the slightly tilted visitable roof is a common circulation area for the building occupants, its impact sound performance was simulated. Although the original Cob_CLT configuration did not meet the requirements imposed on this case, when using resilient materials under the deck slats and acoustic suspenders for the 60 mm suspended ceiling, sufficient sound insulation was achieved, 57 dB.

All the results presented are a prediction based on considerations about the construction elements. Future studies based preferably on laboratory tests on prototypes and *in situ* measurements are required to determine the acoustic performance of the construction elements more reliably, including the effect of the connection between panels and the flanking transmissions.

5 CONCLUSIONS

This paper describes numerical simulations carried out through INSUL software to predict the airborne and impact sound insulation of a construction system based on prefabricated wooden panels developed for the Portuguese market. The results of this investigation contribute to the validation of a construction system in terms of its acoustic performance.

The acoustic performance prediction showed favourable results for airborne sound insulation (Table 1) and partially for impact sound insulation (Table 2), depending on the type of emission space (another dwelling, office, circulation area). Note that all confirmed vulnerabilities have been mitigated.

The acoustic analysis was developed disconnected from a defined and invariable architecture, so it is essential to evaluate aspects such as flanking transmission, interior acoustics, natural ventilation conditions in the façade or mechanical ventilation causing a break in acoustic insulation, and closure elements such as doors, windows and shutter boxes for each project using this construction system.

Future studies based on laboratory tests on prototypes and *in situ* measurements will be carried out.

IMPACT SOUND INSULATION PERFORMANCE OF RAISED DISCRETE FLOATING FLOOR ASSEMBLIES ON MASS TIMBER SLABS

Jianui Zhou[1], Zijian Zhao[2], Chenyue Guo[3]

ABSTRACT: Bare mass timber structural slabs have relatively low impact sound insulation performance. Though certain floating floor assemblies on mass timber slabs can provide adequate single number ratings, such assemblies are mainly effective in the middle to high frequency range. This study presents the impact sound insulation performance of raised discrete floating floor assemblies for mass timber slabs. The raised discrete floating floor assemblies were composed of elastomer blocks, insulation materials**,** wood-based sheathing panels and concrete topping or cement boards. Impact sound insulation tests were conducted on a mock-up building under different excitation sources including human walking, ISO tapping machine and ISO rubber ball. The results showed that raised discrete floating floor assemblies tested in this study could improve the impact sound insulation ratings of the bare slabs by up to 41 dBA under ISO tapping machine excitation. Under different excitation sources, the impact sound pressure level spectra obtained from ISO rubber ball had similar frequency characteristics with that from human walking, though the magnitudes were higher at each octave band. The discrete raised floor without any mass topping had similar performance (L_{Fmax}=74.3 dBA) in attenuating low frequency sound to the continuous floating concrete topping of 50 mm thickness. The advantage of the raised discrete floor assemblies with dry solution boards over the continuous floating concrete topping assemblies based on the ISO tapping machine tests did not exist with the ISO rubber ball testing. Higher topping mass resulted in lower L_{Fmax}.

KEYWORDS: Impact sound insulation, Floating floor, Mass timber, Dry construction

1 INTRODUCTION

Mass timber panels including cross laminated timber (CLT), dowel laminated timber (DLT), nail laminated timber (NLT) and other large-dimension engineered wood panels are used largely as floor slabs in mass timber buildings and hybrid timber buildings due to their dry and fast construction. Exposed wood ceiling is appealing to both designers and occupants. However, bare mass timber panels have relatively low impact sound insulation performance [1], especially in the low-frequency range [2]. The common solution is to add a floating mass topping, such as a concrete topping, to improve the impact sound insulation performance [3]. However, continuous floating concrete topping assemblies had limited improvements on mass timber slabs [4]. It was reported that the apparent impact insulation class (AIIC) of CLT slabs with only continuous concrete topping floated on various market available elastic interlayers was difficult to achieve more than 55 dBA [4].

Conventional raised floor system is normally designed to provide an even finishing floor surface and space for ducts and cables, which is not meant for attenuating impact sound or insulating airborne sound. The discrete raised floor system incorporates elastic mounts for vibration isolation between the raised floor assembly and the structural floor for improved sound insulation performance. Homb et. al. reported that the such floor assemblies had high performance in middle to high frequency range on the light wood frame structural floor [6]. Its acoustic performance has not been fully explored compared with the continuous floating floor system, especially on mass timber floors. Previous study showed that raised discrete floating concrete floor had the potential to provide high impact sound insulation performance for CLT slabs according to typical ISO tapping machine testing [7]. However, it is not clear whether the system performs the same under different excitation sources, especially in the low frequency range, which is of great importance to the application in mass timber buildings.

This study aims to further investigate the impact sound insulation performance of raised discrete floating floors on mass timber slab, especially under different excitation sources including ISO tapping machine, ISO rubber ball and human walking. Moreover, the proposed assemblies

adopt dry construction concepts to minimize cast-in-place concrete toppings.

2 MATERIALS AND METHODS

2.1 MATERIALS

Both CLT and DLT, were selected as the structural floors for testing. The CLT floor was made of 3 pieces of 5-layer (139-mm-thick, 35/17/35/17/35) spruce-pine-fir (SPF) CLT panels (CrossLam CLT 139V). Each CLT panel was 4.0 m long and 1.8 m wide. The DLT floor was made of 2 pieces of 140-mm-thick SPF DLT panels (StructureCraft) with 11 mm oriented strand board (OSB) on the top. Each DLT panel was 5.4 m long and 2.0 m wide. The panel-to-panel and panel-to-wall were connected with ϕ8.5×215 mm fully-thread self tapping screws with spacing of 40 cm. All gaps were sealed by acoustic sealant and tapes.

The raised discrete floating floor assemblies illustrated in Figure 1 were composed of elastomer blocks (AFB (Getzner), AMC25 and AMC40 (AMC Mecanocaucho)), Rockwool insulation material, OSB sheathing panels and mass topping. The AFB had a capacity of 60 kg load per mount, while AMC25 and AMC40 had designed capacity of 25 kg and 40 kg per mount respectively. AFB blocks were glued onto the structural floor with 60 cm spacing. Wood sleepers with a dimension of 19mm × 64mm were glued on the top of AFB blocks by polyurethane glue. 11-mm- thick OSB panels were fastened together with wood sleeper by 38 mm-long wood screws, and the remaining cavity was filled with 89 mm Rockwool insulation. AMC floor block series was made by 50 mm × 50 mm × 25 mm elastomer blocks and AMC innovated metal mounting frame. AMC floor mounts were fixed on structural floor by two 38 mm long wood screws with 50 cm spacing between each mount point. Then, the 50 mm by 50 mm wood sleepers were placed and fixed on the mounts, and 89 mm Rockwool insulation filled the cavity. Finally, 11 mm OSB panel was placed on the top of wood sleepers and fastened by 38 mm in length wood screws.

Four pre-cast 1.6 m × 1.6m normal strength (35 MPa) concrete toppings (38 mm, 50 mm, 70 mm and 100 mm) were floated as mass toppings. The concrete masses were 234, 307, 430 and 614 kg, equivalent to an area density of 91, 120, 168 and 240 kg/m^2, respectively. Besides the pre-cast concrete toppings, two types of cement boards and one type of gypsum board were selected as the dry-solution for floating floor. Fire rated gypsum board is the most commonly used drywall material in residential construction, and it demonstrates fire-resistance property to enhance the fire resistance level of the discrete floating floor. Each floated layer of 11 mm cement board (HardieBacker 500), 11 mm USG cement board and 11 mm gypsum board contributed to 13.4, 11.9 and 7.8 kg/m^2 area density to the system, and two layers of cement boards met the basic requirement of fire resistance [8]**Error! Reference source not found.**. All the cement board and gypsum board toppings were connected with the raised discrete floating floor by 38 mm wood screws.

In the small scale tests, the discrete mount assemblies were about to have a dimension of 1.6 × 1.6 m. Both AMC25 and AMC40 block mounts were assembled as a 5.0 × 3.6 m floor after the impact sound tests on small scale assemblies. In the impact sound test of full size assemblies, double layer USG cement boards and 12.7 mm gypsum boards (7.8 kg/m^2) were installed as mass toppings. Because the raised discrete floating floor has multiple components, each assembly is named as Mass timber_Block type_Insulation_Topping. CLT_AFB_INS_C100 represents that the AFB discrete raised floor with Rockwool insulation in cavity floating 100 mm concrete topping was installed on the CLT structural floor. Moreover, CB and USG represent two types of cement boards while GYP is short for gypsum board. The number after each floating board name indicates the layer of board applied on the discrete raised floor. The full size assembly has "Full" as suffix after the component name.

2.2 IMPACT SOUND INSULATION TESTS

The impact sound insulation tests were conducted using a mock-up building as shown in Figure 2. The mock-up room was built with staggered wood stud walls (140 mm thick) with OSB sheathing panels, two layers of gypsum panels with resilience channels and rockwool insulation batts in the cavity. The mock-up has a height of 2.4 m, an outer floor size of 5.4×4 m^2 and an internal volume of 44 m^3. CLT and DLT floors were constructed on the mock-

https://doi.org/10.52202/069179-0260

up room. The apparent impact insulation class (AIIC) was be measured according to ASTM E1007-16 [9] using an ISO tapping machine (Larson Davis BAS004) and sound pressure meter (Larson Davis 831).

The impact tests using ISO rubber ball were conducted according to JIS A 1418 [10]. On the small scale 1.6 × 1.6 m floor assemblies, the rubber ball was dropped at 1.0 m from the floor surface for 4 consecutive times at center of floating floor with fixed location of sound level meter at the geometry center of receiving room. The locations of rubber ball dropping on full size floor assembly was according to Figure 2 (c). The rubber ball was dropped at each location for 4 times, and total of 20 impacts were recorded at the geometry center of receiving room. For real human walking excitation, a 75kg adult was walking on the floor in a random path for 1 minute, and the sound pressure level meter was fixed at receiving room center as well. L_{Fmax} single number rating was used to quantify the performance of floating floor assembly. The SPL of ISO rubber ball dropping was corrected according to [10].

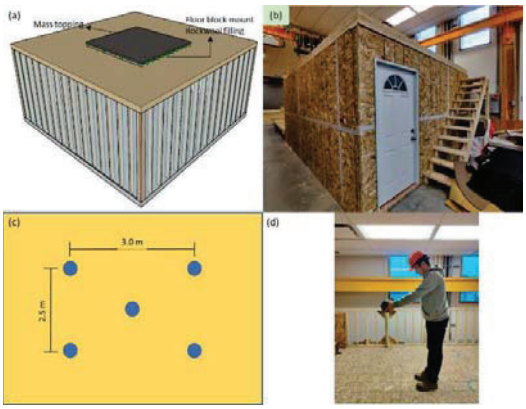

Figure 2: *(a) Sketch of the mock-up room, (b), photo of mock-up room (c) location of dropping rubber ball on full size floating floor and (d) dropping rubber ball*

3 RESULTS & DISCUSSION

3.1 APPARENT IMPACT SOUND INSULATION PERFORMANCE OF SELECTED ASSEMBLIES UNDER ISO TAPPING MACHINE EXCITATION

As listed in Table 1, the AIIC single number ratings for AFB discrete raised floor as well as 3 selected continuous floating floor assemblies on mass timber floor tested in [5]. With only AFB raised discrete floor on the bare CLT floor, AIIC rating increases from 26 to 47 dBA. This basic assembly without a mass topping has higher AIIC rating than that of most of floating concrete assemblies tested on the same CLT floor [4]. The insertion of Rockwool insulation (INS) in the cavity brought AIIC another 3 dBA higher to 50 dBA. The addition of 38 mm concrete topping further improved the AIIC to 58 dBA, which was higher than 55 dBA recommended by [11]. The increasing of concrete topping thickness does not affect much on AIIC rating of discrete floor system. The four concrete mass toppings each brought up single number rating 1 or 2 dBA gradually until 62 dBA with 100 mm concrete topping. The 50 mm mass topping with engineered floor finishing was tested as a potential solution for actual construction with an AIIC of 59 dBA. The overall impact sound insulation performance of AFB discrete raised floor assemblies on CLT and DLT structural floor are similar, which means that the type of structural floor does not affect the impact sound insulation performance of the discrete raised floor system. Furthermore, the concrete thickness did not affect the performance significantly, which indicated that dry construction boards such as cement boards and gypsum boards might be used.

Table 1: *Comparison AIIC ratings between AFB discrete floating assemblies and continuous floating concrete floors*

Structural Floor	AIIC ratings of different floating assemblies (dBA)								
	Bare Floor	AFB	AFB_INS	AFB_INS_C38	AFB_INS_C50	AFB_INS_C70	AFB_INS_C100	AFB_INS_C50 EngFloor	AFB_INS_SF_C50
CLT	21	47	50	58	59	60	62	62	62
DLT	37	43	53	N/A	58	N/A	61	61	60

The apparent normalized impact sound pressure level (ANISPL) curves of the discrete floating floor system on CLT is summarized in Figure 3 (a). As it can be seen, the discrete floating floor assemblies contributed significantly in both frequency regions below 315 Hz and higher than 1000 Hz. Using only AFB mounts covered by OSB, middle to high frequency impact sound pressure level decreased for at least 25 dBA on CLT. The Rockwool filling insulated middle frequency sound more effectively than extreme low or high regions on CLT. Adding a 50 mm concrete topping reduced sound pressure level in the low-to-mid frequency (100 – 400 Hz) up to 20 dBA. As a result, mass topping did not reduce sound pressure level in the high frequency (more than 400 Hz) as significant as it in low frequency range (lower than 400 Hz). A wide peak occurred between 400 and 630 Hz after adding the concrete topping, and that peak was not eliminated with further surface finishing. Still, installing the engineered floor can reduce the negative effect of hard concrete surface in the frequency range higher than 400 Hz. The sound pressure spectra for the assemblies on DLT are shown in Figure 3 (b). The bare DLT floor has much lower peak SPL than bare CLT. The curve for AFB mounts covered by OSB has a major peak at 160 Hz which does not appear in the assembly on CLT. Unlike the plateau below 400 Hz in Figure 3 (a), the spectra in Figure 3 (b) drops linearly right after the occurrence of 160 Hz peak. The filling of Rockwool in the cavity had almost even contribution throughout the entire frequency domain. These differences observed on DLT revealed that the structural floor had noticeable effect on impact sound

https://doi.org/10.52202/069179-0260

insulation according to frequency, despite the AIIC single number ratings did not show strong differences in between. The spectra of floating the 50 mm concrete topping on DLT assembly demonstrates the similar characteristic as that on CLT, with generally flatter shape. The ANISPL spectra characteristics for further layers of toppings beyond the 50 mm concrete are more identical on DLT than CLT. The type of structural floor did not noticeably affect ANISPL spectra of discrete mounts floating concrete topping. In summary, the AFB discrete raised floating floors had high efficiency on impact sound insulation and demonstrated similar performance on both CLT and DLT under ISO tapping machine excitation.

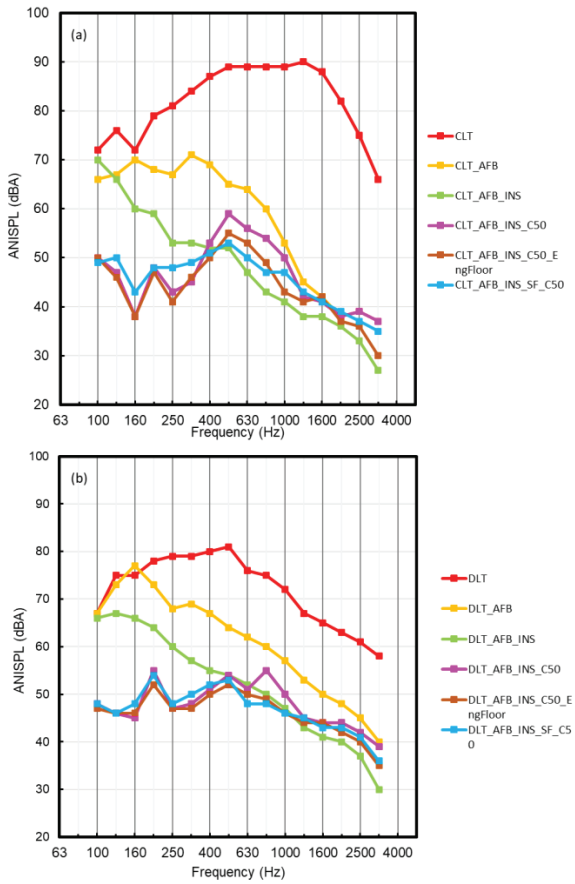

Figure 3: *Impact sound insulation performance of discrete floating floor on (a) CLT and (b) DLT structural floor under ISO tapping machine*

As the discrete raised floor floating concrete toppings have AIIC ratings more than 60 dBA, more types of discrete raised floor with various light-weight dry solutions were tested for pursuing a more environment friendly and lower mass assembly. The results of impact sound test on two types of AMC innovated mounts with various low-mass toppings are discussed below. The maximum allowable load for AMC25 is approximately equal to 38 mm concrete topping, and AMC40 has maximum load capacity for 50 mm normal strength concrete. This is the main reason of only conducting the impact sound test on one concrete topping on each discrete raised floor. The bare DLT floor has AIIC rating of 36 dBA, and the AMC25 floor mounts with OSB surface brought the single number rating 11 dBA higher, which was slightly lower than AFB. With Rockwool insulation, the single number rating increases to 55 dBA. According to Table 2, double layers of cement board (CB2) floating on AMC25 reaches the AIIC rating more than 60 dBA. However, the third layer of cement board (CB3) did not contribute much on impact sound insulation performance, which also indicated that the increase of mass did not contribute much to the performance. Floating double layer of cement boards would fulfil the fire resistance requirement and provided high performance impact sound insulation solution. The finishing layer of engineered wood floor on AMC25 floating CB2 assembly brought the AIIC 1 dBA higher. While this assembly had about only 30% mass of 38 mm concrete topping, the AIIC rating was 62 dBA, which was same as floating a 38 mm concrete topping.

Table 2: *AIIC rating of AMC25 and AMC40 floor block assemblies on DLT*

Floor Block Mount	AIIC ratings of different assemblies (dBA)								
	Bare DLT Floor	DLT_AMC	DLT_AMC_INS	DLT_AMC_INS_CB1	DLT_AMC_INS_CB2	DLT_AMC_INS_CB3	DLT_AMC_INS_CB2_Engfloor	DLT_AMC_INS_C38	DLT_AMC_INS_C50
AMC25	36	47	55	58	61	61	62	62	N/A
AMC40	36	47	52	57	60	60	62	N/A	57

AMC40 has higher allowable load of 40 kg/mount and is able to float 50 mm concrete topping. Floating of 50 mm concrete topping had the same AIIC rating as floating single layer of cement board, with the same single number rating of 57 dBA. Meanwhile, floating CB2 reached the AIIC rating 60 dBA. Similar as AMC25 discrete raised floor, the third layer of CB did not contribute to improving impact sound insulation performance. Comparing the impact sound insulation performance between the AMC25 and AMC40 discrete raised floor floating multiple layers of cement boards, the difference between single number ratings was below 3 dBA benchmark. The increment from single to double layer had slight increase on AIIC, and it kept the same with floating the third layer. Floating 3 layers of CB did not have any noticeable contribution on impact sound insulation. The advantage of higher mass for concrete topping was not favoured in the AMC25 and AMC40 discrete floating floor assemblies, however, the dry solution with cement boards demonstrated high impact sound insulation performance on the discrete raised floor. Choosing adequate floor mount corresponding to topping load is important in

https://doi.org/10.52202/069179-0260

practical applications though the difference was within 3 dBA benchmark.

3.2 IMPACT SOUND PRESSURE LEVEL SPECTRA UNDER DIFFERENT EXCITATION SOURCES

As the correction considering background noise and reverberation time is different in ASTM E1007-16 [9] and JIS A 1418 [10] is different, the directly measured SPL spectra are plotted in Figure 4 for comparison. The two standard impact sources have higher SPL than real human's walking with the steel-toe safety boots on both bare CLT and DLT. It is obvious the ISO tapping machine generated higher SPL on both structural floors. SPL spectra for both rubber ball and human walking demonstrate similar trend on mass timber floors, except the curves for rubber ball are about 20 dBA higher than human walking throughout the entire frequency domain. The SPL of tapping machine increases above 80 Hz, however that decreases for the rubber ball which is more similar to human walking SPL spectra. Human walking generated impact sound between 40 and 50 dBA, with the peak value merely 55 dBA for both SPL curves. The difference between maximum and minimum SPL on human walking is about 15 dBA, which is similar to the trend of rubber ball spectra.

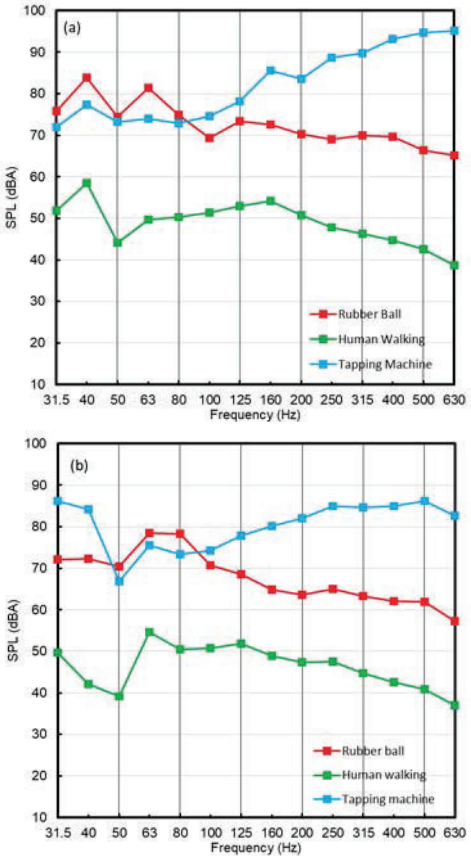

Figure 4: *Sound pressure level curves under different impact sources on bare (a) CLT and (b) DLT*

The SPL curves with three different sound sources on selected (a) continuous and (b) discrete raised floating floors on the DLT floor are shown in Figure 5. The continuous floating concrete assembly consists an elastic interlayer (AFM 35, Getzner) and a 50 mm thick concrete topping. The rubber ball demonstrates the same SPL trend as human walking, and the overall SPL difference between them is within 15 dBA. However, the SPL difference between tapping machine and human walking curve increases up to 30 dBA at 630 Hz. However, the SPL curve characteristics of rubber ball and tapping machine are similar to each other, except the rubber ball generated higher impact sound below 100 Hz. In the frequency range below 125 Hz, all three curves have similar trends with peaks and drops occur at 63 and 50 Hz, respectively. The SPL drop linearly above 125 Hz about 15 dBA for all spectrum, while the total SPL is mainly below 40 dBA.

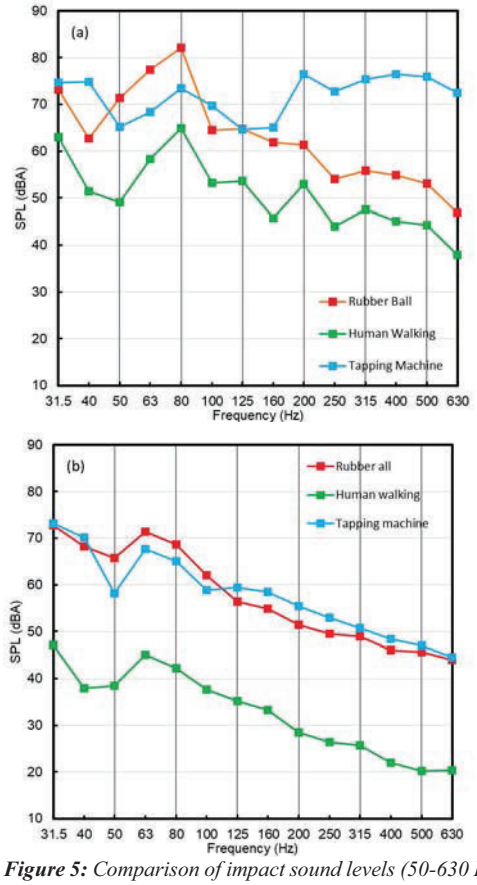

Figure 5: *Comparison of impact sound levels (50-630 Hz) of (a) continuous and (b) discrete floating floor assembly under different excitation sources*

In summary, rubber ball is an excitation source which can generate SPL spectra of similar frequency characteristics with that by human walking on mass timber floors. This is in contradictory to the conclusion that CLT bare floors mimicked the impact sound pressure level values of a bare concrete floor in [12], which was tested using the tapping

https://doi.org/10.52202/069179-0260

machine. ISO rubber ball is more suitable for impact sound testing of mass timber floors in the current study.

3.3 IMPACT SOUND PERFORMANCE UNDER ISO RUBBER BALL EXCITATION

As discussed above, floating double layer cement boards on the base raised floor showed high performance using the tapping machine. Further investigations and modifications are based on this assembly. Two types of cement boards and one gypsum board were selected as the alternative mass topping to concrete topping. According to Table 3: , the AMC40 raised floor floating 50 mm concrete topping is still the best solution with L_{Fmax} of only 64.8 dBA. Among the result of floating dry solution boards above, full size assembly of floating the double layer of USG (USG2) has the best performance. The full size USG2 improved the single number rating for 3 dBA on AMC40 discrete raised floor. However, the single number rating after installing GYP2 was 2 dBA lower than the AMC40 basic assembly. However, at the current stage, there is no performance criteria based the L_{Fmax} single number rating developed for mass timber floors. Future research is required if ISO rubber ball is adopted for standardized testing and evaluation of impact sound insulation performance of mass timber floor assemblies.

Table 3: *L_{Fmax} single number rating for selected discrete floating floor assemblies*

Bare DLT	Bare CLT	DLT+AMC40+INS	DLT+AMC40+INS+ CB2	DLT+AMC40+INS+ CB2 Engfloor	DLT+AMC40+INS+ C50	DLT+AMC40+INS+ USG2 Full	DLT+AMC40+INS+ USG2 Full Engfloor	DLT+AMC40+INS+ GYP2 Full
78.4	81.3	74.3	75.3	71.4	64.8	71.3	71.0	76.5

The impact sound pressure level spectra of two full size assemblies and selected small size floors are summarized in Figure 3.1. Even though JIS 1418 only requires the frequency between 50 and 630 Hz to derive the L_{Fmax} single number rating, the SPL spectra in this figure includes 31.5 to 3150 Hz which beyond the frequency region of both JIS 1418 and ASTM E1007, which shows a wider perspective on rubber ball impact sound test on discrete raised floating floor assemblies. In Figure 3.1 (a), the discrete floating floor assemblies are efficient in higher frequency region. Considering 40 dBA as a benchmark for a quiet room, most assemblies insulate the noise above 1250 Hz very effectively. Floating a 50 mm concrete topping insulates the noise above 200 Hz and makes most noise inaudible, and the assembly with floating 50 mm concrete topping had average 6-10 dBA lower SPL than floating the other dry solution toppings, and the 50 mm concrete topping had about 10 times of unit mass of the cement boards, so adding extra mass further reduced the resonant frequency of the assembly and improved the impact sound insulation performance.

In SPL curves of floating dry solution boards, an obvious peak occurs between 50 and 80 Hz where the L_{Fmax} ratings come from shown in Table 3: . On discrete floating floor system, mass may not be the only factor which affects the impact sound insulation performance, and material selection is critical. The least dense gypsum board (GYP) had better performance than the densest CB between 63 and 200 Hz. Double layer of USG boards brought the SPL below 40 dBA at 630 Hz which was at much lower frequency than 1250 Hz for CB2 and GYP2. Applying 40 dBA cut-off line in the SPL spectra i, floating 50 mm concrete topping dropped below that at 250 Hz. Material property should be considered on selecting the dry solution mass toppings. In summary, the full size USG2 assembly on AMC40 has outstanding performance. The SPL difference between this assembly and floating a small scale 50 mm concrete is within 5 dBA in average.

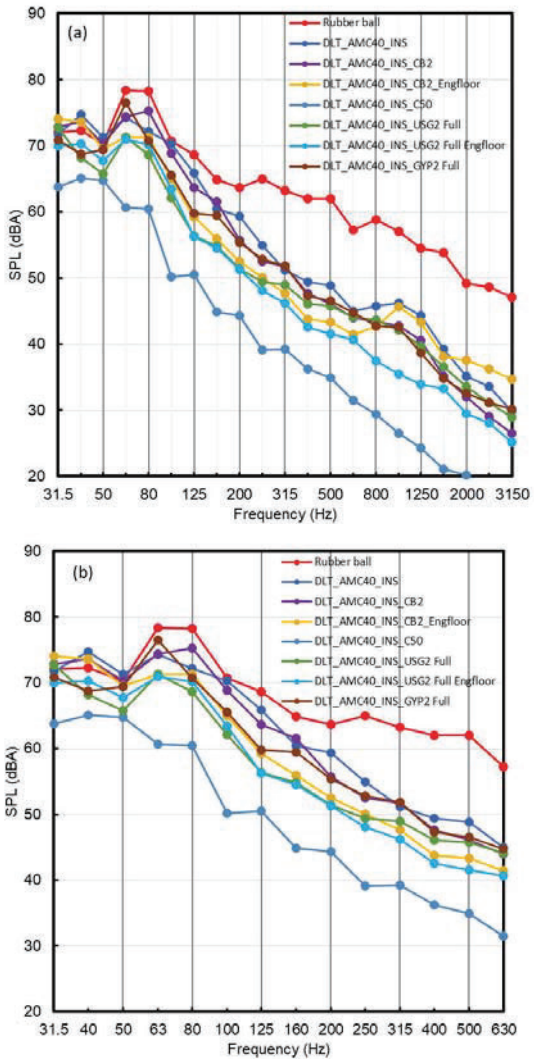

Figure 3.1 (a) The impact sound of discrete floating floor assemblies using the rubber ball (31.5 - 3150 Hz)

https://doi.org/10.52202/069179-0260

4 CONCLUSIONS

The raised discrete floating floor assemblies tested in this study provide high impact sound insulation performance on mass timber slabs. However, the excitation sources are of great importance to the evaluation of the performance.

1. The raised discrete floating floor is an effective method to attenuate impact sound on mass timber floor tested with ISO tapping machine according to ASTM standards. The raised discrete floor system with all three types of floor block mounts were able to reach AIIC higher than 60 dBA. The type of structural floor (CLT and DLT) did not have strong effect on impact sound insulation performance, and the thickness of concrete topping was not critical on improving the AIIC ratings.
2. The comparison between AMC25 and AMC40 floor mounts concluded that the load capacity of floor block mount had minor influence on impact sound insulation performance, and the discrete raised floors had similar SPL curve characteristics. Floating dry solution boards had similar single number rating as floating 38-50mm thick concrete topping, and it can attenuate middle to high frequency sound more effectively.
3. The ISO rubber ball is able to generate impact sound SPL spectra of similar frequency characteristics with that by human walking on bare mass timber floors and both continuous and discrete raised floating floors considering. When tested with the rubber ball, the discrete raised floating floor assembly with dry solution boards has similar single number rating as the selected elastic interlayers floating 50 mm concrete topping. The discrete raised floating floor assembly with 50 mm thick concrete had the lowest L_{Fmax}. However, performance criteria is need for adopting the rubber ball for impact sound insulation performance testing and evaluation of mass timber floors.

SOUND INSULATION IN CROSS LAMINATED TIMBER BUILDINGS AND THE EFFECT OF JUNCTIONS AND FASTENERS

Eli Toftemo[1], Anders Løvstad[2]

ABSTRACT: Sound insulation in cross laminated timber buildings can be challenging and is difficult to predict due to lack of reliable predicting models. Details in either the construction itself or in mounting may cause measurement results to vary significantly. Solutions vary notably between projects. Pre-accepted solutions are sparse and in high demand. Residential buildings are especially challenging and commonly need complementary floors, suspended ceilings and wall linings due to high sound insulation requirements. Clients and consumers in Norway often want the timber to be exposed, which make the flanking sound control essential.

Sound tests on a full scale CLT model have been conducted to identify efficient solutions. Flanking sound paths were tested using various resilient interlayers and fasteners in the junctions, and the vibration level difference across the junctions was measured between rooms. Elastically decoupled angle brackets performed better than ordinary angle brackets and screws that penetrate the vibration protection. Additionally, sound insulation measurements are reported on for various slab constructions, including both light and heavy weight complementary floors.

KEYWORDS: Cross Laminated Timber, junction damping, sound insulation

1 INTRODUCTION

Use of cross laminated timber (CLT) in building constructions has increased rapidly in recent years due to its environmentally sustainable and light weight capacities, rapid and efficient assembly, and other desirable physical parameters as summarized by Di Bella et al. [1]. Consequently, the interest from architects, developers, engineers, and politicians has increased notably. Studies on sustainability such as the overview of life-cycle assessment (LCA) by employing CLT in building constructions presented by Younis et al. [2], finding a possible reduction in greenhouse gas emissions of around 40 % is likely to further enhance the interest in CLT.

Espinoza et al. [3] estimated a growth in annual global CLT production from 2010 to 2015 of 250 %, with most of the growth occurring in new production countries outside Europe. Brandner et al. [4] similarly predicted an accelerated rise in the global production volume towards 2025, and particularly in countries such as Canada, United States and Japan, which is accordance with Plackner [5], who projects a possible annual global production of 3 million m^3 by 2025. Muszyński et al. [6] summarized the above and gives an interesting overview of the global CLT manufacturing plants per 2016. Sandoli et al. [7] reported an increase in CLT production in Europe alone from 650,000 m^3 in 2015 to 1,2 million m^3 in 2020. As the use of CLT has surged, the need for standardization and regulative processes for product, testing, mounting, and requirements of a solid timber construction system with CLT quickly became imminent [4], and is now a continuous ongoing process.

National guidelines and documentation of CLT floor and wall constructions published over the last couple of decades [8,9] give good starting points for dimensioning, where the latter presently is being revised as reported by Mahn et al. [10]. Such guidelines are supplemented by investigations of airborne and impact sound insulation for various floor assemblies and resilient layers with CLT constructions, as done by Verdaxis et al. [11], while Homb et al. [12] collected and compared impact sound insulation for typical floor assemblies in different European countries (and laboratories).

In Norway, CLT constructions in buildings with sound requirements are typically mounted with extensive use of screws, commonly also going through the strategically placed elastic layers, reducing their effect [13]. The dimensions of the CLT slabs and walls vary, but due to airborne and impact sound requirements heavy floating floors, addition of mass directly onto slabs, suspended ceilings and separate wall linings are common measures to ensure sufficient sound insulation quality. The extent of these measures is governed not only by the sound insulation requirements themselves, but in many cases

[1] Eli Toftemo, Brekke & Strand Akustikk, Norway, eto@brekkestrand.no

https://doi.org/10.52202/069179-0261

just as much by which margin the constructors and designers are comfortable with. Experience with directly comparable constructions best enable reduction of such measures, but due to the detailing, vulnerability of construction errors, and variations in junction assembly and in the constructions themselves, such experience is often somewhat limited. Accordingly, Simmons [14] argued that specific experience with the same construction allows for reduced calculation margins with CLT, especially if junctions and lining types are known, while a provisional margin of at least 8 dB is needed for relatively unknown constructions. Such variations are not uncommon when a certain number of presumably identical rooms are included in measurement programs in larger measurement documentation setups, to the authors experience either. When such variations occur, they are usually due to specific construction errors, and not systematic design errors. Systematic deviations from project requirements may also be of such magnitude with limited control of junction design or linings.

CLT is presently considered in buildings with high sound insulation requirements, such as dwellings, cultural centres, and theatres, despite the increased challenges in prediction of sound insulation and vibration compared with heavier materials and constructions. Malo et al. [15] reported on structural design issues with a 14-storey CLT in 2016, and since then even more acoustically complex and higher buildings have been built or are planned in Scandinavia [16].

Additionally, clients and consumers in Norway often want the CLT to be exposed to a large extent, which makes control of flanking sound and junctions essential. Measurements of vibration reduction indices using various elastic interlayers and fasteners have been done by Morandi et. al. [17], who compared junction damping and sound insulation between floors and rooms for a selection of available products with elastic interlayers. Increased knowledge of junction damping and design are essential if wall linings and suspended ceilings should be omitted, the extent of floating floors reduced, and visible timber increased. However, available research results are not always easy to apply in an actual building project.

This paper reports on measurements of flanking sound paths using various resilient interlayers and fasteners in the junctions, and the vibration level difference across the junctions between rooms. Airborne and impact sound insulation measurements are done for various slab constructions, including both light and heavy weight complementary floors. The possible removal of wall linings and suspended ceilings with good junction design is also addressed.

2 THE TEST SETUP

A full-scale CLT mock-up construction was built in an industrial warehouse, with two rooms on the ground floor and one room on the top floor, as shown in Figure 1. The top floor could be lifted from the ground floor by hydraulic jacks, which allows repetitive testing of various resilient interlayers (RI), fasteners, angle brackets or screws commonly used as vibration protection in buildings with sound requirements. The different RI types were applied in the junctions vertically between floors or horizontally between adjacent rooms. These mounting methods were changed and repeated as the rooms were fitted with combinations of suspended ceilings, light or heavy floating floors and wall linings to assess how the mounting method affected the sound insulation and flanking sound transmission.

Figure 1: *Test room set-up.*

A schematic layout of the mock-up is shown in Figure 2, where the room dimensions and thicknesses of the CLT walls and floors are given. Vertical CLT panels were 3-ply of 100 mm thickness throughout. The ground floor and top roof were 3-ply 120 mm thick CLT panels, while the horizontal slabs between the floors and roof of the one-story high part were 5-ply 160 mm CLT. The test rig was delivered from Splitkon AS, element strength classes T15 and T22. The density of the wood is 460 kg/m^3.

Tests of airborne and impact sound insulation were done according to ISO 16283-1 and -2 [18,19], respectively. Variations in damping across building elements were assessed by measurements of velocity level difference across building elements. The velocity level difference is described in ISO 10848-1 [20].

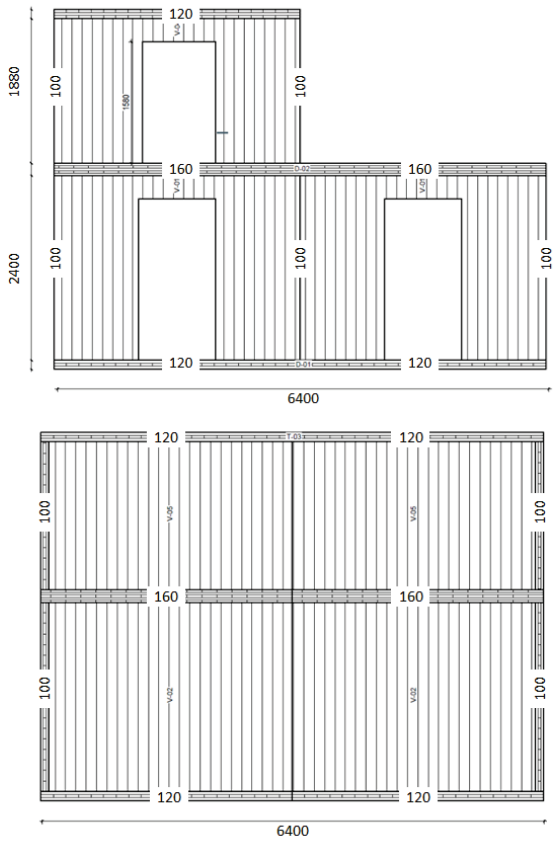

Figure 2: *Vertical section drawings of the test mock-up; a) length section and b) width section. All dimensions are given in mm.*

Four measurement positions were employed on each panel/building element to measure the velocity level difference, as Figure 3 shows. Tests were carried out using three different sound sources; pink noise fed through a loudspeaker, a tapping machine and hammer excitation. The results from hammer excitations have been left out since the excitation proved difficult to control. Results from junction damping shown in this paper have been conducted using a loudspeaker placed on sylomer pads as excitation, with two source positions for each measurement.

Velocity level differences show averaged values of two sets of sensor positions mounted on two corresponding walls, except for horizontal measurements and measurements with the floating floor, where only one set is included. Alltogether eight positions on the slab in the receiving room were used for horizontal measurements of junction damping.

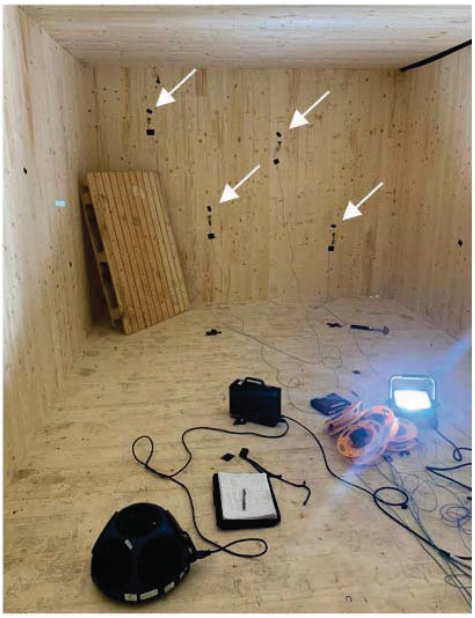

Figure 3: *Photo of sensor setup inside of the test rooms. Sensor positions indicated with white arrows.*

3 MEASUREMENTS RESULTS

3.1 VERTICAL JUNCTION DAMPING

Figure 4 shows the principle vertical junction between floors. The drawing displays a configuration with a RI between the upper wall and the slab and screws connecting the slabs to both the upper and lower wall.

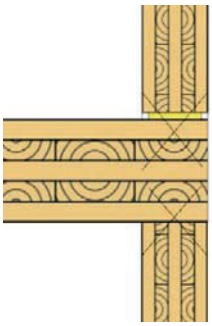

Figure 4: *Drawing of the vertical junction with resilient interlayer and screw fasteners indicated.*

Measurements of velocity level difference between floors using various RI fitted between the floors are shown in Figure 5. The lines show the arithmetic middle value from measurements with each RI type. One measurement (black line) was conducted without using any fastener in the junction between floors.

Measurements using screws and regular angle brackets as fastener resulted in similar results. Angle brackets placed on a RI resulted in marginally better damping above 400 Hz, while elastically decoupled angle brackets gave significantly higher damping.

https://doi.org/10.52202/069179-0261

These tests showed that the type of fastener has a paramount effect on the junction damping between floors.

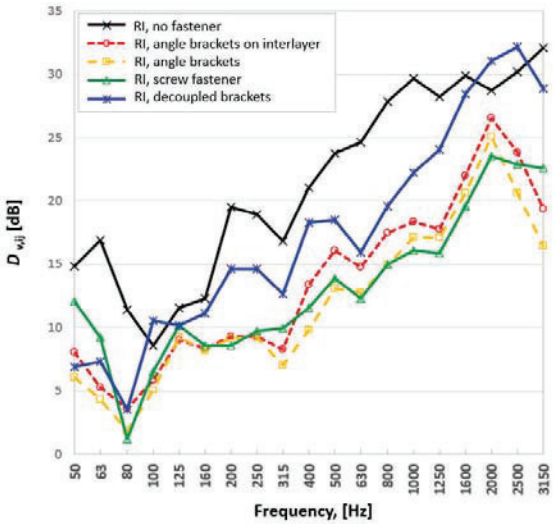

Figure 5: *Measurement results with RI between floors and various fasteners. Blue line shows damping obtained with elastically decoupled angle brackets, red line angle brackets with elastic interlayer between the bracket and the CLT, beige line regular angle brackets, green line screw fasteners and black line without fastener.*

A series of tests were conducted using screws of various thicknesses and centre distance. Both partially threaded (PT) screws, and fully threaded (FT) screws were tested. All screws were mounted diagonally in pairs through the wall-floor junctions between floors. While changing the type of fasteners made an impact on the result, the screw configurations resulted in little variation in junction damping.

An interesting finding is that RI between the floors did not improve the damping around the middle frequencies when screws were inserted through the junction, which corresponds well to results reported by Morandi et al. [17]. This is shown in Figure 6 where a measurement using no RI (black line) is compared to tests conducted with different RIs. This indicates that screws that penetrate the resilient interlayer ruin the effect of the RI and gives limited vibration protection.

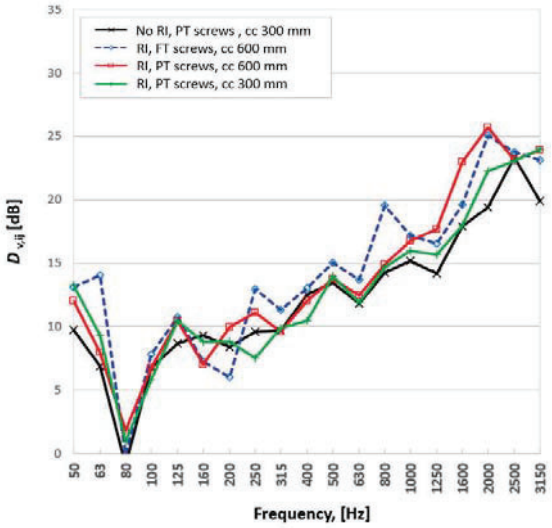

Figure 6: *Measurement results of vertical damping with screw fasteners of various types and spacing. Blue line shows damping obtained with FT screws cc 600 mm, red line PT screws cc 600 mm, green line PT screws cc 300 mm and black PT screws cc 300 mm and no elastic interlayer between the floors.*

3.2 HORIZONTAL JUNCTION DAMPING

Measurements on horizontal junction damping were also conducted. The top floor of the mock-up was removed and the roof slab and connection walls were cut in half, as shown schematically in Figure 7. A floating floor and wall linings were applied in the sending room to control the flanking paths.

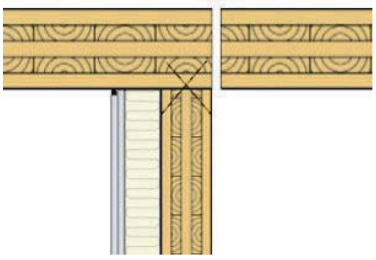

Figure 7: *Drawing of vertical cross section displaying the junction between horizontally adjacent rooms.*

Various fasteners were inserted across the cut between the horizontally adjacent rooms. Sensors were mounted on the roof slab on both sides of the parting wall.

https://doi.org/10.52202/069179-0261

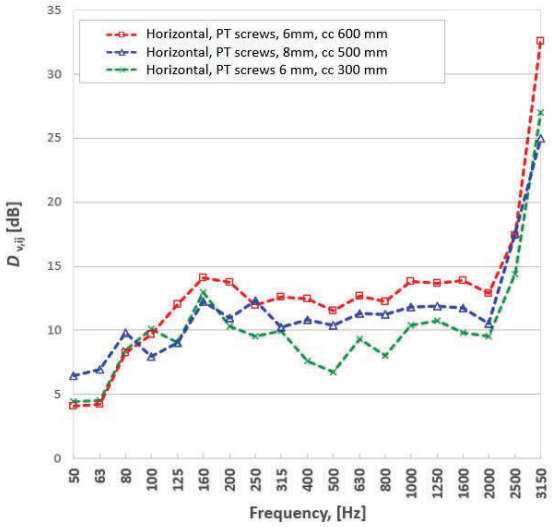

Figure 8: *Measurement results of horizontal damping with screw fasteners.*

Figure 6 and Figure 8 illustrate that screw fasteners measured across horizontal and vertical junctions result in similar damping, around 10 dB, in the middle frequencies. The horizontal damping is higher than in the vertical direction in the low frequencies, while vertical damping is better in the high frequencies.

The results from the horizontal measurements also show improved damping with increased centre distance between screws, as opposed to vertically where the results are the same, as the red and green line in Figure 6 show. Morandi et al. [17] points out that the weight of the overlying structure could cause a connection between the elements that reduces the effect of the type of fastener used.

3.3 VERTICAL JUNCTION DAMPING WITH AND WITHOUT HEAVY FLOOR CONSTRUCTIONS

To add mass to the CLT slab 100 mm gravel was laid directly onto the CLT floor, with a floating floor consisting of 40 mm mineral wool with 70 mm concrete on top.

Measured velocity level differences with and without heavy floating floor are shown in Figure 9. Sylomer is used as elastic interlayer in both measurements, and decoupled angle brackets, GePi 240, as fastener.

Adding the floating floor increased the velocity level difference more than 15 dB from 125-1000 Hz.

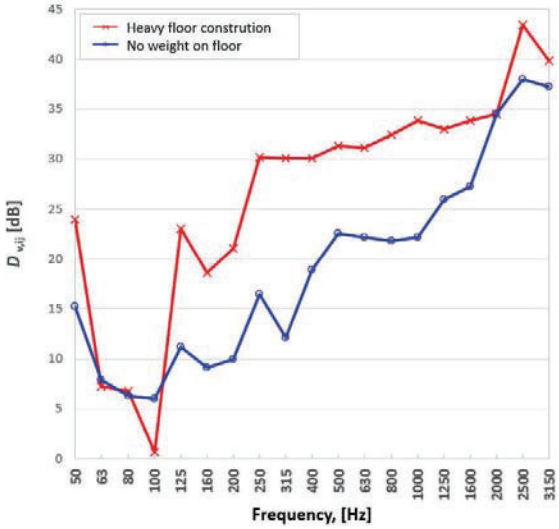

Figure 9: *Measurement results with (red line) and without (blue line) heavy floor construction.*

3.4 SOUND INSULATION WITH FLOATING FLOORS

Airborne and structural sound insulation was measured with different floors constructions, ceilings and linings. Vertical measurements shown below are conducted with various floors as described in Table 1, but without a suspended ceiling to keep the wood exposed in the bottom room. Linings were used to reduce the flanking sound, making the sound travelling directly through the slab would dominant.

Table 1: *Description of floating floor constructions. Exposed CLT ceiling in receiving room.*

Floor type	Floating floor (top to bottom)
A	2x22 mm chipboard, 40 mm mineral wool
B	2x22 mm chipboard, 135 mm joists on 25 mm Sylodyn. Insulated cavity
C	2x22 mm chipboard, 135 mm joists on 25 mm Sylodyn. Insulated cavity. Concrete slabs in cavity covering the majority of the floor area.
D	2x22 mm chip board, 40 mm mineral wool, 100 mm gravel
E	70 mm concrete cast, 40 mm mineral wool, 100 mm gravel

Results for airborne and impact sound insulation with the various floor types described in Table 1 are shown in Figure 10 and summarized in Table 2. As expected, adding weight to the light weight CLT floor construction improves the sound insulation noticeably in the lower frequencies. Gravel added directly to the CLT floor gave considerable improvement, especially for impact sound insulation, as the results with floor types D and E show. The results indicate that the type of the floating floor is not crucial if weight is added directly to the CLT floor.

https://doi.org/10.52202/069179-0261

Measurements C, D and E comply with the current Norwegian minimum requirements for sound insulation between dwellings of $R'_w \geq 55$ dB and $L'_{n,w} \leq 53$ dB.

Table 2: *Results from measurements of airborne and impact sound insulation on various floating floor constructions.*

Floor type	R'_w ($C_{50\text{-}5000}$) [dB]	$L'_{n,w}$ ($C_{I,50\text{-}2500}$) [dB]
A	53 (-2)	57 (6)
B	54 (-2)	55 (5)
C	58 (-1)	52 (3)
D	63 (-3)	44 (9)
E	61 (-2)	43 (7)

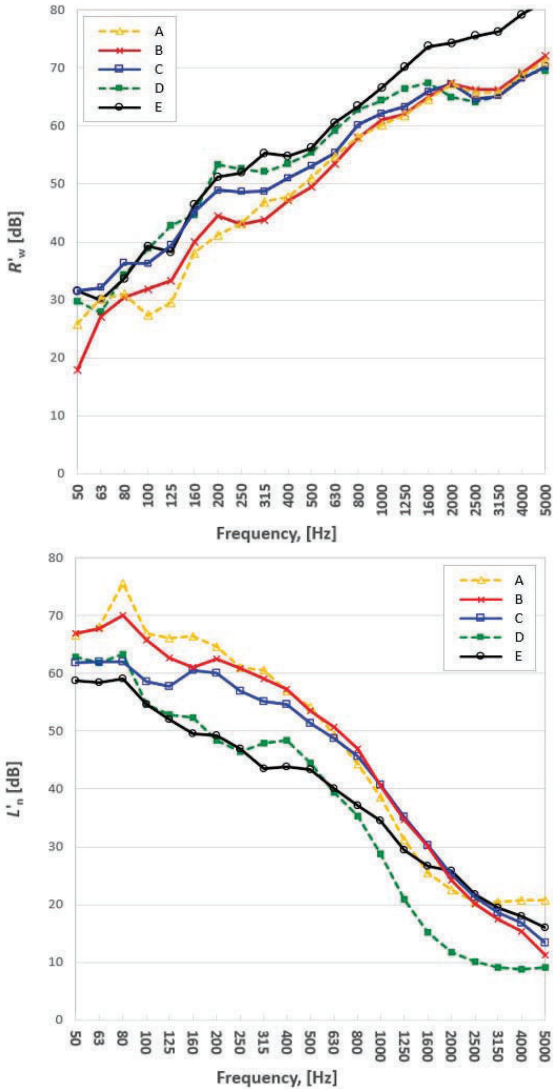

Figure 10: *Vertical airborne (upper) and impact (lower) sound insulation measured between floors with various floor constructions. Slab element was kept exposed in the bottom room, i.e. no suspended ceiling.*

3.5 EFFECTS OF HEAVY FLOOR CONSTRUCTIONS ON SOUND INSULATION WITH EXPOSED CLT

Measurements were performed vertically on a heavy floating floor construction equal to construction E described in Table 1. Elastically decoupled angle brackets were used as fastener in the junction between the floors.

Repetitive tests were done exposing various parts of the CLT construction in the bottom room. All walls and ceiling on the top floor were kept visible throughout the measurements. Results are shown in Figure 11 and summarized in Table 3.

These tests indicate that part of the CLT can be kept visible when using a sufficiently good fastener and applying weight to the floor and still fulfil quite high sound insulation requirements, including the Norwegian minimum requirements for dwellings. Impact sound insulation increased by 6 dB when the suspended ceiling was added. An improvement in the low frequency region from 80-125 Hz can be seen for impact sound insulation with a suspended ceiling, which is especially important to subjective annoyance [21]. Still, the spectrum adaptation terms were equal and smaller without the suspended ceiling for airborne and impact sound insulation, respectively.

The other tests show a up to 3 dB decrease in sound insulation from exposing the wood construction. All three measurements fulfil the minimum sound regulations in Norway between dwellings.

Table 3: *Result table of measurements of airborne and impact sound insulation on heavy top floor and various degree of visible CLT in bottom room.*

Meas. no.	Description	R'_w (+ $C_{50\text{-}5000}$) [dB]	$L'_{n,w}$ ($C_{I,50\text{-}2500}$) [dB]
E	Exposed CLT in ceiling. Linings in bottom room.	61(-2)	43(7)
F	Sound insulated ceiling, exposed wall in bottom room.	62(-2)	39(8)
G	Sound insulated ceiling. Linings in bottom room.	64(-3)	37(10)

https://doi.org/10.52202/069179-0261

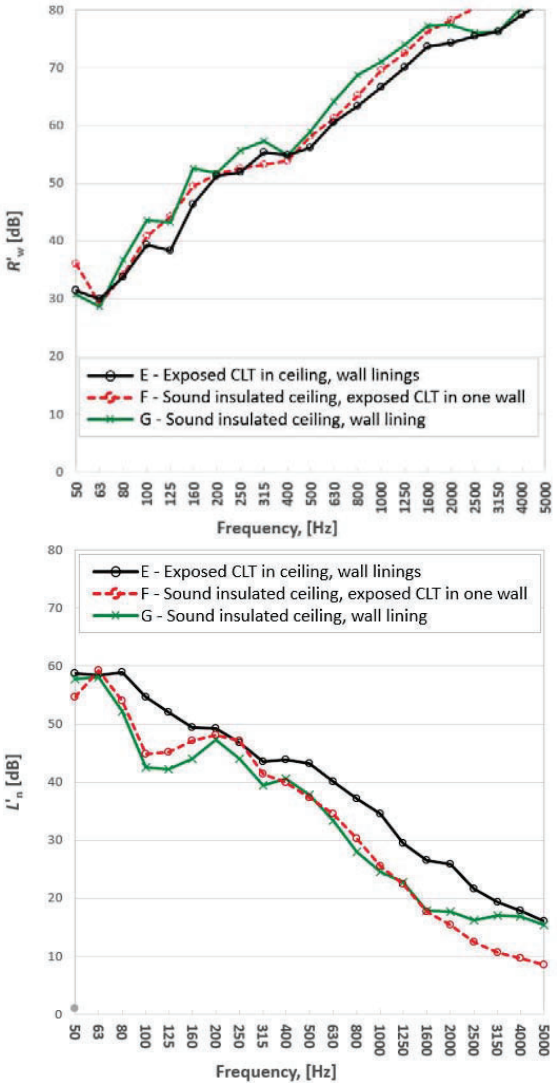

Figure 11: *Vertical airborne (upper) and impact (lower) sound insulation between floors showing effects of visible wall/slab elements.*

4 CONCLUSIONS

The variation in damping between various configurations of elastic interlayers and fasteners in junctions has been assessed by measuring the velocity level difference on a full scale CLT mock-up. Measurements of sound insulation were done in parallel to the measurements of velocity level differences.

Results show that the type of fastener is crucial to the junction damping. The use of elastically decoupled angle brackets proved to increase the damping compared to regular angle brackets and traditional screw fasteners.

Tests conducted on various screw fasteners show low damping effect and little change between various configurations regardless of elastic interlayer. Measurements of horizontal damping proved more sensitive to various configurations of screw fasteners than vertical measurements. As a whole, the test results suggest that the choice of fastener has greater impact on the damping than the type and use of vibration protection.

Heavy floating floors added onto the CLT floor significantly increased the velocity level differences between rooms, as various upper floor constructions were tested. Weight applied directly on to the CLT floor showed a significant increase in low frequency sound insulation.

Three floor constructions using a heavy floor construction were in accordance with the minimum regulations for sound insulation between dwellings in Norway, one of which was measured with exposed CLT in the ceiling. Thus, the measurements of sound insulation reveal that part of the wood can be kept visible when using a favourable fastener and applying weight to the floor.

INFLUENCE OF MECHANICAL FASTENER SPACING ON ACOUSTIC PERFORMANCE IN TIMBER COMPOSITE PANELS

Aedan Callaghan[1], Wilson Byrick[2]

ABSTRACT: Mass timber construction is an increasingly common way of building taller and larger wood buildings utilizing renewable building materials with lower embodied carbon. With a lighter mass and higher flexibility relative to concrete, however, a mass timber panel provides relatively poor acoustic separation between adjacent spaces. This poor acoustic performance combined with the desire for exposed mass timber ceilings means that an additional subfloor layer decoupled by an acoustic interlayer, is often used to provide adequate separation between spaces within the building. In some structural systems, screw fasteners through the acoustic interlayer maybe required. This study investigates the deterioration of the airborne and structure borne sound transmission performance due to the addition of metal fasteners through interlayer 304.8 mm, 609.6 mm and 1219.2 mm on centre (o.c.). The change to both the airborne and structure borne sound transmission is directly related to the spacing of the fasteners, with the most significant decrease in performance noted between 200-4000 Hz. This data provides insight into the performance of composite timber floor systems requiring fasteners through the resilient interlayer and will assist with designing these systems with more certainty in regard to the sound transmission that will occur within the building.

KEYWORDS: Acoustics, Resilient Interlayer, Cross Laminated Timber

1 INTRODUCTION

Mass timber has rapidly gained popularity due to the lighter weight of buildings, faster speed of construction, and lower embodied carbon compared to concrete structures. The most common type of mass timber panel is cross laminated timber (CLT), where dimensional lumber is assembled in alternating directions perpendicular to the previous layer. The panels are then adhered with structural adhesive and pressed into panels, typically with an odd number of layers/plies (3-ply, 5-ply, 7-ply, etc.) [1].

However, with this lower mass and stiffness comes worse acoustic performance. A typical bare 3-Ply CLT at 104.8 mm thickness and having a mass of 53.66 kg/m^2 is measured as having a sound transmission class (STC) and impact insulation class (IIC) of 38 and 21 respectively [2]. To put this in context, the International Building Code (IBC) 2021 section 1206 requires STC 50 or higher and IIC 50 or higher to separate any living units with adjacent spaces [3]. This requires a robust assembly that can provide this 12-point improvement to STC and 29 point improvement to IIC.

To accommodate the desire for the mass timber ceiling to remain exposed, a resilient interlayer between the mass timber structural panel and an additional subfloor mass layer is the most common approach to improving the acoustics. This type of floating floor system can drastically improve both the airborne and structure borne acoustic performance of the timber floor panel. The resonance of floating floors (f_0) has been well studied and can be calculated based on spring stiffness (K_F), air stiffness (K_A) and mass sitting on the spring (m) as shown in equation (1) [4].

$$f_0 = \sqrt{\frac{K_A * K_F}{m}} \quad (1)$$

When the CLT or mass timber panel is designed as the full floor structural system, the additional topping can be fully decoupled and act as the mass layer needed for the floating floor. However, the use of timber composite floor systems can sometimes provide the most efficient structural system for a building and requires the timber and topping, typically normal concrete, to be mechanically connected to utilize the strength of both materials (timber typically in tension, concrete in compression) [1]. Given that a resilient interlayer is often the main form of added sound control to improve the acoustic performance, the addition of mechanical fasteners in this location will inhibit the overall acoustic performance. While many projects have utilized these composite systems with fasteners penetrating through the acoustic interlayer, little data is available to quantify the degradation on the airborne and structure borne sound

https://doi.org/10.52202/069179-0262

transmission of these composite panels compared to the fully decoupled floating floors.

Rigid or semi rigid penetrations through an acoustic isolation system are often referred to as a short circuit as they provide an unintended path for vibrations to travel and bypass the intended isolation system. Previous research on the effects of short-circuiting resilient channels with improper installation showed that the number of fasteners shorting out the resilient channels had a significant impact on performance [5]. Up to a 6dB decrease to the STC rating and 9 dB decrease to the IIC rating has been observed when the fasteners penetrating though the resilient channel into the joists were spaced at 609.6 mm o.c. by 406.4 mm o.c.

This study aims to provide a similar understanding of short circuiting of the resilient interlayer in mass timber. The effect of these short circuits and the influence of spacing will be analyzed with 3 different spacings of 304.8 mm, 609.6 mm and 1219.2 mm on centre (o.c.) based on some common timber concrete composite designs [6].

2 THE ASSEMBLY

A 3-Ply CLT assembly with resilient interlayer and wood subfloor was assembled at Intertek ATI floor ceiling acoustical test chamber. The test chamber has a top opening of 3023 mm by 3632 mm with the exposed area in the receiving room below of 2896 mm by 3505 mm. A plan view of the assembly is shown in Figure 2. Intertek-ATI is accredited to perform ASTM E90 and E492 by the International Accreditation Service.

A cross section of the assembly is shown in Figure 2. In order to be able to add the self-tapping screws in an iterative fashion, a thinner 3-ply CLT was selected as the subfloor panel. A summary of the components in the assembly with thickness and weight are provided in Table 1.

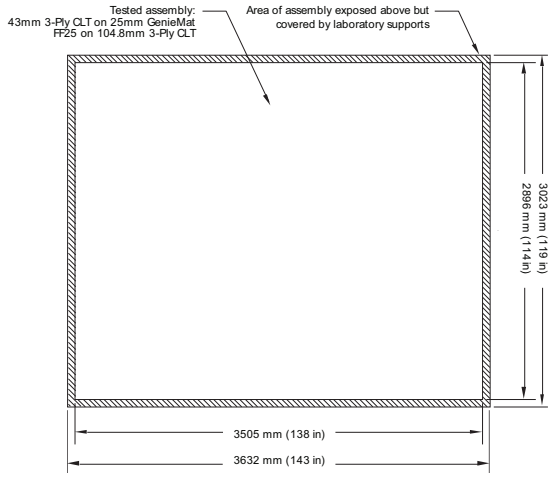

Figure 1: *Plan view of the tested assembly and lab chamber dimensions*

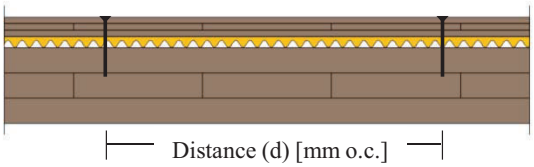

Figure 2: *Section view of the tested floor-ceiling assembly*

2.1 STRUCTURAL PANEL

A 3-ply cross laminated timber was used as the base structural panel for this testing. The panel measured at 104.8 mm thick panel with a mass of 53.66 kg/m^2.

2.2 RESILIENT INTERLAYER

A 25 mm recycled rebounded rubber elastomeric interlayer with a dimpled profile named GenieMat® FF25 was utilized as the decoupling material for this testing. It has an areal mass of 10.2 kg/m^2.

2.3 TOPPING

A thinner 3-ply CLT was used as the topping subfloor layer in this test series. It measured 44 mm in thickness with a mass of 23.43 kg/m2.

2.4 SELF-TAPPING SCREW

Fully threaded self-tapping screw with countersunk head 127 mm length were used for mechanically fastening the subfloor to the structural CLT and penetrate through the resilient interlayer.

Table 1: *Assembly component dimension and weights*

Component	Thickness (mm)	Mass (kg/m^2)
3-Ply CLT (Base)	104.8	53.66
GenieMat FF25	25	10.27
Thin 3-Ply CLT (subfloor)	44	23.43
Total	173.8	87.36

3 TEST PROCEDURES

The assembly was tested according to ASTM E90 and ASTM E492 with 3 different spacings of screws penetrating the resilient interlayer. These short circuits were created by fastening 9, 30 or 99 screws through the 44 mm subfloor panel and 25 mm GenieMat FF25 with 58 mm of embedment into the structural 3-Ply CLT panel. The assembly was tested with no short circuits. The first 9 screws were added at a 1219.2 mm o.c spacing. The assembly was then retested. The number of short circuits was increased to 30 at a 609.6 mm o.c. spacing and retested. Finally, the number of short circuits was

https://doi.org/10.52202/069179-0262

increased to 99 with a 304.8 mm o.c. spacing. The locations of each short circuit are shown in Figure 3A-D.

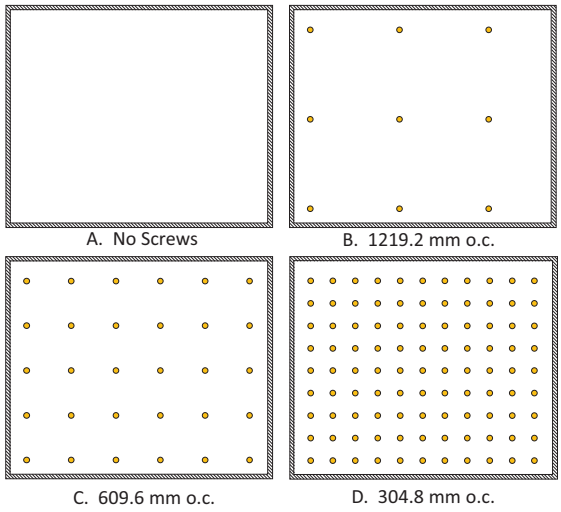

Figure 3: *Location of screws for the various configurations of short circuits. A: baseline case with no short circuits. B: 9 screws spaced 1219.2 mm o.c., C: 30 screws spaced 609.6 mm o.c., D: 99 screws spaced 304.9 mm o.c.*

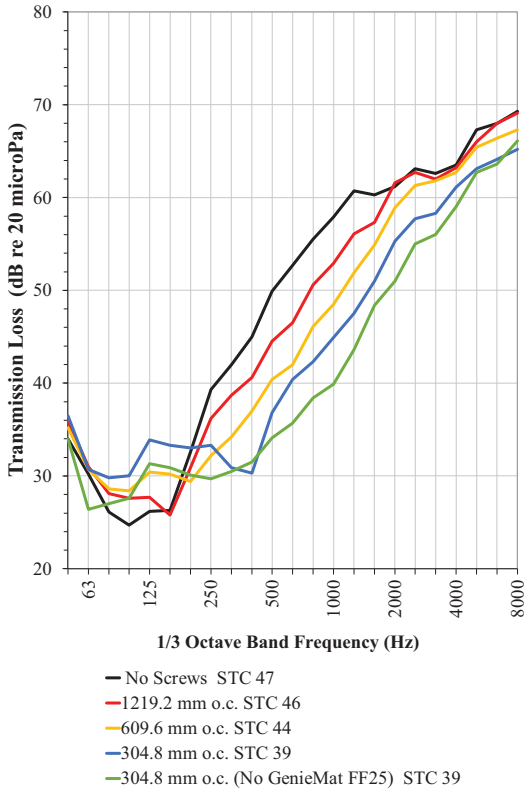
4 RESULTS AND DISCUSSION

A summary of the STC and IIC single number ratings for each fastener spacing can be seen in Table 2. The STC rating decreased from 47 with no short circuits to 39 with screws at a 304.8 mm o.c. spacing. The IIC decreased from 41 with no short circuits to 35 with the screws at 304.8 mm o.c. for a total change of 6 IIC points. The HIIC was most affected by the increase in short circuits and decreased from 52 to 34 over the test series. Meanwhile the LIIC remained quite stable at 50-51 throughout all 4 tested assemblies.

Table 2: *Summary of STC and IIC performance*

Fastener Spacing (mm o.c.)	STC	IIC	HIIC	LIIC
None	47	41	52	50
1219.2	46	40	42	51
609.6	44	38	38	51
304.8	39	35	34	50

The 1/3 octave band frequency plots of transmission loss (TL) and normalized impact sound pressure levels (NISPL) for each test can be seen in Figure 4. While single number metrics are helpful for high level comparisons, the 1/3 octave band comparison provides further insight into the change in sound transmission at various screw spacings.



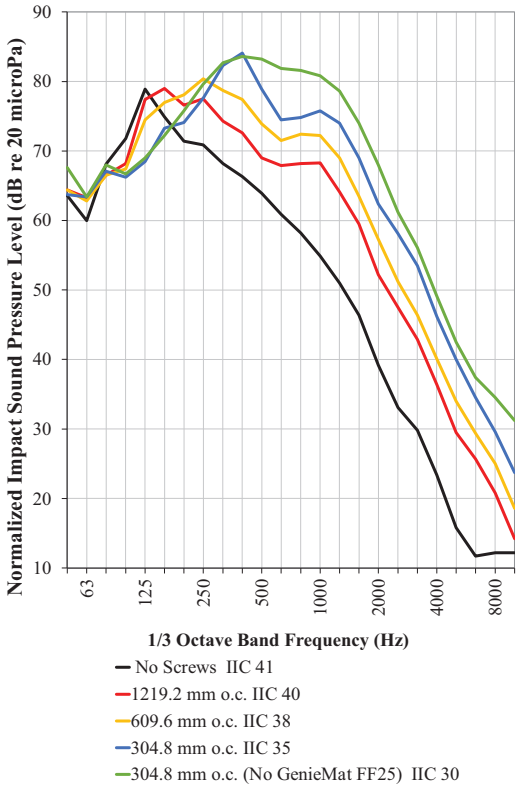


Figure 4: *Transmission loss (Top) and Normalized Impact Sound Pressure Level (Bottom) results of the tested assembly with various screw spacings*

https://doi.org/10.52202/069179-0262

The data shows a relatively consistent shift to the curves with each sequential addition of more screws and reduced spacing. The TLs in the 250-2000Hz range all display a similar slope with an offset in the curves. Table 3 shows the change in TLs across that frequency range for each screw spacing. When the change in each sequential halving of screw spacing is compared, the decreases in TLs were 4 dB, 3.8 dB and 3.4 dB respectively with each increase in fasteners.

Table 3: *Change to TL at each screw spacing from 250-2000Hz*

	Change to TL (relative to no screws)		
1/3 Octave Band (Hz)	1219.2 mm o.c. (dB)	609.6 mm o.c. (dB)	304.8 mm o.c. (dB)
250	-3.1	-7.1	-6.0
315	-3.3	-7.8	-11.1
400	-4.4	-8.0	-14.7
500	-5.4	-9.5	-13.1
630	-6.2	-10.7	-12.3
800	-4.9	-9.4	-13.2
1000	-5.0	-9.4	-13.0
1250	-4.6	-8.8	-13.2
1600	-3.0	-5.4	-9.3
2000	0.4	-2.3	-5.9
Average	-4.0 dB	-7.8 dB	-11.2 dB

When comparing the change in NISPL across the tests, the area with the most consistent shift of the curve appears to be the same frequency range of 250-2000Hz. This data can be seen in Table 4 and shows the average increase to NISPL for each spacing. Across the selected frequency range, the shift is greatest with an average increase in NISPL of 9.4 dB in going from no screw to the 1219.2 mm o.c. spacing with the relative change then 4.2 dB and 3.8 dB respectively for each addition of screws.

Table 4: *Change to NISPL at each screw spacing from 250-2000Hz*

	Change to NISPL (relative to no screws)		
1/3 Octave Band (Hz)	1219.2 mm o.c. (dB)	609.6 mm o.c. (dB)	304.8 mm o.c. (dB)
250	6.6	9.5	6.7
315	6.1	10.5	14.1
400	6.3	11.1	17.8
500	5.1	10.0	15.0
630	7.0	10.6	13.6
800	10.0	14.2	16.6
1000	13.4	17.3	20.9
1250	13.1	18.0	23.0
1600	13.1	17.1	22.6
2000	13.0	18.1	23.2
Average	9.4 dB	13.6 dB	17.4 dB

To better understand the trends across all 1/3 octave bands, the change to TL and NISPL for the 3 different screw spacings (relative to new screws) are plotted in Figure 5.

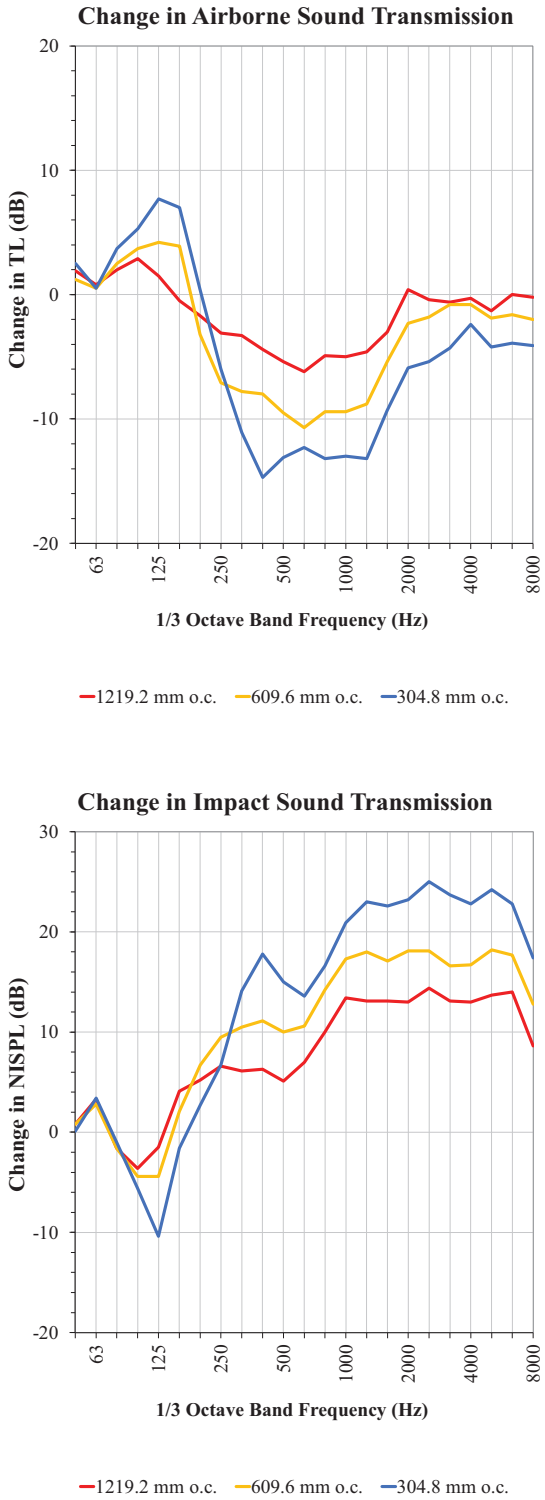

Figure 5: *Change in TL (Top) and NISPL (Bottom) across the 1/3 octave band frequencies.*

https://doi.org/10.52202/069179-0262

When looking at the change in performance in Figure 5, at mid and high frequencies, there is an increase in both airborne and impact sound transmission correlating to the addition of the fasteners through the GenieMat FF25 interlayer. This is in line with the expectation for rigid fasteners acting as short circuits. However, the change across both the TL and NISPL data show an inversion near 200 Hz. In both cases, some improvement from the addition of more fasteners is observed at the low frequencies below 200 Hz. There are no signs of error in the lab testing or issues with background noise at those frequencies, so the improvement is believed to be real. This low frequency range is considered the stiffness-controlled region so the addition of screws stiffening the overall assembly is likely contributing to this improvement.

To evaluate the role of stiffness, the GenieMat FF25 was removed, and the topping panel was reinstalled with fasteners returned at their 304.8 mm spacing. This showed similar low frequency NISPL behaviour, indicating this is fully due to the stiffening effect. However, the TL performance was worse without the resilient interlayer. The resilience and damping properties of the GenieMat FF25 may also be contributing by creating a constrained layer damping system.

Since higher frequency impact sound (400 Hz and up) is more easily rolled off simply by adding a finish floor on a thin recycled rubber underlayment like in concrete construction, a timber composite system that can improve the low frequency impact performance without requiring the addition of concrete could have major benefits. Further research is needed to determine what role the damping properties play and quantify the impact of stiffness compared to a constrained layer damping effect. A prefabricated timber panel. A timber composite system that does not rely on a high embodied carbon material such as concrete would offer a more sustainable system and could allow for further offsite fabrication with the full cassette ready for installation on site. Additionally, a composite panel system that does not incorporate poured concrete is fully de-constructable allowing for all components to be separated, reused and recycled.

5 CONCLUSIONS

The addition of screws penetrating through a resilient interlayer has a significant impact on the acoustic performance and must be considered for adequate STC and IIC performance. Up to a 25 dB increase in NISPL and up to a 14 dB decrease in TL were observed in comparing an assembly with no fasteners through the resilient interlayer to one with screws at 304.8 mm o.c. While very significant to the final performance, the fastener spacing is correlated to a gradual impact on airborne and impact sound transmission and can be taken into consideration during design of the structural system.

ACKNOWLEDGEMENT

I would like to thank the entire Pliteq team for supporting me in this research and providing the resources necessary to carry out the testing. I would also like to thank Vaagen Timbers for providing the CLT panels. Lastly, we are grateful for the opportunity to work collectively to reduce the carbon emissions of new construction and meet Pliteq's goal of ensuring that every scrap tire is recycled

PLASTIC DEFORMATION CONTRIBUTIONS OF CLT AND LTF SHEAR WALLS: DEVELOPMENT OF AN ANALYTICAL CAPACITY MODEL

Angelo Aloisio[1], Yuri De Santis[1], Francesco Boggian[2], Massimo Fragiacomo[1], Roberto Tomasi[3]

ABSTRACT: This paper compares the experimental cyclic response of Cross-Laminated Timber and Light Timber Frame shear walls. The goal is extracting the fractions of the lateral displacement due to sliding, panel's deformation and rocking. The three contributions to the total displacement, expressed in percentage, are then used to develop an analytical capacity model valid for CLT and LTF shear walls. The model is based on the sole equilibrium equations of the hold-down forces, obtained by reducing the pivot length of the hold downs reactions. Additionally, they examine the overstrength of the CLT panel, and LTF sheathing to the shear walls collapse due to the hold-down failure.

KEYWORDS: Experimental cyclic response; timber engineering; shear walls; rocking; Cross Laminated Timber; Light Timber Frame.

1 INTRODUCTION

Currently, the most diffuse timber constructive systems in Europe are based on the use of Light Timber Frame (LTF) and Cross Laminated Timber (CLT) shear walls [1]–[3]. There are numerous and diverse capacity models in the scientific literature for Cross-Laminated Timber (CLT) and Light Timber Frame (LTF) shear walls. Some researches merely attempt to elaborate closed-form models which best seize the observed response. Others, like [4], append to the mentioned efforts, an interpretative framework useful in developing simplified and reliable tools for the prediction of the lateral response. Specifically, [4] developed an analytical procedure and a simplified numerical model for the elastic response of LTF and CLT shear walls. They found that, in the elastic response range of CLT shear walls, 77% of the total displacement is due to rigid-body rotation, 16% to the rigid-body translation and 7% to the panel deformation. Conversely, in LTF shear walls, 45% is expected to the rigid-body rotation, 6% to the rigid body translation, and 45% and 4% to the sheathing-to-framing connection and sheathing panel deformation, respectively. In this paper, the authors investigate CLT and LTF systems in the post-elastic range. The rigor and straightforwardness of elastic analysis vanishes when dissipative phenomena arise. The authors devoted their efforts in interpreting experimental data by clustering the displacement response in rocking, sliding and deformation components. In a second step, based on the observed results, an elementary capacity model based on the sole hold-down experimental response is compared to the experimental results to estimate the related approximation.

2 EXPERIMENTAL TESTS

The results presented in this paper descend from the experimental data on LTF and CLT shear wall tests performed at the University of Trento. [5]–[7]. The first part of this paper focuses on the description of the test setup and the experimental responses. The second part attempts to understand the leading deformation contributes to the shear walls lateral response and proposes a capacity model based on the hold-down contribution. The research novelty of this paper, with respect to [6], [8], derives from the (1) complete report of the cyclic test results on CLT shear walls, (2) comparing CLT and LTF by decomposing the experimental response into rocking, sliding and deformation fractions, (3) the proposal of a novel capacity model driven by hold-down reactions, and (4) the estimation of overstrength factors.
The full description of the test setup of LTF and CLT shear walls is detailed in [5], [9], [10]. Tab.2 summaries the primary outcomes of the cyclic tests. Tab.2 reports only F_u and v_u, F_u measuring the strength capacity, while v_u the displacement capacity. The former expresses ultimate resistance; the latter is related to ductility. The optimum performance of a structural system derives from the optimum balance between resistance and ductility. Therefore, F_u and v_u may be suitable synthetic indicators of the experimental structural performance. Fig.2 presents the results in the form of force-displacement curves.

3 EXTRACTION OF THE PLASTIC DEFORMATION COMPONENTS

The sliding fraction is estimated as the limit of the ratio between the horizontal displacements in points D and B, as illustrated in Fig.1:

$$s := \lim_{u_B \to \infty} \left| \frac{u_D(t)}{u_B(t)} \right| \quad (1)$$

The values of $u_D(t)$ and $u_B(t)$ are direct measures from the experimental campaign, and when plotted, they reveal an hyperbolic behaviour, with a clearly visible asymptote for higher values of the imposed displacement

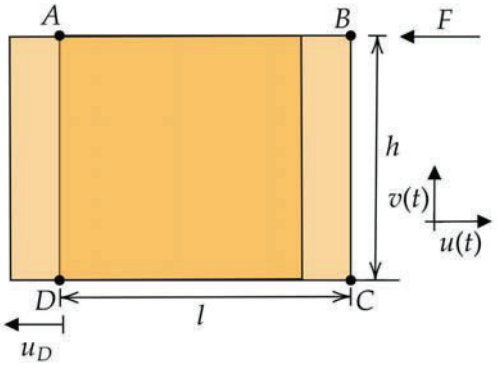

Figure 1*: Illustration of the rigid-body translation of the panel and the adopted notation.*

The relative displacement between the points A-C and B-D is a measure of the diagonal deformations in the East and West directions identified by d_E and d_W respectively. At this stage, the authors assume that the panel manifests a predominant shear deformation, as illustrated in Fig.2.

$$d_{E,W} = r_2 - r_1 \quad (2)$$

The shear displacement δ derives from Eq.(2) by expliciting the two radii r_2 and r_1:

$$\delta = l - \left[(h\sqrt{2} - d_{E,W})^2 - h^2 \right]^{0.5} \quad (3)$$

The ratio between δ and u_B approaches a constant value at higher displacement values. The following definition of the deformation fraction, d, attempts to grasp the approaching asymptot.

$$d := \lim_{u_B \to \infty} \left| \frac{\delta}{u_B} \right| \quad (4)$$

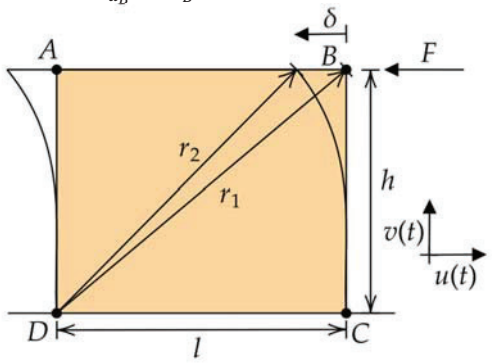

Figure 2*: Illustration of the shear deformation of the panel and the adopted notation.*

The rocking component is estimated as a complement to one of the already estimated sliding and deformation contributions, see Fig.3:

$$r = 1 - (s + d) \quad (5)$$

The whole displacement field of the shear wall is illustrated in Fig.7, where all the contribution to the top displacement u_B are highlighted: u_D represents the sliding contribution while δ represents the deformation contribution, both evaluated in the previous sections. The rocking component can be expressed by θh. By assuming small displacements, the displacements can be written as:

$$u_B - u_D - \delta = \theta h \quad (6)$$

$$v_C = \theta(l - x) \quad (7)$$

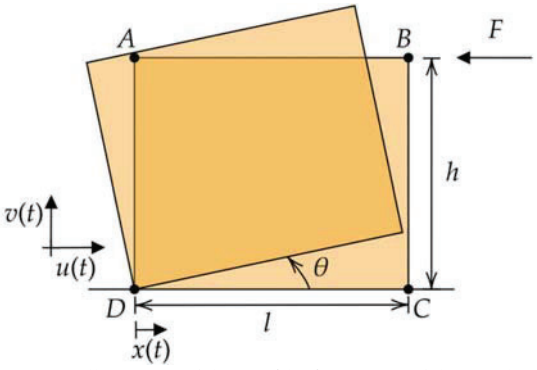

Figure 3 *Illustration of the rigid-body rotation of the panel and the adopted notation.*

https://doi.org/10.52202/069179-0263

4 RESULTS

Tab.3 reports the three displacement contributions in all the tested specimens, expressed as percentages. The displacement components in Tab.3 refer to the post-elastic behaviour. They originate from Eqs.(1),(4),(5) respectively, which present an asymptotic definition of the three displacement fractions. The experimental data reveal that the three displacement components rapidly converge towards a definite value after the elastic phase. The values stationarity proves that the excitation amplitude does not modify the balance between the three contributions after a certain post elastic displacement value.

Table 3: *The table attempts to synthesize the displacement components due to sliding, deformation and rocking, expressed as a fraction of the imposed displacement in point B, estimated using Eqs. (1),(4),(5) respectively.*

CLT NAWH-L20	6.8	0.1	93.0

The prevalent contribution to the total displacement comes from the rigid-body rotation. The rocking motion of LTF shear walls is lower than CLT: LTF shear walls are more deformable than CLT. The vertical load has almost the same effects in both the shear walls: the load increment reduces the rocking component. The vertical load acts as a rotation restraint. The reduction of the base connections determines a significant increment of the rocking motion, like in the case without hold-downs (WHD). Interestingly the test LTF SCREW, which uses screws distributed uniformly on the bottom rail as a sliding restraint, shows that the presence of screws may influence the rocking mechanism, by offering an additional uplift restraint, thus limiting the rocking percentage as seen from Tab.3.

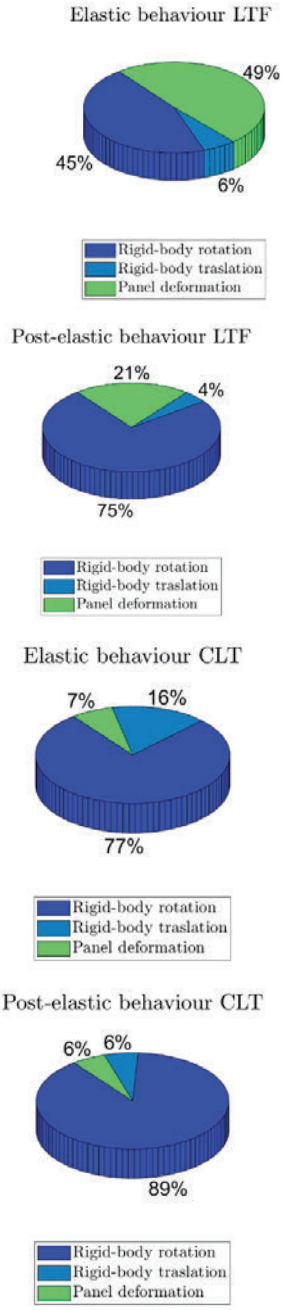

Figure 4*: Percentage of displacement on top of the shear walls due to each single contribution in both the elastic (calculated by* [4]*) and post-elastic range (as calculated from the experimental data. in this paper)..*

The sliding component does not significantly change between LTF and CLT shear walls. The rigid-body translation mainly depends on the transverse resistance of the base connections and does not likely depend on the vertical load. This shred of information conveys some details about the occurring of friction phenomena. The amount of the Coulomb-type friction restraint depends on the vertical load: the substantial independence of the

sliding fraction on the vertical load proves the possible independence of friction in the sliding restraints, primarily provided by the base connections. In the current setup, friction phenomena are then negligible compared to the restraining capacity of the connections.

Additionally, Tab.4 proves the substantial independence of the sliding component on the angle brackets. The CLT shear wall has four angle brackets, while the LTF shear wall has two. Nonetheless, the CLT sliding is lower than LTF. The sliding fractions are quite similar between the two structural typologies and the increment in the number of the angle brackets does not enhance the sliding restraint, likely. The panel deformation changes between LTF and CLT as expected. The impact of deformation on shear walls with low load values and a few base connections (WHD) is shallow and very similar between the two structural typologies. However, as the load increases as well as the base connections, the impact of deformation increases in LTF, while CLT does not deform significantly.

5 CAPACITY MODEL

The dominance of the rocking response due to the hold-downs deformation may inspire the proposal of an elementary capacity model based on the sole hold down reactions. However, the accuracy of the model mostly depends on an accurate estimation of the extension of the compressed area. In contrast with the elastic behaviour, the extension of the compressed area tends towards a sort of plastic asymptote due to the stress redistribution. The definition of the neutral axis is the following:

$$x_p := \lim_{u_B \to \infty} \left| l - \frac{v_C}{\theta} \right| \tag{8}$$

There are no studies about the trend of the stress in the compressed area, which depends on several factors: e.g. the planarity of contact areas, timber grading and the slenderness of the panel.

Tab.4 attests that the extension of the compressed area depends on the vertical load, the in-plane stiffness of the panel and the boundary restraints. The compressed area expands significantly when the vertical load raises, the in-plane stiffness reduces, and there are fewer base connections. An analytical correlation between the x_p variable and the three mentioned variables (vertical load, in-plane stiffness and boundary conditions) is critical for a conservative estimation of forces acting on the base connections. Specifically, the estimation of the pivot point is essential when assessing the force on the hold-downs: the assumption of the pivot point by one edge of the panel would significantly underestimate the hold-down reactions.

Table 4: *Estimate of the asymptotic neutral axis in the considered test configurations.*

Tab.4 lists the expected extension of the compressed area. The second column presents the percentage ratio between the estimated x_p value and the base length l. The x_p extension depends on the balance between deformation and rocking components: the increment of the deformation fraction yields an increment of the x_p value. In this paper, the authors do not investigate the compressed area extension based on mechanical analytical models. This step would entail dedicated research efforts based on adequate mechanical models of the shear wall post-elastic response.

As shown in Fig.5, the wall is assumed to pivot around the position P of its neutral axis, characterized by a compression region of extension x_p; no specific assumption is made regarding the shape of the stress distribution in the compression zone. The contribution of angle brackets to the racking mechanism is neglected. Hereafter follows the equilibrium equations:

$$\uparrow \quad -ql - H + k_C \sigma_C x_p t_{\text{eff}} = 0 \tag{9}$$

$$\circlearrowleft \; Fh - ql\left(\frac{l}{2} - x_p\right) - H(l - x_p) + k_C \sigma_C x_p t_{\text{eff}} l_c = 0 \tag{10}$$

where q is the distributed vertical load, l the wall length, F the top horizontal force, h the wall height, H the hold down reaction force, σ_c the averaged compression stress on timber, k_c a modification parameter which accounts for the increment of resistance due to compression hardening and the shape feature of the stress diagram, x_p the extension of the neutral axis, t_{eff} is the thickness of the wall reacting in compression, l_c is the lever arm of the compression region. The k_c and the l_c factors are in fact unknown.

https://doi.org/10.52202/069179-0263

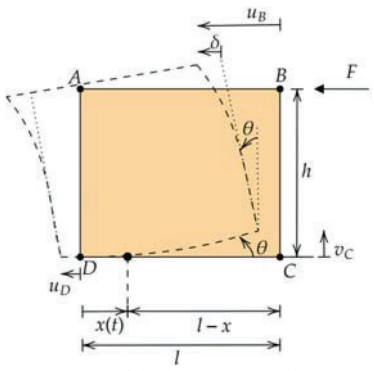

***Figure 5**: Mechanical model of the shear wall.*

The goal of this section is to demonstrate that the cyclic behaviour of the tested shear walls is mainly dependent on the hold-down. The force acting on the wall is then evaluated by considering the sole hold-down contribution to the rotational equilibrium, and neglecting the contribution of the unknown compression stresses in timber:

$$F = H \cdot \frac{\tau \cdot l}{h} + q \cdot \frac{l}{h}\left(\tau \cdot l - \frac{l}{2}\right) \quad | \quad \tau = \frac{l - x_p}{l} \tag{11}$$

Eq.(11) bestows the top horizontal force acting on the wall, given the hold-down force H, the vertical load q and the position of the pivot point x_p. The authors validated this model by comparing, in terms of cyclic curves and maximum force values, the forces measured in point B of the shear wall, with the horizontal force $F(t)$. $F(t)$ is obtained from the simplified model in Eq.(11), using the forces measured on the hold-downs $H(t)$ and the pivot point x_p value estimated in Tab.4. Tab.5 quantifies the discrepancies between the two curves in terms of the maximum forces.

***Table 5:** Comparison between the maximum forces in kN attained by the experimental cyclic tests and the capacity model based on the sole hold-down reactions.*

	Avg |Error|		7.5

Tab.5 proves that a capacity model based on the sole hold down reaction is quite faithful, and an elementary formula for the prediction of the hold-down response could descend by taking the 95% percentile of a Gaussian distribution of the τ factor in Eq.(11). Accurately, the 95% percentiles of the τ factor in the LTF and CLT shear walls are:

$$\begin{aligned} \tau_{\mathrm{LTF},95\%} &= 0.81 \\ \tau_{\mathrm{CLT},95\%} &= 0.86 \end{aligned} \tag{12}$$

These values suggest that the estimate of F needs a proper reduction of the pivot point of the hold-downs. The decrease is higher in the case of LTF shear walls due to the higher deformability. Eqs.(11)-(12) represent simplified formulations possibly useful for engineering purposes, which attempts to avoid underestimating the hold-down reaction by reducing the distance of the rotation point. In conclusion, LTF and CLT shear walls do not display significant differences in the considered configurations. This fact is essentially due to the overstrength of the panel to the base resistance derived from the base connections. Fig.6 illustrates the probability distributions of two resisting mechanisms: the failure reached during testing, mainly due to hold-down collapse, and the OSB sheathing/CLT panel collapse.

Fig.6 illustrates the probability distributions of two resisting mechanisms: the failure reached during testing, mainly due to hold-down collapse, and the OSB sheathing/CLT panel collapse.
The experimental probability density functions of the CLT and LTF shear walls are calculated directly from the values of failure of the cyclic tests. The probability density functions related to the capacity of the CLT panel / OSB sheathings derive by assuming the same variance of the corresponding experimental curves, and by assuming the shear failure of the OSB sheathing in LTF walls and the in-plane torsional shear failure in CLT panels (see [11], [12]). The authors used the following values of strength: $f_{vk} = 6.8$ MPa for OSB/3 and $f_{v,\mathrm{tor},k} = 2.5$ MPa for CLT [13], [14]. Fig.6 expresses the true nature of the considered structural systems. The two systems behave likewise due to the similarity of the base connections. Still, the CLT panel is far more resistant than the LTF when different boundary restraints and loads may activate other resisting mechanisms.

$$\gamma_{RD} = \frac{R_{k,b}}{R_{k,d}} \tag{13}$$

The authors reported the overstrength values, estimated as shown in Eq.(13). $R_{k,b}$ is the characteristic load bearing

capacity of the panel assuming the timber failure mode (brittle), while $R_{k,d}$ the characteristic load bearing capacity of the panel assuming the hold-down failure mode (ductile). The characteristic values are set equal to the 5-th percentile of the corresponding strength distributions. In the considered cases, the overstrength of LTF shear walls is almost two times of that of CLT. The obtained overstrength values are not general and depend from the specific structural configurations and the considered failure modes. The extension of these results to different structural arrangements must be the object of devoted efforts by the authors.

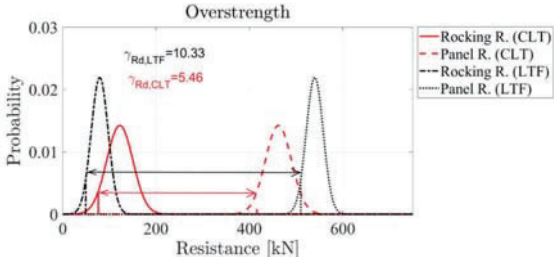

Figure 6: *Comparison between the experimental cyclic response of CLT shear walls and the capacity model based on Hold-Down measured forces.*

6 CONCLUSIONS

Light Timber Frame (LTF) and Cross Laminated Timber (CLT) shear walls exhibit similar response under cyclic loading. The authors compared the experimental test of LTF and CLT wall assemblies characterised by similar geometric features. The rigid-body rotation is the predominant deformation contribution. This contribution, expressed in percentage to the total deformation, is on average 75% and 88% in LTF and CLT specimens, respectively. The rocking response dominance, due to the hold-down deformation contribution, led to an elementary capacity model based on the hold down reactions and the assumption of a pivot point. The 95^{th} percentile of the Gaussian probability distribution of the ratio between the extension of the compressed area and the panel length is about 0.2: the adoption of the panel edge as a rotation point would determine an approximate 20% underestimation of the hold down reactions in the considered capacity model.

ACKNOWLEDGEMENT

The authors acknowledge the research efforts of Paolo Grossi, Paolo Endrizzi, Tiziano Sartori and Ermanno Acler, who carried out the experimental tests with the support of the staff of the University of Trento.

ASEISMIC DESIGN LEVEL USING RESPONSE SPECTRUM FOR WOODEN HOUSES

Koji Yamada[1]

ABSTRACT: Reviewed equations for horizontal resistant force of Japanese wooden houses are discussed in considering both the acceleration response spectrum with sharp peaks and the acceleration response spectrums of observed earthquake motion. This acceleration spectrum with sharp peaks is the sum of Minimum requirement spectrum and the order spectrum. The observed earthquake motions are divided into 2 groups. The one consists of Kobe JMA 1995, the motions distributed by BCJ. The other consists of 592 motions observed from 1996 to 2012 in Japan, their maximum acceleration are over 400 cm/s^2. The new horizontal resistant force is defined as the product of the coefficient of eccentricity ratio, the coefficient of a damping factor, and the coefficient of horizontal resistant force. This coefficient of horizontal resistant force is the function of the ductility factor, the natural period, the period of a response spectrum peak and its acceleration. The verification of the proposed coefficient of horizontal resistant force is checked by the ratio of the ductility factor subjected to input earthquake motions over the set ductility factor. As a result, the response analysis shows that the proposed equations give the safe side of the horizontal resistant force.

KEYWORDS: Acceleration response spectrum, Structural design, Base shear coefficient

1 INTRODUCTION

It is difficult to estimate input earthquake motions accurately in response analysis. Then the response spectra are used to define the input earthquake motions in structural design. In Japan, base shear coefficient is given in structural code. This base shear coefficient is related the acceleration response spectrum in [1]. Therefore, it is useful that the base shear coefficient is calculated from any acceleration response spectrum. In previous paper [2], new equations for base shear coefficient are discussed in considering the acceleration response spectrum with sharp peaks. The new base shear coefficient (Co) is defined as the product of the coefficient of eccentricity ratio(Fes), the coefficient of a damping factor(Fh), and the coefficient of horizontal resistant force(Ds). This coefficient of horizontal resistant force is the function of the ductility factor(μ), the natural period (Ts), the period of a response spectrum peak and its acceleration. This proposed base shear coefficient is discussed by the average of the maximum ductility factors by 10 input motions. In this paper, reviewed equations for horizontal resistant force of Japanese wooden houses are discussed in considering both the acceleration response spectrum with sharp peaks and the acceleration response spectrums of observed earthquake motion. The new horizontal resistant force is defined as the product of the coefficient of eccentricity ratio, the coefficient of a damping factor, and the coefficient of horizontal resistant force. This coefficient of horizontal resistant force is the function of the ductility factor, the natural period, the period of a response spectrum peak and its acceleration.

2 TARGET ACCELERATION SPECTRUM AND ANALYSIS SUPPOSITION

2.1 TARGET ACCELERATION SPECTRUM

The target acceleration spectra are shown in Fig.1. This acceleration spectrum is the sum of Minimum requirement spectrum and the order spectrum. The minimum requirement spectrum has the corner period (Tc), and the order spectrum has the peak periods(Ti).
The input earthquake motions are shown in Fig.2. There 10 input earthquake motions in each spectrum. Each input earthquake motion has random phase and 163.84 sec duration time. The minimum requirement spectrum has the 0.86 sec corner period and 1200gal constant acceleration spectrum region. The target spectrum A has both minimum requirement spectrum and 1400gal peak at 0.4sec natural period. The target spectrum B has both minimum requirement spectrum and 2000gal peak at 0.4sec natural period. The target spectrum C has minimum requirement spectrum, 1400gal peak at 0.4sec natural period and 1400gal peak at 1.2sec natural period. The input earthquake motions are multiplied 0.8 for response analysis of 1 DOF model.

2.2 OBSERVED EARTHQUAKE MOTIONS

The observed earthquake motions are divided into 2 groups. The one consists of Kobe JMA 1995, the motions distributed by BCJ. The other consists of 592 motions observed from 1996 to 2012 in Japan, their maximum acceleration are over 400 cm/s^2.

2.3 PROPOSED BASE SHEAR COEFFICIENT

The proposed base shear coefficient (Co) in Eq.(1) is defined in [2] as the product of the coefficient of eccentricity ratio(Fes), the coefficient of a damping factor(Fh), and the coefficient of horizontal resistant force(Ds). This coefficient of horizontal resistant force is the function of the ductility factor(μ), the natural period (Ts), the period of a response spectrum peak and its acceleration in Eq.(3) - (7). Three restoring force characteristics are considered in this paper(Fig.3). The coefficient is the bearing force of Bi-linear component over the whole bearing force. The parameters of restoring force characteristic are the natural period(T) and the bearing force(Co). The natural periods are set from 0.2 to 3.0sec. The bearing force is calculated by Eq.(1) - (7). The damping factor(ho) is 0.05 basically, are 0.02 and 0.10 for parameter analysis.

$$C_o = F_{es} F_h \overline{D}_s \tag{1}$$

$$F_h = \sqrt{\frac{1+\alpha h_o}{1+\alpha h_{eq}}} \tag{2}$$

$$\alpha = 25$$

$$\overline{D_s} = D_{si} C_{oi} \tag{3}$$

$$C_{oi} = 0.816 * Acc(T) / 980 \tag{4}$$

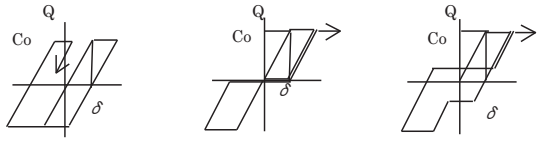
For Minimum requirement

$$D_{sc} = \begin{cases} \dfrac{1}{\sqrt{2\mu - 1}} + \beta \dfrac{T_c - T}{T_c} & T \le T_c \\ \dfrac{1}{\sqrt{2\mu - 1}} \dfrac{T_c}{T} & T > T_c \end{cases} \tag{5}$$

For customer order requirwement

$$D_{si} = \begin{cases} \dfrac{1}{\sqrt{2\mu - 1}} + \beta \dfrac{T_i - T}{T_i} & T \le T_i / 0.8 \\ 0 & T > T_i / 0.8 \end{cases} \tag{6}$$

$$\beta = \begin{cases} 0.1 & Bi-linear \\ 0.5 & Slip \\ 0.5 - 0.4\gamma & Composite \end{cases} \tag{7}$$



a) Bi-linear b) Slip c) composite

Figure 3: *Restoring force characteristic*

Hence, the restoring force characteristic of a wooden house is shown in Fig.4. It seems like the composite type. The calculation value of β is 0.47, I suppose β as 0.5. The natural period of a wooden house is supposed as 0.4 sec. The adequacy of the proposed base shear coefficient at 1/120 rad is checked up by the ductility factor subjected to input earthquake motions over the set ductility factor (μ). Hereinafter, the ratio of the ductility factor subjected to input earthquake motions over the set ductility factor (μ) is called the ductility factor ratio.

https://doi.org/10.52202/069179-0264

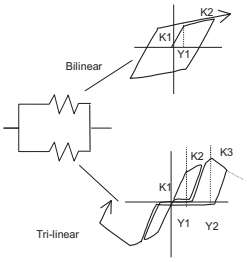


Figure 4: *Restoring force characteristic of a wooden house*

3 VERIFICATION

3.1 VERIFICATION OF PROPOSED BASE SHEAR COEFFICIENT ON TARGET ACCELERATION SPECTRUM

Firstly, the proposed base shear coefficient is checked by input earthquake motions in Fig.2. The ductility factor ratio is shown in Fig.5. The ductility factor ratio is between 0.2 and 0.4. These ductility factor ratios are too small for a design code. The new equations are proposed in Eq.(8) and (9).

For Minimum requirement

$$\begin{aligned} &\overline{D_s} = D_{sc} C_{oc} \\ &C_{oc} = 0.816 * Acc / 980 \\ &D_{sc} = \begin{cases} \dfrac{1}{\sqrt{4\mu - 1}} + \beta \dfrac{T_c - T}{T_c} & T \le T_c \\ \dfrac{1}{\sqrt{4\mu - 1}} \dfrac{T_c}{T} & T > T_c \end{cases} \end{aligned} \tag{8}$$

For customer order requirement

$$\begin{aligned} &\overline{D_s} = D_{si} C_{oi} \\ &C_{oi} = 0.816 * Acc / 980 \\ &D_{si} = \begin{cases} \dfrac{1}{\sqrt{4\mu - 1}} + \beta \dfrac{T_i - T}{T_i} & T \le T_i / 0.8 \\ 0 & T > T_i / 0.8 \end{cases} \end{aligned} \tag{9}$$

The ductility factor ratio in Eq.(8) and (9) is shown in Fig.6. These new equations have an improvement in the range of the ductility factor ratio against in Fig,5.

3.2 VERIFICATION OF PROPOSED BASE SHEAR COEFFICIENT ON OBSERVED EARTHQUAKE MOTIONS

Next, the proposed base shear coefficient is checked by observed earthquake motions. The damping ratios are supposed as h=0.05, 0.10 and 0.20 because of using seismic energy dissipation systems. The ductility factor ratio is shown in Fig.7. The damping ratio is set in proportion to the secant stiffness at 1/120 rad. The ductility factor ratios of some samples are over 1.0. Nevertheless, almost all ductility factors are less than 1.0. proposed equations give the sufficient base shear against earthquakes.

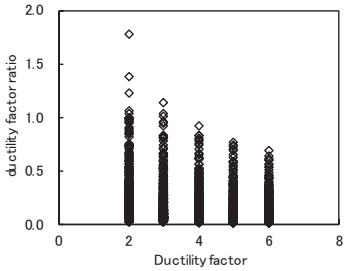
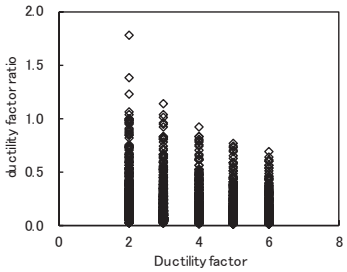
Figure 6: *Ductility factor ratio subjected to earthquake motions in Fig.2 (h=0.05)*

4 VERIFICATION OF PROPOSED BASE SHEAR COEFFICIENT WITH SEISMIC ENERGY DISSIPATION SYSTEM

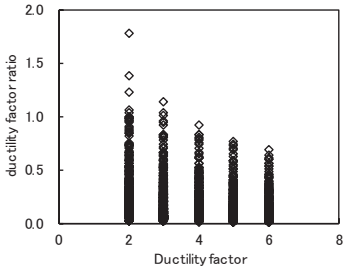
The damping ratio in Fig. 7 is a simple supposition. So the result of Fig. 7 is not applied to actual seismic energy dissipation systems. In this section, a hysteresis damping system and a velocity proportional viscous damping system with relief valve are supposed as actual seismic energy dissipation systems. The hysteresis damping system has the bi-linear restoring force characteristic in Fig. 8. Its yield displacement is 0.5cm and its yield strength is 8kN. The viscous damping system is the brace system, whose 1st damping coefficient is 4 kN/(cm/s), whose 2nd damping coefficient is 0.04 kN/(cm/s), whose relief velocity is 0.9sm/s, and whose stiffness is 20kN/cm. These seismic energy dissipation systems are supposed to be set at 1st floor because the almost Japanese wooden houses collapse at their 1st floor. Their demand in a house is calculated from both of the difference between the set damping ratio value and structural damping ratio 5%, and the 1 loop energy dissipation at 1/120 rad of slope by relative storey displacement of the energy dissipation systems.



a) h=0.05



b) h=0.10



c) h=0.20

Figure 7: *Ductility factor ratio subjected to observed earthquake motions*

https://doi.org/10.52202/069179-0264

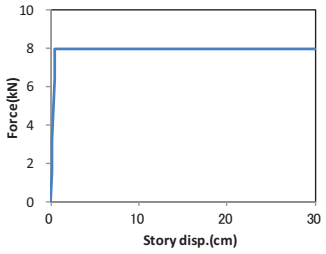


Figure 8: *Characteristic of hysteresis damping system*

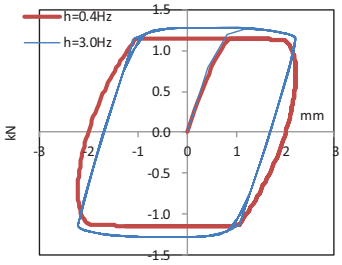

Figure 9: *Characteristic of viscous damping system*

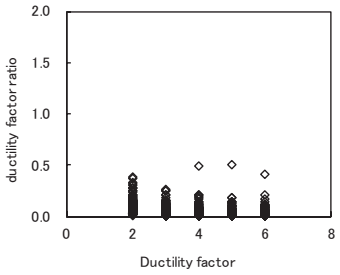
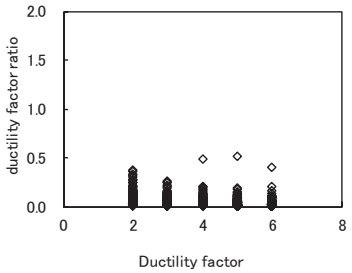
The results are shown in Fig. 10 and Fig. 11. The result on the viscous damping system (Fig.11) is similar to the result in Fig. 7. But the result on the hysteresis damping system (Fig.10) shows that the ductility factor ratio in Fig. 7 is smaller than that in Fig.10.



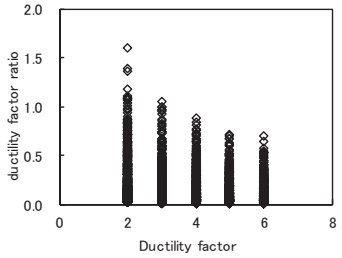
a) h=0.10



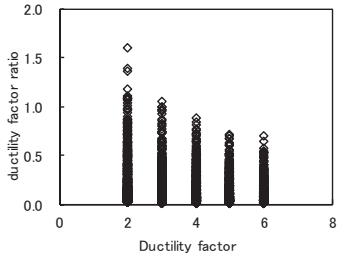
b) h=0.20

Figure 10: *Ductility factor ratio subjected to observed earthquake motions with hysteresis damping system*

The reason is that the consideration of a hysteresis damper is only 1 loop energy dissipation. There is no consideration on its strength. The adequate method to consider the strength of a hysteresis damper is to change β in Eq. (8) and (9). The change of β needs the calculation on the effect of the strength of a hysteresis damper. It is cumbersome procedure. In this paper, a next simple method is proposed. The method is the increase of the 1 loop energy dissipation. The result on double count of 1 loop energy dissipation is shown Fig.12. This figure shows that the ductility factor ratio is a little larger than that in fig.7. But the proposed method is in safe side on structural design.



a) h=0.10



b) h=0.20

Figure 11: *Ductility factor ratio subjected to observed earthquake motions with viscous damping system*

5 CONCLUSIONS

In this paper, new equations for horizontal resistant force of Japanese wooden houses are discussed in considering both the acceleration response spectrum with sharp peaks and the acceleration response spectrums of observed earthquake motion. The new horizontal resistant force is defined as the product of the coefficient of eccentricity ratio, the coefficient of a damping factor, and the coefficient of horizontal resistant force. This coefficient of horizontal resistant force is the function of the ductility factor, the natural period, the period of a response spectrum peak and its acceleration. As a result, the response analysis shows that the proposed equations give the safe side of the horizontal resistant force.

MASS TIMBER BRACED FRAMES WITH MASS TIMBER BUCKLING RESTRAINED BRACES

Emily Wiliamson[1], Chris P. Pantelides[2], Hans-Erik Blomgren[3], Douglas Rammer[4]

ABSTRACT: A mass timber lateral force resisting system (LFRS) is proposed using a timber buckling restrained brace (TBRB) for improved seismic performance in high seismic applications. To develop a high-performance braced frame, it is essential to quantify the behaviour of the connections including failure modes and moment-rotation capacities. Cyclic and monotonic tests were conducted on six mass timber beam-column connections to investigate the response of mass timber joints connected with slotted-in steel plates and mild steel dowels. The goal of the subassembly tests was to measure the maximum rotation of such connections for monotonic and cyclic loads; these results were used to optimize the number of mild steel dowels for the TBRB frame design. The tests showed that the connections with three different steel dowel details reached a maximum rotation of 0.11 rad. with no loss of strength. Scaled tests of a full braced timber frame with a TBRB were carried out to verify the LFRS which included the effect of column axial load and out-of-plane displacements.

KEYWORDS: Braced frame, Buckling restrained brace, Lateral Force resisting system, Mass timber, Seismic

1 INTRODUCTION

Mass timber buildings are popular due to their sustainable characteristics, architectural appeal, and high strength-to-weight ratio. Engineered timber products such as glulam, cross laminated timber (CLT) and mass ply panels (MPP) allow engineers to take advantage of these characteristics. Currently, tall timber buildings must be combined with a lateral force resisting system (LFRS) made of steel or reinforced concrete because current building codes lack defined values for a ductile timber LFRS; this can lead to compatibility issues and increase construction cost and time.

A ductile timber (LFRS) is needed for the expanded use of mass timber in new taller buildings. There has been some work to develop and improve the performance of CLT shear walls [1-6], but shear wall systems can limit the flexibility of the building floor plan. Current timber frames have limited hysteretic energy dissipation and ductility capabilities because they rely on the connections for the response to loading [7-8]. To address this issue, researchers have developed a buckling restrained brace with a timber casing (TBRB) [9]; tests showed that a TBRB exceeds the qualification requirements of a conventional BRB [10]. Researchers have also completed a series of TBRB tests to propose new design methods and avoid certain failure modes such as bulging of the timber restraining element [11]. Furthermore, researchers have successfully tested a full-scale glulam frame with two conventional steel and concrete BRBs in a chevron configuration [12].

The overall performance of a complete TBRB frame (TBRBF) also depends on the beam-column and gusset plate connection performance. Researchers have been interested in the performance of moment resisting timber connections for some time [13-16]; however, dowel-type connections often experience premature failure due to tension splitting of the timber under induced beam-column joint rotations. Additional reinforcement perpendicular to the grain is often required to improve connection performance. Joint reinforcement with screws placed perpendicular to grain using glulam connections achieved a maximum rotation of 0.08 radians [17]. Dowels arranged in a circular pattern using plywood as reinforcing for the joints achieved a maximum rotation of 0.03 radians [18].

In this study, six beam-column joints were designed and tested under monotonic and cyclic loads with varying number of dowels. Mass ply lam (MPL) [19] was used for the beams and columns to provide resistance against perpendicular-to-grain tension splitting in the connection regions due to the additional strength and stiffness provided by the cross-ply veneers included the layup of the material. Informed by the results of the beam-column connection tests, an MPL frame with a TBRB was designed and tested. The frame was tested with multiple levels of axial force applied to the columns and with some out-of-plane displacement imposed on the frame. In addition to the TBRBF subassembly tests, the frame was tested on its own to monitor the condition of the connections and provide an improved understanding on the TBRB contribution to the performance of the subassembly.

2 MASS TIMBER CONNECTION TESTS

The initial phase of the research discussed in this paper includes the design and testing of six beam-column connections [20]. These tests were carried out to provide a clearer understanding of the connection performance including failure modes, moment-rotation relationships and rotation capacity.

2.1 CONNECTION EXPERIMENT DESIGN

The connections designed for the experimental program were meant to represent a beam-column-brace connection within a TBRBF with a beam span of 4.27 m and a story height of 2.90 m (Figure 1). The length of the members was based on cutting the joint out at the mid-span of the beam and at half a story height above and below the joint. The beam and column were 381 mm square MPL, a material made of layers of laminated veneer lumber with different cross grain directions of the veneer layers [19]. MPL in the joist orientation (Figure 2a) was chosen to take advantage of the cross-ply layers in the layup which act as self-reinforcing and attempt to avoid the additional joint reinforcing that is typically required to improve the strength and rotation capabilities of timber connections. The members were connected with 248 MPa, 12.7 mm slotted-in steel plates and 12.7 mm diameter smooth-shank mild-steel dowels (Figure 2). In a beam-column-brace connection, the steel connection plates will extend beyond the timber members to form gusset plates for the TBRB connection, but these were not included in the connection tests. The impact of the gusset plates and brace connection on the performance of the connection was studied in more detail during the MTRBF tests described in Section 3.

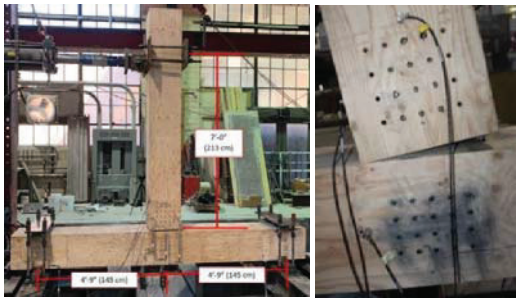

Figure 1: *Beam-column joint setup and maximum rotation for joint with 12 beam dowels*

The connections were designed to resist the overstrength forces from a 267 kN tensile yield strength TBRB using the National Design Specification (NDS) for Wood Construction and the NDS Technical Report 12 for dowel-type connectors [21,22]. The joint was idealized as an equivalent series of three-member connections [23] and the theoretical moment capacity was calculated using the model in [18]. The geometry of the dowel connection was selected to allow yield mode IV to be the limiting yield mode of the design because it is a more ductile yield mode as it is limited by the bending of the steel dowels rather than the crushing of the timber. A 25 mm gap between the end of the beam and the face of the column was built into the connection to allow for large beam rotations without contact with the column.

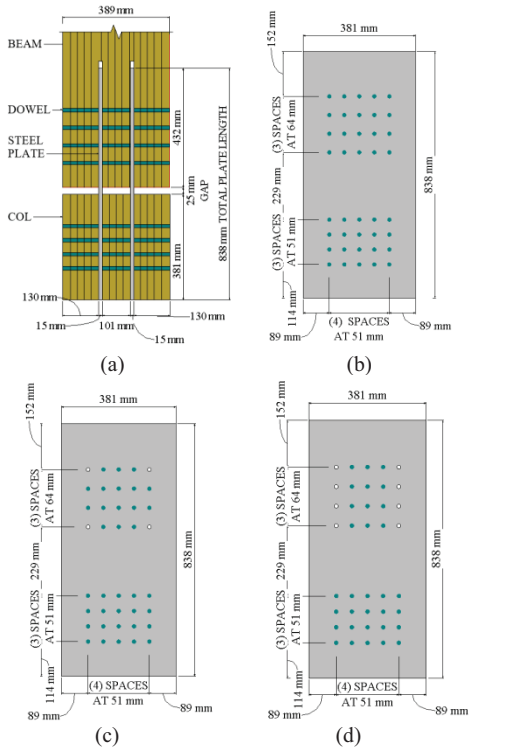

Figure 2: *Connection:(a) section, (b) 20 dowels, (c) 16 dowels, (d) 12 dowels*

Three pairs of connections were tested, each with a different number of dowels in the beam; the first pair had 20 dowels, the second pair 16, and the third pair 12. All connections had 20 column dowels. For each variation, one connection was tested under monotonic loading and one under cyclic loading. The cyclic loading protocol was adopted from ASTM E2126 test method B [24]; the loading protocol was defined with the maximum horizontal displacement imposed on the beam end as 254 mm, which was equivalent to the maximum stroke of the actuator used to apply the load (Figure 3). To facilitate testing, the joint was rotated 90 degrees counter-clockwise so that the 2.13 m beam was vertical; a horizontal load was applied at the beam end (Figure 1).

https://doi.org/10.52202/069179-0265

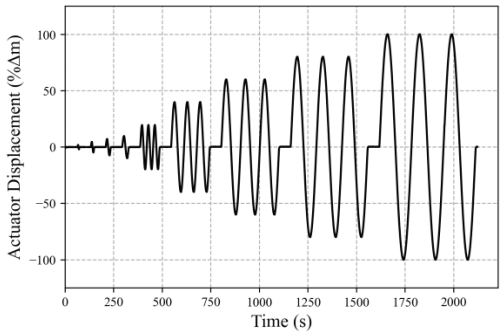

***Figure 3**: ASTM E2126 test method B loading protocol*

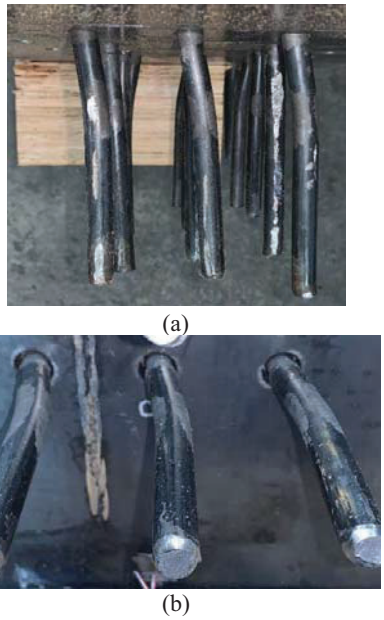
2.2 CONNECTION EXPERIMENTAL RESULTS

All six joints reached a maximum rotation of 0.11 radians without any loss of strength or any visible external damage such as timber splitting in the joint region; the only joint that experienced contact between the beam and column was the joint with 12 dowels in the beam under monotonic loading (Figure 2). The tests were stopped at 0.11 radians of rotation because this was the maximum displacement allowed by the length of the actuator. After testing was complete, the joints were dissected to observe the internal damage to the connection. Although most of the deformation observed was small, the most deformation was observed in the joint with 12 dowels in the beam (Figure 4a). In all tests, the dowels yielded in mode IV as expected based on the design; necking of dowels at the steel plate interface and elongation of the holes in the direction of the force in the respective dowel were observed (Figure 4b). Furthermore, most of the damage was observed in the dowels in the perimeter of the connection.



(a)

(b)

***Figure 4:** Post-test connection dissection (a)bending of the dowels and (b) deformation of the holes in the steel plate*

The moment capacity of the beam-column connections appeared to be proportional to the number of dowels in the beam (Figure 5). The envelope response of these connections can be broken down into three main stages (Figure 5a): the slip stage, the elastic stage, and post-yield stage. The second increase in load exhibited in the 12 beam dowel connection's monotonic response was caused by the contact between the beam and column, which occurred at approximately 0.09 radians. The slip stage occurs in the beginning of the loading because some displacement must be imposed on the connection before it is fully engaged. This is largely due to construction tolerances of the holes, which need to be slightly oversized in order to fit the dowel through the three timber and two steel elements. Once the dowel has overcome the gap and fully engaged with the timber, the connection is able to develop more stiffness and it enters the elastic stage. During this stage, the connection continues to develop strength until the steel dowels begin to yield. After the dowels yield and begin to deform, the connection is not able to resist additional load; however, the connection continues to rotate, resulting in a ductile connection response. The Y and K method [25] was used to estimate the yield point of the connection. The displacement ductility of these connections was then determined to range from 1.8 to 4.1 based on the maximum rotation achieve during testing; however, this is a lower bound because the tests were forced to terminate before a loss in strength occurred due to the limited stroke length of the actuator.

The hysteresis of the cyclic tests (Figure 5b) displays some pinching effects. This is common for timber doweled connections because there is some slack in the connection when the load is reversed and the dowel has some distance to recover before it is fully engaged with the timber again since it may have already crushed it in that region during a previous cycle.

3 TBRBF SUBASSEMBLY TESTS

After evaluating the response of the connections during the connection tests, a TBRBF was designed and constructed for performing cyclic, quasi-static subassembly tests (Figure 6).

3.1 TBRBRF SUBASSEMBY EXPERIMENT DESIGN

The frame was designed as an approximately two-thirds scale, single-bay frame with a column spacing of 3.05 m and a story height of 2.29 m. To properly simulate the performance of a frame in an upper story of a building, the columns were extended beyond the bottom beam to the strong floor. Furthermore, the base of the west column was designed to be a roller to drag the horizontal component of the brace force through the bottom beam to the base of the east column, which was fixed by extending the connection plates 25 mm lower than the base of the column and welding it to the steel support structure. The beams and columns are of the same MPL material and same cross-section as the joint tests described in Section 2. The connections in the frame also have two 12.7 mm thick slotted-in steel plates and are connected by 12.7 mm diameter mild steel dowels. All connections were designed using the same approach as described in Section 2.1 of this paper for the expected forces of a TBRB with a tensile yield force of 178 kN. The expected forces were determined with a compression adjustment factor of 1.25 and a strain hardening factor of 1.45, which were the maximum of each value determined in [9]. The gusset plates are formed by extending the connection plates beyond the timber members; they were reinforced with steel stiffeners and steel cheek plates to ensure the TBRB would be the limiting structural element in the frame. The 25 mm gap between the beam end and column face was also implemented for the connections in the frame.

The restraining element of the TBRB is mass plywood panel (MPP) blocks bolted together on either side of the mild steel yielding core. The MPP blocks were 254 mm wide by 152 mm deep; they were placed so that the laminas were perpendicular to the steel yielding core. To achieve a 178 kN TBRB, the yielding portion of the core was specified to be 13 mm thick by 51 mm wide and have a yield stress of 276 MPa. At the ends of the brace, the core width increases to 178 mm for the pin connection to the two gusset plates. In addition, there are stiffeners welded to the ends of the core to ensure that yielding occurs within the intended yielding zone. Finally, there was a 25 mm diameter dowel welded to the steel core at the midpoint of the yielding zone to promote even load distribution and help keep the core in place within the casing. The TBRBs used in this experimental program had a pin to pin length of 2730 mm and a yielding length of 1554 mm.

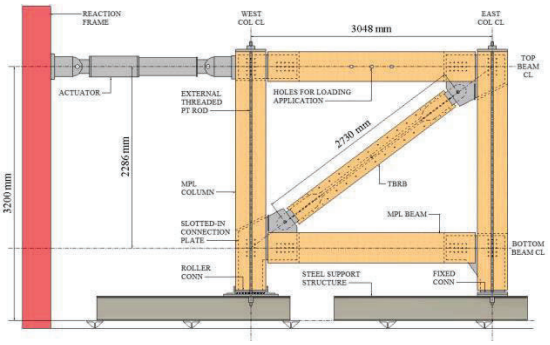

Figure 6: *Experiment of TBRBF*

The same timber frame was used for nine total tests: four TBRBF tests and five bare frame tests. The bare frame tests were done at the beginning of the testing series, at the end of the testing series, and between each TBRBF test. Moreover, the bare frame tests were completed within the elastic range of the frame to provide an understanding of the frame contribution to the subassembly performance and to monitor the condition of the connections after a TBRBF test. Two levels of axial force were applied to the columns during testing: the low-level axial load was equivalent to 5% of the column capacity and the high axial load was equivalent to 12% of the column capacity. The axial force was applied to the columns with two all-thread bars, which were external to the columns and post-tensioned to achieve the desired load level. Each level of axial load was tested once in-plane and once with a 25 mm out-of-plane displacement imposed on the top east connection. A summary of the tests is listed in Table 1.

https://doi.org/10.52202/069179-0265

Similar to the connection tests, the loading protocol adopted for these tests was based on ASTM E2126 test method B [24] (Figure 3). The cycles were defined based on a maximum displacement associated with a drift ratio of approximately 3%. To ensure the connections remained elastic during the bare frame tests, the loading protocol was terminated after the $0.6\Delta_m$ loading step.

Table 1: *Timber Frame Experimental Program*

Test Name	Out-of-plane displacement	Axial Load Level
Bare Frame	None	Low
I-TBRB1	None	Low
I-TBRB2	None	High
O-TBRB3	25 mm	Low
O-TBRB4	25 mm	High

3.2 TBRBF SUBASSEMBLY RESULTS

Frame tests without a TBRB were completed as intermediate steps during the experimental program to monitor the condition of the connections and provide insight into how the TBRBF performance compares to the bare frame performance. The hysteresis in Figure 7 is representative of all the bare frame tests that were conducted throughout the testing series since the connections experienced minimal damage during both the bare frame tests and the TBRBF tests. Because they were carried out as intermediate steps, the tests were concluded earlier in the loading protocol to ensure the connection remained mostly elastic; the slender hysteresis loops and no significant excessive drift at zero force confirm this assumption.

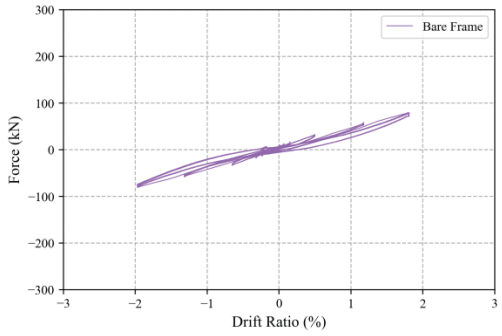

Figure 7: *Bare frame hysteresis*

The hysteresis curves for the TBRBF tests are shown in Figure 8; Figure 8a shows the response of the frames with low axial force applied to the columns and Figure 8b shows the response of the frames with high axial load. Both the level of axial load and the intentional out-of-plane displacement had little impact on the performance of the subassembly. There is a slight decrease in stiffness between the first TBRBF test, I-TBRB1, and the subsequent tests due to the slight crushing of the timber in the dowel regions caused by the first test. Some slip can be observed when the load was reversed; this is due to the movement of the dowels within their respective holes before the dowels are fully engaged. The TBRBF tests were able to achieve similar forces in tension and compression as expected from a BRB system. Furthermore, at the same drift ratio, the TBRBF resisted 3.0 to 3.8 times the amount of lateral load than the bare frame.

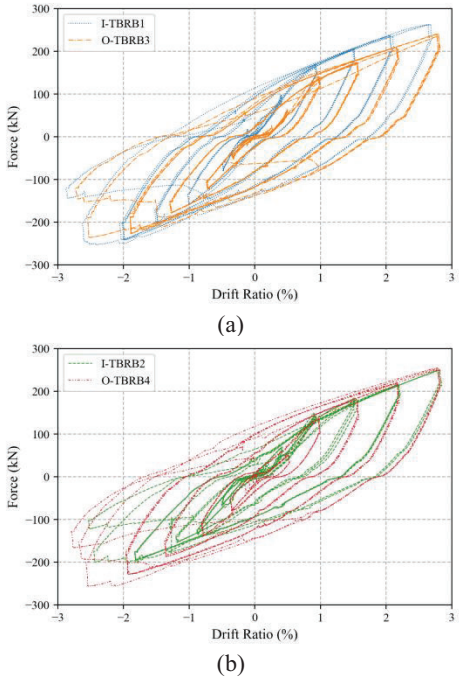

Figure 8: *TBRBF Hysteresis curves (a) low axial load and (b) high axial load*

All four of the hysteresis curves are relatively stable with minimal pinching. This indicates effective hysteretic energy dissipation (Figure 9) from the diagonal TBRB core plate. Test O-TBRB4 shows the most energy dissipation because it was allowed to complete the entire loading protocol despite TBRB failure. This shows that the system is able to continue to dissipate energy even after TBRB failure. Test I-TBRB2 dissipated the least amount of energy of the TBRBF tests because a weld in the support structure fractured during the test which caused the east column to behave as a rocking column and limited the amount of force the system was able to resist when the actuator was pulling the frame to the west (negative drift ratio). Figure 9 demonstrates the impact of the TBRB on the subassembly's ability to dissipate energy effectively. When comparing the energy dissipated by the TBRBF to the energy dissipated by the bare frame after the same number of cycles, the TBRBF dissipates 4.0 to 8.6 times the hysteretic energy dissipated by the bare frame.

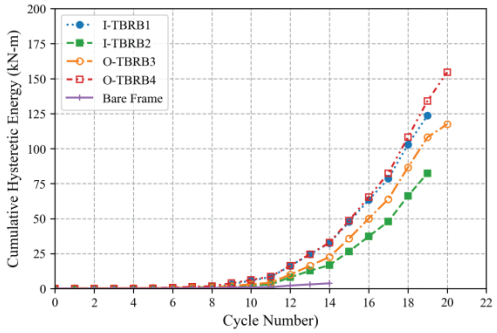

Figure 9: *Cumulative hysteretic energy*

The secant stiffness was calculated for each cycle to show the stiffness degradation of the system throughout the loading protocol. It was calculated based on the peak forces and displacements achieved for each cycle. Figure 10 shows a comparison between the stiffness of test I-TBRB1 and the first bare frame test. Since the connections provide limited moment-resisting capabilities, the stiffness of the bare frame is smaller than the stiffness of the TBRBF.

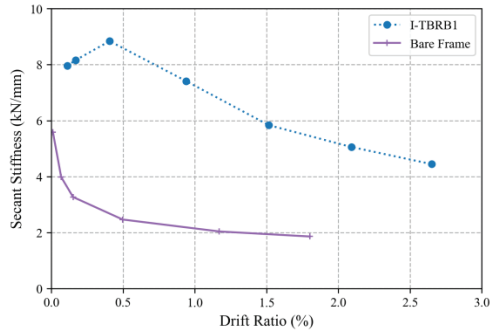

Figure 10: *Stiffness comparison between TBRBF and bare frame*

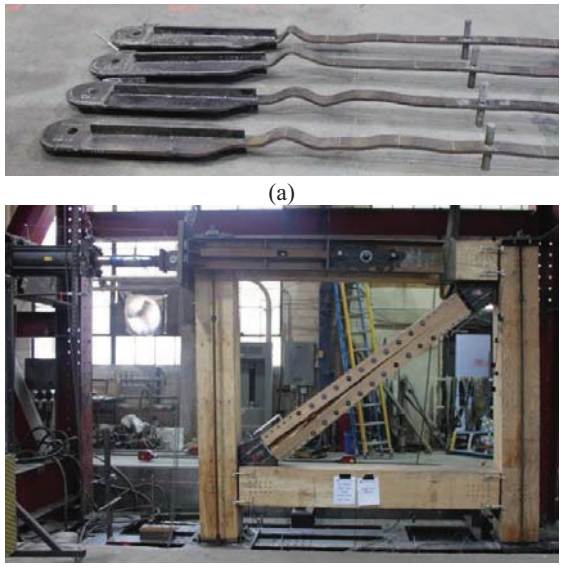
In addition to the hysteretic energy and the stiffness degradation, the ductility of the TBRBF system was evaluated using the Y and K method [25] because it is able to effectively estimate the yield point of a timber structure even when the connections have a lower initial stiffness consistent with what is observed with the dowel-type connections [26]. The maximum displacement ductility for the TBRBF tests determined by the Y and K method ranged from 3.1 to 3.5. To properly compare to existing research, the yield point and ductility was also estimated using the EEEP method [24]; the maximum displacement ductility determined by this method ranged from 2.1 to 2.9. This is double the ductility found for conventional timber brace frames [27], and comparable to the findings of research in which timber frames were tested with conventional steel-concrete BRBs [12].

All TBRBF tests experienced failure of the TBRB during the compression segment of the second cycle of the 100%Δ_m loading step. The failure was initiated by weak axis buckling of the steel core near the end of the yielding zone (Figure 11a). As the amplitude of the buckled core increased with higher displacement cycles, the casing began to split between the layers at the location of the largest wave; the splitting eventually propagated along the length of the casing (Figure 11b)



(a)

(b)

Figure 11: *TBRB failure modes (a) weak axis buckling of the steel cores and (b) splitting of the MPP casing*

The connections of the timber frame experienced no visible external damage such as tension splitting or timber crushing. After the testing series was complete, the connections were dissected to investigate if there was any internal damage; there was very slight bending of the dowels, which indicates that the connections may have remained mostly elastic during the TBRBF tests as well as the bare frame tests. Throughout testing, the rotation of the connections was monitored by linear variable displacement transducers (LVDTs); they recorded a maximum rotation of 0.036 radians during the testing series.

4 CONCLUSIONS

Six beam-column joint specimens were tested which achieved a rotation of 0.11 rad. This large rotation shows that the connections behave in a ductile manner, a good characteristic of an element in a LFRS. The MPL material did not experience any perpendicular to grain splitting; this eliminates the need for costly joint reinforcement and confirms the hypothesis that the cross-grain layers would behave as self-reinforcing by providing additional stiffness in the perpendicular-to-grain direction. Additionally, the 25 mm gap helped avoid crushing of the timber by preventing contact between the beam end and column face. The bending moment that the joint was able to resist was proportional to the number of dowels in the beam. The results of these tests showed that the existing

https://doi.org/10.52202/069179-0265

methods for connection design are applicable for this type of connection and result in a ductile response.

After the connection tests, a series of timber frame tests were completed including four tests with a TBRB and five tests with the bare frame. All four TBRBFs achieved similar forces and drifts in both tension and compression; the TBRBs consistently failed during the compression portion of the 100%Δ_m step of the loading protocol. The failure mode was weak axis buckling of the steel core near the end of the yielding zone. The increasing amplitude of the waves eventually caused the MPP casing to split along its length. The TBRB improved the performance of the subassembly by improving the hysteretic energy capabilities by 4.0 to 8.6 times and increasing the lateral load capacity by a factor of 3.0 to 3.8. The ductility of the TBRBF was evaluated using two methods and was found to be comparable with other timber frames using conventional BRBs and double the ductility of conventional timber braced frames.

The same frame was used for all nine tests with no visible damage to the connections. This demonstrates the resilience of this TBRBF system where the TBRB can be removed and replaced following a seismic event, without the need to replace the bare timber frame. Further testing including full-scale dynamic tests is suggested to confirm the findings of this study.

EFFECT OF SMALL DEFORMATION DUE TO MODERATE EARTHQUAKES ON THE SHEAR PERFORMANCE OF SHEAR RESISTING WALL

Ryo Inoue[1] , Takuro Mori[1], Shinya Matsumoto[2]

ABSTRACT: In order to confirm how cyclic deformation due to moderate earthquakes during the use period of a wooden house affects the shear resisting wall, in-plane shear experiments with cyclic deformation on the walls using plywood and gypsum board were conducted. As a result, it was found that the maximum load and the yield load are not significantly affected even if the wall received repeatedly small deformation. The load reduction due to repeated deformation of gypsum board wall was larger than plywood wall. Additionally, the stiffness of repeated specimens was reduced accordingly. The calculated load reduction trend of sheathed walls subjected to repeated small deformations from the experimental results of nailed joints was found to be generally expressible. It was found that the response deformation of wooden houses during the major earthquake may increase as the stiffness of shear resisting walls decreases.

KEYWORDS: Cyclic deformation, Plywood wall, Gypsum board wall, Moderate earthquake, Shear performance

1 INTRODUCTION

Increasing the continuous use of wooden houses after the major earthquake is important not only for maintaining the assets, but also for early city reconstruction. For the purpose, it is necessary to build high seismic performance house and/or to appropriately evaluate the residual seismic performance at the time of seismic diagnosis after moderate earthquakes.

Cyclic deformations due to small and medium-class earthquakes may reduce seismic performance in existing houses. Especially in large deformations, it is known that the deterioration of shear performance due to multiple cyclic deformations. It has been reported that when the amount of repeated deformation is large, such as during a large earthquake, the deterioration of the shear performance is large [1]. In addition, some examples have shown the effect of cyclic loading on the structural performance of shear resisting walls [2].

However, these existing reports are mainly aimed at improving the accuracy of response prediction during large earthquakes and the prediction of seismic behaviour of wooden houses. They are targeted at large deformation for large earthquakes. Therefore, there are very few examples of studies of large numbers of small deformation repetitions, and the effects of such repetitions have not been clarified. In Japan, small and medium earthquakes often occur. For example, in Ibaraki Prefecture, for the past 30 years, there have been about 300 earthquakes of intensity 3 [3]. It is important to understand to what extent the accumulation of small deformation caused by such earthquakes affects the seismic performance of wooden houses and their response deformation during large earthquakes.

Therefore, in the previous report [4], single shear tests in which nailed joints using plywood, OSB, MDF, and gypsum board were repeatedly displaced many times assuming small and medium earthquakes were conducted. As a result, it was clarified that plywood, OSB, and MDF showed almost the same load reduction tendency. And gypsum board had a particularly large load reduction compared to other boards.

In this report, in-plane shear experiments on the walls were conducted to confirm the effect of repeated small deformation on the shear performance of plywood walls and gypsum board walls.

2 OUTLINE OF EXPERIMENT

Table 1 shows a list of specimens, and Figure 1 shows the configurations of specimens. The specimen was 1P (b=910, h=2730 mm) wall. Two kinds of panels, plywood (t=9mm) and gypsum board (t=12.5mm) were used. A 105 x 180 mm hybrid beam (E105-F300, Japan Agricultural Standards) was used for the beam. A 105 x 105 mm Sugi glulam lumber (E65-F225, JAS) was used for the columns and base. The base-column and base-beam were joined by two N90 nails and VP plate with a short tenon. Plywood and gypsum board were fastened with N50 nails @ 150mm. There are two types of loading schedules; SC (Standard cyclic schedule) and NC (Numerous cyclic schedule). The SC was set to pull up to 1/15 rad after repeatedly deforming of ± 1/450, ± 1/300, ± 1/200, ± 1/150, ± 1/100, ± 1/75, ± 1/50 and 1/30 rad. For NC specimens, after the loading schedule shown in Table 2, additional loading was performed according to the same schedule as the SC specimen. The target deformation of multiple repetition was set assuming the maximum inter-story deformation of a wooden house during an earthquake with a seismic intensity of 3 to lower 5. The number of repetitions in each step was set by examining the number of observations at each prefectural office location for each seismic intensity from the Seismic Intensity Database [3] and using the maximum number. The loading was performed by displacement control, and the load was applied using a 300 kN jack. Figure 2 shows the test set up and transducer position. Experiments were conducted using a tie-rod system that restrained the column legs from lifting. Loading was displacement-controlled using the true deformation angle (Equation 1). It is obtained by subtracting the slip of the base and vertical displacement of the columns from the top deformation of wall. In equation 1, 2730 mm is the specimen height and 910 mm is the specimen width.

$$\gamma_0 = (\delta_1 - \delta_2)/2730 - (\delta_3 - \delta_4)/910 \quad (1)$$

3 RESULT OF EXPERIMENT

Figure 3 shows the load-displacement envelope as the mean of each specimen group. Table 3 shows the strength characteristic values calculated by the perfect elasto-plasticity model [5]. The stiffness calculated using the slope between 0.1 P_{max} and 0.4P_{max}. The ductility factor μ is the ratio of δ_u to δ_y. The short-term allowable shear capacity P_a is the minimum value among P_y, 2/3P_{max}, 0.2$P_u\sqrt{(2\mu-1)}$, and P_{150} (load at 1/150 rad). The wall multiplier is the short-term allowable shear capacity divided by 1.96 kN and the width of the wall (0.91 m in this case), and is an index used in wall amount calculations (a common design method for wooden houses in Japan).

In both cases of plywood and gypsum board, repeated small deformations had no clear effect on the envelope curve of load-deformation relationships and ductility. In addition, comparing the mean values, it was found that there was no significant difference in maximum, yield and ultimate load between the SC and NC specimens regardless of whether the panel was plywood or gypsum board. There was also no difference in wall multiplier, indicating that even when subjected to repeated small deformations, the design performance can be expected to be similar to the shear performance of the sound condition. Furthermore, there was no difference in failure properties (Photo 1) between SC and NC specimen.

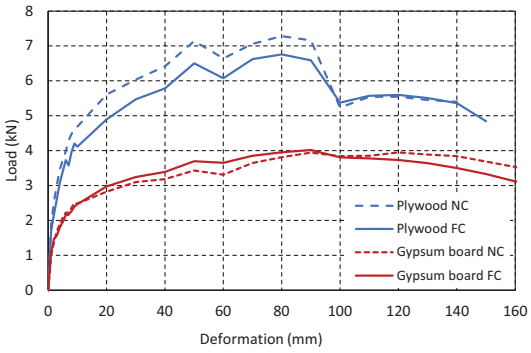

Figure 3: *Load-displacement envelope curve*

Photo 1: *Failure of specimen*
(Right: Gypsum board wall, Left: Plywood wall)

Figure 4 shows the transition of the load residual rate at the target displacement of 1/2000, 1/1000, 1/450, 1/300 and 1/200 rad. Here, the first load for each step is shown as 100%. Similar to the experiment of nailed joint [4], it

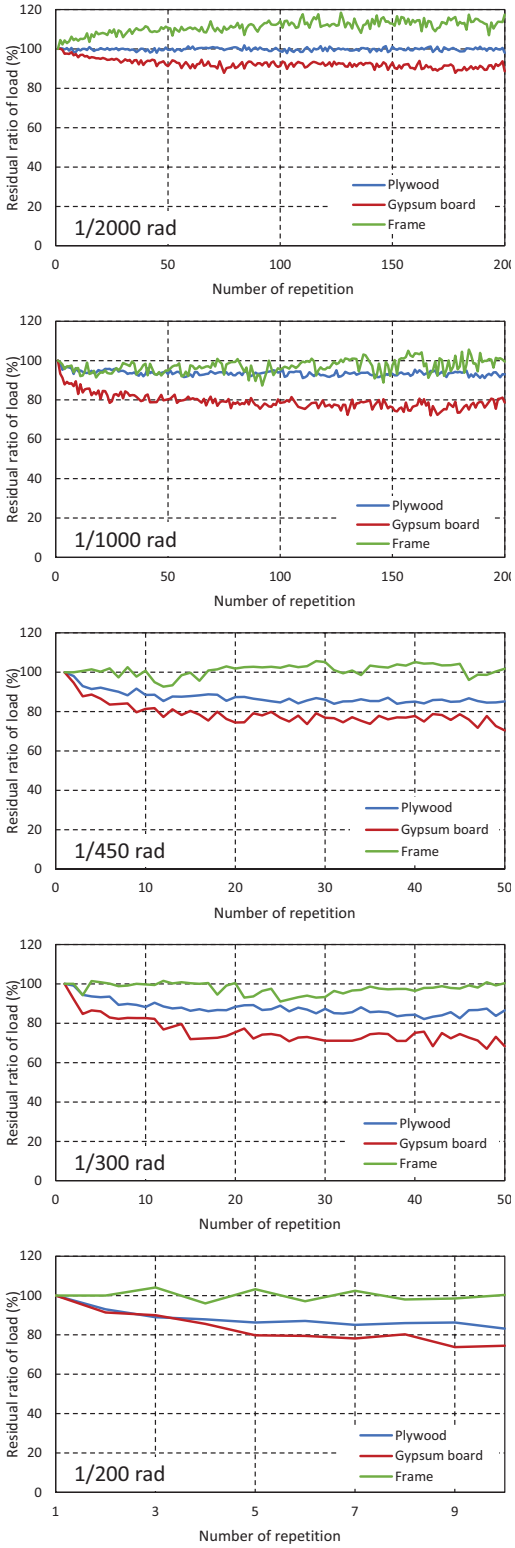

Figure 4: *Transition of the load residual rate*

https://doi.org/10.52202/069179-0266

was found that the load reduction of the gypsum board wall was larger than the plywood wall. In the nailed joint experiment, for example, the load residual ratio at the end of the repetition assuming 1/1000 rad was about 80% for plywood and about 70% for gypsum board. However, in the wall experiment, the load was maintained about 90% on the plywood wall even at the same deformation angle, and the load was maintained about 80% even on the gypsum board. In other words, the load reduction tendency was gradual. It is considered that this is because the target deformation in the nailed joint experiment was set assuming the nail with the largest amount of deformation in the wall, and the amount of deformation of the nail was smaller than expected. No significant tendency for the load to decrease was observed in the range of the number of repetitions of this experiment in the frame only specimen at any deformation angle.

Figure 5 shows the transition of equivalent stiffness and equivalent damping factor obtained by the equivalent linearization method. As with the load reduction, both equivalent stiffness and equivalent damping factor decreased after 5 to 10 repetitions at the beginning of each step, confirming that even small deformations have an effect. However, in subsequent repetitions, a convergence trend was observed, with a gradual decrease or levelling off, and no sudden decrease was observed.

4 PREDICTION AND DISCUSSIONS

The experimental results of the nailed joints [4] are used to examine whether the load residual ratio obtained in the wall experiments can be explained. For the plywood-sugi-N50 nailed joints, the relationship between load residual ratio and number of repetitions at each deformation (step) obtained in the previous report is expressed in both logarithms as shown in Figure 6. The load residual ratio-number of repetition relationship was considered as a proportional relationship, and the slope was calculated for each deformation by linear regression. The intercept of the approximate line was set to 2, since the residual load percentage for the new deformation was 100%. The slopes obtained for each deformation were plotted side by side for each deformation as shown in Figure 7. The larger the deformation, the larger the slope of the approximate straight line, indicating a larger load degradation. Here, it was determined that there is a roughly proportional relationship between the amount of repeated deformation and the slope of the approximate line. Since no load degradation occurs when the deformation is 0, the slope was obtained by linear regression with the intercept set to 0. Using the obtained slope, the equation for residual load at any deformation and any number of repetitions was derived as in Equation 2. The same procedure was performed for gypsum board wall, and the equation for residual load was obtained from Figure 7.

$$\text{Load residual ratio (\%)} = 10^2 \cdot N^a \qquad (2)$$

where a=deceleration index

Plywood: a = -0.047x, gypsum board: a = -0.077x

x: deformation (mm),

N: number of iterations (times)

Several models have been proposed to calculate the load-deformation relationship of sheathed walls using experimental results of nailed joints; Tuomi [6] et al. proposed a relatively simple method to estimate the

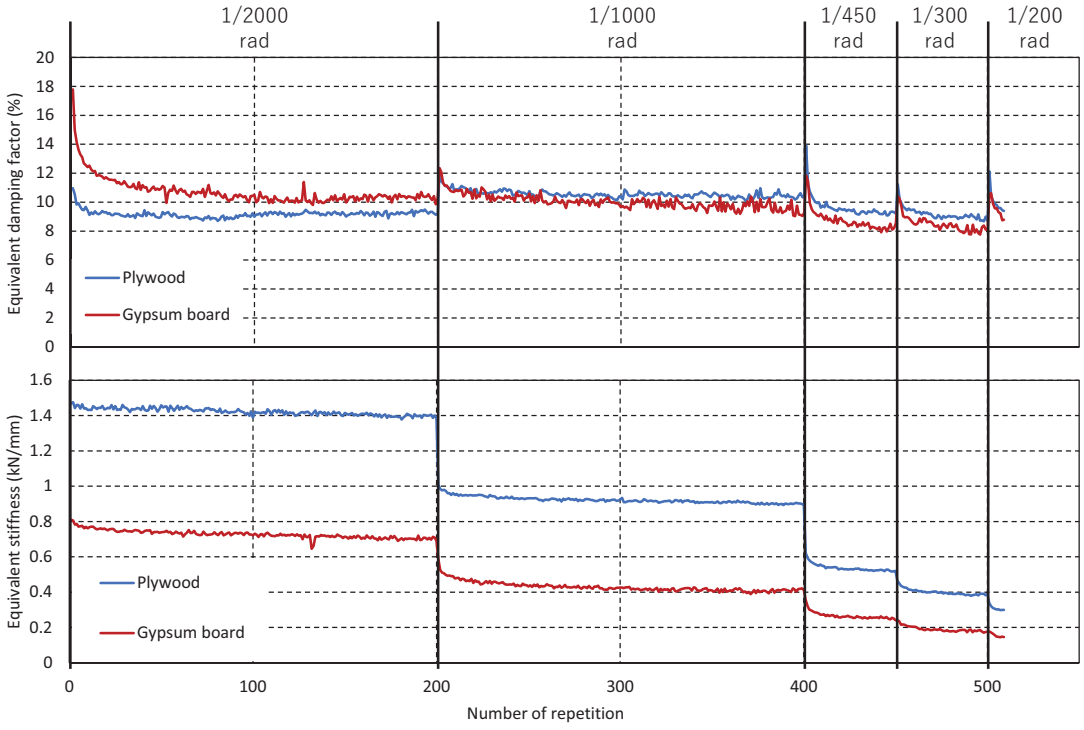

Figure 5: *Transition of equivalent stiffness and damping factor*

https://doi.org/10.52202/069179-0266

deformation behavior based on the assumption that nails driven into the four corners are displaced in the diagonal direction. Kamiya [7] and Murakami [8] proposed a model that determines the direction of rotation of a face material based on the equilibrium of forces.
Furthermore, Toda et al [9] have modified the equation to adapt to the case where part of the nailed joint has deteriorated due to biodeterioration, and where nails with different load-displacement relationships are mixed within the wall. The calculation method is cited from reference [9] as Equation 3 – 14. Since the equations used in the calculations were proposed with the intention of being used in design, the calculated results of load are slightly lower than the experimental results. The distance from the origin of the coordinates to the neutral axis is expressed by Equation 3 and 4, where i is the serial number of each nail and the load by each nail is considered.

$$x_0 = \frac{\sum x_i \times p_i}{\sum p_i} \quad (3)$$

$$y_0 = \frac{\sum y_i \times p_i}{\sum p_i} \quad (4)$$

x_0: Distance from the coordinate origin to the neutral axis in the x direction (mm)
x_i: x-coordinate of nail with number i (mm)
p_i: Load by the nail with number i (mm)
y_0: Distance from the coordinate origin to the neutral axis in the y direction (mm)
y_i: y-coordinate of nail with number i (mm)

The moment-rotation angle relationships in the x- and y-directions are given in Equation 5 – 7, respectively. And the relationship between the deformation angle of the wall and the rotation angle in the x- and y-directions is given in Equation 8.

$$M_x = K_x \times \theta_x \quad (5)$$

$$M_y = K_y \times \theta_y \quad (6)$$

$$M_x = M_y \quad (7)$$

$$R = \theta_x \times \theta_y \quad (8)$$

M_x: Moment in x direction (Nmm)
K_x: Rotational stiffness in x direction (Nmm/rad)
θ_x: Rotation angle in x direction (rad)
M_y: Moment in y direction (Nmm)
K_y: Rotational stiffness in y direction (Nmm/rad)
θ_y: Rotation angle in y direction (rad)
R: Deformation angle of the wall (rad)

Considering the secant stiffness of each nail, the rotational stiffness is shown in Equation 9 and 10. The deformation of each nail is expressed in Equation 13 using Equation 11 and 12.

$$K_x = \sum K_i \times (y_i - y_0)^2 \quad (9)$$

$$K_y = \sum K_i \times (x_i - x_0)^2 \quad (10)$$

$$\delta_{ix} = (y_i - y_0) \times \theta_x \quad (11)$$

$$\delta_{iy} = (x_i - x_0) \times \theta_y \quad (12)$$

$$\delta_i = \sqrt{{\delta_{ix}}^2 + {\delta_{iy}}^2} \quad (13)$$

K_i: Secant stiffness of nail with number i (N/mm)
δ_{ix}: x-direction displacement of nail with number i (mm)
δ_{iy}: y-direction displacement of nail with number i (mm)
δ_i: Displacement of nail with number i (mm)

Equation 3 – 12 can be obtained by convergence calculations, and the relationship between any given deformation angle of the wall and the corresponding shear force can be obtained using Equation 14.

$$P \times H = M_x = M_y = \frac{K_x \times K_y}{K_x + K_y} \times R \quad (14)$$

H: Height of the wall (mm)

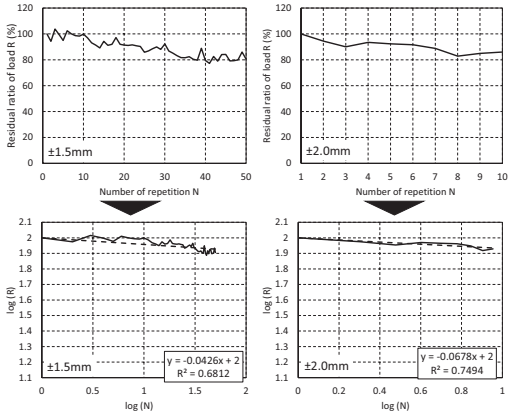

Figure 6: *Relationship between logarithmic load residual ratio and number of repetitions*

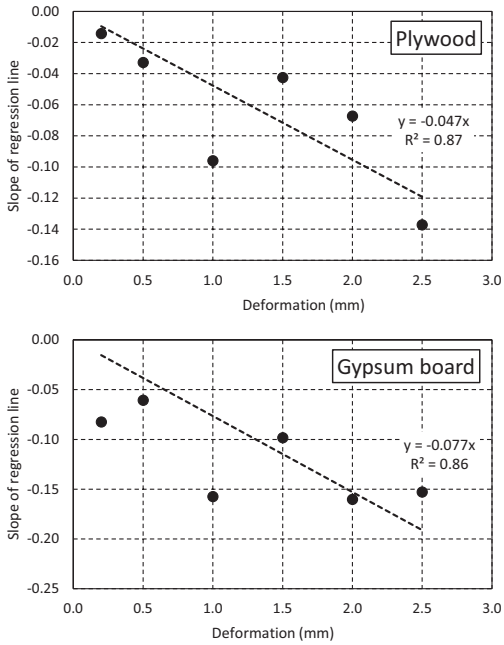

Figure 7: *Relationship between deformation and slope of regression line*

https://doi.org/10.52202/069179-0266

In this study, based on this calculation method, the load residual ratio corresponding to the amount of deformation and repetition for each nail was calculated from Equation 2 and multiplied by the load of each nail to calculate the load on the wall. Then, the load residual ratio of the entire wall was calculated. Comparison of the estimated results with the experimental values is shown in Figure 8. The experimental results are shown up to 1/200 rad, which was the subject of the repeated experiments, and the estimated values are shown up to 1/200 rad with a lower limit of 30% load residual.

For the plywood walls, the load reduction due to the 1/2000 rad repetitions is evaluated somewhat larger, but it can be said that the load reduction trend in the shear experiments of wall can be expressed. For gypsum board, the estimated value at 1/1000 rad repetitions was evaluated to be on the dangerous side compared to the experimental value. The reason for this is unknown. However, for the other deformation repetitions, it can be concluded that the experimental results are well represented. In conclusion, it was confirmed that the load-reducing tendency of shear resisting walls using face materials due to repeated small deformations can be generally estimated by repeated experiments on nailed joints.

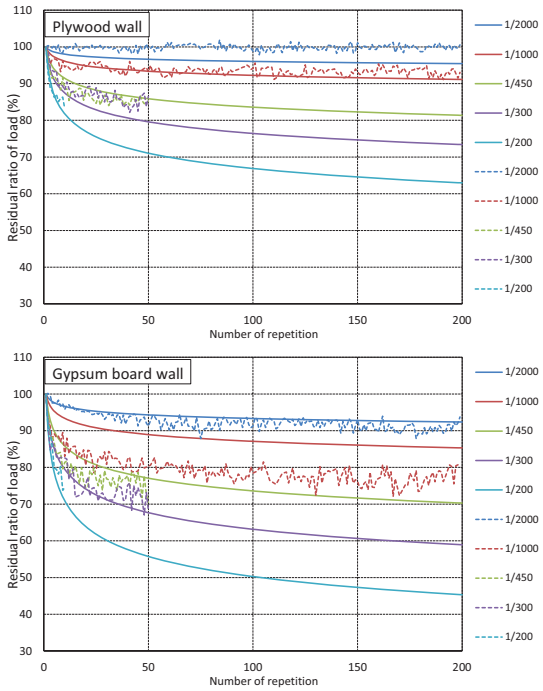

Figure 8: *Comparison between estimated value and test result of load residual ratio*
(*Solid line: test result, dotted line: prediction*)

5 CONCLUSIONS

In-plane shear experiments on the walls were conducted to confirm the effect of repeated small deformation due to moderate earthquakes on the shear performance of plywood walls and gypsum board walls.

As a result, it was found that the load reduction and equivalent stiffness reduction due to repetition of the same deformation were observed even in the case of repeated small deformations for the sheathed wall. Furthermore, the rate of load reduction due to repeated deformation in the gypsum board wall was larger than that in the plywood wall.

On the other hands, it was found that the maximum load and yield load are not significantly affected even if the wall received repeatedly small deformation.

The calculated load reduction trend of sheathed walls subjected to repeated small deformations from the experimental results from nailed joints was found to be generally expressible.

EXPERIMENTAL TESTING OF HIGH-CAPACITY SINGLE AND COUPLED CLT SHEAR WALL SYSTEMS

Ben Moerman[1,2] and Minghao Li[1,3]

ABSTRACT: This paper presents an experimental study on three types of balloon-framed cross-laminated timber (CLT) shear wall configurations: (a) a single wall, (b) a coupled wall with a half-lap joint between wall piers, and (c) a coupled wall with steel link beams between wall piers. Three-storey, 2/3-scale CLT wall specimens were cyclically tested to failure and the results are presented to compare the performance between wall types. All specimens used 5-ply, 205mm-thick CLT wall panels with the same base connections of mixed-angle screw hold-downs and notched shear keys. The beam-coupled wall achieved a peak strength of 592kN and demonstrated the best performance among the wall configurations with the highest strength, stiffness, energy dissipation, and least amount of degradation under repeated load cycles. All the wall specimen exhibited ductile failure modes and demonstrated their feasibility to be designed for lateral load resisting systems in buildings.

KEYWORDS: CLT, Shear Walls, Cyclic Loads, Self-tapping Screws, Coupled Walls, Hold-downs

1 INTRODUCTION

Cross-laminated timber (CLT) buildings are gaining global interest from architects, engineers, and owners. For CLT buildings built in seismic regions, CLT shear walls are critical to providing adequate earthquake resistance. It is well recognised that the lateral performance of typical CLT shear walls is governed by their connections [1], primarily because: (a) CLT panels have inherently high in-plane strength and stiffness and (b) conventional connections used in CLT structures have relatively low strength and stiffness.

Pei et al. [2] presented a review of experimental research on conventional CLT shear walls for seismic resistance which typically follow platform construction methods and use commercially available light gauge metal hold-downs or shear brackets with small diameter nails or screws. Connections with small, slender fasteners can achieve ductile behaviour and dissipate energy by fastener yielding and local timber embedment crushing around the fasteners [3]. They are currently the industry standard for connecting CLT walls as they are readily available and easy to specify. However, these connectors normally have a limited design capacity of less than 100 kN [4] and are often not strong and stiff enough to impose significant in-plane stresses on the CLT wall panels, particularly when relatively thick panels with 5 or 7-ply layups are used. Therefore, conventional connectors are not structurally efficient for applications in multi-storey buildings with CLT shear walls subjected to high seismic or wind demands.

Compared with small diameter nails and screws, larger diameter steel dowels or bolts can be used to create higher capacity hold-downs in CLT shear walls. Large-scale hold-down testing on 5-ply CLT panels with a group of 16-Ø20mm mild steel dowels and 25mm-thick steel knife plates found maximum connection strength exceeded 1000kN [5]. Further experimental research [6] showed the advantages of increased row spacing and end distance to encourage more ductile hold-down responses under cyclic loading.

Self-tapping screws have been widely used in mass timber construction due to their relatively high strength and ease of installation. When installed at 90° to the timber grain, slender screws can provide ductile responses and behave like typical dowel-type fasteners. When installed at an inclined angle to the timber grain, these screws are engaged primarily in withdrawal and can provide high connection strength and stiffness. For mixed angle screw connections, it is possible to achieve a balanced behaviour with high strength, high stiffness, and high ductility. Wright et al. [7,8] tested mixed angle screwed hold-downs and found peak strengths exceeded 600kN.

The previously mentioned experimental programmes on dowelled and screwed hold-downs demonstrate the ability of CLT hold-downs to achieve higher strengths than currently available commercial connectors. Furthermore, shear keys at the base of walls (similar to castellated connections studied by Brown et al. [9]) allow much higher shear capacities when compared to conventional angle brackets with groups of ring shank nails or small diameter screws. The use of these higher capacity

connections in combination with coupled wall configurations allows CLT shear walls to be a more practical solution in mid-rise buildings.

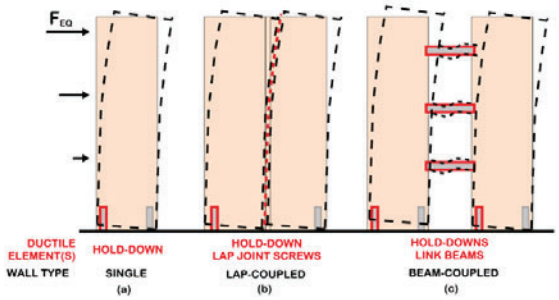

Figure 1: *(a) Single wall, (b) coupled wall with a lap joint, and (c) coupled wall with steel link beams.*

Figure 1 describes three types of multi-storey CLT walls: (a) a single wall, (b) a coupled wall with a screwed vertical half-lap joint (lap-coupled (LC)), and (c) a coupled wall with steel link beams (beam-coupled (BC)). The designated ductile elements where yielding is promoted in each wall type are also highlighted in Figure 1. All other components should be designed to have adequate strength to prevent premature failure in the system that may compromise its integrity during an earthquake. In this study, the hold-downs in each wall type are designed as ductile elements. In the LC and BC wall types, the lap joint screws and link beams, respectively, are additional ductile elements. The BC configuration is a form of hybrid wall system which uses ductile steel elements to enhance the hysteretic energy dissipation of a primarily timber-based structural system, similar in concept to the addition of steel buckling restrained braces in timber frames [10,11].

This study compares the lateral behaviour of the three different wall types with the results of four large-scale cyclic wall tests.

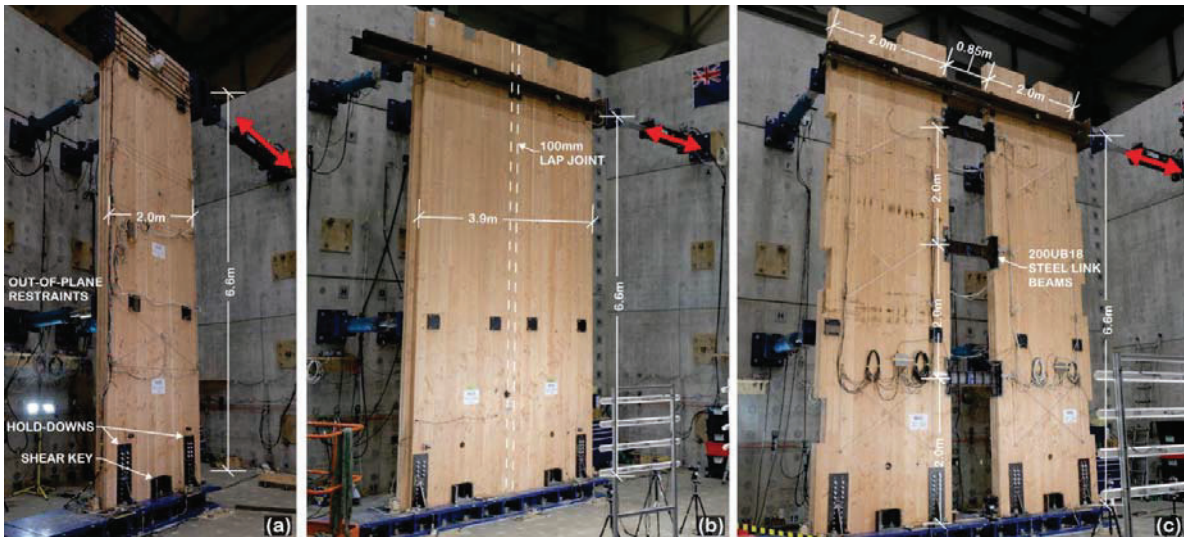

Figure 2: *Test specimen overview and experiment setup: (a) Single wall, (b) Lap-coupled wall, and (c) Beam-coupled wall.*

2 EXPERIMENT DETAILS

The test setup for each CLT wall configuration is shown in Figure 2. The specimens were proportioned and detailed as three-storey walls scaled by a factor of 2/3 and loaded laterally at a height of 6.6m. The CLT panels were created from grade SG8 (per NZS3603 [12]) Douglas-fir boards with a layup of 45/35/45/35/45mm.

Each wall specimen used the same type of mixed-angle screwed hold-downs, based on the previous testing by Wright et al. [7,8]. The ratio between the Ø12x260mm partially threaded inclined screws and the Ø12x180mm partially threaded inclined screws was 1:1.5. One hold-down bracket was installed on each side of the wall specimen. The combination of mixed angle screws creates a hold-down with high stiffness (due to the 45° screws) and reasonably high ductility (due to bending of the 90° screws). The typical hold-down and shear key used in each specimen are shown in Figure 3. The shear keys were installed in a full-depth, 250x350mm notch at the centre of the wall base. The vertical contact faces of the shear key were angled at a slope of 1:25 to prevent binding when the wall base rotated.

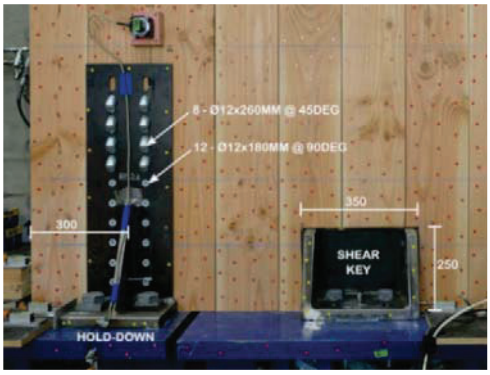

Figure 3: *Mixed-angle screwed hold-downs and shear keys.*

https://doi.org/10.52202/069179-0267

The lap-coupled walls used Ø10x200mm partially threaded screws in the 100mm-wide vertical half-lap joint with spacings of 200mm and 100mm for wall specimens LC1 and LC2, respectively. Therefore, LC2 was designed to achieve a greater degree of coupling.

The beam-coupled wall (Figure 1c) used dissipative, 200UB18 steel link beams with capacity-designed [13] screwed end plate connections to provide coupling action between the CLT panels. Link beams were installed at each level with a vertical spacing of 2m.

Each specimen was subjected to the CUREE cyclic loading protocol [14], shown in Figure 4. The reference wall drifts to define the CUREE protocol were determined based on preliminary pushover analyses and are reported with the results in Table 1.

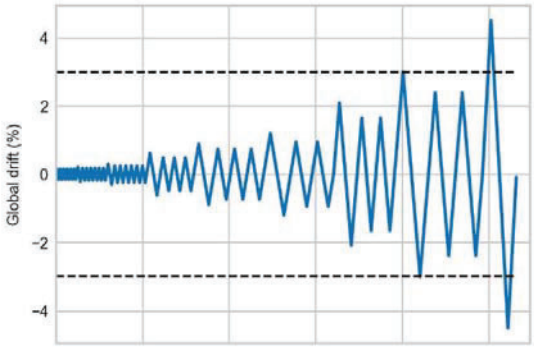

Figure 4: *Example of CUREE loading protocol (D_{ref}=3.0%).*

3 DAMAGE OBSERVATIONS

Each wall specimen primarily experienced damage in its designated ductile elements, which are described in Figure 1. No damage was observed at the shear keys in any test specimen. A moderate degree of toe crushing was experienced by each specimen due to a concentration of compression force but it did not lead to a brittle failure or result in sudden strength loss.

The mixed angle screwed hold-downs in each specimen experienced screw bending and withdrawal, in addition to local embedment crushing around the fasteners, as shown in Figure 5, due to the high uplift force demand. No screws in the hold-downs experienced fracture during the experiments, even though the maximum hold-down uplift displacement exceeded 100mm during the experiments.

The LC walls experienced significant damage to the screws in the vertical lap joint, as shown in Figure 6. Initial damage of screw bending and withdrawal was evident by the screw heads protruding from the timber surface (Figure 6a). Significant local crushing occurred internally around the lap-joint fasteners in the vertical direction (Figure 6b). Following completion of the test, the lap joint screws were uninstalled but many of them fractured due to the applied reverse torque (Figure 6c), indicating significant damage accumulated in the screws. Figure 6d shows the mechanism of a typical screw yielding in the half-lap joint.

Figure 5: *Typical damage observed in mixed-angle screw hold-down connections: (a) screw withdrawal and (b) local wood crushing.*

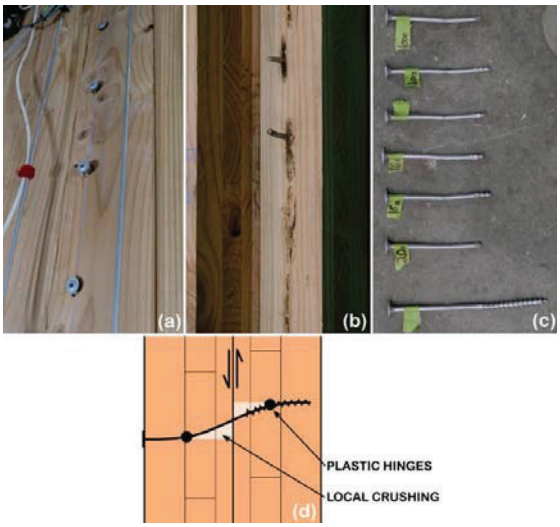

Figure 6: *Observed damage in screwed half-lap joint for LC walls: (a) Screw withdrawal, (b) local crushing inside half-lap. (c) removed screws, and (d) screw yielding mechanism.*

The BC wall experienced severe damage to the steel link beams, as shown in Figure 7. The webs yielded over the full length of the beams. In addition, the flanges adjacent to the end plate stiffeners yielded and eventually buckled inelastically. No damage was observed in the capacity-designed screwed end plate connections; therefore, the capacity design was successful.

Figure 7: *Typical damage to steel link beams in beam-coupled wall specimen.*

4 COMPARISON OF RESULTS

Key experimental results, including wall strength, stiffness, ductility, and energy dissipation are summarized in Table 1. As expected, the single wall had the lowest strength, stiffness, and energy dissipation; however, it may provide the most simple and economic structural form for CLT shear walls. The LC and BC (coupled) walls demonstrated higher strength and stiffness and more energy dissipation. The displacement ductility factors ($\mu=D_u/D_y$), varied between a minimum of 3.5 (LC1) and 7.6 (BC).

The LC walls had the lowest yield drift, which is beneficial because the system's hysteretic damping of the earthquake excitation (i.e., energy dissipation) begins at a lower drift level. As timber lateral systems are often drift-controlled, a low yield drift is advantageous for seismic design [15]. The average peak strength of LC1 normalized by its wall length (F_{max}/L) was 17% less than that of the single wall, despite having the same hold-downs and using twice as much timber volume. This was primarily due to the fastening pattern of its vertical joint in which screws were installed with 90° to the timber surface and with a 200mm spacing. The vertical joint was not sufficiently strong and stiff to promote a significant degree of coupling. LC2 was similar to LC1 except it used a 100mm screw spacing in the vertical joint. In contrast, it obtained 53% greater energy dissipation and peak strengths were 23% and 64% greater than those of LC1 in the positive and negative loading directions, respectively. Furthermore, its stiffnesses were 40% and 26% greater in the positive and negative directions, respectively. Apparently, more fasteners used in the vertical joint provided a more efficient lap-coupled wall type. However, caution must be exercised by the designer because if the half-lap joint is too strong, the energy dissipation of the system may be compromised.

The BC wall exhibited the highest strength, stiffness, drift capacity, and energy dissipation of the three wall types. This configuration involves a greater degree of fabrication and construction complexity. However, given its enhanced structural performance, it is likely that fewer walls would be required in a given building and therefore its application may be more economical than single or lap-coupled walls. Furthermore, it provides a practical wall configuration which can accommodate repetitive window or door openings in the architectural plans.

The force-displacement plots of the four wall specimens are shown in Figure 8. All wall specimens exhibited a ductile failure mode with damage concentrated in the designated regions described previously in Figure 1. The hysteresis loops show typical features of cyclically loaded timber connections: strength and stiffness degradation, and the pinching effect. The pinched behaviour is a result of cumulative local crushing around the yielding screws in the hold-downs and/or half-lap joints. The BC wall test showed the least amount of pinching due to the influence of the ductile link beams which yielded without exhibiting pinched behaviour on a component level.

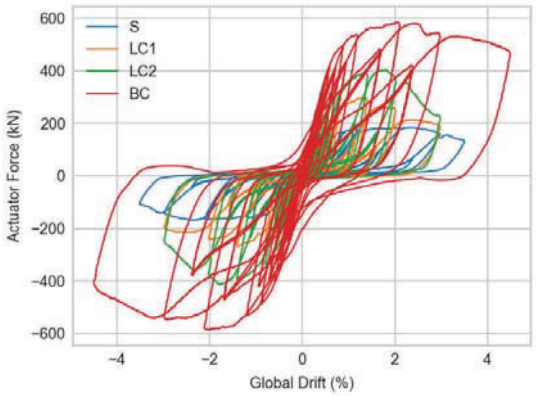

Figure 8: *Comparison of global drift vs. base shear.*

The energy dissipation of the primary and first two trailing cycles (characteristic of the CUREE loading protocol in Figure 4) are shown for each of the four wall tests in Figure 9. The pinched hysteretic behaviour and corresponding loss of energy dissipation is evident when comparing the amount of energy dissipation in the primary and trailing cycles for each wall type. Both the S and LC specimens exhibited minimal energy dissipation on their trailing cycles. However, the BC wall dissipated a reasonable amount of energy on its trailing cycles due to the influence of the steel link beams.

5 CONCLUSIONS

This study conducted experimental testing on four balloon-type CLT shear walls with three wall configurations: a single wall, a coupled wall with screwed half lap joints, and a coupled wall with steel link beams. The cyclic performance of each specimen was evaluated and compared. Based on the test results, the following conclusions are drawn:

1. Mixed angle screwed hold-downs can provide a feasible, high-capacity hold-down connection for multi-storey CLT shear walls subjected to earthquake loading.
2. All three wall types in this study exhibited ductile failure modes and experimentally demonstrated their feasibility as lateral load resisting systems.
3. For the coupled walls with screwed half lap joints, the degree of wall coupling was governed by the screw spacing which can be optimized to achieve a balance of wall strength, stiffness, and energy dissipation.
4. Displacement ductility factors varied between the wall types, with the lowest value observed in the lap-coupled wall specimen LC1 and the greatest value observed in the beam-coupled wall specimen BC.
5. The beam-coupled wall BC with steel link beams demonstrated the greatest strength, stiffness, and energy dissipation, while also exhibiting the least amount of pinched hysteresis. However, it is more complex to fabricate and construct than the other wall types.

EXPERIMENTAL TESTING OF MIXED ANGLE SCREWED HOLD-DOWN CONNECTIONS FOR CLT SHEAR WALLS

Thomas Wright[1] and Minghao Li[2]

ABSTRACT: Cross laminated timber (CLT) shear walls are an efficient lateral load resisting system for mass timber buildings. Ductility and energy dissipation of timber buildings is mostly provided by well detailed connections. Therefore, to achieve good seismic performance of CLT shear walls, hold-down connections must be not only strong and stiff but also ductile with sufficient displacement capacity to meet the drift demands. A novel hold-down connection is proposed using a mixture of screws installed at an inclined angle and 90° to the grain. The respective benefits of inclined and 90° screws can be combined to create a strong, stiff, and ductile connection. Two stages of experimental testing were undertaken with target connection capacities of 600 kN and 1200 kN respectively. The experimental results confirmed that mixed angle screws can provide a strong, stiff, and ductile hold-down solution for CLT shear walls. The optimal ratio of φ12mm inclined screws to φ10mm 90° screws was 1:2, and the optimal ratio of φ12 mm inclined screws to φ12 mm 90° screws was 1:1.5. The primary failure modes were screw withdrawal and wood embedment crushing. Only localised damage of timber around the screw holes was observed and this was repaired with epoxy. New screws were then reinstated with a small offset to the original screw locations and the repaired hold-down connections were found to have the same or even slightly better performance.

KEYWORDS: Cross Laminated Timber, CLT, Hold-down Connections, Self-Tapping Screws, Mixed Angle, Cyclic Loading, Shear Walls, Ductility

1 INTRODUCTION

Cross-laminated timber (CLT) shear walls are commonly used as lateral load resisting systems in mass timber buildings. It is well understood that timber exhibits brittle behaviour when it reaches failure loads, particularly under tension. Therefore, when designing a building to resist seismic loading, any ductility or energy dissipation has to be provided by connections between timber elements. Therefore, in seismic countries like New Zealand, CLT shear walls are often designed with capacity design principles so that the CLT wall panels remain elastic while specified connections have ductile behaviour under severe ground shaking. To achieve optimal seismic performance, these ductile connections must be well detailed with sufficient strength, stiffness, and ductility / displacement capacity to allow the building to yield and dissipate earthquake energy.

Self-tapping screws are widely used for mass timber construction including CLT buildings. They are made out high strength steel and are easy to implement on site with hand tools. Previous research on self-tapping screws has highlighted the benefits of installing screws at an inclined angle to the grain in terms of strength and stiffness [1]–[3]. However, it is well recognized that with this increase in strength and stiffness, ductility / displacement capacity is compromised as the inclined screws primarily transfer load in an axial tension action. Screws installed perpendicular to the grain (or 90° screws) have relatively low strength and stiffness compared with inclined screws, but as they are relatively slender and can deform well and have good ductility / displacement capacity when loaded laterally. Previous research on timber to timber connections by Tomasi [4] showed that connections comprised of mixed angle screw installations, i.e. a combination of inclined screws and 90° screws, can lead to optimised connection behaviour with high strength, high stiffness and reasonably good ductility. When both inclined and 90° screws are used in a connection, their contributions are superimposed with the inclined screws providing high strength and stiffness, and the 90° screws providing high ductility and displacement capacity.
Further research has adopted this concept for in-plane joints between CLT shear walls [5] and orthogonal joints for C-shaped post-tensioned CLT shear walls [6]. Given the clear performance benefits of mixed angle screws, over inclined or 90° only installations, it is proposed to extend on previous research and develop mixed angle screwed hold-down connections for CLT shear walls.

Typical timber connections designed with ductility are susceptible to damage during a major seismic event. If these connections can be repaired quickly and economically, seismic resilience of timber buildings can be improved. It is well understood that the timber material

https://doi.org/10.52202/069179-0268

is relatively easy to work with on site and likely to be repaired.
Projects such as the SOFIE project have highlighted the feasibility of repairing CLT shear wall buildings [7], [8]. Methods that have been used include removing damaged fasteners and reinstalling new ones at an offset and installing new hold-down brackets. To enact a successful repair, it is important that damage is concentrated to the connections, brittle failure of the timber element itself is avoided, and there is an easy access to conduct the repair.

This paper provides an overview of an experimental research program at the University of Canterbury to develop a robust hold-down connection solution for high capacity CLT shear walls that uses mixed angle self-tapping screws. The key research objectives are listed as follows:

- Assess the performance of mixed angle screws in CLT hold-down connections;
- Determine the optimal ratios of inclined to 90° screws for optimal seismic performance;
- Investigate connection damage under cyclic loading and compare to other connection systems with similar capacity; and
- Determine options for post-earthquake repair and evaluate performance of repaired connections

2 EXPERIMENTAL PROGRAMME

A total of 55 connection tests of mixed angle screwed hold-downs were conducted over two testing stages. Stage 1 consisted of 46 hold-down specimens with approximately 600 kN target capacity. Stage 2 consisted of 9 larger hold-down specimens with approximately 1200 kN target capacity. Of the 55 tests, 36 were conducted on original connections and 19 were conducted on repaired connections.

2.1 TESTING PROGRAMME

Table 1 and Table 2 show the test matrix of Stage 1 (labelled as S1) and Stage 2 (labelled as S2) on the original and repaired connection specimens, respectively. Repairs were not undertaken for all the original specimens due to time constraints. The 36 original connection specimens were grouped into 9 test sets with 5 distinct connection layouts. The 5 connection layouts tested in Stage 1 are shown in Figure 1. Stage 2 only tested one connection layout shown in Figure 2. This layout is a scaled-up version of Configuration 5 from Stage 1. In the test matrices test sets are labelled (stage)-(material species)-(screw configuration). a1 spacings were 60 mm for both Stage 1 and Stage 2. a2 spacings were 65 mm for Stage 1 (32 mm considering fasteners from both sides) and 60 mm (30 mm) for Stage 2. These spacings are shown for a typical connection layout in Figure 3.

2.2 TESTING APPARATUS

The testing apparatus for Stage 1 is shown in Figure 4. A steel reaction frame is used in conjunction with a single 1000 kN hydraulic actuator. Load was transferred to the CLT specimen using an inclined screw connection for Configurations 1-2, 4-5, and a dowelled connection for lower capacity single sided tests of Configuration 3.
Displacement was measured by 4 potentiometers measuring between the steel hold-down and timber surface as shown in Figure 6.
The testing apparatus for Stage 2 is show in Figure 5. The test specimen is laid horizontally compared to the vertical configuration in Stage 1, with two 1000 kN actuators anchored to the strong wall. The reaction force was provided by a steel frame with 1500 kN design capacity. Similar to Stage 1, load is transferred into the CLT specimen using two large inclined screw connections. As the test specimen is laid horizontally, rollers are used to support its gravity load, and also to restrain it from out of plane buckling under compressive loading. Displacement is measured by 6 string potentiometers placed between the timber specimen and the steel hold-down bracket.

2.3 MATERIALS

All CLT material was manufactured by XLAM New Zealand. Lamella were graded to meet NZS3603:1993 SG8 grade (8 GPa mean elastic modulus), with Douglas fir specimens using New Zealand grown Douglas fir, and radiata pine specimens using New Zealand grown radiata pine [9]. For Stage 1 testing Douglas fir specimens were 5-layer 175 mm thick with a 45/20/45/20/45 layup, and for Stage 2 Douglas fir specimens were 5-layer 205 mm thick with a 45/30/45/30/45 layup. For both stages, radiata pine specimens were 205 mm thick with a 45/30/45/30/45 layup. All moisture contents were found to be approximately 11% following the standard [10]. Density was calculated in accordance with the standard [11], with mean and characteristic densities of both the Douglas fir and radiata pine CLT specimens being presented in Table 3.

Inclined screws were SPAX ϕ12x260 mm partially threaded (PT) screws with countersunk heads. 90° screws were either SPAX ϕ10x180 mm PT screws with washer heads, or SPAX ϕ12x180 mm PT screws with countersunk heads. Inclined angles were achieved using 12 mm Rothoblaas VGU inclined washers.

Table 3 - *Mean and characteristic densities of CLT specimens*

Species	Douglas Fir		Radiata pine
Stage	Stage 1	Stage 2	Stages 1 & 2
Mean Density (kg/m^3)	496	472	460
Characteristic Density (kg/m^3)	440	429	417

2.4 LOADING PROTOCOL

The loading protocol used was from ISO 16670 as shown in Figure 7 [12]. The loading protocol is a half cycle protocol loading only in the tension direction, similar to what would be expected in the hold-down connection of a CLT shear wall. For both stages of testing, the targeted loading rate was 0.2 mm/sec.

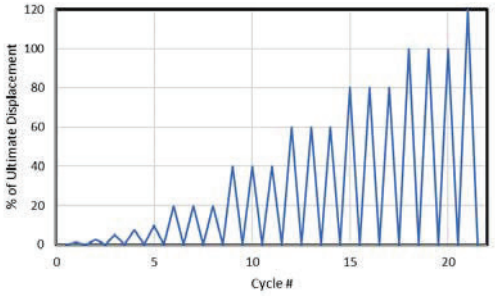

Figure 7: *Cyclic loading protocol based on ISO16670*

2.5 REPAIR METHODOLOGY

The repair process presented in this paper is made up of two steps. The first step is to enact a repair on the timber that has been damaged by screw withdrawal and embedment crushing. The second step is to install new screws at locations with a small horizontal offset to the original locations such that the screws are installed into fresh timber.

2.5.1 Step 1: Repair holes with epoxy

As shown in Figure 10, the failure modes of mixed angle screw connections are primarily withdrawal for inclined fasteners and withdrawal and embedment crushing for 90° fasteners. These embedment failures leave large vertical holes in the timber with loose and torn fibres around the edges. First the holes were cleaned of loose timber. For inclined screws this was done by drilling out the screw hole with a long series drill bit. This drill bit was sized to suit the Hilti Epoxy injection tube such that epoxy could be injected under a small amount of pressure to force out air and fill all the voids. For 90° screws, the holes were first reamed with a drill bit, then the edges where significant embedment failure had occurred were tidied up by removing loose or damaged timber fibres either with pliers and chisel, or with a handheld electric router. Holes were then vacuumed and blown out with compressed air to clear them of dust. Epoxy was then injected into the holes from the inside out, using the pressure of the epoxy to force the nozzle out of the hole. In this study Hilti HIT RE-500 was used with the standard nozzles and extension tubes used for concrete anchors. Excess epoxy was wiped off, and once cured the area sanded to remove any excess epoxy from the timber surface.

2.5.2 Step 2: Reinstate fasteners with an offset

The second step is to reinstate the connection with new fasteners. Small cold-formed hold-downs such as the Rothoblaas WHT with small nails or screws could be reinstalled beside the original hold-down position. However, the mixed angle screw connections tested have fasteners with larger diameter and hence larger row spacing. Due to the much larger dimensions and capacity of these mixed angle screw hold-downs, the change in level arm required to install beside the damaged connection would significantly impact the strength of the wall. A large shift would also require any anchors into the foundations to be moved which may not be practicable if cast in place. Therefore, a small horizontal shift of half row spacing is used. For the connections tested the shift was 16.25 mm for Stage 1, and 15 mm for Stage 2. This shift places the replacement screws half-way in between the repaired holes from the original fasteners.

This horizontal shift may require new brackets to be constructed or can be achieved using well planned details. In Stage 1 testing, the offset was achieved simply using a large tolerance on the hold-down bolt holes. In Stage 2 it was done by creating two sets of brackets with holes offset by 15 mm. These two sets can be used on either end of a shear wall and swapped post-earthquake when repair is required.

3 RESULTS

Experimental results are shown in Table 4 in terms of key performance parameters including strength, stiffness, ductility, and ultimate displacement. For the definition of yield point and ductility, two approaches are presented.

https://doi.org/10.52202/069179-0268

The first approach is described by EN12512, where the yield point is found at the intersection between the initial stiffness and a second line tangent to the curve at 1/6 the slope of the initial stiffness [13]. Due to the high stiffness of these mixed angle screw connections, this approach seems to significantly underestimate the yield force and displacement estimated by visual inspection. The second approach is the equivalent energy elastic plastic (EEEP) approach which derives an equivalent elastic perfectly plastic curve based on equal energy or area under the force displacement curve [14].

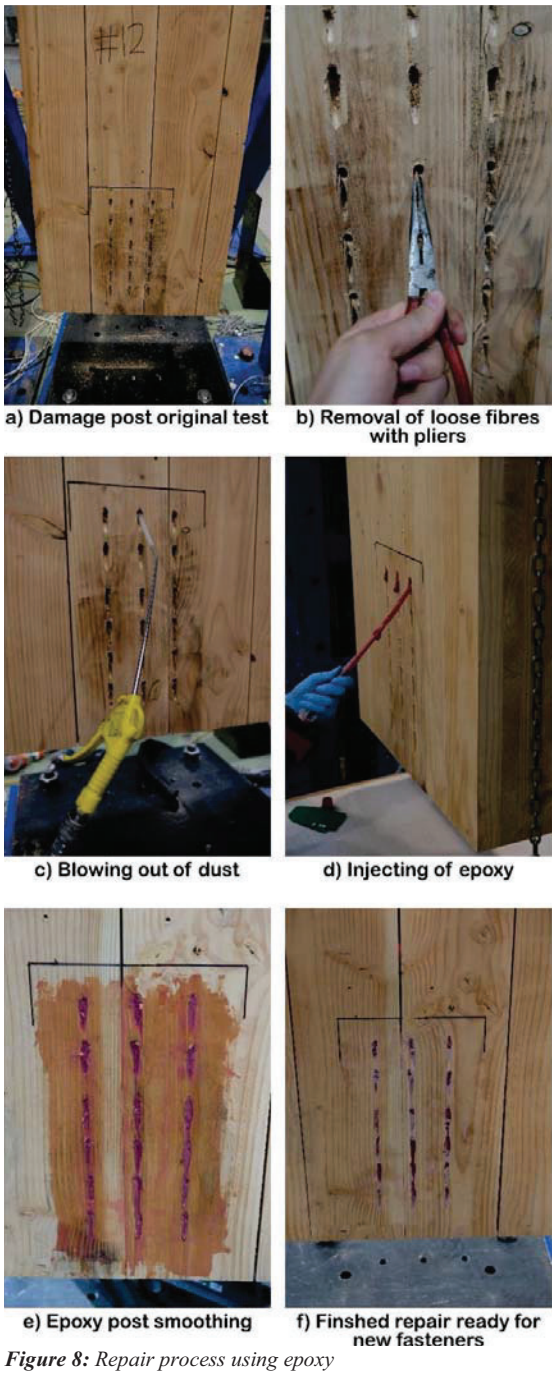

Figure 8: *Repair process using epoxy*

The EEEP method was found to provide a good representation of the yield point compared to what would be visually identified, except in cases where the force increased significantly post-yield. In these cases, the EEEP method was found to slightly overestimate the yield point. Both EN12512 and EEEP results are presented for comparison in Table 4 and Table 5. Due to some initial non-linearity in the elastic portion of the force displacement curve, stiffness values were determined using a similar approach to [15], whereby a regression analysis was undertaken on multiple sections of the initial elastic portion of the force displacement curve.

Representative hysteric force-displacement curves of the mixed angle screw connections are shown in Figure 9. These plots overlay the monotonic and a representative cyclic curve from testing. For the connections where repair was undertaken, the corresponding repaired tests are also shown on the same plot.

4 DISCUSSION

4.1 CONNECTION PERFORMANCE

Overall, satisfactory performance of the mixed angle screw hold-down connections was observed with high strength, stiffness, and ductility. Peak loads F_{max} in Table 4 show the mean value was 500 to 650 kN for Stage 1 double sided connections, 350 kN for Stage 1 single sided connections, and 1081 to 1286 kN for Stage 2 double sided connections. Stiffness values varied between 212 and 269 kN/mm for Stage 1 tests and 361 and 370 kN/mm for Stage 2 tests. Despite using the regression approach described above, the stiffness was found to be quite variable and the expected correlation between the connection tests with more 90° fasteners and higher stiffness was not observed. The variability of stiffness might be due to the initial conditions and friction between the steel side plate and the timber surface. Therefore, more research is required to better understand this. It is also noted that no initial slips were observed or corrected for, with the initial non-linearity in the elastic portion of the force displacement curve being of higher stiffness than that reported.

All of the tested connections exhibited high connection ductility. Ductility is commonly defined as the ratio of ultimate displacement to yield displacement [13]. As discussed, the method of determining yield displacement can have a large impact on the value obtained. Therefore, the ductility and yield displacement values from both the EN12512 approach and the EEEP approach are presented. As the ultimate displacement was relatively large, and the yield displacement was small (between 1 and 3 mm), relatively small changes of the yield displacement can make large changes to the ductility value. For example, if yield displacement changes from 1 to 2 mm, the ductility will be the half. Therefore, for the mixed angle screw connections, it is also recommended to consider the ultimate displacement or displacement capacity of the connection as well. A comparison between S1-RP 4 and S1-RP-2 explains why the ultimate displacement should be considered. The mean ductility of S1-RP-4 is 17.6 with the mean ultimate displacement of 31.4 mm while the mean ductility of S1-RP-2 is 13.2 with the mean ultimate

displacement of 36.6 mm. Due to its lower yield displacements, S1-RP-4 turned out to have a higher ductility value even though it had 5 mm less ultimate displacement.

4.2 CONNECTION DAMAGE/FAILURE MODES

As mentioned in Section 2, all the screws used in this study were partially threaded. The inclined screws were designed to fail in the withdrawal mode as the threaded length was controlled to avoid the tensile failure of the screw shank. It is critical to avoid tensile failure of the screws in the mixed angle screw connections as it allows the gradual transfer of load from inclined screws to 90° screws when the deformation increases.

The 90° screws were loaded laterally and caused localised embedment failure. At large displacements they began to withdraw from the timber. In Figure 10a, the elongated holes were caused by embedment crushing, and ***Figure 10***b shows a section cut through the fastener holes, clearly showing the embedment crushing and the fastener plastic hinge location. The hinges formed in the screws are shown in Figure 11. The 90° screws form two hinges, one right under the steel plate, the other at a depth into the timber. The inclined fasteners, as shown in Figure 11 can also form hinges as they undergo bending actions at high displacements as well, but to a lesser extent.

Throughout the testing, no block tear out or other brittle failure modes were observed.

https://doi.org/10.52202/069179-0268

4.3 OPTIMAL RATIO BETWEEN INCLINED AND 90° SCREWS

For the mixed angle screw connections tested, all the configurations showed high strength, stiffness and ductility. The designer can choose the ratio of inclined to 90° screws based on the performance required. In general, a connection with more 90° screws will have a higher post yield force increase (or post yield stiffness) due to significant rope effect of the 90° screws at high displacements.

To determine a recommended ratio, further criteria would need to be defined. Efficiency, post yield force increase, and energy dissipation are all compared at length in the literature [16]. The conclusions of [16] can be replicated by visual inspection of the force displacement plots in Figure 9. In general, a connection that can sustain the yield force till a large displacement is desired. Literature also suggested that an increase in force post yield is desirable in terms of limiting drift [17]. From Figure 9 it can be determined the connections using Configuration 2 and Configuration 5 meet these criteria better. Therefore, the optimal ratio of ϕ12 mm inclined screws to ϕ10 mm 90° screws was 1:2; and it was 1:1.5 for ϕ12 mm inclined screws and ϕ12 mm 90°.

4.4 FEASIBILITY OF POST-EARTHQUAKE REPAIR

A key observation from this study was the localised and confined damage to the CLT in comparison to extensive damage in the dowelled CLT hold-down connections tested in a previous study [18]. With the localised damage, post-earthquake repair of these connections becomes viable, and tests were undertaken to evaluate the performance of the repair by comparing original and repaired tests of the same experimental specimen.

To evaluate the effectiveness of the repair, strength, stiffness, and ultimate displacement are compared in Figure 12. Figure 12a shows a comparison of maximum force for each original and repaired test. From Figure 12 it can be seen that all repaired tests reached a higher maximum force than the original tests. This increase averaged 5.5% over all tests with a maximum of 15%.

Figure 12b shows a comparison of stiffness, with the original and repaired stiffnesses being similar for most tests.

Figure 12c shows a comparison of ultimate displacement, with repaired tests having lower ultimate displacement for all but two results. This may be in part due to the definition of ultimate displacement being dependent on the maximum force which was higher for the repaired tests. Given the increase in strength, and similar stiffness values, the epoxy repair and shift method is deemed to be effective in repairing this type of connection post-earthquake.

Figure 13 shows the epoxy repair of the connection after the repaired test. Overall the epoxy has filled the damaged holes well, with no large trapped pockets of air. There are some small air bubbles in the epoxy, but given the difference in strength between the epoxy and the surrounding timber material, these are unlikely to cause adverse effects.

5 CONCLUSIONS

The paper presents an experimental study on large-capacity CLT hold-downs using mixed angle self-tapping screws. Monotonic and cyclic tests were undertaken to assess the hold-down performance. The key conclusions are:

- Mixed angle screws can provide a strong, stiff, and ductile hold-down connection system for CLT shear walls;
- The optimal ratio of inclined screws to 90° screws was 1:2 for ϕ12 mm inclined and ϕ10 mm 90° screws, and 1:1.5 for ϕ12 mm inclined and ϕ12 mm 90° screws. These ratios led to connections with high strength, high stiffness, and high ductility;
- Under cyclic loading, mixed angle screws can be detailed such that the primary failure modes are screw withdrawal and wood embedment crushing. This leaves only localised damage and results in repairable damage in timber; and
- Localised damage observed in mixed angle screw hold-down connections can be repaired with epoxy and the screws reinstated with a small offset to original fastener holes leading to the same or even slightly better performance.

DYNAMIC PERFORMANCE OF A FULL-SCALE WOOD FRAME SUBJECTED TO CYCLIC LOAD TESTING

Félix Bouffard[1], Jean Proulx[2]

ABSTRACT: The strength-to-weight ratio of wood structural elements makes them very attractive on an engineering design point of view. This is one of the reasons why wooden buildings are known to perform well during seismic events of medium and high intensities. However, ductility and over strength factors, making it possible to design structures having the capacity to resist a seismic event by its inelastic properties, are not well characterized and leads to a local over design of assemblies and critical wood sections. The primary objective of this study is to characterize the cyclic behaviour of a diagonally braced full-scale frame. This study focuses on capacity design to have the dowel assemblies as the main dissipator of energy. A full-size frame specimen was subjected to cyclic loading. The frame was built with glulam timber elements joined together with hidden steel plates and fastened with dowels. The cyclic loading results demonstrated a global ductile behaviour, a good redistribution of the internal efforts in the assemblies, a reduction of the secant stiffness after the yielding point, increment of the dissipation of energy, great over-strength, and minor damage in the timber elements. This supports the use of this type of frame with a capacity design focused on a ductile behaviour.

KEYWORDS: Seismic behaviour, Full-scale, Wood frame, Cyclic loading, Glulam, Capacity design, Seismic force resisting system

1 BACKGROUND AND MOTIVATION

Various research studies have been conducted on wood as a material, and there is a greater understanding of its mechanical properties. It is now possible to use wood and to manufacture it in such a way as to obtain structural products with a mechanical resistance increasingly comparable to that of steel, and allowing to build high rise buildings. On a structural engineering point of view, wood is a very light and strong material. Therefore, wooden buildings perform relatively well during seismic events of medium and high intensities. However, wood as a material possesses low ductility properties and brittle failure modes. The National Building Code of Canada (NBCC) [1] is giving more room to allow the design and construction of all-wood Seismic Force Resisting Systems (SFRS) into new buildings. When designing engineered wood structures, ductility and over-strength factors are used. These coefficients, making it possible to design structures entirely in wood having the capacity to resist a seismic event by its inelastic properties, are very low. The problem is that a low global demand stemming from small, underdeveloped force modification factors leads to a local over design of connections and critical wood sections. SFRS built entirely from engineered wood therefore require more material for compliance purposes. In the NBCC, the R_d factor considers the ductility of the system and its ability to absorb energy, and the R_o factor considers the overstrength of the structure.

Due to the increasing use of timber braced frame in practice, multiple configurations of these systems were developed, and this leads to new questions. Previous research [2]–[5] has been conducted to evaluate the behaviour of such systems, investigating the influence of capacity design, connection behaviour, brace configuration as well as the protocols used for cyclic testing. The behaviour of timber braced frames is generally highly influenced by its energy absorption capacity and overall ductility which is governed by a proper design [2]. The main components of interest in capacity design of such structures are generally the connections in the joints, as there is existing knowledge on ductile failure modes. Connectors type and their configuration in wood elements directly influence the behaviour of local wood to steel assemblies and the overall behaviour of a structure [3]. Braced frames with diagonal wood elements have been tested in different configurations to evaluate their performance. Frames with X-brace or K-brace were shown to have desirable lateral stiffness and can be improved with a design focused on ductile failure modes [5]. On a global perspective, other researchers focused their attention on cyclic protocols used to ensure proper characterization of timber frames. Cyclic testing patterns with sequences composed of multiple cycles can be demanding in terms of the effects on the results. It is therefore important to have a representative loading protocol that simulates the behaviour of a real seismic energy demand to correctly establish the properties of interest [4].

The literature review emphasized the need for studies on the dynamic performance of a full-scale braced frame designed according to industry standards, which would give information to professionals in regards of the critical parameters to be used for design. The primary objective of this study is to characterize the cyclic behaviour of a diagonally braced frame of a three-storey wooden building and identify the current design challenges. The full-size specimen is a braced frame with a diagonal glulam wood element connected with two dowel

assemblies that are designated to be the fuses in accordance with the principle of capacity design.
A testing methodology was established with suitable properties for a full-scale loading protocol in the structural laboratory of the University of Sherbrooke. This test allowed for the analysis of the energy dissipation capacity, resistance parameters and lateral stiffness of the frame. The results of this research provides information on how to approach such problems and behavioural data for future research.

2 APPROACH

2.1 STANDARD WOOD BUILDING

To incorporate elements that would be observed in an actual timber construction, the fictional "benchmark" building proposed by the Canadian Wood Council (CWC) [6], as shown in Figure 1, was used as a reference. This three-storey building is 12.192 m high, has a ground area of approximately 1440 m^2 and a typical grid spacing of 7.62 m by 7.62 m in each direction. Using SAP2000 [7] and S-Frame [8], the building was modelled and analysed to find the critical load combination, including seismic and snow loads.. The use of different commercial software allowed for a verification of the results to ensure reliable loading targets for laboratory testing. The numerical analysis showed that the critical SFRS was on the long side of the building. The equivalent static load method for a building located in Montréal (City Hall), Canada on a class C soil was used to establish the applied seismic force. The uniformly distributed roof loads are 1.5 kPa and 2.3 kPa for dead load and snow load respectively. For the floors, the uniformly distributed loads are 3 kPa and 2.4 kPa for dead load and live load, respectively. In the context of this research, the R_d and R_o factors for such a structure were chosen to be 2.0 and 1.5 for a moderately ductile system with ductile connections respectively. The total hypothetical weight of the building was assumed to be 11204 kN resulting in a lateral seismic force at ground level of 1481 kN. Accidental torsion was considered during the redistribution of the seismic force in each storey. These forces were then reproduced on the specimen with the experimental setup.

Figure 1: *Standard wood building by the CWC*

2.2 FRAME DESIGN

Due to the fragile properties of wood, there must be pre-assigned ductile elements that will yield firstly to impose a safety measure. All elements that must be oversized compared to an unprotected element are non-energy dissipating elements. The specimen of this research was designed using the capacity design approach. This allowed to pre-determine the components that would fail first. Therefore, all the elements, except for the two dowel assemblies in the brace element were overdesigned to have a linear deformation behaviour. To determine the appropriate geometry of the non-dissipating elements of the specimen, a reduction of the seismic force based only on the overstrength factor was used. As for the ductile assembly, its design was based on the CSA O86-14 adapted the European model [9] for ductile deformation of steel connectors in wood. Both reduction factors accounting for overstrength, and ductility were used to reduce the seismic force for the dowel connections design. The "g" mode was prioritized to be the governing mode of deformation to fully utilize the yield of the dowels and the crushing of the wood.

2.3 CONNECTION STIFFNESS ASSUMPTIONS

During the design phase of the specimen, the challenge was the determination of the connection properties. Since bracing systems, similar to the one in this research, are usually composed of two steel to wood connections and a diagonal element, they have a direct influence on the total drift of the SFRS. The problem is that the stiffness of these connections is not documented by Canadian standards, which means that professionals must rely on values that are not necessarily representative of values that could be observed in the field. This leads to a misrepresentation of the drift ratio of wood SRFS in large-scale buildings.
To solve this issue, the slippage modulus, K_{ser}, established in the SIA 265 standard [10] and by the Eurocode 5 (E5) [11] was used to characterize the stiffness and the drift of the specimen. For Canadian SPF 12c-E class wood, the density of $\rho = 455\ kg/m^3$ was used according to the CSA O86-14 standard. Drift displacement of the whole system was assumed by using the relationship of derivation of connection and system stiffness developed by Chen and Popovski [12].

3 FULL-SCALE WOOD FRAME

3.1 MATERIALS

All the timber elements were joined with grade 350W steel plates and fastened with grade A325 dowels in respect of the ASTM standards. The steel plates connecting the braced assembly were 19.1 mm thick and the column plate were 12.7 mm thick. The 56 dowels (28 at each end) connecting the brace element had a diameter of 9.5 mm and the other 53 dowels had a diameter of 19.1 mm. All the dowels had a length of 342.9 mm. They were hammered in place, as per typical on-site instructions. Yield point of all steel elements was 310 MPa. All the requirements from CSA S16-14 [13] were considered during the design phase of these elements. All the wood members were made of glued laminated Canadian spruce-

https://doi.org/10.52202/069179-0269

pine-fir (SPF) wood produced by Art Massif in accordance with CSA O122-16 [14] and CSA O177-06 [15] for produce and manufacturing requirements respectively. The bracing and column elements had a stress class of 12c-E and the beam element had a stress class of 20f-Ex. The average moisture in the laboratory and of the specimen were respectively 6.6% and 6.2% during the test. The modulus of elasticity considered for 12c-E and 20f-Ex grades were 9700 MPa and 10300 MPa respectively. All the requirements from CSA O86-14 [9] were respected during the design phase of these elements.

3.2 EXPERIMENTAL SPECIMEN

The experimental frame, as shown in Figure 2, represents the braced frame at ground level of the bay perpendicular to the longest length of the standard building. The specimen is 7680 mm long centre to centre of the columns and 4540 mm high from the bottom of the column feet to the centre of the beam. Figure 3 shows the layouts of the specimen as well as the configurations of the connections. The section dimension of the bracing element and columns are 365 mm by 381.7 mm. To ease the manufacturing process and simplify the experimental setup, the beam element was oversized compared to the original plan and were made 365 mm by 555.2 mm. The common design coefficients for all the components of the specimen in respect to the CSA O86-14 standard were load-duration factor (K_D) of 1.15, service-condition factor (K_S) of 1.00, treatment factor (K_T) of 1.00 and system factor (K_H) of 1.00. The resistance of the specimen is governed by the yielding resistance of the brace connections that were assigned to be the ductile elements in the capacity design method used. The resistance of the brace assemblies was calculated to be 552 kN (factored) and 689 kN (nominal). All the other elements were designed to withstand more than the maximum force of the actuators to ensure proper load distribution in the fuses of the whole system.

Figure 2: *Full-scale wood frame*

3.3 SPECIMEN ASSEMBLY CHALLENGES

Assembly of the specimen took place in the structural laboratory of the University of Sherbrooke with the help of the lab technicians, the support of a candidate to the engineering profession and professional engineers.

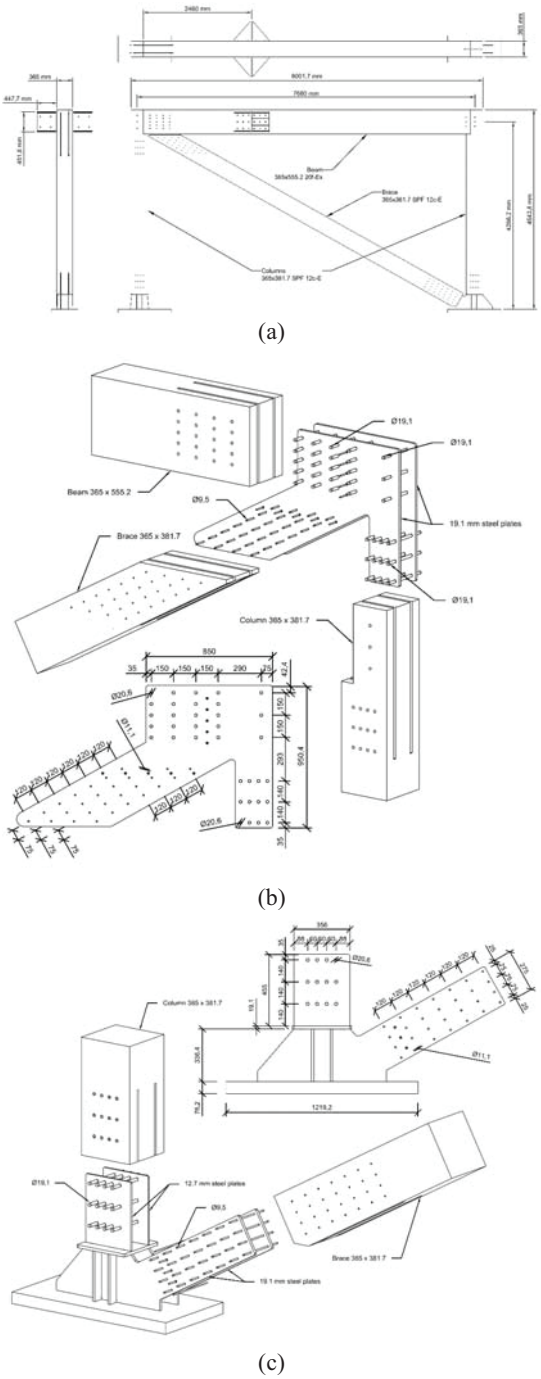

Figure 3: *Specimen layout: full-scale wood frame (a), top brace connection (b) and bottom brace connection (c)*

Some challenges occurred during the assembly due to the scale of the specimen. The wood elements arrived with an unknown degree of humidity which was approximated to be high due to the possible exterior storage of the wood slats prior to assembly. Since the laboratory is well aerated and kept dry, multiple cracks started to appear on the specimen until the day of the test. These cracks, as shown in Figure 4 (a), were carefully monitored to ensure

the integrity of all the components. After testing, the specimen was cut at precise locations to establish the depth of the cracks and none of them were identified as critical. It showed that all the cracks were on the surface only and did not change the integrity of the wood.

Another challenge was the alignment of the holes in the steel plates. Even though all the holes in the wood and in the steel were drilled by a computerized numerical control machine, some holes were not precisely aligned, as shown in Figure 4 (b). In general, the misaligned holes were forced, and the dowels passed through. However, one of the holes in the single column connection was grinded to allow the 19.1 mm dowel to pass through. It was evaluated that only one enlargement of a hole in the single column connection would not affect the results du to the scale of the specimen. It was also established that this would somehow represent errors observed on a construction site and the enlargement technique used was as per typical on-site instructions.

The beam to column connection opposite to the top corner of the diagonal element was composed of a 270 mm by 270 mm by 12.7 mm thick steel plate. A total of six dowels (three in the beam and three in the column) ensured that the pieces would stay together. This assembly was not designed to withstand forces arising from the lifting of the specimen. Therefore, a steel bracing system, as shown in Figure 4 (c), was screwed onto the specimen. Once the specimen was in its testing position and no uplift forces were applied on the beam, the steel brace was removed, and the twelve lag screw holes (six on each side) were filled with the same glue used to manufacture the wood elements. Wooden dowels were used to block the glue filled holes. No cracking was observed du to the installation of the temporary steel bracing prior to the gluing and blocking of the holes.

Since the laboratory setup did not allow for the beam to be dismounted from the simple column throughout the test, a safety block was installed. This 347 mm by 350 mm by 130 mm thick glulam block was installed on the face of the column directly under the beam as shown in Figure 4 (d). Four 8 mm in diameter by 240 mm long screws were installed at a 90-degree angle and 8 mm in diameter by 350 mm long screws were installed at a 45-degree angle. These screws ensured that the beam would be supported in the case of a detachment from the column during the pulling cycles. A clearance of approximately 2 mm was ensured between the beam and the block to allow for movements without interfering the results.

4 EXPERIMENT PARAMETERS

4.1 TEST SET UP AND INSTRUMENTATION

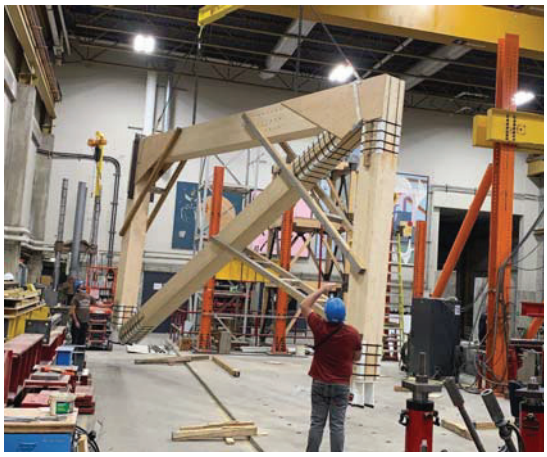
The experimental setup was composed of three essential systems for the proper functioning of the laboratory tests. The guidance system ensured that the loads are appropriately transmitted to the specimen system. It also ensured that the specimen did not deviate from its lateral trajectory. All of this was documented by the

https://doi.org/10.52202/069179-0269

instrumentation system linking the specimen movements to the data collection tools.

As shown in Figure 5, the specimen was assembled horizontally and temporarily braced with additional timber elements. These braces allowed the specimen to be lifted vertically in its testing position while ensuring minimum efforts in the dowel assemblies. Columns steel bases were made of 15.9 mm and 19.1 mm thick steel plates welded to 1219.2 mm long by 609.6 mm wide and 76.2 mm thick foundation plates. These plates were anchored with high resistance steel rods to the concrete reaction floor.

(a)



(b)

Figure 5: *Specimen bracing: bracing system (a) and lifting (b)*

A 12 m reinforced concrete reaction wall with a shear strength of 8000 kN, an overturning resistance of 25000 kNm and a punching resistance of 1500 kN was used to anchor two hydraulic actuators. The actuators were from MTS System Corporation and were controlled by the MTS FlexTest-60 system. The maximum capacity of each actuator was 500 kN and they had a displacement range of ±250 mm. The heads of the actuators were anchored to metal braces bolted into the wood beam with 18 one inch in diameter bolts. Hinges at the base and at the head of the actuators allowed to eliminate the bending moment generated by the gravity forces. To simulate the gravity load from above stories, two high-strength rods were anchored in each foundation plates to apply 292 kN of force in the long axis of each of the columns. The rods were connected to a transfer beam at the top of the columns which ensured the correct distribution of the load. The steel beams were connected to a load cell system which ensured that the loading remained constant during the test. The load variation was negligible due to the small angles generated. As shown in Figure 6, the out-of-plane bracing system was made up of four W section steel columns on which two beams were mounted. These beams included a network of rollers and guides ensuring that the specimen did not deviate from its lateral axis when subjected to a cyclic loading.

Potentiometers, linear variable differential transformers (LVDT) and load cells, as shown in Figure 7, were used to capture all the required data for the analysis of the frame's behaviour.

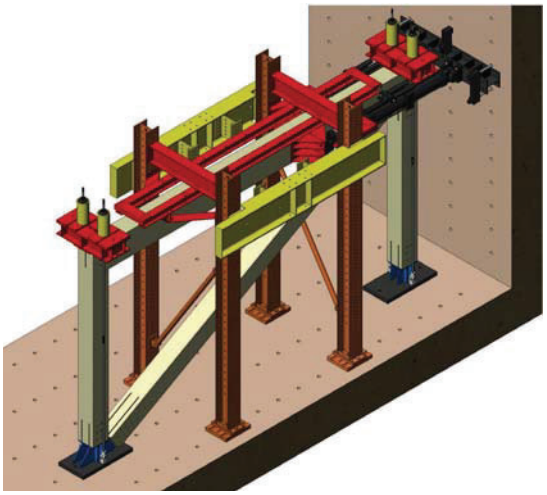


Figure 6: *Guidance system of the laboratory set up*

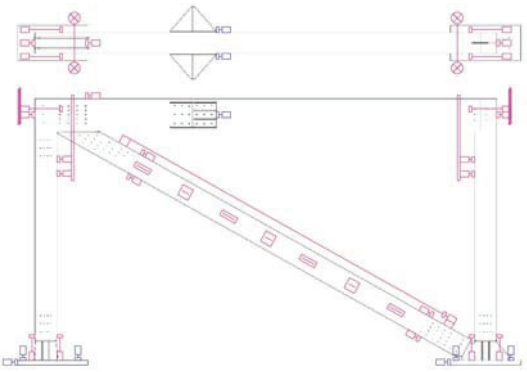

Figure 7: *Instrumentation set up*

4.2 LOADING PROTOCOL

Due to the availability of only one specimen, multiple Due to the availability of only one specimen, multiple parameters were established to ensure proper testing of

the frame. Test method A also known as the Sequential-Phased Displacement Procedure (SPD) in the protocol from the American Society of Testing and Materials E2126-19 [16] was used as a reference. The SPD method shown in Figure 8 involves multiple phases of controlled loading cycles that incrementally increase the displacement of the structure. Two patterns of reversed cyclic loading were applied to the specimens. The first displacement pattern was divided in three phases with the amplitude based on the anticipated first major event (FME). The FME was established to be the first significant limit state to occur. Each phase had a displacement of 25% (step 1), 50% (step 2) and 75% (step 3) of the anticipated FME. The second displacement pattern was composed of an initial phase, a decay phase and a stabilization phase that increased after each cyclic phase of pattern 2 is completed. The initial phase had one cycle at 100% displacement (step 4) of the anticipated FME. The decay phase had three reversed cycles that decreased the initial phase amplitude by steps of 25% of the displacement. The stabilization phase had three cycles that replicated the amplitude of the initial phase. This pattern was repeated until one of the stop criteria was achieved.

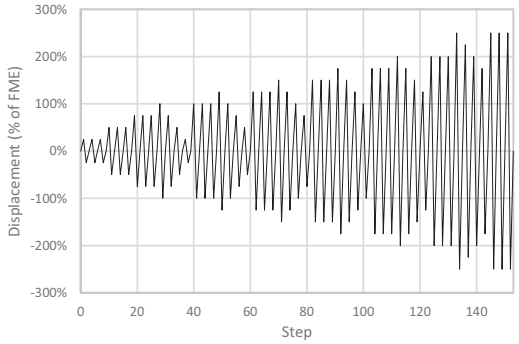

Figure 8: *Loading procedure*

Since only one specimen was available to test, no monotonic test was performed to establish the FME nor the ultimate displacement of the specimen. However, theoretical calculations based on the SIA265 standard [10], Eurocode 5 (E5) [11], E5 platform [17] and Popovski's method [12] were made to evaluate the FME. Due to the capacity design of the frame, the first major event was defined as the yield point of the dowels inside the assemblies of the frame. The lateral force of 482 kN corresponding to an assumption of a 9.21 mm drift was established as the FME for the final test. Through previous testing on large-scale wood structural members at the University of Sherbrooke, it was determined that a loading rate of 0.5 mm/s would be used. This rate was chosen based on the recommendations of the laboratory professionals, as faster loading rate would not have allowed the test to be paused before a possible critical event with potential negative impacts on the specimen. The sampling rate of the instrumentation was set at 50 readings per second.

Two preliminary cyclic load tests followed by a final destructive test were conducted. The first preliminary test (Test 5%) consisted of a triangular wave loading pattern at very low loading rate with a lateral force of 24.1 kN equivalent to 5% of the FME. The goal of the first preliminary test was to ensure proper operation of the instrumentation and loading system. The second loading test (Test 100%) consisted of steps 1 to 4 of method A controlled by force parameters. The goal of the second test was to validate the overall stiffness of the system and to confirm if the theoretical values of the FME were well evaluated. The established limits allowed to stay in the elastic domain and potentially enter the initial phase of the plastic domain. In this case, the force control of the actuators was programmed to perform a lateral thrust of 481.4 kN. Based on the results of the second test, the lateral stiffness of the system and the FME was confirmed. Then the complete loading protocol (Test final) was performed in displacement control until one of two stop criteria was achieved.

The two stop criteria were an observation of a degradation of more than 20% of the specimen's resistance and when the maximum force of 1000 kN of the actuators is achieved. The final test was terminated because the maximum force of the actuators was achieved. However, a maximum lateral force of approximately 1100 kN was applied on the specimen due to a slight increase of the laboratory hydraulic pump capacity.

5 EXPERIMENTAL OBSERVATIONS

5.1 HYSTERETIC BEHAVIOUR OF THE WHOLE FRAME

The hysteretic curves shown in Figure 9 represent the average lateral displacement of the top section of the specimen. It was calculated as the average drift of the two upper assemblies at the vertical centre line of the beam. A correction of the curve in reference to the elongation and compression of the wood was applied to ensure proper representation of the true displacement.

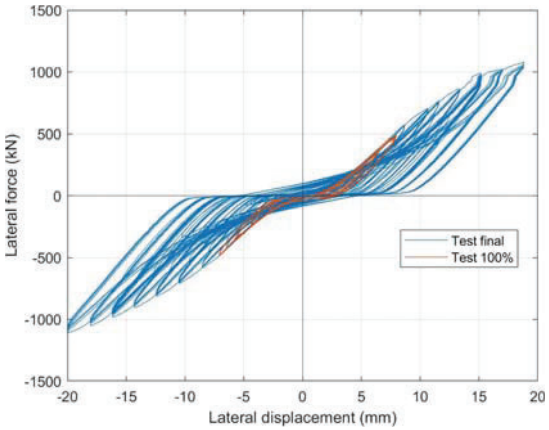

Figure 9: *Hysteresis curve*

It is observed that the curve of the Test 100% shows a very similar elastic behaviour to that of the Test final. In both tests, during return to point zero, the curves don't show any flattening, which means that the specimen remained in the linear deformation domain for both tests. An

https://doi.org/10.52202/069179-0269

average of the difference in displacements at each cycle of about 0.5 mm was recorded. This difference is explained by the fact that the 100% test was performed in force control while the final test was performed in displacement control.

Observation of the hysteresis curve past the yielding point of the brace assemblies shows a broadening of the curves that characterizes an overall ductile behaviour. The stability of each subsequent cycle demonstrates that there is a dissipation of energy increasing at a stable rate. There is also a shift in the curve before the engagement of the elements that resist the lateral force. This phenomenon is common in wood structures and can be explained du to the 1 mm clearance in the connections slots and holes to facilitate assembly. This clearance creates a slight shift in the curves when there is a change in the direction of the force.

5.2 LATERAL STIFFNESS

Lateral stiffness of the system subjected to a cyclic force is determined using the secant stiffness defined by the ratio of force to displacement as shown by the Equation 1 [18]:

$$k_i = \frac{|F_i^+| + |F_i^-|}{|X_i^+| + |X_i^-|} \quad (1)$$

where F_i^+ ; F_i^- are the peak loads of each cycle and X_i^+ ; X_i^- are the relative displacements of the same cycles.

Analysis of the stiffness curve, shown in Figure 10, shows that there is a loss in the overall stiffness of the specimen once the sequence of cycles at the FME amplitude is passed. The FME is achieved when there is a lateral displacement of 9.21 mm. In the test, an average force of approximately 576 kN was required to achieve this displacement. This corresponds to a specimen secant stiffness of 68447 kN/m.

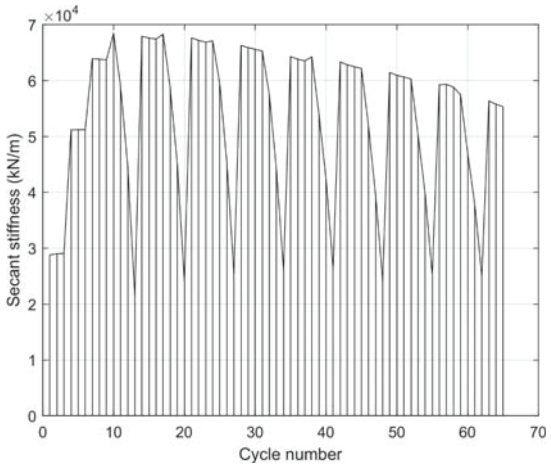

Figure 10: *Secant stiffness curve*

The curve of the following cycles shows that there is a loss of stiffness until the end of the test. Therefore, it can be established that the FME was exceeded, and that the specimen shows a behaviour with plastic failure modes. However, it should be noted that the exceedance of the elastic limit was probably achieved between the FME cycle and the next higher cycle. Hence, the CEN method [19], was used to define the slope of the envelope in the linear domain. Note that the slope (K_α) shown in Figure 11 was evaluated for comparative purposes, as it was not possible to measure the maximum strength of the specimen. As a result, the stiffness in the linear domain is estimated to be 86659 kN/m.

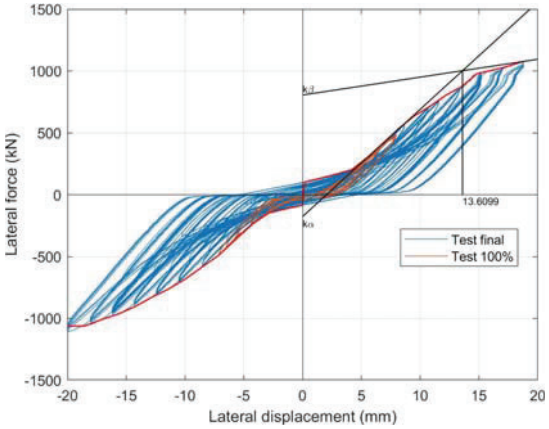

Figure 11: *Approximation of CEN method*

5.3 ENERGY DISSIPATION

The amount of energy dissipated by the specimen is determined by measuring the area of the hysteresis curve in respect of each cycle as shown by Equation 2 [20]:

$$E_{Di} = \int F_i(x)dx \quad (2)$$

where $F_i(x)$ is the hysteresis curve function in accordance with the lateral displacement.

The ratio of dissipated energy is the ability of the overall system to dissipate energy over the strain energy required to deform it. In the case where there are no mechanisms to dissipate energy, the ratio would be zero. However, at each subsequent cycle during the test, there was at least one energy dissipation mode present that ensured a ratio increase. It can be determined using Equation 3 and Equation 4 [20]:

$$E_i = \frac{E_{Di}}{2E_{S0i}} \quad (3)$$

$$E_{S0i} = \frac{k_i u_{0i}^2}{2} \quad (4)$$

where E_{S0i} is the deformation energy per cycle, k_i is the lateral stiffness of the system and u_{0i} is the maximum displacement.

The gradual increase of the energy dissipation ratio shown in Figure 12 is explained as a result of increased friction, cracking, and especially due to the yielding of the brace assemblies.

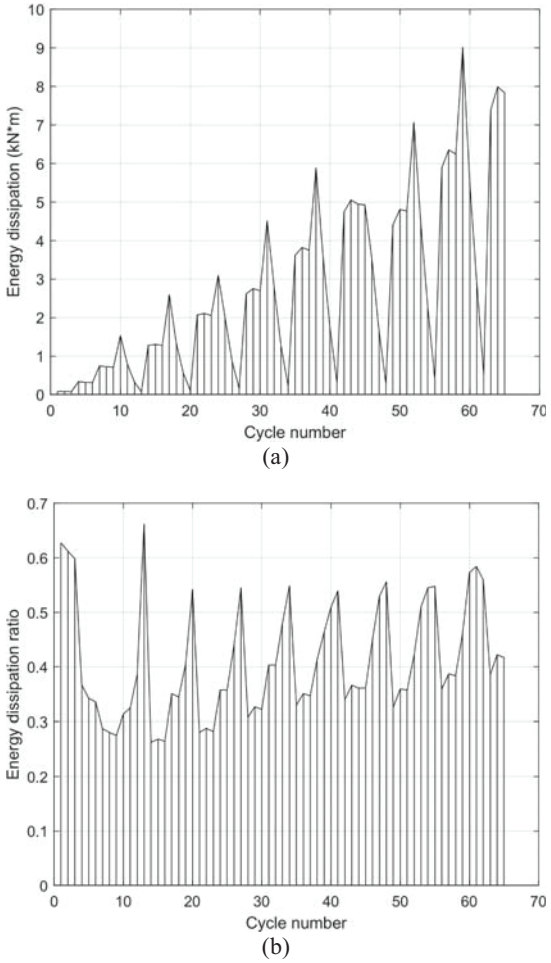

Figure 12: *Energy dissipation: energy dissipation per cycle (a) and energy dissipation ratio (b)*

5.4 STRENGTH DEGRADATION

When a structure is subjected to cyclic forces simulating the forces of earthquake aftershocks, the structure in question may suffer more damage than anticipated. That is why it becomes very important to consider the rate at which SFRS degrade in strength [21]. The degradation under cyclic loads was characterized using the degradation coefficient defined by the equation [18].

$$\lambda_i = \frac{F_i}{F_{max}} \tag{5}$$

where F_i is the force of the observed cycle in a sequence and F_{max} is the peak load of the same sequence.

As expected, the results obtained shows that all the cycles in the elastic domain of the specimen shows negligible strength degradation. Past the elastic limit, the first cycles of each phase corresponds to the maximum load of reference. The subsequent cycle shows a loss of strength due to the crushing of the wood in the connections. Figure 13 illustrates the loss of strength during the test when the lateral load is directed in the east and west directions. The strength degradation trend is relatively stable. Due to the large over-capacity, a degradation of 3.73% was observed when the maximum lateral force was applied.

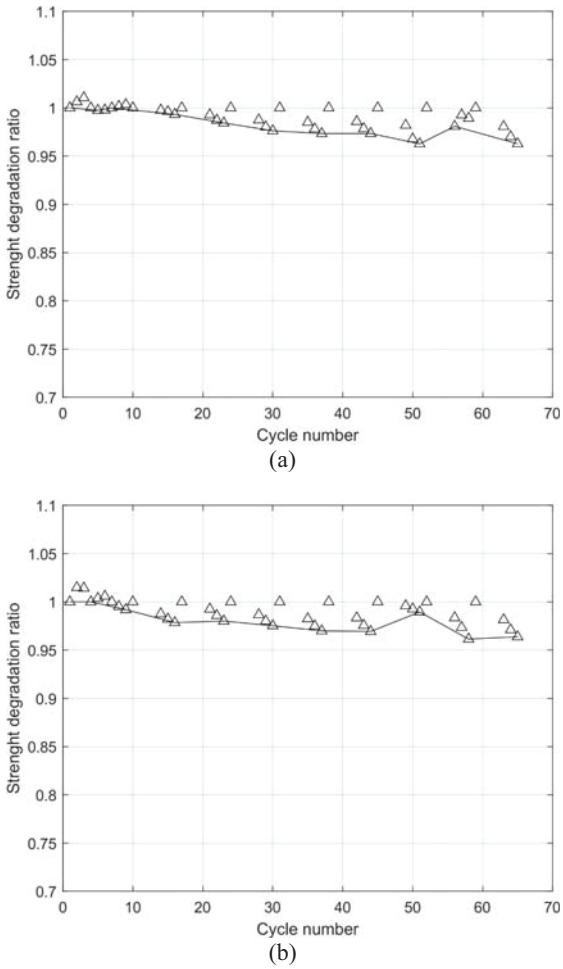

Figure 13: *Strength degradation ratio: load traveling in the east direction (a) and the west direction (b)*

5.5 R_D AND R_O MODIFICATION FACTORS

The R_d factor considers the ductility of the system and its ability to absorb energy, and the R_o factor considers of the excess in resistance of the structure. The force modulation factor R_d ensures that the structural system has the capacity to absorb energy, while having acceptable deformations. When a building is designed with a R_o factor greater than 1, it is considered that the structure can undergo inelastic deformations and that the connections can deform ductile.

According to a study [22], the modification factor R_d is defined by the equation 6.

$$R_d = \sqrt{2\mu - 1} \tag{6}$$

where μ is the ductility expressed as the ratio of displacement at failure to displacement at yield.

The ratio P_{max}/P_y is used to calculate the R_{yield} factor in the evaluation of the coefficient which considers the

https://doi.org/10.52202/069179-0269

excess strength of the structure. Equation 7 is explained in a study [23] to calculate the R_o factor.

$$R_o = R_{size} \cdot R_{\phi} \cdot R_{yield} \cdot R_{sh} \cdot R_{mech} \quad (7)$$

where R_{size} is the overstrength arising from restricted choices for sizes of elements and rounding of sizes and dimensions equal to 1.05; R_{ϕ} is the factor accounting for the difference between nominal and factored resistances equal to 1.43; R_{yield} is the ratio of actual yield strength to minimum specified yield strength; R_{sh} is the overstrength due to the development of strain hardening equal to 1.00 and R_{mech} is the overstrength arising from mobilizing the full capacity of the structure such that a collapse mechanism is formed equal to 1.00.

Since failure of the specimen was not achieved, it is important to note that the value of the displacement and force found with the method used to determine the yielding point can be improved. In addition, it is crucial to obtain the displacement and force at the point of failure in order to properly evaluate the modification factors. Thus, solely to provide an overview of the test results, the following R_d^* and R_o^* values were calculated with the results at the point of maximum force applied to the specimen. The ratio P_{max}/P_y was used to calculate the R_{yield} factor. It is important to consider that the NBCC takes a conservative approach by assuming that the R_{yield} factor is equal to 1.00. However, our tests show that the R_{yield} value is higher and therefore a larger value of the R_o^* factor would be expected. In addition, the calculated values may be considered as underestimated due to the fact that the point of failure is probably higher than the point of maximum force applied on the specimen during testing. R results from our tests lead to calculated value of R_d^* equal to 1.87 and a R_o^* value equal to 2.85.

6 CONCLUSION

Evaluating the seismic behaviour of a full-scale wood frame under cyclic loading to obtain seismic properties for optimization and better understanding of such a system was achieved during this research. The elastic performances of the specimen based on capacity design was evaluated. The following conclusions come from the observations of the specimen and the analysis of the results:

1. The overall behaviour of the system demonstrated that the use of a preliminary test in the elastic domain was an adequate method to validate the elastic stiffness of the specimen in order to establish the limits of a destructive test.
2. The braced frame system, from this research project, demonstrated the same behavior several times during the preliminary tests and during the final test in the elastic domain.
3. In comparison with the study of Xiong and Liu [5], it can be concluded that the overall behaviour of the diagonally braced structure is comparable to a K-braced bolted system.
4. An increase in the ratio of dissipated energy with increasing amplitude of each cycle is observed.
5. There is a loss of stiffness of the overall system passed the elastic limit of the fuse elements.
6. The strength degradation of the system was influenced by the yielding of the fuse elements.
7. The tests in this research project resulted in a value for the R_d^* coefficient that was close to the value established by the 2015 NBCC. The test value is underestimated and therefore a a somewhat higher value would be expected when testing to complete failure. This value would slightly exceed that of the 2015 NBCC.
8. The tests in this research project resulted in a value for the R_o^* coefficient that is much larger than the value established by the 2015 NBCC. This value is also underestimated, as tests were not completed to failure. Thus, there is room for improvement in the proposed CNBC value for system types similar to the one in this research project.
9. Based on the observations of the specimen in this research, a great deal of overstrength is associated with wood frame systems due to the oversizing of the unprotected elements.
10. A lack on information in Canadian standards about stiffness properties of steel connectors in wood was identified. Other national standards can be used to establish preliminary assumptions, but further research should be conducted to provide models with respect to Canadian materials.

In order to better understand the complete behaviour of the frame, it would be appropriate to create a numerical model using different finite element software and use the results for calibration purposes. In this way, a complete model of the SFRS and the structure could be compared to a typical design practice. These results would allow to establish the ductility of the frame and the force modification factors associated with it. To further extend the project, the calibration of such a model could lead to the dynamic finite element analysis of different types of structures with the same SRFS. Thus, these studies could establish a starting point for Canadian standards with respect to the introduction of new requirements related to the seismic behaviour of wood structures.

ACKNOWLEDGEMENT

The authors would like to acknowledge the funding from the National Sciences and Engineering Research Council of Canada and the Québec FRQNT fund. The authors also recognize Art Massif for their collaboration and funding, and for providing the frame for this project. This study was carried out in collaboration with the CIRCERB research Chair at Université Laval, and the CEISCE research centre, Finally, the authors are grateful for the technical support of the staff at Université de Sherbrooke structures laboratory.

World Conference on Timber Engineering Oslo 2023

EXPERIMENTAL PARAMETER STUDY ON CLT SHEAR WALLS WITH HIGH-PERFORMANCE SELF-TAPPING SCREW CONNECTIONS

Yuxin Pan[1], Thomas Teflissi[2], Thomas Tannert [3]

ABSTRACT: This paper presents experimental investigations on the performance of Cross-laminated Timber (CLT) shear walls with high-performance self-tapping screw (STS) connections. Hold-down and panel-to-panel connections were tested under monotonic and quasi-static reversed cyclic loading. The derived design values of STS were significantly higher than those calculated using the current Canadian Standard for Engineering Design in Wood. Subsequently, a total of twenty-six CLT shear walls (in single-, double- and triple-panel configurations) were tested under monotonic and quasi-static reversed cyclic loading. The shear walls consisted of 5-ply, 139 mm thick and 3 m high CLT panels with aspect ratio of either 2:1 or 3:1, and different numbers of STS in the connections. The shear wall strength and corresponding displacements increased with the number of screws in hold-downs and spline joints, further it increased with number of connected panels and decreased as a function of aspect ratio.

KEYWORDS: Mass timber; cross laminated timber; self-tapping screws, seismic design

1 INTRODUCTION

High-rise mass timber construction has been successfully re-introduced across North America [1]. The 2020 version of National Building Code of Canada [2] and the 2021 version of the International Building Code [3] have increased the building height limit of mass timber structures up to 12 stories and 18 stories, respectively.

Extensive experimental and analytical research on the seismic performance of Cross-laminated Timber (CLT) shear walls was conducted over the last decade, demonstrating that connections govern their strength, stiffness, ductility, and energy dissipation. A capacity design philosophy is normally employed, where the dissipative components are designed to be ductile and absorb energy while non-dissipative parts are over-designed [4].

However, previous work on self-tapping screws (STS) found connections to be between 2 and 6 times stronger than the design values derived using standard provisions [5]. In consequence, the energy-dissipative connections may be severely over-designed and remain elastic during seismic events. The resulting increased stiffness potentially increases the seismic force demands and put the 'capacity-protected' structural components at risk.

2 OBJECTIVE

In this research, CLT shear walls with high-performance STS connections were investigated to determine the strength, stiffness, yield point, failure point, and ductility of a rocking wall system as a function of the number of STS in the connection, and subsequently develop appropriate and economic design values for the STS.

3 EXPERIMENTAL INVESTIGATIONS

3.1 CONNECTION TESTS

The CLT panels were strength grade 191V2, 5-ply, 139 mm thick. Both HD and SB were made of custom steel plates of grade 44W/300W. The HD was 186 mm wide, 435 mm high, with a 70 mm long base plate, thickness 12.7 mm (vertical part) and 25 mm (base plate). 21 ø13 mm holes were prepared in the vertical part for installing STS; the base plate had 2 ø19 mm holes for installing bolts. The SB was 340 mm wide with a length of the vertical and horizontal plate equal to 127 mm and 89 mm, respectively, and a constant thickness of 6.35 mm. It had 8 ø 11 mm vertical slots, for installing the STS to eliminate any uplift resistance. STS ø12×120 mm were used as fastener for HDs and SBs. The panel-to-panel vertical splines was surface mounted 25×140 mm D-Fir plywood attached with ø8×100 mm STS. Figures 1, 2 and 3 show the drawings for each connection detail.

3.2 SHEAR WALL TESTS

A total of 26 CLT shear walls were assembled and tested, including 4 single panel (SP), 16 coupled panel (CP), and 6 triple panel (TP) walls. The shear walls consisted of 3 m tall CLT panels, either 1.5 m or 1.0 m wide, resulting in aspect ratios of 2:1 and 3:1, respectively, see Figure 4. All wall configurations were tested with two HDs, CP and TP shear walls with one HD on the outside edge of the outside panels. For all configurations, one SB was mounted at the midpoint of each CLT panel. The CP and TP shear walls were coupled vertically using a screwed plywood spline joint on one side. The splines were attached to the panels with either 13, 16, or 19 screws per panel edge side (total 26, 32, 38 screws per spline). All SBs were fully attached to the walls with 8 STS, while the HDs had 9, 11, 13, or 15 screws each. The screw types matched the connection tests.

The lateral loads were applied by a actuator at the top of the left wall panel through a steel plate connected to steel H-beam. The H-beam was placed on two wooden blocks at the center of each panel. A 10 kN/m superimposed vertical gravity load was applied representing a moderately loaded wall in a two-storey system. This gravity load system simultaneously prevented out-of-plane horizontal movements in addition to allowing for the lateral movement of the shear wall.

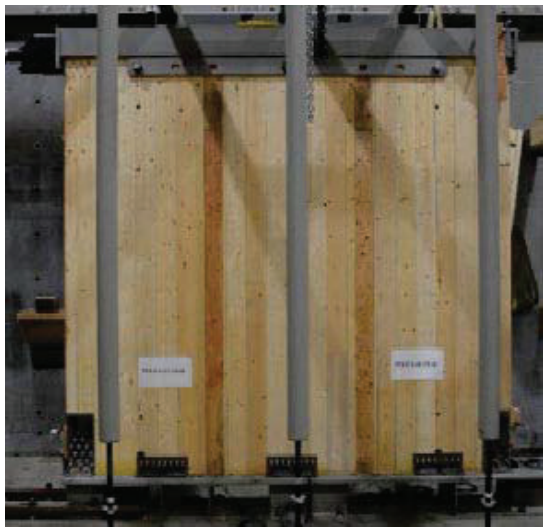

Figure 4: *Full-size triple-panel CLT shear wall tests*

3.3 ANALYSIS

For each connection and shear wall test, the strength, stiffness, displacement, and ductility were determined and analyzed. The maximum forces (load-carrying capacity) from both positive and negative phases (F_{max+} and F_{max-}) were recorded for the reversed cyclic tests. The displacements corresponding to these forces, d_{Fmax+} and d_{Fmax-} were the measurements at the top right corner of the shear walls.

4 RESULTS

4.1 HOLD-DOWN RESULTS

The typical failure mode of the HD was fastener yielding. The corresponding hysteresis behavior of the HD connections combined with a representative monotonic curve are presented in Figure 5. Until reaching capacity, the HD showed little stiffness degradation with increasing displacement. Beyond the capacity, distinct nonlinear degradation and pinching behavior in cyclic re-loading was observed. Throughout the entire loading history, the HDs showed almost the same high unloading stiffness.

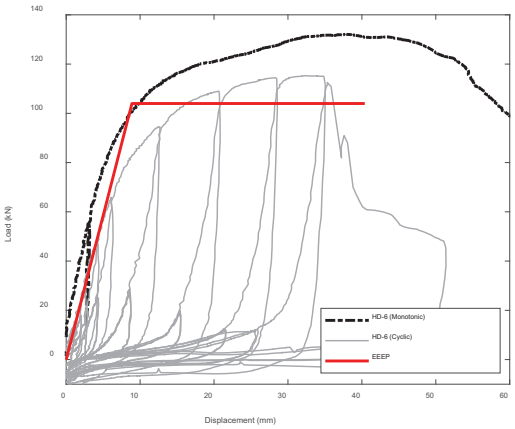

Figure 5: *Typical HD connection hysteresis curve*

4.2 SPLINE RESULTS

The hysteresis behavior of typical spline joints combined with a representative monotonic curve is shown in Figure 6. The curves showed high re-loading stiffness combined with degradation and pinching effects. A small amount of cyclic strength degradation was also observed in the tailing cycles with reduced displacement. Displacement above approximate 30 mm caused brittle failure. Overall, both the strength and displacement capacities under cyclic loading were reduced when compared to monotonic loading. Load-carrying capacity linearly increased with the number of STS. From 2 screws to 8 screws, all strength parameters increased about fourfold regardless of the loading type, e.g. F_{max} increased from 15 kN to 57 kN under monotonic loading and from 11 kN to 46 kN under cyclic loading.

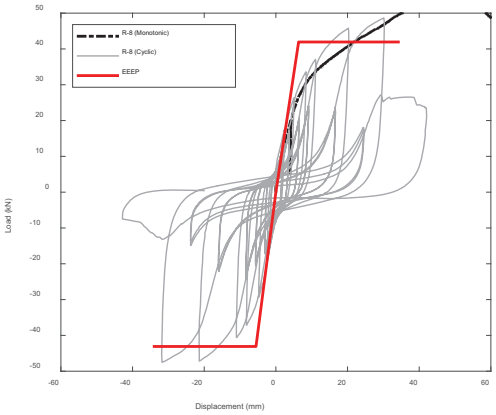

Figure 6: *Typical spline hysteresis curve*

4.3 CONNECTION DESIGN VALUES

Since CSA O86 does not provide any design guidance for STS, the design provisions for lag screws are commonly used by practitioners to calculate the design values. These values are dramatically smaller than the experimental results, see Table 1, confirming that STS in energy-dissipative connections may be severely over-designed and are likely to remain elastic during seismic events. As a consequence, the non-dissipative connections that require capacity protection are also over-designed; however the wood components may no longer be capacity protected.

As an alternative, the test results were used to derive expected performance values: $R_d = k_{mod} \cdot R_k / \gamma_{mod}$, where R_d is the design resistance, R_k is the characteristic value of load-carrying capacity of a single screw, k_{mod} is modification factor taking into account the duration of load and moisture content, and γ_{mod} is the material property factor. Herein, k_{mod} = 0.9 (for short-term action and dry condition) and γ_{mod} = 1.3 were applied. R_k was determined from the test data, assuming that the strength distribution follows a lognormal distribution. The expected performance design values for a single screw in HDs and spline joints were derived using Equation (1) based on $R_{k0.05}$, see Table 5. The design resistance for a single HD screw was 11.8 kN, which was still only 69% of the experimental values, but significantly better than that calculated based on CSA O86 provision (almost 3 times higher). Similarly, the derived resistance for spline joint screw was only 70% of the experimental value but more than 3 times higher than the values based on CSA O86 provisions.

Table 1: *Connection test results*

Connection	Screw Type	Characteristic strength (kN/screw)			Resistance (kN/screw)	
		5th percentile	Mean	95th%	Derived	CSA O86
HD	12Ø×120 ASSY Kombi	17.1	19.4	22.1	11.8	4.1
Spline	8Ø×100 ASSY Eco	4.6	5.0	5.5	3.2	0.9

https://doi.org/10.52202/069179-0270

4.4 SHEAR WALL TEST RESULTS

The effects of four parameters: i) the number of STS in HDs, ii) the number of STS in spline joints, iii) the wall aspect ratio, and iv) the number of panels (SP, CP, TP) on the CLT shear wall performance were investigated. The results are summarized in Table 2; the monotonic load-displacement curves are shown in Figure 7.

Under monotonic loading, the curves were initially linear up to 5 mm displacement when nonlinear behavior started due to plastic deformation in the spline joints connections. After reaching the peak, the curves exhibited a sudden drop because of the HD screws exceeding their capacity.

Figure 7a provides a comparison between SP and CP with different number of STS in HDs (9 vs 15). All shear walls exhibited similar performance at the beginning of loading but reached different load-carrying capacities, F_{max}, as a function of number of STS, following a similar linear relationship observed in HD connection tests. For example, for CP3 and CP1 which had 11 and 15 HD screws, respectively, F_{max} increased from 163 kN to 213 kN (31% increase). The displacement at maximum loads, d_{max}, as well as yield point and failure point were also a function of number of STS.

The impact of the number of STS in the spline joints is illustrated in Figure 7b for CP walls with 13, 16, and 19 STS in the spline and the same HD configuration (9 STS). While the performance of CP4 and CP5 with 19 and 16 screws was similar in terms of strength, displacement, and stiffness, when the number of spline screws was reduced to 13 in CP6, a distinct reduction in performance was observed: when compared with CP4 of 19 screws: F_{max} was reduced by 19%, d_{max} was reduced by 14%,

The significant impact of the panel aspect ratios (2:1 for CP3/5 and 3:1 for CP11/12) on the performance of shear walls with the same connector configuration is shown in Figure 7c. F_{max} for CP3 and CP5 were 23% and 39% higher than those from CP11 and CP 12, respectively.

Finally, the influence of the number of panels for panels with an aspect ratio of 3:1 is illustrated in Figure 7d. Going from CP to TP with the additional SB and spline joint, a higher capacity and stiffness was achieved. F_{max} for TP1 and TP2 were 24% and 42% higher when compared to those from CP11 and CP12

4.5 SHEAR WALL FAILURE MODES

The wall failure modes are presented in Figure 8. All coupled walls exhibited rocking behavior, as seen in Figure 8a. With increasing lateral displacement, some minor plastic deformations occurred in SB, see Figure 8b. Similar to the failure modes observed from connection tests, at the end of each test, the screws in HD were heavily damaged with a failure combination of yielding and withdrawal, and eventually developed plastic hinges, as seen in Figure 8c. Caused by the relative displacement between adjacent panels in the multi-panel tests (CP and TP walls), failure of spline wall-to-wall joints were observed, including screw yielding combined with fracture (TP3), as seen in Figure 8d.

5 CONCLUSIONS

The performance of CLT shear walls with high-performance self-tapping screw connections was investigated under monotonic and cyclic loading. Connection tests and full wall tests were carried out to derive design values of STS. The following conclusions can be drawn:

1) The strength and stiffness of connections were found to linearly increase with the number of screws. The derived design values of STS from the connection tests under short-term cyclic loading were about 3 times higher than those calculated in accordance with the current CSA O86 provisions for lag screws. This shows that STS in energy-dissipating connections are extremely over-designed when designed in accordance with CSA O86 and may not yield as intended.

2) The strength capacity and the corresponding displacement of the shear walls decreased linearly with the reduction of screws in HD. The same trend was also found for the spline joints connections.

3) The aspect ratio had a significant impact on the performance of the coupled shear walls. 2:1 aspect ratios increased load-carrying capacity by 40%, and decreased deformation capacity by 30%.

HORIZONTAL - LOADING TEST OF STEEL BAR-TIMBER COMPOSITE COLUMNS FOR LOW- RISE BUILDING

Yuuto Shimoirisa[1], Takahiro Iju [2], Takao Ohta [3], Kazuya Mori[4], Shinichi Shioya[5]

ABSTRACT: In light of the current climate crisis, there has been much recent interest in using timber structural members in large buildings, and moreover, in severe earthquake prone, such as Japan, they are more desired on the grounds of light weight of timber members. We are developing a frame system formed by timber members reinforced by deformed steel bars (i.e. rebars) using epoxy resin adhesive. The column could produce, in mechanical properties, better performance than those of reinforced concrete structure (RC). This paper reports horizontal-loading experiment of its column specimens, its results. The specimens were modelled for three-storey buildings, i.e., low-rise buildings. Performance of the specimens indicated to be better than that of RC columns with the same size except difference in material between wood and concrete.

KEYWORDS: Composite timber, Column, Deformed steel bar, Moment-resisting connection, Re-centering

1 INTRODUCTION

In light of the current climate crisis, there has been much recent interest in using timber structural members in large buildings, as timber is as renewable natural resource. Cross-laminated timber (CLT) is a typical timber element, however, CLT structural system very often restricts building planning, owing to CLT being a plate member. The demand for a timber structural system of slender beams and columns is high.

S. Shioya has proposed a structural system for building construction, adopting Hybrid Glulam Timber members using Steel bars (HGTSB, nicknamed as “Samurai” in Japan), has developed the structural design methodology, and has constructed the first prototype building, a two-way frame structure using the structural system [1,2].

We are now developing more refined and more commercial competitive structural system for buildings adopting HGTSB and its structural design methodology. This paper reports an experimental loading test of columns for low-rise buildings with three storeys or less.

2 BACKGROUND

A study on rebar-mixed composite timber to improve bending stiffness and strength of timber beam was initialized by Granholm [3]. Also, after then, studies were and have been being conducted by using other materials beside rebar, however, most of the studies focused on only bending stiffness and strength of the composite beams under short-term or long-term loading. Connection between column and beam has nearly never been studied so as to use performance of the composite members, such as moment-resisting connection for rigid frame.

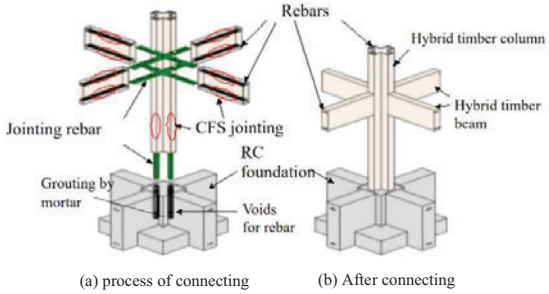

Figure 1: *Beams-column-footing connection*

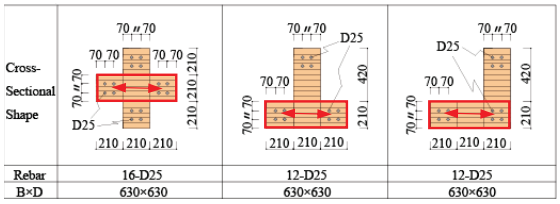

Figure 2: *Representative cross-section of column*

S.Shioya has already developed a technique for rigid connection of rebars inside the composite timber, using carbon fiber plastic sleeve (CFS) and epoxy resin adhesive with works similarly to work process of the glued-in-rod, and reported performance of the column adopted the technique as shown in Figure 1 [2,4].

3 CROSS-SECTIONS OF COLUMN

As Young’s modulus of rebar is approximately 31 times as much as that of timber (Japanese Ceder) by bending, arrangement of rebars nearer the outer on cross-section will produce more increase of bending stiffness and strength. In the panel of connection between column and beam, development length of rebar of beam is required to

be longer for transmission of axial force of the rebar between the composite beam and column.

On the other hand, in general, magnitude of axial force of columns for low-rise buildings is smaller than that for high-rise buildings. Therefore, the column for low-rise buildings is nearly never required comparative large cross-section area.

As a result of considering them, configurations for cross-section of column for low-rise buildings of two-way-frame may be chosen to be +, T, or L-shaped cross-section as shown in Figure 2, while rectangular portion (enveloped by red line in the figure) in the cross-section mainly resists lateral forces. Also, one-way frame may choose only rectangular cross-section according to planning of buildings. S.Shioya reported a loading experiment of one column specimen with + shaped cross-section for low-rise building [2] and two column specimens with square cross-section for middle rise building [4] . This paper reports an experiment of column specimens with rectangular, T, and a new +-shaped cross-sections.

4 EXPERIMENTAL TEST FOR COLUMN WITH RECTANGULAR CROSS-SECTION

4.1 SPECIMEN

Two columns with rectangular cross-section was selected with scale ratio of 2/3. Figure 3 illustrates the specimen. The specimen was modelled, considering connection between RC foundation and HGTSB column on ground floor of building. Area ratio of rebars (8-D16) to column's gross-area (140mm x 400mm) was 2.8%. The column and RC foundation were connected by using the CFS at joint between rebar and jointing rebar at bottom of its column. The column bottom was connected to a reinforced concrete stub. After shaping the hybrid column, heat-resistant epoxy adhesive shown in Table 1 was filled in insertion hole on column bottom for joint rebar, and then the joint rebar ,8 pieces of D16 for this case, were inserted in the holes each to bond the built-in carbon fiber plastic sleeve (CFS) with the joint rebar. After the adhesive hardened, the column bottom and the RC stub were connected by inserting its joint rebars into voids in the RC stub, for anchorage, and then filling non-shrinkage grout into the column bottom-stub gap and the voids of RC-stub simultaneously. Fresh concrete of nominal strength Fc42 was casted for concrete of the RC-stub. Nominal strength of the no-shrinkage grout is 61.3 N/mm^2 at 4 weeks. Glulam timber was prepared according to E65F255 in Japanese Agriculture Standard, and resorcinol-based resin adhesive was used for glulam timber. Table 1 lists Young's modulus and strengths of laminas of timber of which section size was 25×25mm^2; the number was 10; loading was conducted as four-point bending. Strain was measured by foil strain gauges. Moisture content of lamina test pieces was 14.8%, and those density was 0.45g/cm^3. Table 2 lists mechanical properties of rebar by testing. Table 3 lists mechanical properties in the catalogue of the epoxy adhesives used to bond the rebar.

4.2 CARBON FIBER PLASTIC SLEEVE (CFS)

Figure 4 shows shape and dimensions of a CFS used, which is specified for joint rebar/deformed bar D16. Each rebar is inserted through holes at both ends of the CFS; the CFS is filled with epoxy adhesive shown in Table 3 to join both-side rebars in rigid. This joint was confirmed to produce rigid connection, as shown Figure 5. For more information on CFS, please refer to Reference 2 and 4.

4.3 YIELD SECTION OF REBAR

As shown in Figure 6(a) in the next page, the joint rebar is devised to yield at the section between the RC stubs and the CFS, resulting in plastic elongation and contraction only over the section. The wood around the rebar is devised to be such that even if the rebar yields, the wood portion will not crack.

4.4 MECHANISM OF MINIMIZING RESIDUAL DEFORMATION OF COLUMN

As shown in Figure 7(a), yield bending moment/M_y of a column, which yields in bending by tensile rebar yielding, consists of the moment component/${}_sM_y$ borne by the tensile rebar and the moment component/Mn borne by the axial force. The yielded rebar will generate plastic elongational deformation, resulting in plastic rotation angle in column bottom. After unloading, residual deformation occurs in the column due to its plastic rotation angle. In order to reduce the residual deformation, tensile-yielded rebar needs to yield in compression, and the reduction can be achieved by the moment/Mn by axial force. M_n is defined as restoring moment, and ratio of '$M_n/{}_sM_y$' is named as the restoring moment ratio/γ. When γ is larger than 1.0, the residual deformation of column decreases more. Moreover, when residual vibration after maximum response deformation of building during earthquake is taken into account, the plastic rotation angle can decrease even if 'γ' is smaller than 1.0.

4.5 LOADING

Figure 8 shows set-up for loading. The vertical load/F_v was applied to column head; horizontal deformation at horizontal force height was gradually increased; the horizontal force was applied positively and negatively repeatedly, increasing the horizontal deformation. F_v divided by axial force capacity of column/N_u is defined as 'η' (=F_v/N_u); axial force capacity/N_u is assumed to be product of compressive strength/F_c of glulam timber (F_c=20.6N/mm^2) and cross-sectional area of the column (Fc・b・D). b is column width and D is column depth. Figure 9 shows target displacement protocol for lateral loading. Target deformation angle/R_t was calculated by dividing the horizontal deformation by height h_F (=1400 mm).

i) Specimen No.1(R16)

At first, axial force/F_v was maintained to be constant at an axial force ratio/η of 16%, and target deformation angle was gradually increased up to 1/50 rad. This is the first stage. After this, residual displacement was returned to zero and angel/R_t was returned to 1/200 and again R_t was gradually increased up to 1/50. This is the second stage. Additional residual vibration loading was applied at R_t indicated by symbol '●' in Figure 9 to investigate performance of minimizing residual deformation. The application rule for this residual vibration loading is described in the next section. This is the third stage.

After this stage, in order to investigate the performance under unexpected Mega-earthquake, R_t was increased up to 1/30. and loading was repeated three times each. This stage is the fourth stage. After this, the force was applied until fracture of column. This stage is the fifth stage.

ii) Specimens No.2 (R10) and No.2 (R30)

No.2 was one specimen, but No.2 (R10) was assumed to be characteristic during range where horizontal force was applied at η of 10% and No.2 (R30) was done to be that during range where the horizontal force was applied at η of 30%. With setting η being 10%, reversed repetitive loading was applied gradually increasing Rt from 1/400 to 1/50. This stage is the first stage of No. 2 (R10).

After this, the vertical load/F_v was increased to η of 30%; R_t was returned to 1/400.; lateral force was applied repeatedly with R_t gradually increasing up to 1/50. This is the first stage of No.2 (R30). The same process as the first stage was repeated three times, alternating η between 10% and 30%, as shown in Figure 9(b). These processes are the second, third, and fourth stages of No. 2 (R10) and No. 2 (R30), respectively. At the end of the fourth stage, No. 2 had experienced eight cycles of repetitive loading to 1/50. After this stage, with η setting 30%, repetitive loading was applied by increasing R_t to investigate the

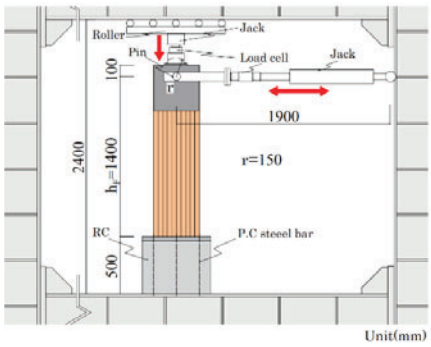

Figure 8: *Set up for loading*

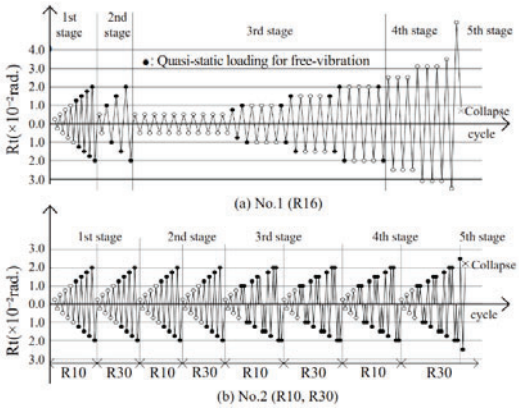

Figure 9: *Target displacement protocol for lateral loading*

performance during unexpected Mega-earthquake until fracture of column. This stage is the fifth stage.

4.6 QUASI-STATIC LOADING FOR FREE-VIBRATION

In order to reveal that residual deformation be minimized after maximum response deformation during an earthquake, quasi-static loading was applied after it reached the target deformation angle/Rt by assuming damped free vibration. For more information of the loading force, please refer to previous reference [4]. Figure 10 schematically shows a hysteresis loop obtained by the loading. Final residual deformation 'δ_F' was taken as the average of 'δ_2' and 'δ_3'.

4.7 MEASUREMENT METHOD

Figure 11 shows set-up for measurement of displacement and strain. Displacement transducer/Disp.1 and Disp.2 were used to measure horizontal deformation between the stub and horizontal force-applied point; Disp.3-Disp.6 were used to measure angle of rotation over hinge region of column bottom; Disp.7and Disp.8 were used to measure shear slip deformation in the loading direction between column bottom and stub surface.

4.8 EXPERIMENTAL RESULTS

4.8.1 Failures and force-deformation relationship

Figure 12 shows final failures. Figure 13 and Figure 14 show horizontal force-deformation angle relationship.

i) No. 1 (R16)

Figure 13(a) shows relationship of the first stage. A tensile rebar yielded at R=+1/137 rad. and bending capacity was almost determined. Figure 13(b) compares loop of the se -cond stage with envelope of the first stage. In the first stage, initial stiffness was maintained up to +75.3 kN at +1/137. In the second stage, the stiffness decreased at 45.1 kN and +1/235. This is due to the Bauschinger effect, as shown in Figure 3(d), where once steel yields, the proportional limit stress decreases in subsequent cyclic loading loops. Figure 13(c) compares envelope over the loops after the third stage with those of the second stage. The envelope of the second stage was almost the same as that of the third stage loops; Figure 13(e) and (f) and (g) show loops at typical target deformation angles. The first loop of the first stage is compared with last loop of the third stage; at R_t=1/100, the proportional limit is reduced as mentioned above; at R_t=1/50, loops of the first and third stages are almost identical. In the third stage, lateral force at Rt=1/400 was applied 10 times, and thereafter, loading was repeated 5 times at each target up to 1/50. When repetitive loading of the first and second stages were added, loading was applied at least seven times from 1/400 to 1/50. Even with such many cyclic loadings, the loops after steel rebar yielded were hardly degraded. Figure 12(a) shows final failures. At the end of the third stage, no damage was observed in timber, and as shown in Figure 12, only thin cracks were observed on the top face of RC stub due to pull-out of joint rebar, and maximum width of cracks was less than 0.3 mm. The damage did not progress at all until the fourth cycle of 1/30. Final fracture occurred at -1/140 to negative direction after the loading was applied up to +1/18.

ii) No.2(R10) and No.2(R30)

Figure 14(a) and (b) show the first stage, in which tensile rebar of No.2(R10) yielded at +1/155. In No.2(R30), force at proportional limit also decreased due to the Bauschinger

effect because the joint rebar of column had already yielded at No.2(R10).

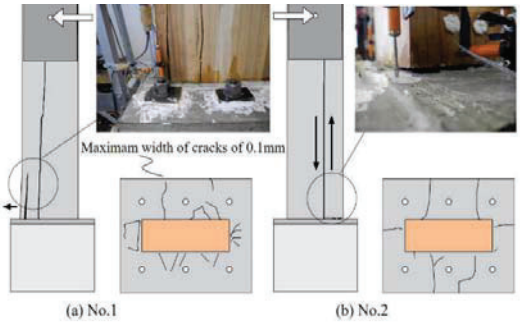

Figure 12: *Observed failures until 5th stage*

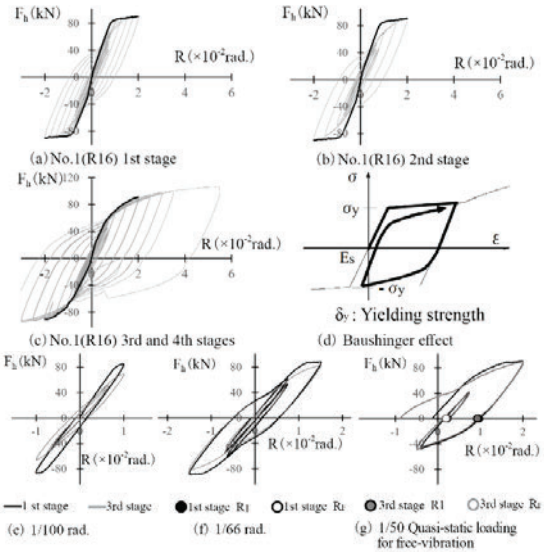

Figure 13: *Lateral force -displacement angle relationship of NO.1*

https://doi.org/10.52202/069179-0271

Figure 14(c) and (d) show the second stage. Envelope of the first stage is shown in comparison with that of the second stage: No.2 (R10) had a lower load at the proportional limit due to the Bauschinger effect; No.2 (R30) had also lower load at the proportional limit in the first stage; envelope of the first and second stages were almost the same in positive loading, and horizontal capacity of the second stage decreased slightly after 1/100 in negative loading.

Figure 14(e)and (f) show a comparison of the third-stage loop and the second-stage envelope; Figure 13(g) and(h) show a comparison of the fourth-stage loop and the third-stage envelope. Envelopes of the third stage almost encircles loops of the fourth stage, and no damage in column occurred after the fourth stage of No. 2 (R30). At the time, the column was subjected to eight cycles of incremental repetitive 1/400-1/50. After this, the fifth stage was applied to confirm final fracture with maintaining axial force ratio η of 30%.

Figure 12(b) shows final failures. The column failed in shear with a vertically crack at the web at +1/45.

From the results of No.1 and No.2 above, it is highly possible to realize a design in which the column connected to RC foundation are subjected to 8 cycles of incremental and repeated loading from 1/400 to 1/50, with axial force ratio η of 10-30%, with little damage and little degradation in loop after joint rebar yielded.

4.8.2 Residual deformation suppression and restoring moment

Figure 13(g) and Figure 14(i) show examples of loops of residual vibration loading at Rt=1/50. Restoring moment ratio γ of each specimen was 0.34 for No.1 (R16), 0.22 for No.2 (R10), and 0.62 for No.2 (R30). Final residual deformation angle/R_F is indicated by symbol '○' according to the method of identifying residual deformation described in Section 4.6. The larger the restoring moment ratio/γ is, the smaller the final residual deformation angle is.

Figure 15 shows variation of residual deformation angle with the target deformation angle/R_t and compares each stage. It can be seen that the angle/R_F decreases from R_1 due to the residual vibration loading, where R_F is deformation/R angle at δ_F in Figure 10(b) and R_1 is the deformation angle at δ_1.

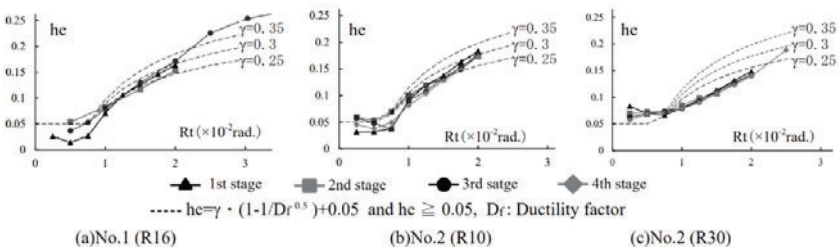

Figure 17: *Equivalent viscous damping factor/ h_e*

https://doi.org/10.52202/069179-0271

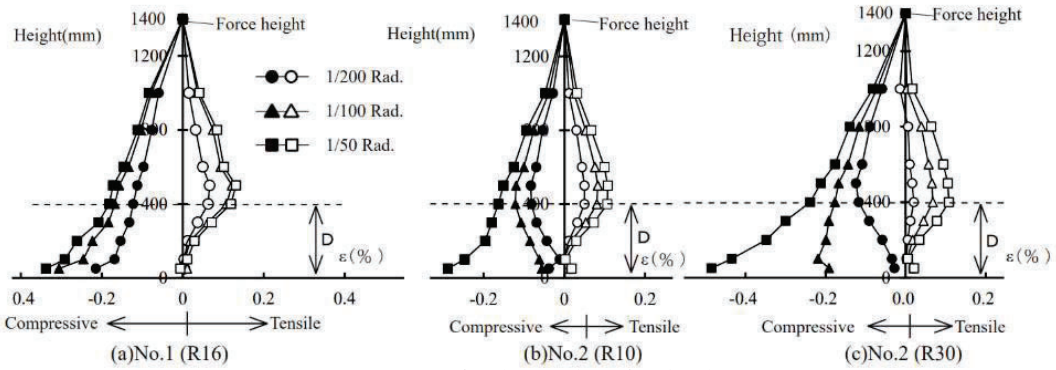

Figure 18: *Strain distribution of wood surface by*

Visually allowable limit angle of 1/400 for the residual deformation angle is shown in the figure as a horizontal, one dot chain line. This value is the upper limit of deformation angle at which column leaning cannot be visually recognized. If γ is greater than 0.34, the residual deformation angle was suppressed to 1/400 or less up to the range where target deformation angle was 1/50 or less.

4.8.3 Dissipated energy and equivalent viscous damping constant

Figure 16 shows variation of the amount of dissipated energy at each target deformation angle loop. Since the dissipated energy is mainly plastic energy by yielding of joint rebar in column, cycles with the same target deformation angle had similar amount in irrespectively of the magnitude of axial force.

Figure 17 shows variation in the equivalent viscous damping constant/h_e of each loop. h_e is smaller for larger values of axial force ratio/η. As h_e is calculated by dividing the amount of dissipation energy of loop by the target deformation and its capacity, larger axial force ratio decreases more the value of h_e. It is necessary to consider the effect of axial force for h_e.

4.8.4 Distribution of strain in column by bending

Figure 18 shows distribution of vertical strain of wood surface by bending. On the compressive surface, the strain distribution increased at the column bottom. On the tensile surface, distribution of strain increases downward from force applied point of column head and decreased to zero from a height of 400 mm to column base. The range is demonstrated not to adhere to the assumption of the plane section used for calculation of bending capacity and stiffness.

4.8.5 Estimation for stiffness and bending capacity

Elastic stiffness was calculated for three cases shown in Figure 19. The column bottom was assumed to be fixed-ended; Cal.1 in Figure 19(a) was calculated using the cross-sectional secondary moment/E_wI_e including the rebar. Cal.2 in Figure 19(b) was calculated using the flexural stiffness E_wI_w of Glulam timber column by ignoring rebar. Cal.3 in Figure 19(c) was calculated by dividing the hinge of column bottom into two half section, with the bending stiffness of the half section on the base side as bending stiffness/E_sI_s resisted by only joint rebar and bending stiffness of the upper half section as average of bending stiffness /E_wI_e of the composite column and E_sI_s. The reduction of tensile strain of wood near the

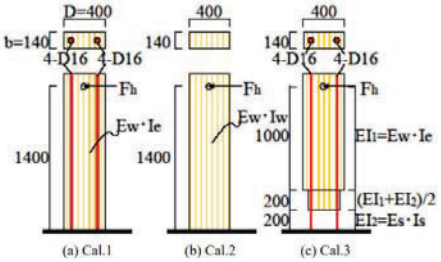

Figure 19: *Assumed bending stiffness for calculations*

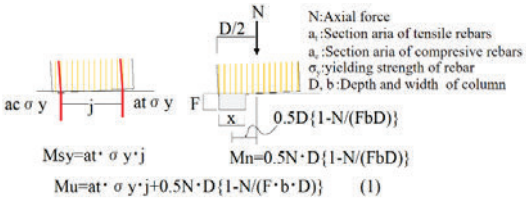

Figure 20: *Stress assumed for ultimate bending moment*

column bottom in Figure 18 was taken into account. Length of the hinge was assumed to be 400 mm of column depth. This is Cal.3. Shear deformation was considered as resisted by the cross-section of timber, with a shape factor of 1.2 and ignoring the rebar. Shear modulus of elasticity of wood was assumed to be 800 N/mm^2 referring to the shear strain in Figure 11(c). Young's modulus for timber and rebar were based on material test. Figure. 21(a) shows loops of horizontal load -deformation angle relationship for No. 1 (R16); the calculated elastic stiffnesses are indicated as straight lines of thick, thin and one dot chain line. The experimental elastic stiffness is between Cal.1 and Cal.2 and close to the elastic stiffness of Cal.3. Figure 21(b) compares those of calculation with the envelope up to joint rebar yielding. On the positive loading, the stiffness by Cal.3 estimates experimental stiffness, while, on the negative loading, the experimental stiffness is somewhat larger. The load-deformation angle relationship calculated by replacing wood of specimen with concrete of compressive strength/Fc(30N/mm^2) is shown in the figure by one dot chain line. The column base was assumed to be fixed ends, taking into account rebar for the bending stiffness of column. The stiffness of RC column is greater until flexural crack occurs, after which The stiffness decreases and approaches that of the specimen. It can be confirmed that the stiffness of the composite columns is close to that of RC column. The capacity was determined by dividing the bending capacity moment/M_u

https://doi.org/10.52202/069179-0271

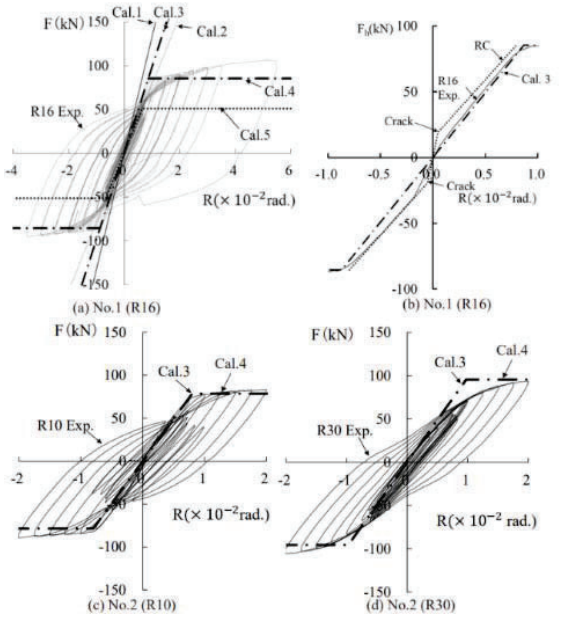

Figure 21: *Skeleton curves of experiment loop and calculation*

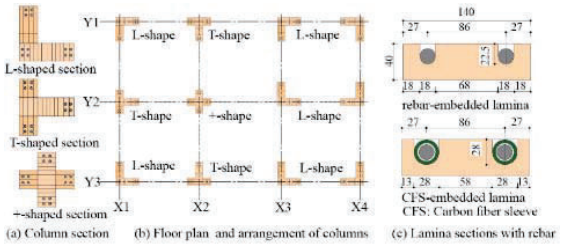

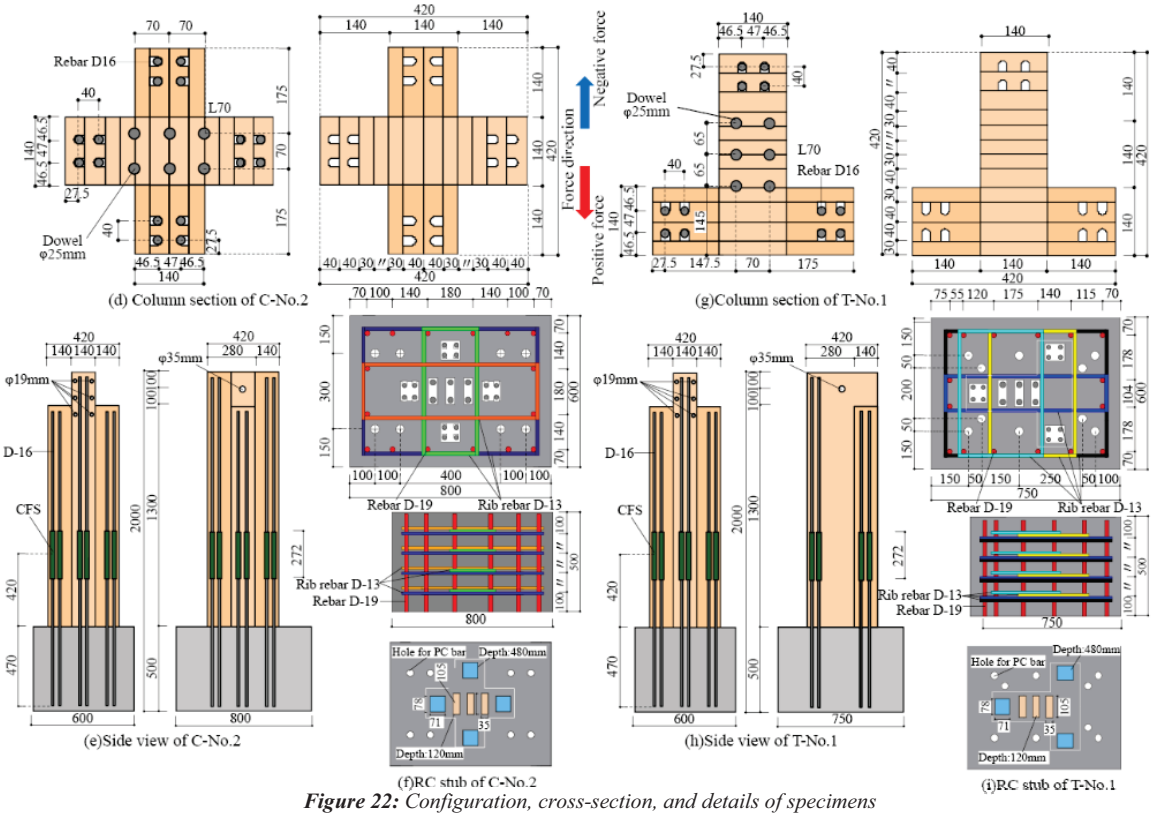

Figure 22: *Configuration, cross-section, and details of specimens*

by the horizontal loading height (h_F=1400 mm) where the joint rebar of column bottom yields, as shown in Figure 20. Sum of bending moment/M_{sy}, which can be resisted by joint rebar in yielding, and bending moment/M_n, which can be resisted by axial force/N and compressive zone of wood. This capacity is Cal.4. Yield strength of rebar was taken as a material test value and compressive strength/F_c of timber was taken as 22.5 N/mm^2, which is a standard value for timber. It can be seen in Figure 21(a) that the calculated capacity almost estimates the capacity at which the rebar yields.

In Figure 21(a), bending capacity of Glulam timber column in Figure 19(b) is shown by horizontal dotted line, where the timber is assumed to reach its bending capacity at column bottom. This is Cal.5. The yield capacity of the specimen is 167% of Cal.5, confirming that connection capacity for the composite column base is extremely high. Figure 21(c) and 21(d) show No. 2; in Figure 21(d), R30 experienced the loading up to 1/50 at No.2(R10) and then started the loading, so that the stiffness of column was reduced before yielding due to the Bauschinger effect and the experimental stiffness was smaller than the calculated relationship. Excluding this, it can be found that skeleton curve by Cal. 3 and Cal. 4 can estimate roughly skeleton curve of experimental force-deformation angle loops.

5 LOADING TEST FOR COLUMN WITH + AND T -SHAPED CROSS-SECTION

As described in Chapter 3, in low-rise buildings, there are three possible shapes of column cross-sections in terms of

https://doi.org/10.52202/069179-0271

architectural plan, as shown in Figure 22(a); L-shaped section column alone, as seen between the X3-X4 axes in Figure 22(b), can constitute a two-way rigid frame.
The L-section column is desirable because of the fitting of column and wall and because of the efficiency of the use of room and corridor.
The L-section column also have the advantage of having only one secondary bonding surface in production.
However, L- section column is difficult to apply in loading test due to eccentricity. If the floor slab is provided for the entire building, effect of the eccentricity in the column is negligible small and therefore, the mechanical performance of the L-shaped column in building will approach that of T-shaped section column.
In this study, it was determined to investigate performance of T-shaped section column specimen.
A horizontal loading test have already been carried out on +-shaped section columns subjected to strong-axis bending of Glulam timber to reveal their elasto-plastic characteristics [2]. This horizontal loading test were carried out on a +-shaped section column subjected to weak-axis bending and a T-shaped section column to investigate the elastic-plastic properties, and the method for estimating the skeleton curve of horizontal load-deformation angle relationship was discussedd.

5.1 SPECIMEN

Figure 22(d)-(i) show cross-sections, shapes, and dimensions of specimens. The number of specimens was two: one with a + shaped cross-section (C-No.2) and the other with a T-shaped cross-section (T-No.1). The height of force point was 1400 mm. Scale of specimen was approximately 2/3 of actual dimensions. The columns were manufactured by first gluing together a rectangular section of 140 x 420 mm (hereafter referred to as the main section) and a square section of 140 x 140 mm (hereafter referred to as the orthogonal 'Part A'), and then gluing these sections together into a +-shaped cross-section and a T-shape section. The +- shaped section column had a total rebar area ratio p_g of 3.24% and a tensile rebar area ratio p_t of 1.62%; the T-section column had a total rebar area ratio p_g of 2.43% and a tensile rebar area ratio p_t of 1.62%. The connection of RC stub and column bottom and the yield length of rebar was the same as in Section 4.3. Glulam timber was JAS cedar laminated timber of the same grade E65F255 (with finger joints) and adhesive for gluing was resorcinol-based resin. Table 5(a) lists mechanical properties of lamina by testpieces. Table 5(b) lists mechanical properties of rebar by testpieces.

5.2 LOADING AND MEASUREMENT

Method and system for loading were the same as in Figure 8. The axial force on column was chosen to be 194 kN as the axial force ratio η of 10%, while axial force on the T-shaped section column was chosen to be 121 kN as the axial force ratio η of 6%. The axial capacity N_u is the product of the compressive strength F_{wc} (20.6 N/mm²) of standard strength of Glulam timber and the gross cross-sectional area of timber in the column. The deformation angle is the same as Section 4.5.

5.3 EXPERIMENTAL RESULTS

Figure 25 shows final failures and Figure 26 shows the horizontal load-deformation angle relationship of column in the first stage.
i) +-shaped section column (C-No.2)
Under positive loading, rebar in tensile side yielded in tension at +1/118 at +95.0 kN (Y_{t1}), while rebar in compressive side also yielded in compression (Y_{c1}). After this, the second-tier rebar in the tensile side yielded in tension at +1/100 rad., +99.4 kN (Y_{t2}) and the second-tier rebar in the compressive side yielded in compression at +1/78, +105.0 kN (Y_{c2}). These points are shown in Figure 26. After the rebars yield, horizontal stiffness decreased and the load increased at a constant stiffness, i.e., the secondary stiffness. This is seemed to be due to the rebar in Part A still being in elastic and the stiffness of wood in compression. At the peak of the cycle (+121.4 kN, +R=1/57) when the target deformation angle/Rt was +1/57., strain of rebar in the tensile side of Part A was 1743 μ and it had not yielded yet. At R=-1/59 , -125.5 kN on the negative loading, as shown in Figure 25(a), a vertical crack occurred in the Part A near the border with the main section, and then load dropped rapidly. This was the time of maximum load. At this time, strain of the rebar in the main section was 1804μ and it had not yielded yet. From these results, it can be concluded that the specimen failed in shear before the column bottom reached ultimate bending capacity. It is explained that the rebar in the orthogonal sections increased bending capacity and increased shear force of column, and, as a result, shear failure occurred. After this, the column split in two by the

https://doi.org/10.52202/069179-0271

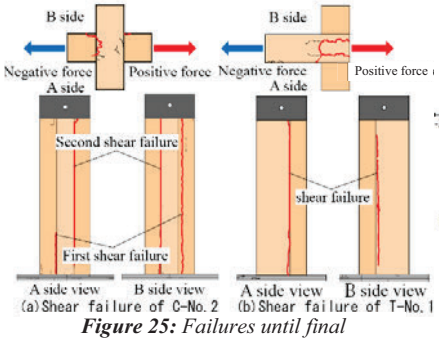

Figure 25: *Failures until final*

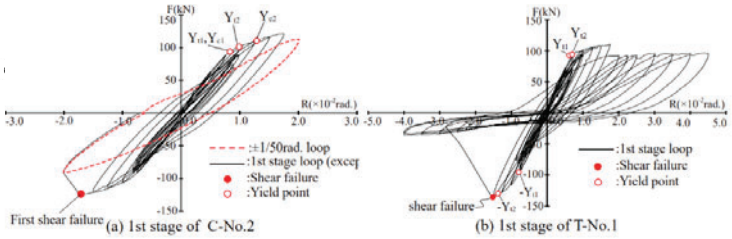

Figure 26: *Lateral force-displacement angle relationship of 1st stage*

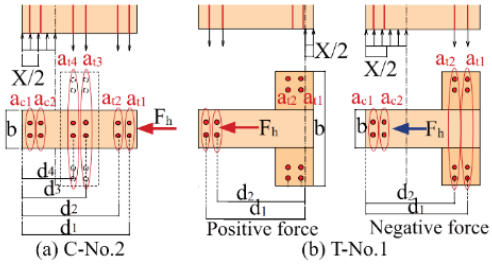

Figure 28: *A model for C-No.2 and T-No.1 at bending capacity*

vertical crack and resisted horizontally and exhibited horizontal capacity and provided a stable loop up to ±1/50 rad. After this, residual deformation was returned to 0.0 mm, and the second stage of loading was applied repeatedly by gradually increasing the target deformation angle from ±1/200 to ±1/50.

Figure 27(a) compares loops of the second stage (solid black line) with the final ±1/50 loop of the first stage (red dotted line). The black loops are enveloped by the red dashed loop, and after the vertical cracking, a stable loop was exhibited by the segmented elements. Figure 27(b) and (c) show loop of the third stage and the loop of the fourth stage at R_t=±1/50. The red dashed loop is the same as those in Figure 27(a).

In Figure 27(b), the loop of R_t=1/50 exhibited almost no deterioration, and in Figure 27(c), it exhibited +114.5 kN up to R_t=+1/33 on positive loading. However, immediately after that, at +100.6 kN during unloading, new vertical cracks occurred as shown in Figure 25(a). After this, the stiffness and capacity decreased in both negative and positive loading, and the capacity was +68.2 kN in the positive loading and -76.3 kN in negative loading. The column resisted as three separated elements and exhibited stable loops up to R=+1/22 such that they could resist the vertical load until the final deformation. Because of the presence of rebars within the divided elements, they could resist to axial forces and a constant horizontal force, even when split by shear failure.

(b) T-shaped section column

On the positive direction, the first outer rebar in tensile side yielded in tension at R=+1/123 at +97.8 kN 'Y_{t1}' and the second rebar in tensile side yielded in tension at R=+1/113 at 98.2 kN 'Y_{t2}'. At this, it can be judged that bending capacity had almost been reached. After this, the load increased with a constant and gradual stiffness, which might be caused by the elastic resistance of the rebar near the tensile side among the two-tier rebar in the flange of the T-section.

On the negative direction, the first rebar in the tensile side yielded in tension at R=-1/117 '-Y_{t1}', and the second-tier rebar yielded in tension at Rt=-1/65, -134.7kN, slightly exceeding yielding strain/ 'Yt_2'. Compressive yielding of rebar in the compression could not be judged from strain gauge values because the rebar had already yielded on the positive direction. Immediately after this, as shown in Figure 25(b), vertical cracks occurred so that the orthogonal section (Part A) and the main section were separated, resulting in a sudden drop in load.

It can be judged that the specimen, on the negative loading, failed in shear just before reaching the bending capacity. After this, the two separated elements resisted as a column, respectively, and capacity on the positive loading was +94.8 kN. The negative load capacity was -34.5 kN.

Even with T-shaped cross-section, care should be taken in design of the column because the bending capacity increases in the direction of loading in which the orthogonal columns are in tension, resulting in shear failure due to the increased shear force.

5.3.1 Elastic stiffness

As well as the calculation in Section 4.8.5, a hinge section in the column bottom was assumed to be column depth of 420 mm.

5.3.2 Yield bending capacity

Equation (1) in Figure 20 can be modified to apply to + and T-shaped cross-sections as follows. Figure 28 shows symbols for assumed cross-sections and dimensions.

$$M_r=\Sigma\alpha_i \cdot a_{t\,i} \cdot \sigma_y \cdot j_i \quad (2)$$

$$M_n=0.5 \cdot N \cdot D \cdot (1-X) \quad (3)$$

$$M_u=M_r + M_n \quad (4)$$

where, $a_{t\,i}$, $a_{c\,i}$: Gross cross-sectional area of rebar in each tier as tensile rebar or compressive rebar, σ_y : yield strength of rebar, α_i : Adjustment factor for stress at bending capacity, j_i : Distance from the centroid of the combined compressive forces to each rebar tier, $j_i=d_i-X/2$, X: Depth of the bending and compressive zone

$$X=(N +\Sigma \alpha_i \cdot a_{t\,i} \cdot \sigma_y - \Sigma a_{ci} \cdot \sigma_y)/(F_{wc} \cdot b) \quad (5)$$

https://doi.org/10.52202/069179-0271

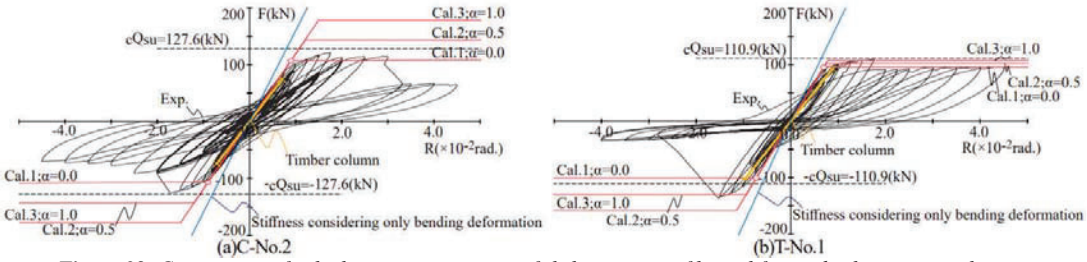

Figure 29: *Comparison of calculation to experiment of skeleton curve of lateral force- displacement angle*

5.3.3 Calculation and Experimental Result

Figure 29 shows a comparison of the calculated result of the skeleton curve and the experimental loops. Initial stiffness was calculated separately for bending and shear deformation. Material test values were used for wood and rebar.

(a) Elastic stiffness

The bending stiffness, assuming the plane cross-section, was calculated for total cross-section area, taking rebar into account. The shear modulus of wood was assumed to be 812 N/mm^2 and the shape factor of shear deformation to be 1.68. The shear resistance area is the horizontal cross -section area of the main cross-section of the wood, the column bottom and in the section from the column head down to column depth. The intermediate section between those were assumed to be the cross-section area of the full cross-section, including the orthotropic sections.

Initial stiffness with only the bending deformation component is shown by blue solid line. The relationship with red solid line shows that added shear deformation. By considering shear deformation, the initial stiffness of both specimens has been accurately estimated by the model shown in Figure 19.

(b) Yielding capacity

+-shaped section columns were assumed to be tension-yielded or compression-yielded, with four two-tier rebar groups on either side of the main section, concentrated at the centroid of each group. The αi in Equation (5) for rebar is assumed to be values at range of 0.0-1.0; the eight rebars in the orthogonal section were also concentrated in the center of the column cross-section. The calculated capacity with αi =0.0 is indicated by symbol '○' as yielding capacity. Shear force was calculated by dividing the yield moment by the height from the loading point to base. Both positive and negative capacities were approximately estimated. After yielding, the column attempted to reach Cal. 3 capacity, i.e. αi=1.0, but it was seemed its shear force had reached the shear capacity and then shear failure has occurred.

The number of rebars resisting in tension in T-shaped section column depends on direction of loading. For positive loading, the two-tier rebar in tensile side were assumed to yield and the α_i of the third rebar in the flange at the orthogonal section was assumed to 0.0, 0.5 and 1.0, where compressive reinforcement bars were neglected. On the negative loading, four rebars in the first-second tiers from the compressive side in the main section were assumed to yield in compression, the first-tier rebar from the tensile side was assumed to yield and α_i was set to 0.0, 0.5 and 1.0 to the second-tier rebar. Yield capacity ○ with α_i being to 0.0 approximately estimates capacity at the positive and negative proportional limits of the experiment. The column width/b was assumed to be 420 mm for the positive loading and 140 mm for the negative loading. In the future, we are going to investigate a method for estimating the shear capacity.

6 CONCLUSION

Horizontal loading tests were conducted on rectangular ,+, and T-shaped cross-sectional columns of which bottoms were planned to yield by bending, assuming the first floor of low-rise building consisting of rigid joined frame using HGTSB, and the elasto-plastic behavior of the column was clarified. The results are summarized below.

1) The horizontal stiffness and the bending capacity of the column was higher than those of ordinary glulam timber column with its same cross-section assuming that the column bottoms were fixed-end.
2) When the column axial force ratio was less than 0.25, they were hardly damaged even after subjected many times, of which one is cyclic loading from 1/400 to 1/50. After joint rebars of the column bottom yielded, its loops were shaped to exhibit abundant energy dissipation. The only degrading property was the reduction in bending moment of the proportional limit, due to the Bauschinger effect that occurs after the rebar yield.

EVALUATION OF VIBRATION PROPERTY OF HIGH-DAMPING TWO-STORY TIMBER STRUCTURE BASED ON RESONANCE CURVE

Yuji Miyazu[1]

ABSTRACT: This paper aims to evaluate the vibration property of a two-story timber structure which has energy dissipation devices to enhance the seismic performance. Oil dampers and friction dampers are considered as the energy dissipation devices in this study. Steady-state response of a two-degree-of-freedom system which has the nonlinear springs with the force-deformation relation of timber structure and the dampers is derived by using the equivalent linearization technique and the sequential quadratic programming. Through the comparison of the resonance curves of the models with/without dampers, it is found that the friction damper reduces the story drift mainly around the first mode while the oil damper works to decrease the story drift both around the first and the second modes.

KEYWORDS: Steady-state response, Resonance curve, Two-story timber structure, High-damping structure

1 INTRODUCTION

Recent years in Japan, energy dissipation devices such as oil dampers and friction dampers are widely used to enhance seismic performance of low-rise timber buildings, especially two-story wooden houses. In some previous researches, the effectiveness of installing energy dissipation devices into timber structures is evaluated numerically through time history seismic response analysis; however, it is also important to investigate the effect of dampers theoretically based on dynamics of structures in order to discuss the vibration property of timber structure that have energy dissipation devices.

The author derived steady-state response of a single-degree-of-freedom system which has a nonlinear spring of ENCL model [1] and viscous and friction elements as energy dissipation devices by using Caughey's equivalent linearization technique [2] in the previous work [3]. In this paper, the steady-state response of a two-degree-of-freedom system are derived in a same manner as the previous method [3] and discuss the vibration property based on resonance curves.

At first, a force-deformation relation model and analysis models used in this study are summarized in Chapter 2. Then, the steady-state response of the two-degree-of-freedom system are derived by using Tajimi's [4] and Caughey's methods [2] in Chapter 3. Finally, the vibration property of a two-story timber structure with energy dissipation devices are discussed in Chapter 4.

2 FORCE-DEFORMATION RELATION OF TIMBER STRUCTURE AND ANALYSIS MODEL

The force-deformation relation of a timber structure is simulated by an extended normalized characteristic loop model (ENCL model) [1] expressed by Eq. (1). $L_1(x)$ and $L_2(x)$ are loading and unloading curves, respectively. The variable x is the deformation normalized by the maximum deformation of the hysteresis loop. A, B, n_1, and n_2 are the parameters which control the shape of the hysteresis loop.

$$\left.\begin{aligned} L_1(x) &= \mp Ax^4 + Bx|x|^{n_1} + (1-B)x \pm A \\ L_2(x) &= \pm Ax^4 + Bx|x|^{n_2} + (1-B)x \mp A \end{aligned}\right\} \quad (1)$$

A represents the force at a y-intercept, and an absorbing energy increases with the increase of the value of A. B controls the slip behaviour of the loop, and a tangent stiffness decreases with the increase of the value of B. n_1 and n_2 control the curvature of the loading and unloading curves, and the curvature increases with the increase of the values of n_1 and n_2.

In this paper, these parameters are adjusted to simulate the force-deformation relation obtained through the static cyclic loading test on the timber beam and column frame combined with plywood panel [5]. Figure 1 shows the force-deformation relation simulated by ENCL model, and its parameters are listed in Table 1. The deformation and the force are expressed by μ and r, and these values are normalized by the deformation and the force at 1/360 rad, respectively.

Figure 2 illustrates the composition of the analysis models used in this study. The Basic model is the two-degree-of-freedom system which has nonlinear springs with the ENCL model and dashpots representing the inherent structural damping. The VD model has additional dashpots (Dashpot 2) to consider the viscous force added by oil dampers. The FD model has elastic-perfectly plastic springs (EPP springs) which express the stiffness and the friction force added by friction dampers.

Figure 2: *Composition of analysis models*

3 STEADY-STATE RESPONSE

The equation of motion is formulated as Eq. (2) using story deformation represented by u_1 and u_2 for the first and the second stories, respectively.

$$\left.\begin{aligned} &m_2\left(\ddot{u}_2+\ddot{u}_1\right)+\left(c_2+c_{\mathrm{d}2}\right)\dot{u}_2+k_2Q_2=-m_2\alpha\cos pt \\ &m_2\ddot{u}_2+\left(m_1+m_2\right)\ddot{u}_1+\left(c_1+c_{\mathrm{d}1}\right)\dot{u}_1+k_1Q_1=-\left(m_1+m_2\right)\alpha\cos pt \end{aligned}\right\} \tag{2}$$

where m_i is the mass of ith node, c_i is the viscous damping coefficient of the ith story related to inherent damping of timber structure, $c_{\mathrm{d}i}$ is the viscous damping coefficient added by oil dampers in the ith story, k_i is the stiffness of the ith story, Q_i is the function of restoring force of the ith story, α is the magnitude of an excitation, and p is the circular frequency of the excitation. Here, we approximate the solution of Eq. (2) as follows.

$$u_i=\mu_i\cos\left(pt-\varphi_i\right)\qquad\left(i=1,2\right) \tag{3}$$

The restoring force of ith story is approximated as follows by using Caughey's equivalent linearization technique.

$$k_iQ_i=k_i\left(k_{ei}u_i+c_{ei}\dot{u}_i\right) \tag{4}$$

where

$$k_{ei}=C_i,\quad c_{ei}=-\frac{S_i}{p} \tag{5}$$

C_i and S_i in Eq. (5) are the values defined in the Caughey's equivalent linearization technique, and they are calculated as the summation of the values of ENCL and EPP springs as formulated in Eq. (6).

$$\begin{aligned} C_i&=C_{i_\mathrm{ENCL}}+C_{i_\mathrm{EPP}} \\ S_i&=S_{i_\mathrm{ENCL}}+S_{i_\mathrm{EPP}} \end{aligned} \tag{6}$$

C_{i_ENCL} and S_{i_ENCL} are calculated by Eq. (7) which was derived in the previous study [3].

$$\begin{aligned} C_{i_\mathrm{ENCL}}&=\frac{2}{\mu_i\pi}\left[\int_{-\frac{\pi}{2}}^{0}r_iL_1\left(\cos\theta\right)\cos\theta d\theta\right. \\ &\qquad\left.+\int_{0}^{\frac{\pi}{2}}r_iL_2\left(\cos\theta\right)\cos\theta d\theta\right] \\ &=\frac{2r_i}{\mu_i\pi}\left\{\frac{\sqrt{\pi}}{2}\left(\frac{\Gamma\left(\frac{n_1+3}{2}\right)}{\Gamma\left(\frac{n_1+4}{2}\right)}+\frac{\Gamma\left(\frac{n_2+3}{2}\right)}{\Gamma\left(\frac{n_2+4}{2}\right)}\right)B+\frac{\pi}{2}\left(1-B\right)\right\} \\ S_{i_\mathrm{ENCL}}&=\frac{2}{\mu_i\pi}\left[\int_{-\frac{\pi}{2}}^{0}r_iL_1\left(\cos\theta\right)\sin\theta d\theta\right. \\ &\qquad\left.+\int_{0}^{\frac{\pi}{2}}r_iL_2\left(\cos\theta\right)\sin\theta d\theta\right] \\ &=\frac{2r_i}{\mu_i\pi}\left\{-\frac{8}{5}A+\frac{1}{2}\left(\mathrm{B}\left(1,\frac{n_2+2}{2}\right)-\mathrm{B}\left(1,\frac{n_1+2}{2}\right)\right)B\right\} \end{aligned} \tag{7}$$

C_{i_EPP} and S_{i_EPP} are calculated by Eq. (8) based on the method proposed by Caughey [6].

$$C_{i_\mathrm{EPP}}=\begin{cases}\dfrac{F_i}{\mu_{yi}\pi}\left(\theta^*-\dfrac{\sin2\theta^*}{2}\right) & \mu_i>\mu_{yi} \\ \dfrac{F_i}{\mu_{yi}} & \mu_i\le\mu_{yi}\end{cases} \tag{8}$$

$$S_{i_\mathrm{EPP}}=\begin{cases}\dfrac{-F_i}{\mu_{yi}\pi}\sin^2\theta^* & \mu_i>\mu_{yi} \\ 0 & \mu_i\le\mu_{yi}\end{cases}$$

where $\theta^*=\cos^{-1}\left(1-2\mu_{yi}/\mu_i\right)$, F_i is the ratio of the yield force of the EPP spring to the force of the ENCL model in the ith story at 1/360 rad. μ_{yi} is the yield deformation of the EPP spring in the ith story. By substituting Eqs. (3) and (5) for Eq. (4), and by replacing $pt-\varphi_i$ with θ_i, the restoring force of the ith story is expressed as follows.

$$k_iQ_i=k_i\mu_i\left(C_i\cos\theta_i+S_i\sin\theta_i\right) \tag{9}$$

First, we replace $pt-\varphi_2$ with θ_2 in Eq. (3) to obtain Eq. (3').

https://doi.org/10.52202/069179-0272

$$u_1 = \mu_1 \cos(\theta_2 + \varphi_2 - \varphi_1), \quad u_2 = \mu_2 \cos\theta_2 \tag{3'}$$

By substituting Eqs. (3') and (9) for the upper equation of Eq. (2), we obtain Eq. (2').

$$\begin{aligned} &-p^2 m_2 \{\mu_2 \cos\theta_2 + \mu_1 \cos\theta_2 \cos(\varphi_2 - \varphi_1) - \mu_1 \sin\theta_2 \sin(\varphi_2 - \varphi_1)\} \\ &-(c_2 + c_{d2}) p \mu_2 \sin\theta_2 + k_2 \mu_2 (C_2 \cos\theta_2 + S_2 \sin\theta_2) \\ &= -m_2 \alpha (\cos\theta_2 \cos\varphi_2 - \sin\theta_2 \sin\varphi_2) \end{aligned} \tag{2'}$$

Since Eq. (2') is an identity, we obtain the following relations.

$$\begin{aligned} &-p^2 m_2 \{\mu_2 + \mu_1 \cos(\varphi_2 - \varphi_1)\} \\ &\qquad + k_2 \mu_2 C_2 = -m_2 \alpha \cos\varphi_2 \end{aligned} \tag{10-1}$$

$$\begin{aligned} &p^2 m_2 \mu_1 \sin(\varphi_2 - \varphi_1) - (c_2 + c_{d2}) p \mu_2 \\ &\qquad + k_2 \mu_2 S_2 = -m_2 \alpha \sin\varphi_2 \end{aligned} \tag{10-2}$$

By multiplying $-i$ to Eq. (10-2) and adding it to Eq. (10-1), we obtain Eq. (11).

$$\begin{aligned} &-p^2 \mu_1 e^{-i\varphi_1} \\ &+\left[-p^2 + \frac{c_2 + c_{d2}}{m_2} pi + \frac{k_2}{m_2}(C_2 - iS_2)\right] \mu_2 e^{-i\varphi_2} = -\alpha \end{aligned} \tag{11}$$

Next, we replace $pt - \varphi_1$ with θ_1 in Eq. (3) to obtain Eq. (3'').

$$u_1 = \mu_1 \cos\theta_1, \quad u_2 = \mu_2 \cos(\theta_1 + \varphi_1 - \varphi_2) \tag{3''}$$

By substituting Eqs. (3'') and (9) for the lower equation of Eq. (2), we obtain Eq. (2'').

$$\begin{aligned} &-p^2 m_2 \mu_2 \{\cos\theta_1 \cos(\varphi_1 - \varphi_2) - \sin\theta_1 \sin(\varphi_1 - \varphi_2)\} \\ &-(m_1 + m_2) p^2 \mu_1 \cos\theta_1 - (c_1 + c_{d1}) p \mu_1 \sin\theta_1 \\ &+ k_1 \mu_1 (C_1 \cos\theta_1 + S_1 \sin\theta_1) \\ &= -(m_1 + m_2) \alpha (\cos\theta_1 \cos\varphi_1 - \sin\theta_1 \sin\varphi_1) \end{aligned} \tag{2''}$$

Since Eq. (2'') is also an identity, we obtain the following relations.

$$\begin{aligned} &-p^2 m_2 \mu_2 \cos(\varphi_1 - \varphi_2) - (m_1 + m_2) p^2 \mu_1 \\ &\qquad + k_1 \mu_1 C_1 = -(m_1 + m_2) \alpha \cos\varphi_1 \end{aligned} \tag{12-1}$$

$$\begin{aligned} &p^2 m_2 \mu_2 \sin(\varphi_1 - \varphi_2) - (c_1 + c_{d1}) p \mu_1 \\ &\qquad + k_1 \mu_1 S_1 = (m_1 + m_2) \alpha \sin\varphi_1 \end{aligned} \tag{12-2}$$

By multiplying $-i$ to Eq. (12-2) and adding it to Eq. (12-1), we obtain Eq. (13).

$$\begin{aligned} &\left[-p^2 + \frac{c_1 + c_{d1}}{m_1 + m_2} pi + \frac{k_1}{m_1 + m_2}(C_1 - iS_1)\right] \mu_1 e^{-i\varphi_1} \\ &\qquad - \frac{m_2}{m_1 + m_2} p^2 \mu_2 e^{-i\varphi_2} = -\alpha \end{aligned} \tag{13}$$

Equations (11) and (13) can be written in matrix form in the same manner as Kikuchi et al [7]:

$$\begin{Bmatrix} \mu_1 e^{-i\varphi_1} \\ \mu_2 e^{-i\varphi_2} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}^{-1} \begin{Bmatrix} -\alpha \\ -\alpha \end{Bmatrix} \tag{14}$$

where

$$\begin{aligned} A_{11} &= -p^2 \\ A_{12} &= -p^2 + \frac{c_2 + c_{d2}}{m_2} pi + \frac{k_2}{m_2}(C_2 - iS_2) \\ A_{21} &= -p^2 + \frac{c_1 + c_{d1}}{m_1 + m_2} pi + \frac{k_1}{m_1 + m_2}(C_1 - iS_1) \\ A_{22} &= -\frac{m_2}{m_1 + m_2} p^2 \end{aligned}$$

The story drift μ_i is expressed by Eq. (15).

$$\begin{Bmatrix} \mu_1 \\ \mu_2 \end{Bmatrix} = \frac{\alpha}{|A_{11}A_{22} - A_{12}A_{21}|} \begin{Bmatrix} |A_{22} - A_{12}| \\ |A_{11} - A_{21}| \end{Bmatrix} \tag{15}$$

Equation 15 cannot be solved explicitly since A_{12} and A_{21} are also the function of μ_i; therefore, the sequential quadratic programming (SQP) was used to solve the optimization problem formulated by Eq. (16).

$$\begin{aligned} &\text{Minimize} \quad f = \left|\mu_1 - \frac{|A_{22} - A_{12}|}{|A_{11}A_{22} - A_{12}A_{21}|}\alpha\right| \\ &\qquad + \left|\mu_2 - \frac{|A_{11} - A_{21}|}{|A_{11}A_{22} - A_{12}A_{21}|}\alpha\right| \\ &\text{subject to} \quad 0 \le \mu_i \le 12, \quad i = 1, 2 \end{aligned} \tag{16}$$

4 RESONANCE CURVE

4.1 PARAMETER OF ANALYSIS MODEL

The detail of the analysis models used here is listed on Table 2. The parameters of c_{d1} and c_{d2} are the viscous damping coefficients added by oil dampers in the first and the second story, respectively. In all the models, m_1 and m_2 are unity, and the values of c_1 and c_2 are decided to let the model have the inherent structural damping of 1% to the initial stiffness of the ENCL springs.

The M1 is the basic model in this study. The mode shape of the first mode in the elastic region of the M1 is an inverted triangle, which is expected to have an almost uniform deformation along the height of the model under ground excitation. The k_1 and k_2 of the M1_R_1.25, 1.5 and 2 are 1.25, 1.5 and 2 times larger than those of the M1, respectively. The M1_V_3%, 5% and 10% has dashpots representing oil dampers in all the stories, and the viscous damping coefficients of the dashpots are decided to have the damping ratio of 3%, 5% and 10% to the initial stiffness of the ENCL springs, respectively. The M1_F_0.1, 0.3 and 1 contain EPP springs representing friction dampers in all the stories. The number put after F_ means the value of F_i which is the ratio of the yield force of the EPP spring to the force of the ENCL model in the ith story at 1/360 rad as mentioned in Chapter 3. The yield deformation of the EPP spring is 1/360 rad in all the M1_F models.

The M2 is another basic model in this study. The stiffness k_1 and k_2 of the M2 are unity, so the story drift in the first story is supposed to become larger than that of the second story under ground excitation. This type of two-story wooden houses is very common in Japan because most houses have many rooms, i.e. many walls, in the second story. For the M2 model, strengthening only in the first

Table 2: *Parameters of analysis models*

story by increasing stiffness, installing oil dampers, and installing friction dampers are considered in this analysis. In the models of the M2_R_1.25, 1.5 and 2, the stiffness of the first story increases by 1.25, 1.5 and 2 times compared with that of the M2. The M2_V_3%, 5% and 10% have the dashpots the viscous damping coefficients of which are calculated by $c_{d1} = 2h_d\sqrt{(m_1 + m_2)k_1}$ in the first story, where the value of h_d for each model are 0.03, 0.05 and 0.1, respectively. The M2_F_0.1, 0.3 and 1 have the EPP spring in the first story, and the yield forces are 0.1, 0.3 and 1, respectively. The yield deformation of the EPP spring is 1/360 rad in all the M2_F models.

4.2 RESULT AND DISCUSSION

4.2.1 M1 model

Figure 3 shows the resonance curve of each story of the M1 with α = 0.1, 0.2, 0.3 and 0.34. The horizontal axis of the figure is the ratio of circular frequency of excitation p to the first natural circular frequency ω_0 of the M1. As an overall feature, the value of μ_1 and μ_2 in the first mode significantly increase with increase of α, whereas those value around the second mode have little or no increase. It is seen that the value of p/ω_0 at the peak in the first mode moves to the left side, which means the model shows softening behaviour under strong excitation. This result agrees to intuitive understanding because the equivalent stiffness of the model gradually decreases with increase of the story drift as shown in the force-deformation relation in Figure 1. It is also confirmed that the jump phenomenon occurs around the fist-mode peak, which is generally seen in the non-linear system.

When the attention is focused on the result with α = 0.34, the shape of the curve around the first mode dramatically changes, and the model has more than three solutions at the same p/ω_0. It is presumed that this phenomenon is caused by the strong non-linearity in the range of large deformation; however, more investigations including the verification of stability is needed.

4.2.2 M1_R, M1_V and M1_F models

The resonance curves of the M1_R, M1_V and M1_F with α = 0.34 are displayed in Figure 4 (a), (b) and (c), respectively, in comparison with the M1. The purpose here is to clarify the effect of increasing the stiffness, installing oil dampers and installing friction dampers on the reduction in the story drift of structures.

When the stiffness increases by 1.25, 1.5 and 2 times, μ_1 and μ_2 in the first mode gradually decrease and the p/ω_0 at the peak moves to the right side, but in the second mode the maximum values of μ_1 and μ_2 are almost the same as those of the M1. Similar feature is seen in the result of the M1_F models shown in Figure 4 (c), while quite different trend can be seen in the M1_V models shown in Figure 4 (b). First of all, installing oil dampers reduce the story drift not only around the first mode but also around the second mode. Secondly, the change of the value of p/ω_0 at the peak is insignificant compared with the results of M1_R and M1_F. Thirdly, oil dampers does not work to reduce the story drift in the range of $0 \le p/\omega_0 < 0.4$ where external force act as almost static load.

In order to investigate the response characteristics of the three strengthened models, M1_R_2, M1_V_10% and M1_F_1, against large excitation, the resonance curves of these models with α = 0.68 are compared in Figure 5.

https://doi.org/10.52202/069179-0272

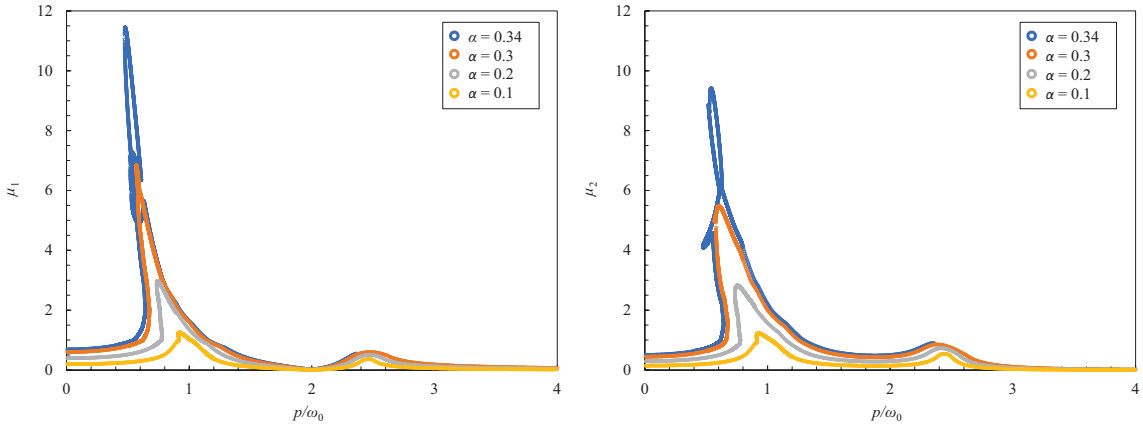

Figure 3: *Resonance curves of the M1 with α = 0.1, 0.2, 0.3 and 0.34 (left: first story, right: second story)*

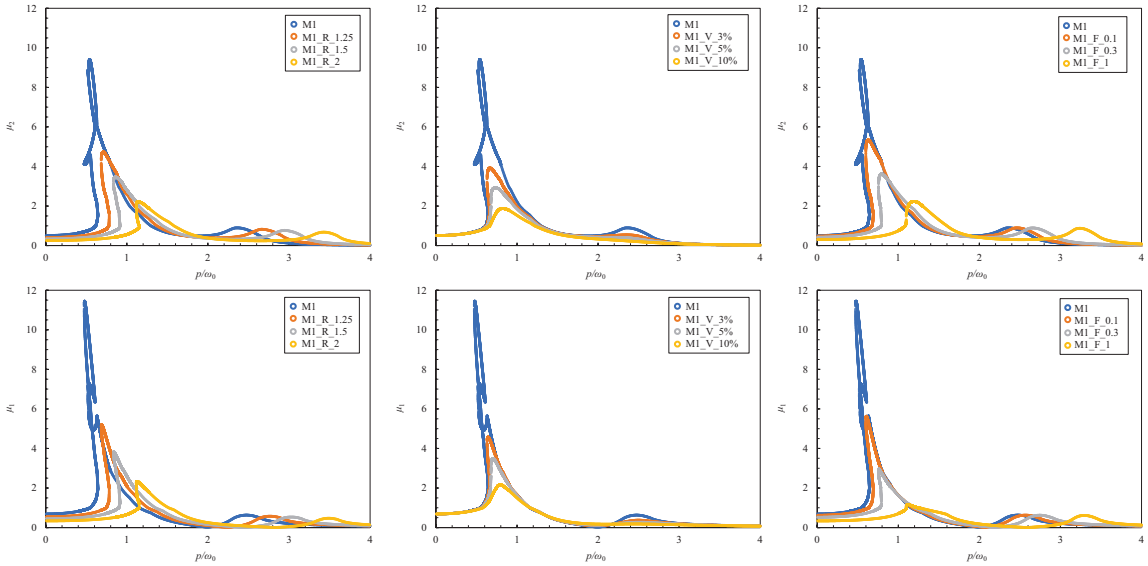

(a) M1 and M1_R_1.25, 1.5, 2 *(b) M1 and M1_V_3%, 5%, 10%* *(c) M1 and M1_F_0.1, 0.3, 1*

Figure 4: *Resonance curves of the M1, M1_R, M1_V and M1_F with α = 0.34 (top: second story, bottom: first story)*

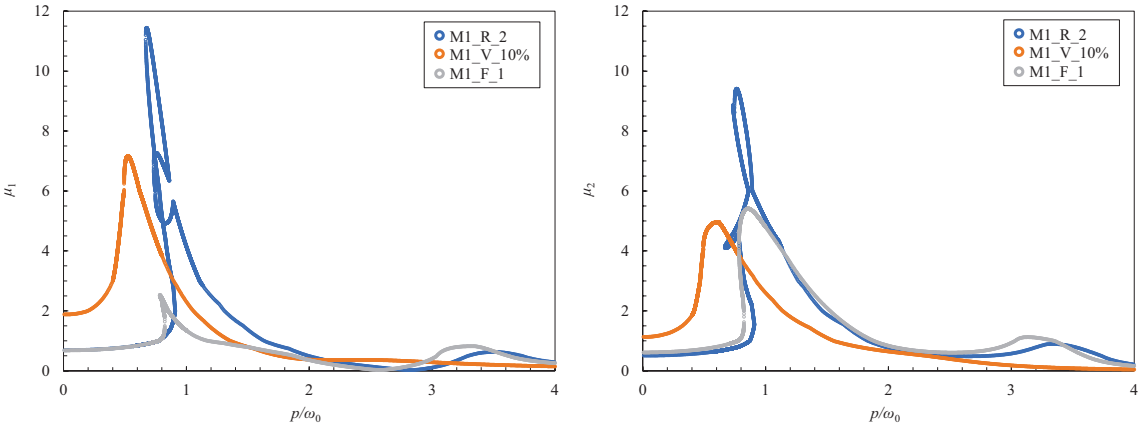

Figure 5: *Resonance curves of the M1_R_2, M1_V_10% and M1_F_1 with α = 0.68 (left: first story, right: second story)*

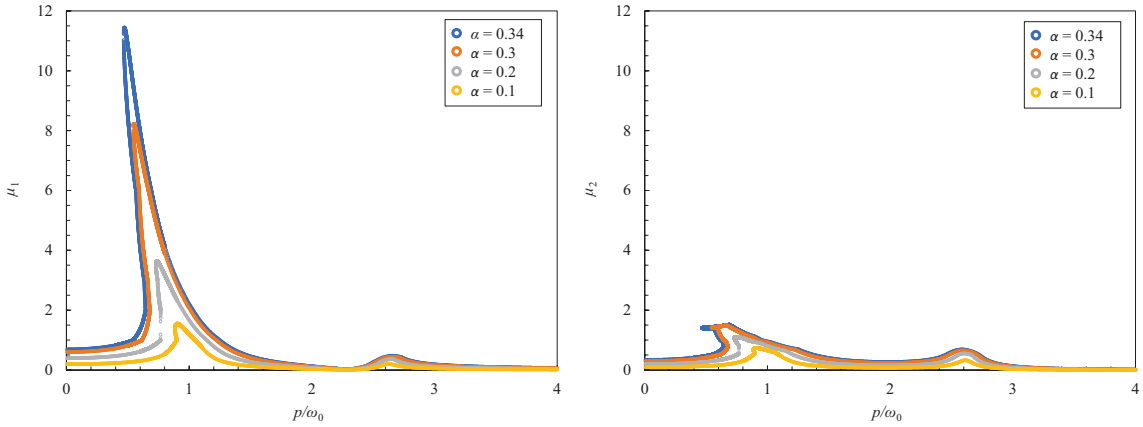

Figure 6: *Resonance curves of the M2 with α = 0.1, 0.2, 0.3 and 0.34 (left: first story, right: second story)*

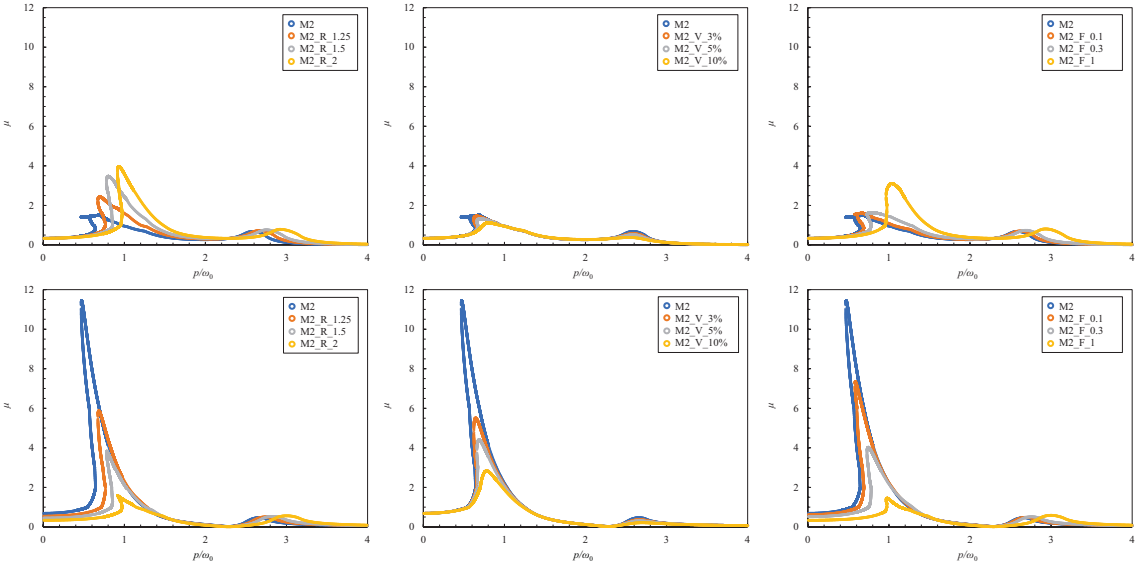

(a) M2 and M2_R_1.25, 1.5, 2 *(b) M2 and M2_V_3%, 5%, 10%* *(c) M2 and M2_F_0.1, 0.3, 1*

Figure 7: *Resonance curves of the M2, M2_R, M2_V and M2_F with α = 0.34 (top: second story, bottom: first story)*

Although these three models have similar peak values of μ_2 under the excitation with $\alpha = 0.34$, the maximum value of μ_2 of the M1_V_10% and M1_F_1 under the excitation with $\alpha = 0.68$ are smaller than that of the M1_R_2. This result indicates that the effect of strengthening by increasing stiffness, installing oil dampers and installing friction dampers highly depends on the magnitude of excitation.

4.2.3 M2 model

Figure 6 indicates the resonance curve of the M2 with α = 0.1, 0.2, 0.3 and 0.34. In this model, the story drift in the first story much larger than that of the second story especially under large excitation. This result explains the soft-story mechanism of two-story wooden houses caused by very strong earthquakes such as 1995 Kobe earthquake and 2016 Kumamoto earthquake occurred in Japan. It is also seen that the jump phenomenon occurs around the first mode and the shape is less complicated than that of the M1.

4.2.4 M2_R, M2_V and M2_F models

In Figure 7, the resonance curves of the M2_R, M2_V and M2_F are compared with that of the M2 in the same manner as Figure 4. It is seen in Figure 7 (a) that the increaseing of the stiffness of the first story decreases the story drift in the first story μ_1 but increases the story drift in the second story μ_2, indicating that when we strengthen only first story, we have to pay attention to the response of the second story even if the original structure has the relatively low stiffness and strength in the first story.

In the case of installing oil dampers or friction dampers only in the first story, the story drift in the first story gradually decreases with increase of the capacity of the dampers without significant increase of the story drift in the second story. It is presumed that the reason of this result is dut to the feature of the damper which works to

https://doi.org/10.52202/069179-0272

increase mainly damping performance not stiffness and strength.

5 CONCLUSIONS

The steady-state response of the two-degree-of-freedom-system with ENCL and EPP springs were derived and the vibration property of two-story timber structure with energy dissipation devices were discussed based on the resonance curve. The following conclusions are obtained from this study:

1. The two-degree-of-freedom-system which has ENCL springs with the parameters of timber structure shows softening behaviour and jump phenomenon around the first mode in the resonance curve.
2. The strengthening by increasing stiffness and installing friction dampers reduce the story drift only around the first mode, whereas installing oil dampers reduces the story drift both around the first and the second modes.
3. In the two-story timber structure which has relatively low stiffness in the first story, installing dampers only in first story reduces the story drift in the first story without significant increase of the story drift in the second story.

YIELD MECHANISM OF PERFORATED PLATE CONNECTIONS FOR MASS TIMBER SYSTEMS

Hossein Daneshvar [1], Thomas Tannert [2], Ying He Chui [3], Carla Dickof [4]

ABSTRACT: Mechanical connections are often the only source of ductile behaviour in mass-timber systems. This paper presents an experimental study on using perforated steel plates as a dissipating energy device, also called a seismic fuse, to enhance the structural performance of mass timber systems during extreme loading events. A target application of the perforated plate connection is in braced timber frames. Six perforation patterns were developed based on preceding experimental and numerical studies and tested under cyclic loads. These different patterns targeting one or multiple yielding mechanisms: shear, axial (tension and compression), and bending. The hysteresis performance and failure mechanism of the perforated plate systems showed that the selected patterns provided reliable yield mechanisms and that damage to timber elements can be avoided when the fuses are combined with capacity-protected dowel-type fasteners. In addition, the results of cyclic tests demonstrated sufficient ductility and ultimate displacement for specific patterns, e.g., specimens with long oval perforations, to achieve the desired energy dissipation.

KEYWORDS: Braced Timber Frame, Ductile Connections, Structural Fuse, Perforated Steel Plate, Seismic Force Resisting System

1 INTRODUCTION

The design of tall timber buildings in high seismic regions is still a challenge, mainly due to the limited energy dissipating systems and/or connections with high-performance and established practical design procedures for seismic force resisting system (SFRS). Due to the inherent brittleness of wood, other ductile materials, such as steel, are used to provide the ductility required in a seismic event. Conventionally, metal dowel-type fasteners, e.g., nails, drift pins, screws, or bolts, are a common source of ductility in timber structures. However, due to the damage they may cause to the timber components, it is beneficial to localize damage in a certain part of the structure, called seismic fuses, that are replaceable after a seismic event, with little damage to the rest of the structural system. Perforated plates are categorized as a "yielding damper" in which kinetic energy due to seismic motions is dissipated through the yielding of the steel component. In steel frames, the perforated plate fuse concept has been shown to be successful as documented in previous studies [1-8].

Specific to timber structures, Zhang et al. [9] applied glued-in, perforated plates in hold-down connections. Focusing on a specific perforation pattern confirmed their predictive ability and scalability when shear yielding was dominant. Blomgren et al. [10] and Morrell et al. [11] used a specific perforated pattern in panel-to-panel connections in cross-laminated timber shear walls. Dires and Tannert [12] extended the work on such fuses by using the concept of internal panel-to-panel connections and hold-downs. Daneshvar et al. used perforated plate fuses to panel-to-panel connections [13] and base shear connections [14] in shear walls, as well as to end brace connections in braced timber frames (BTF). They developed an analytical model for strength and prediction of ultimate deformation, verified by limited test results on specific perforation patterns. An example of such fuses at the end of a glulam brace member is shown in Figure 1.

Figure 1 showcases an example of shear yielding of a 12 mm thick plate with a 10 mm diameter circular perforation with a centre-to-centre spacing of 25 mm. The "link" element, defined as the minimum clear distance between two adjacent perforations, dictates the behaviour of the connection. Previous studies confirmed that the characteristic behaviour of the link elements could reasonably predict the behaviour of the connection system made of perforated plates [9, 13, 14]. However, despite adequate ductility being achieved under monotonic loading, the corresponding ductility under cyclic loading was substantially decreased, necessitating further investigation.

2 EXPERIMENTAL PROGRAM

2.1 OBJECTIVE

Based on the findings from previous research [9, 13, 14], it was postulated that the reduced ductility under cyclic loading was related to the onset of shear yield failure of the link elements between circular holes. An additional test program was deemed necessary to investigate perforation patterns to achieve flexural and axial yielding of the perforation, as opposed to the shear yielding in the earlier experimental phase. The main goal is to enhance the response of the connections in the cyclic behaviour, increasing the ductility and ultimate displacement the specimens can endure by delaying the fatigue-type failure initiations in the link elements.

2.2 FUSE PATTERNS

Six perforation patterns, as listed in Table 1, were designed and subsequently tested at the UNBC Wood Innovation Research Laboratory in Prince George, Canada. A total of twelve end brace connection specimens were tested using Method C of ASTM E2126 [15]. When the specimens were loaded by an axial force, the stress fields around the perforation zones could be in shear, axial, flexural, or a combination thereof, depending on the perforation shape and pattern. The perforation details for the oval patterns are shown in Figure 2 as a sample.

Table 1: *Fuse types tested*

Type	Fuse Pattern[1]	Specimen code
1	Oval	EBC-O
2	Circular Staggered	EBC-S
3	Circular Staggered – Buckling Restrained	EBC-BR
4	Oval Staggered (Modified)	EBC-OS[2]
5	Long Oval	EBC-LO
6	Smooth Diamond	EBC-SD

[1] Each specimen had two replicas, resulting in twelve total tests labelled, e.g., EBC-O-1 and EBC-O-2.
[2] EBC-OS-1 and EBC-OS-2 had a minor difference, c.f. section 3.4.

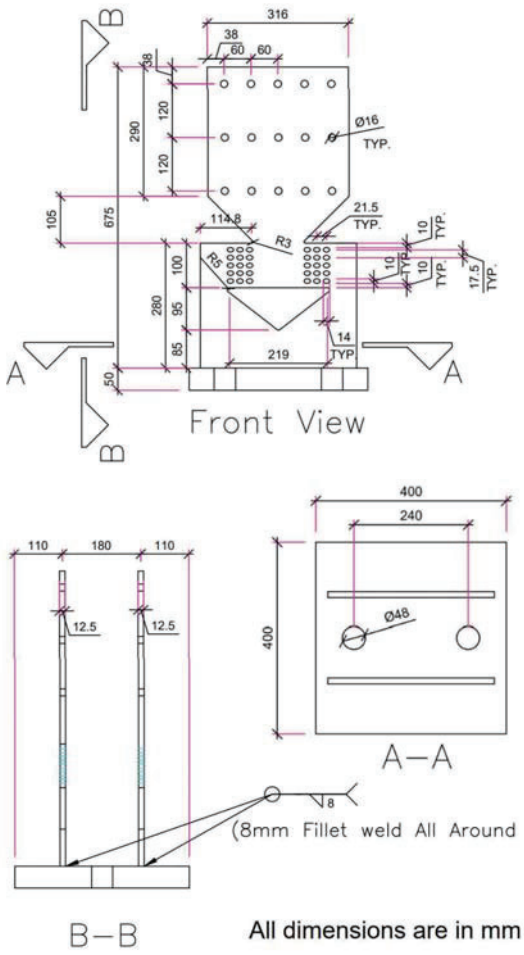

Figure 2: *Sample fuse end for EBC-O*

2.3 MATERIALS, METHOD, AND INSTRUMENTATION

The perforated plate fuses were applied to end brace connections in BTF. However, it can be noted that the perforation patterns can also be utilized in other timber SFRS, such as CLT shear walls. The timber member was 1.1 m long, 365 mm x 380 mm spruce-pine glulam grade 12c-E according to CSA O86 [16].

As shown in Figure 3 (a), the specimens consisted of fuses and capacity-protected dowel-type connections at one end (bottom) and capacity-protected connection at the other end (top). Fifteen and twenty tight-fit steel dowels of diameter 16 mm were used in the capacity-protected and fuse end connections, respectively. The specimens were instrumented using six Linear Variable Differential Transformers (LVDT), as shown in Figure 3 (b), labelled LVDT1 to LVDT6. The average displacement of the perforation zones was recorded by LVDT1 and LVDT2 . LVDT3 to LVDT6 were used to monitor the deformation in the capacity-protected steel dowels.

3 RESULTS

The deformed shape and its corresponding load-deformation hysteresis curves for selected specimens are shown in Figures 4 and 5, respectively. Detailed analysis of the test results is currently in progress at the time of writing this paper. Some preliminary findings and test observations are presented below.

3.1 EBC-O

The signs of yielding in all the link elements, both horizontal and vertical, were obvious before failure initiation. It is not easy to distinguish if the yielding of links is flexural or shear; however, considering the link elements' aspect ratio, it seems reasonable to assume shear-flexural yielding. The failure is initiated with a sudden rupture of inner link elements and propagates vertically to other elements in the row. Almost the same failure mode was observed in both replicates; the failure mode of EBC-O-2 is shown in Figure 5 (a). The other rows, while uniformly yielded, did not experience any rupture. Both specimens achieved similar ultimate displacements but different peak loads. The hysteresis curve of EBC-O-2 is shown in Figure 6 (a). As can be seen, the curve is wide, with substantial energy dissipation capability.

3.2 EBC-S

Due to a mistake in load application, EBC-S-1 was subjected to a monotonic load and buckled. EBC-S-2 was loaded cyclically, as anticipated; but similarly failed due to the global buckling of the knife plates, as shown in Figure 5 (b). The weak line was found where the perforation ends, and the triangular cut-out is maximized. While global buckling of the plates could be used as a source of energy dissipation, the difference in tensile and compressive responses, as noted in Figure 6 (b), might make it difficult to predict the onset of yielding. The pinching behaviour due to the buckling of the plate in compression is evident. Pattern EBC-S was initially aimed at achieving axial yielding in the perforation zones. The observed buckling behaviour necessitated modifying the perforation patterns to achieve the target failure mode. This led to the buckling restrained specimens of EBC-BR, as discussed below, in 3.3.

3.3 EBC-BR

EBC-BR contains a larger perforation diameter compared to EBC-S. In addition, four stiff plates were welded to the outer sides of the knife plates. The failure mode of EBC-BR-2 is shown in Figure 5 (c). As can be seen, these two major changes caused the shift in failure mode from global plate buckling to axial yielding of link elements, as intended. The link on the inner rows is mainly ruptured due to excessive yielding, while there were no ruptures observed in other rows, although significant yielding was observed. Figure 6 (c) depicts that this fuse pattern possesses ample wide hysteresis curves, with improved strength and ultimate displacement, compared with EBC-S.

3.4 EBC-OS

EBC-OS-1, similar to EBC-S-1 and EBC-S-2, globally buckled at the weak line of the minimum cross section. Increasing the size of perforations in EBC-OS-2 shifted the failure mode from global buckling to rupture in the perforation zones, as seen in Figure 5 (d). The intended axial yielding mechanism is achieved in the EBC-OS-2. Also, the pinching observed due to buckling in the hysteresis loops of the EBC-OS-1 faded away in the EBC-OS-2 responses, as shown in Figure 6 (d). The larger perforations also allow an increase in ultimate displacement achieved by the specimen.

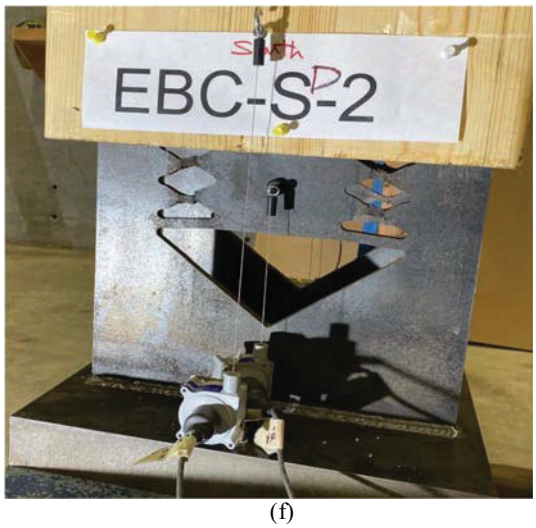
(c)



(f)

Figure 4: *Failure modes and deformed shapes*

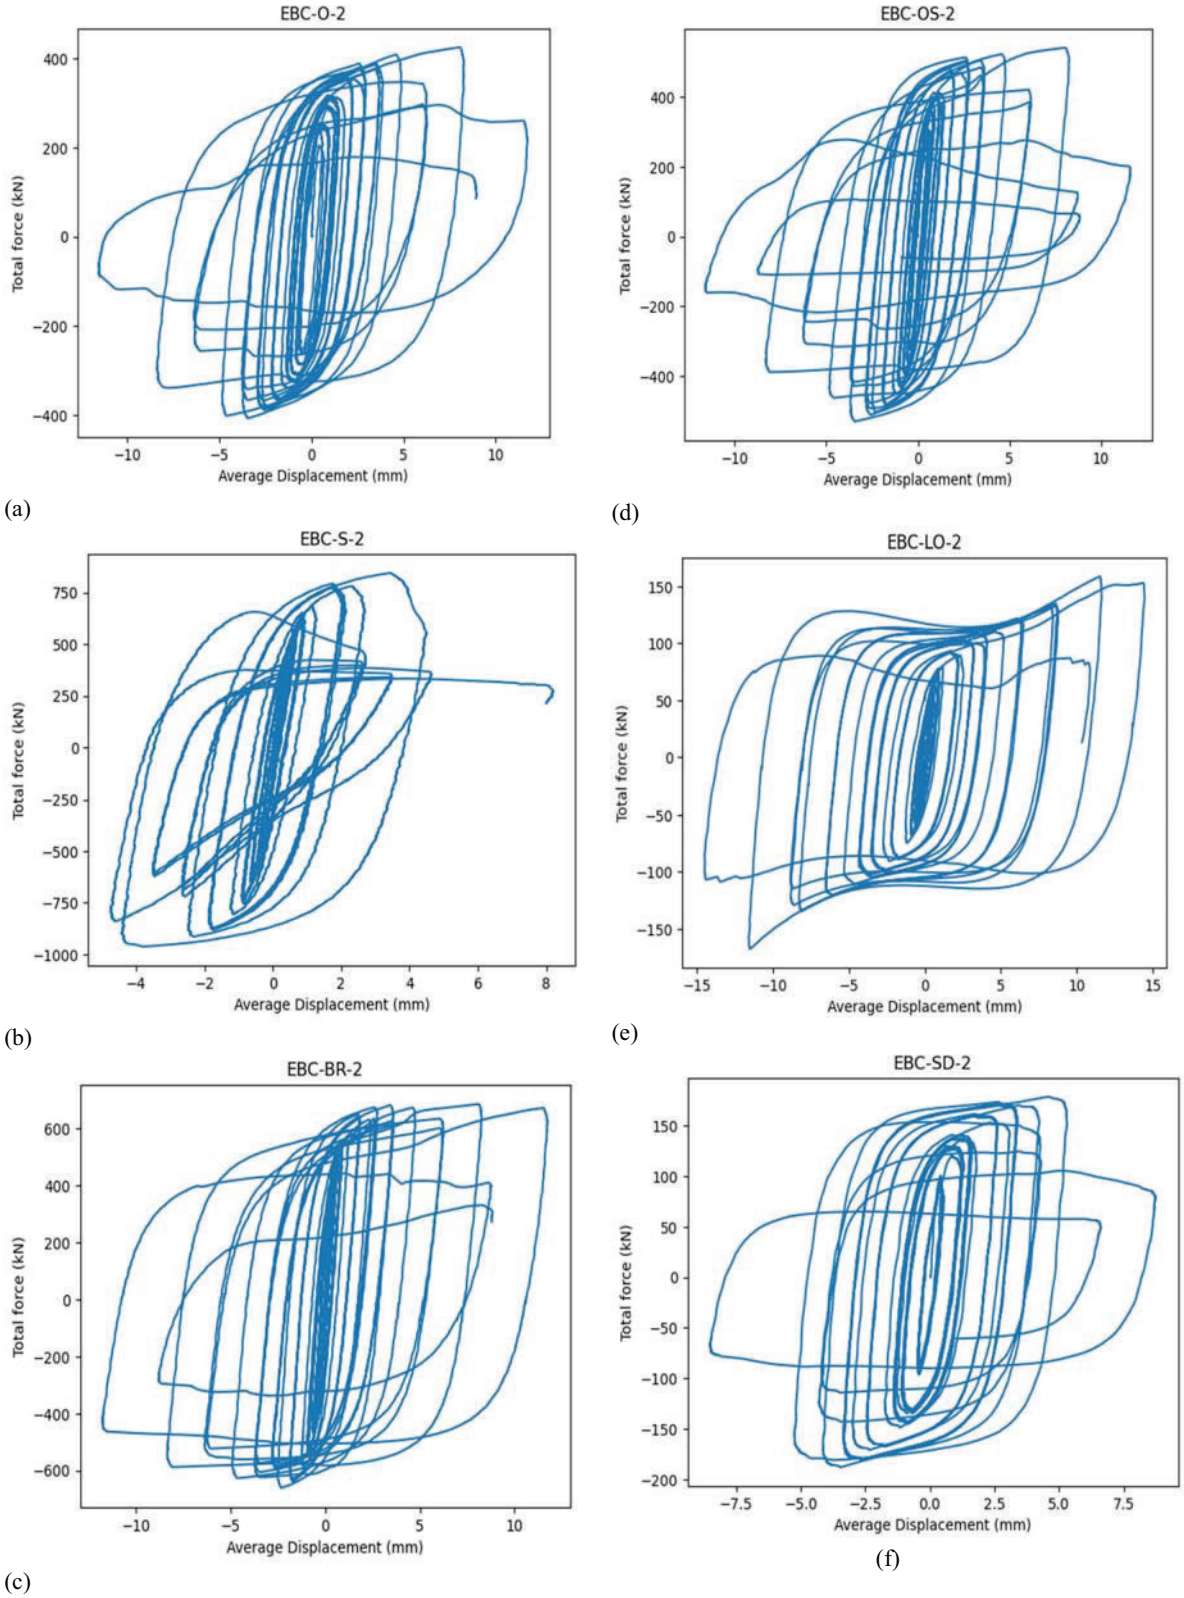


Figure 5: *Hysteresis curves*

https://doi.org/10.52202/069179-0273

3.5 EBC-LO

The target failure mode for this pattern was flexural yielding, achieved by forming two plastic hinges at the ends of link elements. The two specimens behaved almost the same. Figure 5 (e) shows the failure mode of EBC-LO-2); the outer plastic hinges experienced rupture first in the majority of perforation zones, and then the failure propagated to the inner plastic hinges of the link elements. The hysteresis loops of the two specimens were almost the same; see Figure 6 (e) corresponding to EBC-LO-2, for instance. The results show reasonable ductility for the fuses, with large open hysteretic loops reflecting the ability of the fuse to dissipate energy. Significant ultimate displacements were observed with this pattern compared with other patterns, suggesting that the flexural mechanism, achieved with the long oval-shaped perforations, could be the desired pattern to improve the fuse behaviour under cyclic loading.

3.6 EBC-SD

Like EBC-LO specimens, the intended yielding mechanism for EBC-SD specimens was also flexural yielding. However, instead of two plastic hinges at the ends of the link elements, a non-prismatic cross section was used to force the formation of the plastic hinges in the middle of the link elements. The intended failure mode was achieved in both specimens; Figure 5 (f) shows the EBC-LO-1 failure mode. Although the hysteresis loops are wider compared to the EBC-LO pattern, limited ultimate displacement caused the dissipative energy capability of the fuse to be insignificant, see Figure 6 (f). However, the hysteresis behaviour of the fuse, in terms of the area enclosed per cycle, looks promising and may be enhanced with minor revisions in the future.

3.7 FUSE REPLACEABILITY

As illustrated in Figure 7, all damage was concentrated in the perforation zones . The capacity-protected steel dowel connections were undamaged and could be disassembled. The fuse end connection can be easily removed after the cyclic tests, representing the resiliency of the fuse with no damage to the timber component. To reliably design capacity-protected dowel-type connections, research to quantify the over-strength factor is ongoing.

4 CONCLUSIONS

Under cyclic loading, twelve full-scale end brace connection specimens with six different steel plate perforation patterns were tested. These perforated plates, developed based on preceding experimental and numerical studies, were intended to be seismic fuses. The triggered yielding mechanisms were shear, axial, flexural, or a combination. Long oval perforations provided the best performance regarding ductility, energy dissipation, and ultimate displacement. The evaluated perforated plate patterns provided resilient solutions that could be replaced after yielding failure.

EXPERIMENTAL CHARACTERISATION OF GLULAM SHEAR WALLS UNDER LATERAL CYCLIC LOADING

Giuseppe D'Arenzo[1], Werner Seim[2]

ABSTRACT: This paper presents the results of an experimental campaign aimed at investigating the lateral response of glulam (glued laminated) shear walls subjected to horizontal cyclic loads. The objective of the study is to explore the potential of this engineered wood product to be used as an alternative lateral load-resisting element in platform timber constructions. The lateral response of massive wooden shear walls is governed by the wall-base connections; therefore, in addition to shear wall tests, cyclic tests were carried out on hold downs and angle brackets attached to glulam elements. Results of the experimental tests of both connections and shear walls showed failure mechanisms characterised by relatively large plastic deformation of the nails and with significant ductility levels. This results in the potential of glulam shear walls being adopted as the lateral load-resisting element of platform timber constructions in seismic prone areas.

KEYWORDS: Glued Laminated Timber, Shear Walls, Experimental Tests, Cyclic Behaviour

1 INTRODUCTION

Mass Timber constructions are gaining in popularity among designer communities as they respond well to today's need for sustainability, permit design with a large architectural freedom and have overcome many limits of traditional wooden structures. The expression "mass timber" refers to the massive, engineered wood products (EWP) which are used for the construction of these structures; glued laminated (glulam) and cross-laminated timber (CLT) are the most widely spread product types. Glulam is used mostly for structural one-dimensional elements, such as beams and columns, whereas CLT is used mostly for planar elements, such as walls and floors. Today's large availability of different EWPs that respond well to different needs of the construction industry results in the possibility of realising mass timber buildings with different structural systems. Among the latter ones, structural systems with shear walls have been largely adopted in the construction practice, CLT panels being the product adopted most.

CLT buildings with shear walls are realized by connecting the CLT panels by means of mechanical anchors and screws. The mechanical anchors are used at the base of the walls, while the screws are used for panel-to-panel connections. The mechanical anchors typically adopted in CLT shear walls are hold downs and angle brackets; the first ones are used at the wall ends to prevent the wall rocking, while the second ones are spread along the wall base and are used to prevent the shear wall sliding.

The lateral behaviour of structural systems made of CLT shear walls has been largely investigated in the last decade, with particular focus on their seismic performance. Shaking table tests on multi-storey CLT buildings [1], racking tests on CLT shear walls [2,3], and cyclic tests on sub-assemblies and connections [4] were conducted, showing the high dissipation capacity and good seismic performance of CLT structures and sub-components. These experimental programmes were instrumental in understanding the seismic behaviour of these structural typologies and in defining the calculation models and specifications needed for the design.

Structural systems with shear walls can also be realised by using different EWPs, such as glulam or laminated veneer lumber (LVL). However, less studies have been conducted on shear wall systems made of glulam and LVL, having the majority of these experimental investigations been conducted on timber walls with dampers and low-damage connection systems. For instance, Wrzesniak et al. [5] investigated the rocking behaviour of glulam shear walls anchored to the foundation with dampers, while Iqbal et al. [6] investigated the seismic resistance of post-tensioned LVL walls coupled with U-Flexural plate dissipators.

If on one hand the use of low-damage systems and dissipators improves the seismic performance of timber walls, on the other hand traditional connection systems are more adopted in practice due to their simplicity of design. However, to authors' knowledge, no studies investigating the seismic performance of glulam and LVL shear walls anchored with traditional hold downs and angle brackets are available in the literature, with the consequence that the relevant information needed for the design are not available to practitioners. This represents a relevant gap of scientific knowledge, which may negatively impact the spread of innovative timber structural systems.

With the aim of filling this gap, this paper presents an experimental study investigating the lateral response of glulam shear walls subjected to lateral loading, and the cyclic response of traditional hold downs and angle brackets attached to glulam elements. In particular, the cyclic behaviour of such structural components is investigated, to explore the potential of glulam shear wall elements to be used in platform timber buildings in seismic prone areas. The evaluation of quantities relevant

https://doi.org/10.52202/069179-0274

for the seismic design, such as the strength, stiffness, ductility of connections, energy dissipation, and impairment of strength, is carried out, providing valuable insights into the seismic design of structures with glulam shear walls.

2 EXPERIMENTAL TESTS

2.1 MATERIALS

Experimental tests were conducted using glulam specimens with strength class GL24h.
Hold downs type HTT22E and angle brackets type AE116 from Simpson Strong Tie were used for the experimental tests. The geometrical and mechanical properties of both hold downs and angle brackets are described in the ETA-07/0285 [7]. The mechanical anchors are shown in Figure 1 (a) and (b).
Annular ringed nails CNA 4×60 mm from Simpson Strong Tie were used for the connection between the mechanical anchors and the timber elements, see Figure 1 (c). The geometrical and mechanical properties of the nails are described in the ETA-04/0013 [8]. The mechanical anchors were connected at the base with bolts M12 and M16, strength class 8.8.

2.2 METHOD

The lateral behaviour of massive wooden shear walls is governed by the wall base connections. Hold down connections are normally used at the extremities of the wall to prevent rocking, while angle bracket connections are used in the centre of the wall to prevent sliding. Accordingly, the methodology used in this study involved experimental investigations of hold downs and angle brackets subjected to tensile and shear loads, respectively, along with full-scale tests at wall level.

2.3 LOAD PROTOCOLS

The connections were tested in monotonic and cyclic regime according to EN26891 [9] and EN12512 [10], respectively.
The monotonic tests were performed in force control, in order to perform the unloading and reloading path prescribed in the EN26891. The load protocol of the monotonic tests is shown in Figure 3 (a). Two different load protocols were used for the cyclic tests of hold downs and angle brackets due to the different test setups. Hold downs, which were tested for tensile loads, were loaded with an only positive displacement path with imposed displacement ranging from zero up to a specific positive value, see Figure 3 (b). Angle brackets, which were tested under shear loads, were loaded with fully reversed displacement path with positive and negative displacements, see Figure 3 (c). Both hold down and angle bracket cyclic tests were performed in displacement control with a rate varying from 0.1 to 0.5 mm/sec.

2.4 EVALUATION OF MECHANICAL PARAMETERS

Mechanical parameters were evaluated according to EN12512 [10]. The stiffness of the connections, K_{el}, was evaluated according to the method B of the EN12512 as the slope of the line that intersects the load displacement curve in the points of ordinate equal to 10% and 40% of the maximum force. The intersection between the stiffness line and the line with slope equal to one-sixth of the stiffness line and tangent to the load displacement curve defines the yielding point, from which the yielding displacement, V_y, and the yielding load, F_y, are evaluated. The point with the highest ordinate of the load displacement curve defines the maximum force, F_{max}, and the relative displacement, V_{max}. The ultimate force, F_{ult}, is evaluated as the ordinate of the load displacement curve when a 20% reduction of the maximum force is reached. The abscissa of the point of ultimate force defines the ultimate displacement, V_{ult}. Finally, the ductility, D, is evaluated as the ratio between the ultimate displacement and the yielding displacement. Figure 2 shows an example of experimental curve with the relative yielding, maximum and ultimate point.
According to EN12512, the cyclic behaviour of the timber connections is expressed using three parameters: the dissipated energy, E_d, the equivalent viscous damping ν_{eq}, and the impairment of strength, ΔF. The dissipated energy is computed as the area enclosed by each hysteretic loop and is useful for evaluating the total energy dissipated

Figure 1: *(a) Hold downs, (b) angle brackets and (c) annular ringed nail used for the experimental tests.*

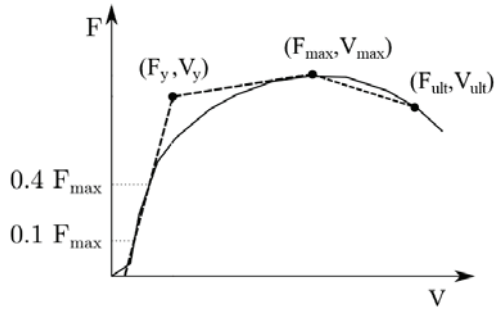

Figure 2: *Representation of the yielding, maximum and ultimate point according to EN12512.*

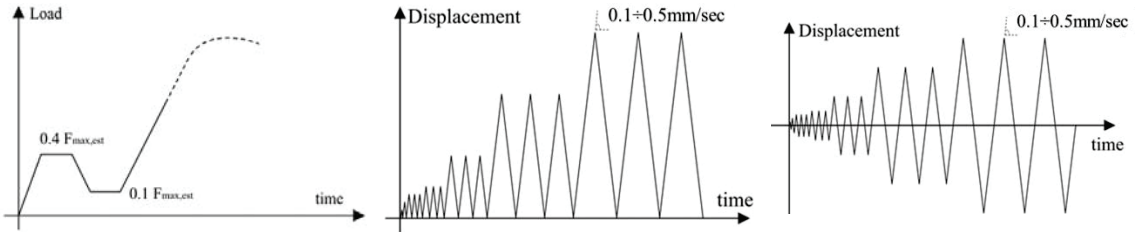
https://doi.org/10.52202/069179-0274



(a) (b) (c)

Figure 3: *Load protocol for (a) monotonic tests, (b) cyclic tests of hold downs, (c) cyclic tests of angle brackets and shear walls.*

during the test when presented cumulatively. The equivalent viscous damping is evaluated at each hysteretic loop and represents the ratio of dissipated energy, E_d, to available potential energy, E_p, multiplied by 2π. The available potential energy E_p is calculated using the maximum force, F_i, in each cycle and the corresponding displacement, V_i, and is expressed as $E_{p,i} = 1/2 \cdot F_i \cdot V_i$. The impairment of strength, ΔF, which quantifies the strength degradation of timber connections, is determined by the difference between the strengths of the first and third envelope curves at the same displacement level. In this study, the normalized form of ΔF, $\Delta F_{1\text{-}3}$, is presented by dividing the impairment of strength by the strength of the first envelope.

2.5 TEST SETUP

2.5.1 Connection Tests

The experimental tests on the mechanical anchors were carried out with the universal machine RBO-2000 with a maximal capacity of 800 kN and a displacement range of ±150 mm. The lamella orientation of the glulam elements was chosen in order to simulate the real condition in which the connections work, when they are anchored to the shear wall. Figure 4 (a) and (b) shows the test setups of the tension and shear tests, for hold downs and angle brackets, respectively. Figure 5 (a) and (b) shows the photos of the hold down and angle bracket test setups. The displacements of the specimens were measured by means of Linear Variable Displacement Transducers (LVDTs) placed on the timber element.

Hold downs were fastened to the glulam elements with 15 annular ringed nails and anchored to the bottom steel plate with one bolt M16. Angle brackets were fastened to the glulam elements with 12 annular ringed nails and anchored to the bottom steel plate with two bolts M12.

One monotonic (n_m) and six cyclic (n_c) tests were performed for each configuration, for a total amount of 14 experimental tests on connections.

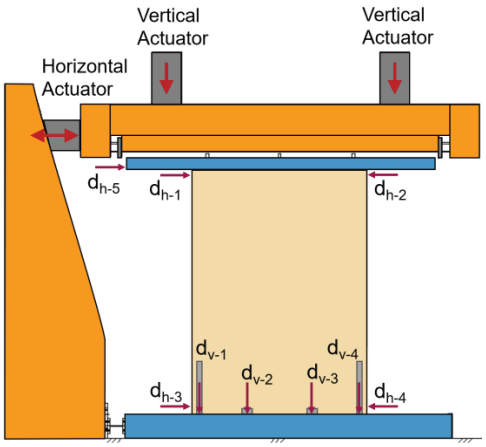

Figure 6: *Shear wall test setup.*

Figure 7: *Photo of the shear wall test setup.*

2.5.2 Shear Wall Tests

Figure 6 and Figure 7 show the test setup used for the shear wall tests. The shear walls had a height of 2500 mm, a length of 1500 mm, and a thickness of 140 mm. All experimental tests were performed with a constant vertical load applied on the top of the shear wall of 30 kN/m. The shear walls were anchored with two hold downs in the shear wall corners, to prevent the shear wall rocking, and with two angle brackets, to prevent the shear wall sliding. Horizontal and vertical loads were applied to the wall specimens through one horizontal and two vertical hydraulic actuators with 400 kN capacity. The vertical actuators were connected to a horizontal steel beam, which was screwed to the shear wall head with self-tapping screws 8×160 mm spaced at 100 mm. The timber walls were anchored through the wall-base connections to a steel beam, which was anchored to a strong floor.

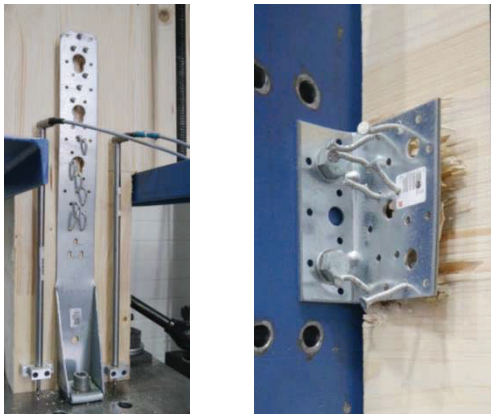
Nine LVDTs were used to measure the wall displacements, see Figure 6. The shear wall lateral displacements were measured with two LVDTs (d_{h-1}, d_{h-2}) placed in the two upper corners of the shear wall. Two horizontal LVDTs (d_{h-3}, d_{h-4}) were used to measure the sliding displacements while four vertical LVDTs (d_{v-1}, d_{v-2}, d_{v-3}, d_{v-4}) were used to measure the rocking of the shear wall as well as the vertical displacements of the two hold downs and the two angle brackets. A horizontal LVDT (d_{h-5}) was used to measure the horizontal displacements of the steel beam connected to the upper side of the shear wall.

The experimental program on shear walls included two cyclic tests in total.

3 RESULTS

3.1 MECHANICAL ANCHORS

The mechanical behaviour of hold down and angle bracket connections was characterised by high ductility and capability to withstand relatively large cyclic displacements. The behaviour of the connection systems was, to a large extent, comparable to that of traditional hold downs and angle brackets attached to CLT elements (see, for instance [4]).



(a) (b)

Figure 8: *Photo of connection specimens at the end of the tests: (a) hold downs, (b) angle brackets.*

Table 1: *Mechanical parameters evaluated from the load displacement curves of monotonic and cyclic connection tests.*

Test type	n_m	n_c	K_{el}	F_y	V_y	F_{max}	V_{max}	F_{ult}	V_{ult}	D
	[-]	[-]	[kN/mm]	[kN]	[mm]	[kN]	[mm]	[kN]	[mm]	[-]
Hold downs	1	6	8.05	43.20	4.96	55.69	15.90	44.55	28.15	5.71
Angle brackets	1	6	3.69	27.90	7.53	32.39	14.70	25.91	21.01	2.99

https://doi.org/10.52202/069179-0274

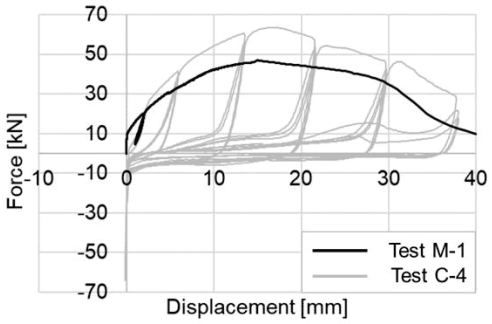


Figure 9: *Typical load displacement curve of a hold down connection.*

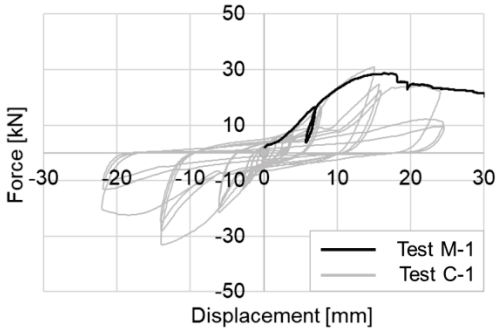

Figure 10*: Typical load displacement curve of an angle bracket connection.*

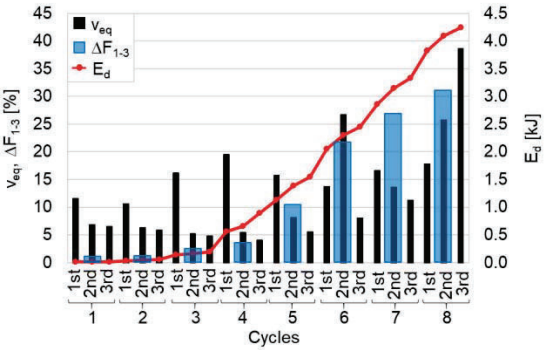

Figure 11: *Average cyclic properties of hold down tests.*

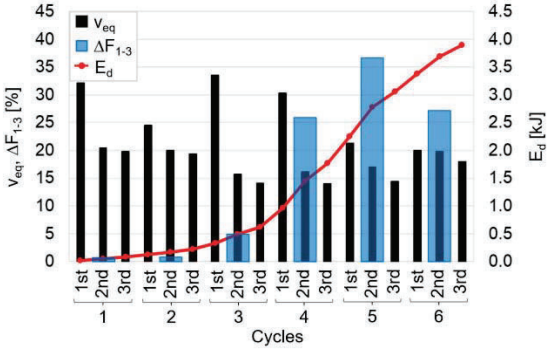

Figure 12: *Average cyclic properties of angle bracket tests.*

In general, hold down connections showed a failure in the nails of the steel-to-timber connection with one or two plastic hinges, see Figure 8 (a). The hold down steel brackets showed small deformation, while the overall displacement of the tests was mainly provided from the nails of the steel-to-timber connection.

Angle brackets connections showed a failure in the nails of the steel-to-timber connection with one or two plastic hinges combined with a failure due to the opening of the wooden lamellas composing the glulam element. In all tests, the metal brackets showed small deformation, while the overall displacement of the tests was mainly provided from the nails of the steel-to-timber connection, see Figure 8 (b).

Typical load displacement curves of hold downs under tension and angle brackets under shear are shown in Figure 9 and Figure 10, respectively. Table 1 summarizes the average mechanical parameters of the connection tests evaluated according to EN12512.

The results show that the hold down connections have a higher stiffness of 8.05 kN/mm as compared to the angle brackets, which have a stiffness of 3.69 kN/mm. The maximum loads the connections can withstand before failure show variation between the two connection types, with the hold down connections having a higher maximum load capacity than the angle bracket connections. For the hold down connections, the maximum load value is 55.69 kN, while for the angle bracket connections, the maximum load value is 32.39 kN. The ductility was higher for the hold down connections with a value of 5.71, compared to the angle bracket connections with a value of 2.99. The higher performances of the hold downs compared with the angle brackets are due to the larger number of nails used in the connection with the timber panel.

Figure 11 and Figure 12 shows the cyclic properties of hold downs and angle brackets, respectively. The graphs report the number of cycles in the horizontal axes, while two vertical axes are used to plot the dissipated energy (E_d), the equivalent viscous damping (ν_{eq}), and the normalised impairment of strength ($\Delta F_{1\text{-}3}$).

Averagely, 4.24 kJ and 3.89 kJ were dissipated at the end of the hold down and angle bracket tests, respectively. The average equivalent viscous damping was 12.7 % and 20.6 % for hold down and angle bracket tests, respectively. The normalised impairment of strength showed an increasing trend up to the failure of the connections with maximum values of 31.5 % and 36.5 % for hold downs and angle brackets, respectively.

3.2 SHEAR WALLS

The mechanical behaviour of the shear walls was governed by the connections and characterised by large ductility and capability to withstand large cyclic displacements. The behaviour of the wall was, to a large extent, comparable to that of traditional CLT shear walls (see, for instance, [2]).

https://doi.org/10.52202/069179-0274

Table 2: *Mechanical parameters evaluated from the load displacement curves of cyclic shear wall tests.*

Test type	n_c	K_{el}	F_y	V_y	F_{max}	V_{max}	F_{ult}	V_{ult}	D
	[-]	[kN/mm]	[kN]	[mm]	[kN]	[mm]	[kN]	[mm]	[-]
Shear walls	2	3.44	33.70	9.90	55.29	55.60	44.23	71.10	7.55

In general, the deformation mechanism was governed by the wall-base connections, while the panel deformation was negligible. The shear walls failed with a prevalent rocking mechanism with failure in the nails of the hold downs, see Figure 13 and Figure 14. The nails of the angle brackets showed also plastic deformations, due to the bidirectional tensile-shear loads they were subjected to. At the end of the tests, the hold down steel brackets showed small deformation whereas larger deformations were reached in the angle brackets' steel.

Figure 15 shows the load displacement curves of the shear wall tests, while Table 2 summarizes the average mechanical parameters of the shear wall tests evaluated according to EN12512.

The results show that the glulam walls have an average stiffness of 3.44 kN/mm, a maximum load of 55.29 kN and an ultimate lateral displacement of 71.10 mm. The average ductility of the shear walls is 7.55, indicating that the shear walls have a significant amount of deformation capacity beyond the yield point.

Figure 16 shows the cyclic properties of wall tests. Averagely, 27.1 kJ were dissipated at the end of the shear wall tests, with an average equivalent viscous damping of 13.6 %. The normalised impairment of strength showed an increasing trend up to the failure of the connections with maximum value of 10.8 %.

4 CONCLUSIONS

This paper presented an experimental study on the cyclic behaviour of glulam shear walls and typical hold down and angle bracket connection systems fastened to glulam elements with annular ringed nails.

The EN12512 procedure was used to calculate relevant design parameters for connections, including stiffness, strength, ductility, impairment of strength, and equivalent damping ratios. This data is significant when evaluating the seismic performance of timber structures since the majority of seismic forces and energy dissipation occur at the wall-base connections.

The mechanical behaviour of the connections was characterized by local deformation of the nails embedded into the timber and low deformation of the mechanical anchors. Hold down connections showed higher performance in term stiffness, strength, and ductility than angle bracket connections due to the higher number of nails used in the steel-to-timber joint. The mechanical behaviour of the shear walls was governed by the connections and characterised by large ductility and capability to withstand large cyclic displacements.

Results of this experimental study showed that typical hold down and angle bracket connection systems attached to glulam elements and glulam shear walls exhibit a ductile behaviour with mechanical performance similar to that of hold downs and angle brackets attached to CLT elements and CLT shear walls.

CYCLIC LOAD TESTS AND NUMERICAL ANALYSIS OF CLT SHEAR WALLS WITH GIR JOINTS

Shuhei Uesugi[1], Daisuke Kadono[2], Katsuhide Murakami[3], Masahide Murakami[4]

ABSTRACT: Four CLT shear wall specimens with GIR joints were subject to cyclic loading. The tensile anchor pre-yielding type specimens exhibited great performance and non-slip response because the M24 ABR steel anchors connected to the GIR joints contributed to resisting in compression. A numerical model using OpenSees was developed to simulate the global response and confirm the energy absorption. A crack was confirmed in one of the specimens before the GIR exhibited its ultimate strength. It is presumed that edge clearance distance may affect CLT shear walls performance for large deformations. The analysis model results are in good agreement with the experimental testing. Finally, the energy absorbed by the tensile bars on the compression side have been quantified.

1 INTRODUCTION

Cross-laminated timber (CLT) structures have attracted significant attention during the past decade to realise a low-carbon society and carbon sequestration. CLT shear walls are one of the most effective structural systems because of their high strength and in-plane stiffness. CLT shear walls and hybrid structures, such as combined CLT shear walls and steel moment frames have been proposed in the past [1-5]. CLT shear walls are characterised by their rocking behaviour, and the performance of the joints at the ends has a significant impact on the behaviour of the entire CLT shear wall performance [6]. However, it is difficult to realize high-strength and high ductility CLT walls because the strength and ductility of distributed connectors are limited.

In Japan, where earthquakes occur frequently, there is a need for the development of such high-strength and high ductility CLT walls. Aiming at the development of CLT shear walls which final failure properties can ensure high energy absorption properties with stable and ductile failure at the joint, if sufficient tensile performance can be secured using GIR joints that can ensure relatively high bearing capacity, a design method will be similar to reinforced concrete beam members calculation in terms of bending performance.

The authors designed CLT shear walls using GIR joints with high expected strength and confirmed the structure performance by cyclic loading tests. A numerical model is created using OpenSees to simulate the global response and the characteristics of GIR joints are discussed from the viewpoint of energy absorption.

2 SPECIMENS

Figure 1 shows the configuration of Specimen 1 and the steel base. The 0.95 m width and 1.95 m hight CLT shear wall was made of 5-layer, 7-ply cedar S60A CLT panels (@30 × 7 = 210 mm), which were glued with resorcinol adhesive along the width. The strong axis direction of the CLT panels was set in the vertical direction. The GIR joints were filled with epoxy resin adhesive (AICA Kogyo JB-3) and were used for the tensile and shear resisting joints. The anchorage lengths of the tensile and shear rebars were 750 mm and 210 mm, respectively, with D22 bar diameter and rebar grade SD345 which were manufactured by JFE Steel Corporation / Mizutori Works.

Tensile rebars were connected to M24 ABR anchors (manufactured by Dai-rock Ltd.) via mechanical couplers inside the wall base. The yielding capacities of the tensile rebars and ABR anchors were 133.5 kN and 115.0 kN, respectively, and the ABR anchors were expected to yield first. The lower flange of the steel base was tightened by nuts from the upper and lower side. A horizontal stiffener plate was arranged in the middle of flanges to increase the compressive buckling resistance of the M24 ABR anchors. Due to the nuts and the stiffeners, the M24 steel bars are expected to contribute to high energy absorption. Shear rebars were connected to shear plates (PL-12), and the joints between shear bars and shear plates were reinforced by fillet welding. There were long holes along the loading direction at the upper flange of the steel base so as not to the tensile rebars resist to the horizontal force.

Figure 2 shows the arrangement of the GIR joints of each specimen. Specimen 1 had tensile rebars at the second layer from the outside. Specimen 2 had two tensile rebars

[1] Shuhei Uesugi, Nikken Sekkei Ltd., Japan, uesugi.shuhei@nikken.jp
[2] Daisuke Kadono, Nikken Sekkei Ltd., Japan, kadono.daisuke@nikken.jp
[3] Katsuhide Murakami, Nikken Sekkei Ltd., Japan, murakamik@nikken.jp
[4] Masahide Murakami, KINDAI Univ. Faculty of Architecture, murakami@arch.kindai.ac.jp

https://doi.org/10.52202/069179-0275

at the fourth layer from the outside. Both specimens have eight shear-resistant rebars in the middle, placed in fiber direction layers and in the middle eight shear-resistant rebars were placed in fiber direction layers. Specimen 3 had no shear bars, and specimen 4 had only two shear bars. Specimens 1 and 2 were intended to check the tensile-yielding-procedures while specimens 3 and 4 were for checking the shear-yielding-procedures.

3 TEST SETUP

As shown in Figure 1, the specimens were placed horizontally to the ground and supported vertically by linear slider that do not constrain horizontal deformation, thus out-of-plane stiffening was not provided. A constant axial force of 246 kN was applied.

Loading was applied by gradually increasing the cyclic inter-story drift from 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50, 1/40, to 1/30. These cycles were repeated three times for each amplitude up to ±1/30. Loading was

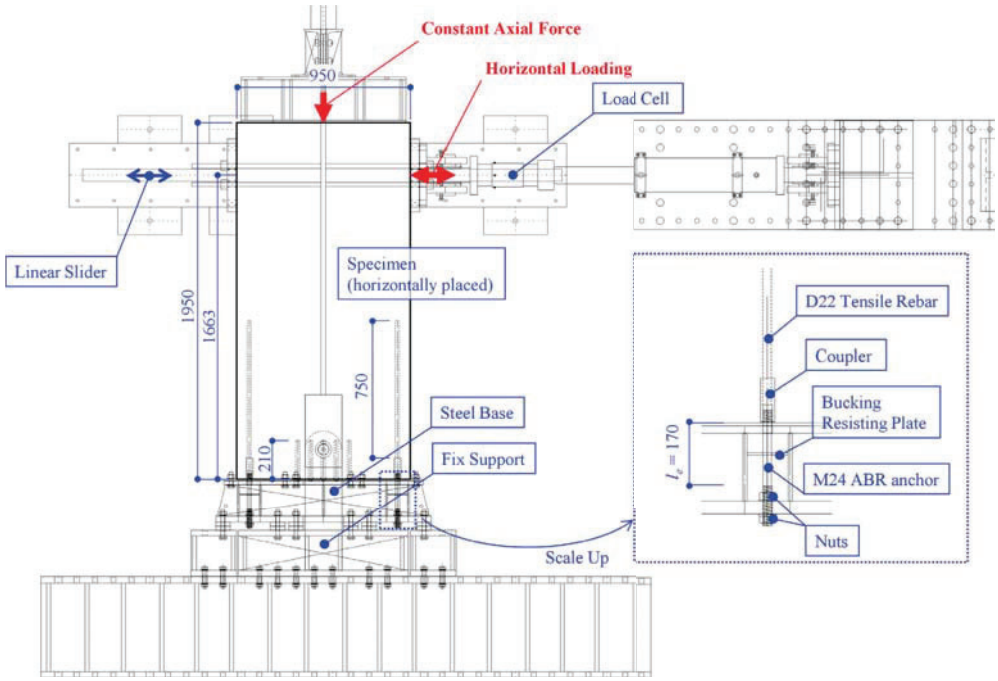

Figure 1: *Configuration of specimen 1 and test setup*

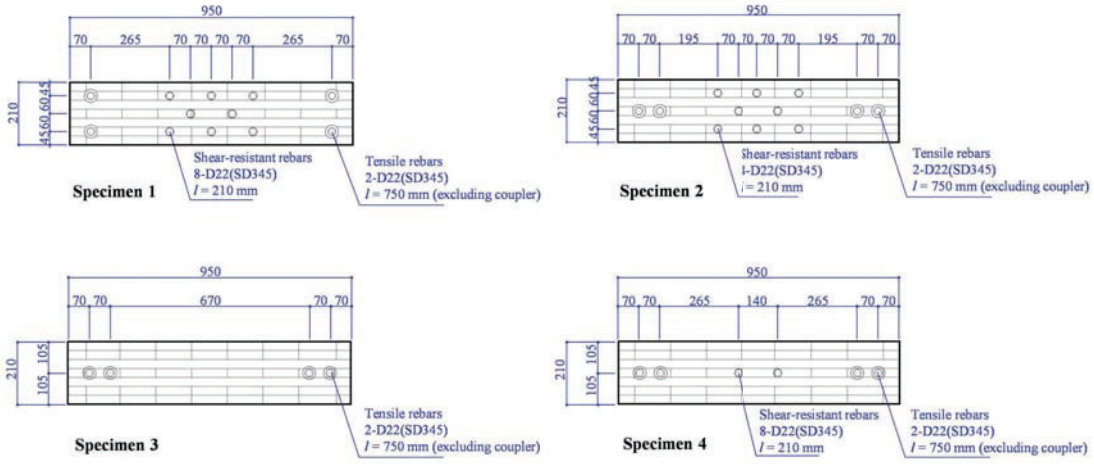

Figure 2: *Arrangement of GIR joints [Unit mm]*

https://doi.org/10.52202/069179-0275

continued until rupture of tensile bars or failure of CLT shear walls was confirmed.

Loading histories for specimen 3 was 1/450 (268kN-3*c*, 402kN-1*c*, 536kN-1*c*), 1/300 (268kN-3*c*, 402kN-1*c*, 536kN-1*c*), 1/100 (268kN-3*c*), 1/75 (402kN-2*c*) and 1/50 (536kN-1*c*). The constant axial force was changed to conform the friction between CLT and steel base and effect of axial force difference. The *c* indicates the number of cycles. In specimen 3, L-shaped steel was installed to restrain horizontal displacement of the CLT shear wall footings at the end of the 1/300 cycle. Figure 3 shows the relationship between shear drift angles and the number of cycles of specimen 3.

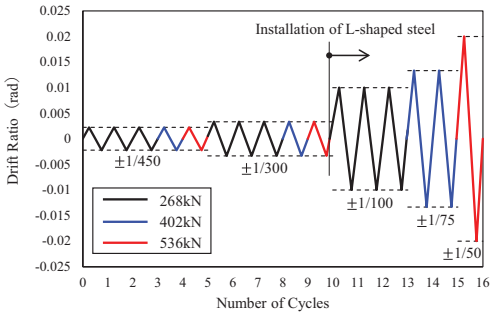

Figure 3: *Loading history at specimen3*

4 TEST RESULTS

4.1 GLOBAL RESPONSE

Figure 4 shows the relationship between horizontal force and horizontal displacement of each specimen (specimen 1 through 4). Specimen 1 exhibited yielding of the tensile rebar during the first excursion up to ±1/100. Subsequently, a stable response was observed up to ±1/75, and CLT cracked at the first excursion up to -1/50. At the second +1/30, the tensile bars were pulled out from CLT, and there was a sudden decrease of the horizontal force. Specimen 2 showed a stable response up to ±1/30, and fracture of the tensile bars was confirmed at a horizontal displacement of about +100 mm. Because tensile bars were arranged inside for specimen 2, the maximum strength of specimen 2 was slightly weaker than specimen 1. In Specimen 3, the adhesive between the CLT and shear plates peeled off after passing 1/450, and the friction between the CLT and shear plates and the shear of the tensile bars resisted against horizontal force up to 1/300. Fracture of the tensile bars was confirmed after the horizontal displacement reached 120 mm. Finally, for specimen 4, the ultimate shear force of 62.0 kN, which is equivalent to the ultimate shear force of two shear bars, was reached at 1/450 of a cycle, but the shear force continued to increase after that because of the tensile rebars acting to resist not only tensile force but also shear force.

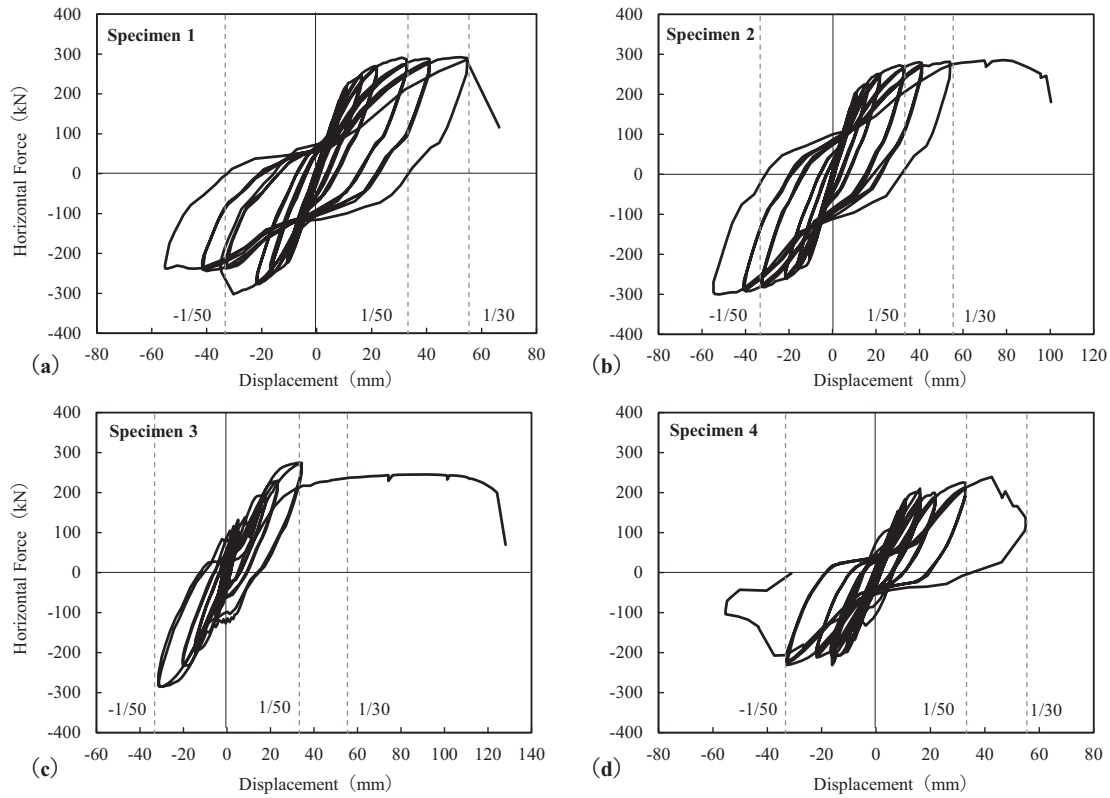

Figure 4: *Global response: (a) Specimen 1; (b) Specimen 2; (c) Specimen 3; (d) Specimen 4*

https://doi.org/10.52202/069179-0275

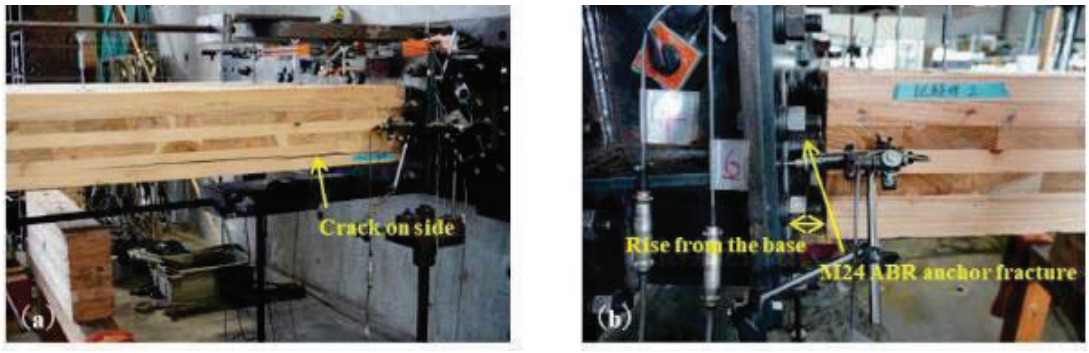

Figure 5: *Damage condition: (a) Specimen 1; (b) Specimen 2*

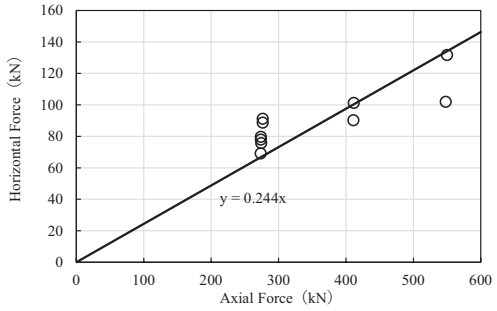

Figure 6: *Friction coefficient measured at specimen3*

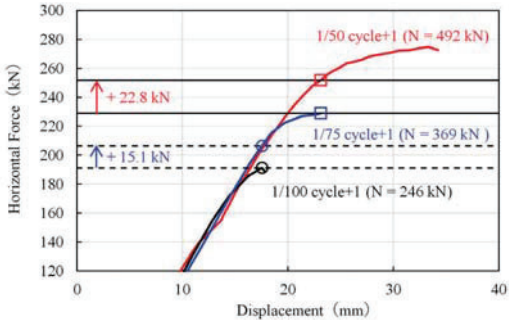

Figure 7: *Effect of axial force measured at specimen3*

The historical response of specimens 1 and 2, which were of the tensile bar pre-yielding type, was spindle-shaped, and energy absorption in the second and fourth quadrants was confirmed.

4.2 DAMAGE CONDITION

Figure 5 shows the damage of specimens 1 and 2. Specimen 1 had a crack on one side whereas specimen 2 had no damage. In the GIR joint with D22 rebar anchored 750 mm into the CLT, it was suggested that the CLT may have cracked and failed before the GIR exhibited its ultimate strength, because of the edge clearance distance. In the large deformation range, the separation between the CLT shear wall footing and the steel base increased, indicating that tensile forces were acting on the shear bars, which were expected to resist only shear forces.

4.3 FRICTION COEFFICIENT

Figure 6 shows the relationship between maximum horizontal and axial forces for each cycle measured on the positive side of the 1/450 and 1/300 cycles of specimen 3. The coefficient of static friction between the CLT and the steel base was calculated by the horizontal force divided by the axial force. The top flange of the steel base had a long hole along loading direction therefore the tensile bars didn't resist the shear force under such a small deformation range. The slope of the regression line (which means the static friction coefficient) was determined to be 0.244 using the least-squares method.

4.4 EFFECT OF AXIAL FORCE

Figure 7 shows the relationship between horizontal force and horizontal displacement for the first positive side up to 1/100, 1/75, and 1/50 for specimen 3. The horizontal forces increased by 15.1 kN by changing the axial force from 1.0 to 1.5 times during the transition from 1/100 to 1/75 cycles, and by 22.8 kN changing the axial force from 1.5 to 2.0 times during the transition from 1/75 to 1/50 cycles. The advantage of the self-centering ability: that the axial force snapped back to the initial position, was observed.

5 NUMERICAL ANALYSIS

5.1 NUMERICAL ANALYSIS MODEL

Hummel proposed a method for analysing the behaviour of CLT walls, which predicts the maximum strength and global response [7].

An attempt was made to reproduce the global response of specimen 2 using OpenSees, a general-purpose structural analysis framework [8]. Figure 7 shows an overview of the numerical analysis model, in which the CLT wall was represented by plastic beam-column elements and multi-springs were placed between the CLT wall footing surface, which was assumed to be rigid body, and the steel foundation. Tensile springs were placed at the same positions of the tensile and shear resisting bars, and a horizontal shear spring was placed in the center of the rigid body to consolidate the stiffness of the eight shear resisting bars.

https://doi.org/10.52202/069179-0275

Table 1 summarizes spring property of each spring. Detailed calculations are showed in the following section.

5.2 TENSILE SPRING PROPERTY OF TENSILE BARS

The elastic stiffness k_e of the tensile spring representing the tensile rebar and anchor was calculated from the following equation.

$$1/k_e = 1/k_{clt} + 1/k_a + 1/k_f \quad (1)$$

where k_{clt} = pull-out stiffness from GIR joint, k_a = tensile stiffness of ABR anchors, k_f = stiffness due to out-of-plane bending of the bottom flange

From previous studies [9,10], the tensile stiffness of the GIR joint with 750 mm anchorage length was 114 kN/mm, and the tensile stiffness of the D22 rebar exposed 300 mm length was 264 kN/mm. Pull-out stiffness from GIR joint was calculated by the series spring relationship.The tensile stiffness of ABR anchor was calculated from the axial stiffness with an effective length of 170 mm.

From the element tensile test of the M24 ABR anchor, the yield strength F_y, the ultimate strength F_u, the displacement of the yield shelf δ_1, and the secondary stiffness K_p were calculated. The stiffness after reaching the ultimate strength was set to zero. The yield strength in compression was set to 121 kN, which is the buckling strength following the Japanese code [11]. The effective buckling length l_b was set to 62.5 mm considering the stiffeners. Factors of safety were not considered when calculating the buckling strength in order to obtain a compression strength close to the actual behaviour. The stiffness after reaching the compressive yield strength was set to zero.

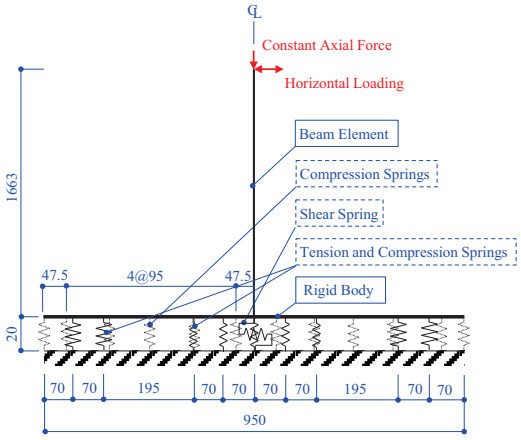

Figure 8: *Numerical analysis model*

5.3 TENSILE SPRING PROPERTY OF SHEAR RESISTING BARS

For the tensile stiffness of the shear resisting bars, a pullout stiffness of 54.5 kN/mm with an anchorage length of 210 mm was substituted for the tensile stiffness of the shear resisting bars from a previous study [12]. The shear resisting bars were assumed to resist only in tension since the effect of the shear resisting bars wasn't ignored in the large deformation range.

5.4 COMPRESSION SPRING PROPERTY OF CLT

The compression spring characteristics of CLT shear wall footing were calculated from the compressive stiffness and stress specified in the CLT-related Notification Manual and the Design and Construction Manual [12]. The effective width of the compression springs was set to 47.5 mm for the springs located at both ends of the rigid body, and 95 mm width for the other compression springs.

5.5 COMPARISION WITH TEST GLOBAL RESPONSE

Figure 9 compares the experimental and analytical global response of specimen 2. The analysis was in good agreement with the experiment results. The initial stiffness of the experimental and analytical results agreed at 19.1 kN/mm, and the maximum positive strength was 286 kN and 316 kN, respectively. The excursion to

Table 1: *Spring properties*

Type of springs	Tensile spring representing tensile resistance bar	Compression spring representing CLT wall	Tensile spring representing shear resistance bar	Shear spring representing shear resistance bar
Relationship between deformation and force				K_e Elastic Stiffness [kN/mm]	128	16.8 (edges) 33.7 (the others)	54.5	14.4
F_y Yielding strength [kN]	141(tension) 121(compression)	115 (edges) 230 (the others)	99.4	–
K_p Plastic Stiffness [kN/mm]	0.581	0.168 (edges) 0.337 (the others)	–	–
F_u Ultimate strength [kN]	201	–	–	–

https://doi.org/10.52202/069179-0275

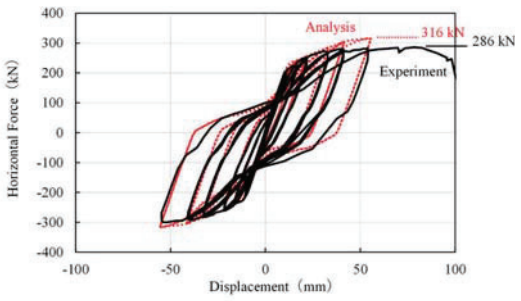

Figure 9: *Comparison experiment vs analysis*

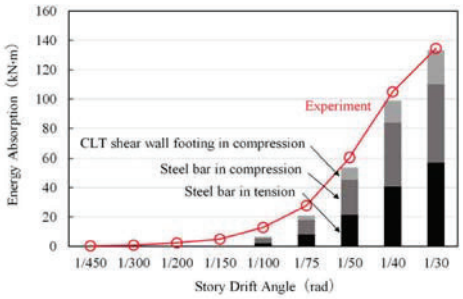

Figure 10: *Energy absorption*

unloading point from the peak strength, the experimental and analytical response showed slightly different behaviour. This difference is presumably due to the unloading stiffness of the tensile spring, that is set to be the same as the initial stiffness on the analysis, and there seems to be room for improvement in the modelling of the tensile spring.

5.6 ENERGY ABSORPTION

Figure 10 shows a comparison between experimental and analytical absorbed energy up to each cycle. The absorbed energy in the experiment is the sum of the horizontal displacement multiplied by the horizontal force at that point, i.e., the area bounded by the curve of the global response. The energy absorbed in the analysis was calculated from the response of tensile springs (simulating tensile resisting rebars) and compression springs (simulating the CLT wall footing). The energy absorption of tensile springs was defined as tension absorption when the axial force of the springs worked in tension and compression absorption was the opposite.

The larger the horizontal displacement, the better the agreement between the experimental and analytical values, with a difference of 3.37% at the 1/30 cycle. For the same cycle, the ratio of steel bars and CLT shear wall footing springs to the total energy absorption was 82.3% and 17.7%, respectively.

The energy absorbed by the steel bars on the compression side was 39.8% of the total energy absorbed, which means that the global response of the CLT shear wall exhibits a non-slip response.

6 CONCLUSION AND SUMMARY

Four CLT shear wall specimens with GIR joints were subjected to cyclic loading to examine the performance. A numerical model using OpenSees was developed to simulate the global response and confirm the energy absorption ability. Key results and observations are summarized below:

Specimens 1 and 2, which focused on using tensile rebars, exhibited great performance up to the 1/75 and exhibited a non-slip response because the M24 ABR steel anchors contributed to resisting in compression. In the GIR joint with D22 rebar anchored to the CLT by 750 mm, it was suggested that the CLT may crack and failed before the GIR exhibited its ultimate strength depending on the distance of edge.

The analysis model following Hummel proposed method reproduced the experimental behaviour of CLT shear wall specimen adequately. However, there was some room for improvement in the modelling of the tensile spring. The energy absorbed by the tensile resisting bars on the compression side was 39.8% of the total energy absorbed.

FULL-SCALE 3-D SHAKE TABLE TEST OF A TEN-STORY MASS TIMBER BUILDING

Shiling Pei[1], John W van de Lindt[2], Jeffrey Berman[3], Keri Ryan[4], James D. Dolan[5], Steve Pryor[6], Sarah Wichman[7], Aleesha Busch[8], Reid Zimmerman[9]

ABSTRACT: This paper provides a summary of the design, construction, and test planning of a shake table test program of a full-scale ten-story mass timber building. The shake table test program is a component of the experimental research work conducted as part of the NHERI TallWood project funded by the U.S. National Science Foundation. The goal of the NHERI TallWood project is to develop resilience-based seismic design methods for tall wood buildings through the adoption of a mass timber rocking wall lateral system and various detailing strategies for deformation-tolerant structural and non-structural connections and subassemblies. In this paper, the design configuration of the test structure is introduced, the construction process of both the structural and non-structural systems is explained, and the intended testing plan is presented. At the time of this writing, the construction of the building has been completed while the instrumentation process is ongoing. The authors intended to present initial results from the tests at the WCTE 2023 conference.

KEYWORDS: NHERI TallWood project, Shake table test, Tall wood building, Resilience, Seismic Design, Mass timber rocking wall

1 INTRODUCTION

Recently, mass timber construction materials such as cross laminated timber (CLT) have enabled taller wood construction projects including medium-to-high-rise mass timber buildings in the U.S. and around the world. Examples are the 10-story Forte building in Melbourne, Australia; the 18-story Mjøstårnet building in Norway; the 18-story Brock Commons building at the University of British Columbia, and the 27-story Ascent building in the U.S. Many of these tall wood buildings utilized non-wood lateral force-resisting systems such as reinforced concrete core walls or steel braced frames. At the same time, new mass timber-based lateral force-resisting systems have been proposed. Research on such systems continues at an impressive pace worldwide, including on post-tensioned mass timber rocking wall systems [1-3] and platform-framed CLT shear wall systems [4]. It is likely future mass timber buildings will continue to utilize a mixture of conventional and innovative lateral systems. However, amongst new mass timber lateral force-resisting systems, the post-tensioned mass timber rocking wall arguably demonstrates the greatest potential to enable a new type of tall wood building design that can achieve resilience and rapid return to functionality following an earthquake. Thus, the building can remain structurally damage free during design level earthquakes and be quickly repairable after maximum considered earthquakes.

The NHERI TallWood project was initiated in 2016 with the objective of developing a resilience-based seismic design methodology for tall wood buildings. Through funding provided by the U.S. National Science Foundation and U.S. Forest Service, the research team worked collaboratively with industry partners to develop design schematics, modelling tools, and resilience-based assessment methods in the past six years towards the goal of realizing a method to design a mass timber building based on functional recovery time. Based on past experience and assembly test data [2], the project team has completed the design of a 10-story mass timber building specimen with extracted features from realistic archetype buildings and under various physical constraints. One of the major constraints is the NHERI shake table dimensions (7.6x12.2 m) at the University of California San Diego (UCSD).

The shake table at UCSD is the world's largest outdoor shake table, thereby allowing a full-scale 10-story specimen to be constructed totalling approximately 34 meters in height. Building construction was completed in

December 2022, and instrumentation will continue through February 2023 with over 700 channels of displacement, acceleration, and strain sensors. The tests are scheduled to be conducted between March and May of 2023. The building performance during testing will be compared to the resilience objectives intended during the design process, thus validating resilience-based seismic design approach proposed.

2 BUILDING CONFIGURATIONS

The test building utilizes a mass timber beam-column grid with mass timber floor panels as the gravity force-resisting system. Four post-tensioned rocking walls (two in each direction, constructed using CLT and mass plywood panels (MPP) respectively) serve as the lateral force-resisting system for the building. The gravity system of the building was designed using typical office live load. The beams and columns were sized considering 2 hour fire condition with exposed wood (i.e., considering a sacrificial layer of wood for wood charring). The basic design information about the building is listed in Table 1.

Table 1: *Basic design parameters for the test building*

Building Characteristics	Value
Number of stories	10
Total height	34.1m
Total floor area	840m^2
Design floor load (Dead/Live)	3.1/3.1 kN/m^2
Total building weight	295 MT
Design location	Seattle WA
Estimated period	1.8 sec

There is a large array of different mass timber materials used in the construction of the building, including CLT, Mass Plywood Panel (MPP), Glu-Laminated Timber (GLT), Veneer Laminated Timber (VLT), and Nail/Dowel Laminated Timber (NLT/DLT). The composition of different material types on various building components is shown in Figure 1. Aside from the structural system, selected floors also have non-structural partition walls and exterior envelop installed to evaluate their performance during the tests. A rendered building configuration is shown in Figure 2.

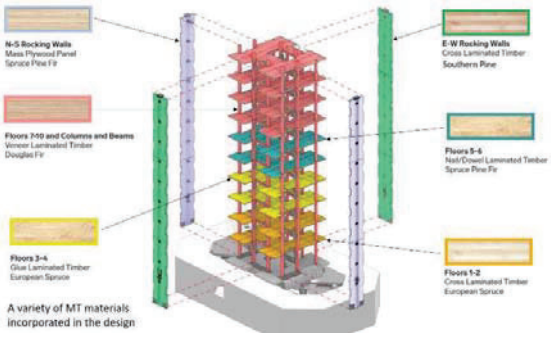

Figure 1: *Variety of mass timber material and components included in the tall wood test building*

Figure 2: *Rendering of the 10-story test building on the NHERI@UCSD outdoor shake table (Rendering courtesy of Lever Architecture)*

3 DESIGN AND CONSTRUCTION PROCESS

The objective of the NHERI TallWood Project is to develop a resilience-based seismic design methodology for tall wood buildings. The test building was designed with the objective of quantifying resilience, essentially time to functionality, as a function of building damage. In order to use resilience as a design metric, one of the first steps is to develop and validate an approach to assess and predict building damage and associated repair time following an earthquake. A fragility-based approach was utilized to link building response (i.e., floor acceleration and inter-story drift) to component and system damage, and then from damage to repair time [5]. This approach will be calibrated and validated using data obtained from the shake table tests.

As for the design of the test building, the project team took an indirect approach to address resilience. First, basic configuration parameters (e.g., rocking wall length, post-tensioning (P/T) force level, etc.) of the building and lateral force-resisting system were estimated using a prescriptive design method developed by collaborators of the project team [6]. This approach is largely force-based using demands generated with the modal response spectrum method from ASCE 7 [7] and a linearized model in ETABS [8]. Then a full nonlinear dynamic model in OpenSees [9] was used to evaluate acceleration and drift limits necessary to achieve the target resilience. Aside from the rocking wall lateral force-resisting system, which is designed to exhibit nonlinear behaviour (i.e., rocking behaviour at the base and yielding of energy dissipaters), all other structural components are designed to remain essentially elastic with negligible damage through providing sufficient overstrength or appropriate connection detailing.

Construction of the test building started in July 2022. Before construction, the outdoor shake table at UC San Diego was expanded by adding 4 cantilevered concrete foundation blocks to the long edge of the shake table. See

https://doi.org/10.52202/069179-0276

Figure 3. This expansion provided a roughly 11 x 11 meter footprint for building construction. Four steel foundation beams were also installed on the shake table serving as the base of the rocking walls. All foundation components were connected to the shake table through post-tensioned steel rods. The post-tension forces were determined based on the calculated shear demands from the numerical models. Before construction started, the ground motions intended to be used during the test were replayed on the shake table to ensure clearance and to determine the tuning parameters for the shake table control.

Figure 3: *Foundation system added on the NHERI@UCSD outdoor shake table before construction started*

Construction of the NHERI TallWood test building structural system lasted for approximately 4.5 months. Swinerton Mass Timber/Timberlab was the structural contractor and planned the erection and construction engineering for the building process. The construction of the test building was especially challenging due to the limited floor plan area on the shake table, which makes temporary bracing congested. Temporary post-tensioning of the rocking walls on the lower floor had to be implemented in order to utilize the partially completed rocking wall panels as the lateral bracing system for construction loads.

The two pairs of mass timber rocking walls are a key component of the test building. Aside from the material and some minor dimensional differences, the CLT and MPP rocking walls utilized the same design. The rocking wall panels are strengthened at the base corners with steel armor plates. The post-tensioning rods were installed on the outside of the wall panels near the centre of the wall. Because of the height of the building, each rocking wall consists of 3 individual mass timber panels that had to be spliced on site. The splice connection was designed as a series of steel tension and shear rods embedded in the wall using special epoxy material. During the fabrication of the wall panels, a number of the predrilled holes at the panel splices were fabricated out of tolerance. This resulted in a change in connection design during construction to use coupler steel plates at the splices in order to bridge the mismatched hole coordinates. Between the rocking wall panel and bounding columns on each side of the wall, steel U-shaped flexural plates (UFP) were installed in order to provide energy dissipation to the lateral force-resisting system. Photos demonstrating the main details along the height of the rocking wall system can be seen in Figure 4.

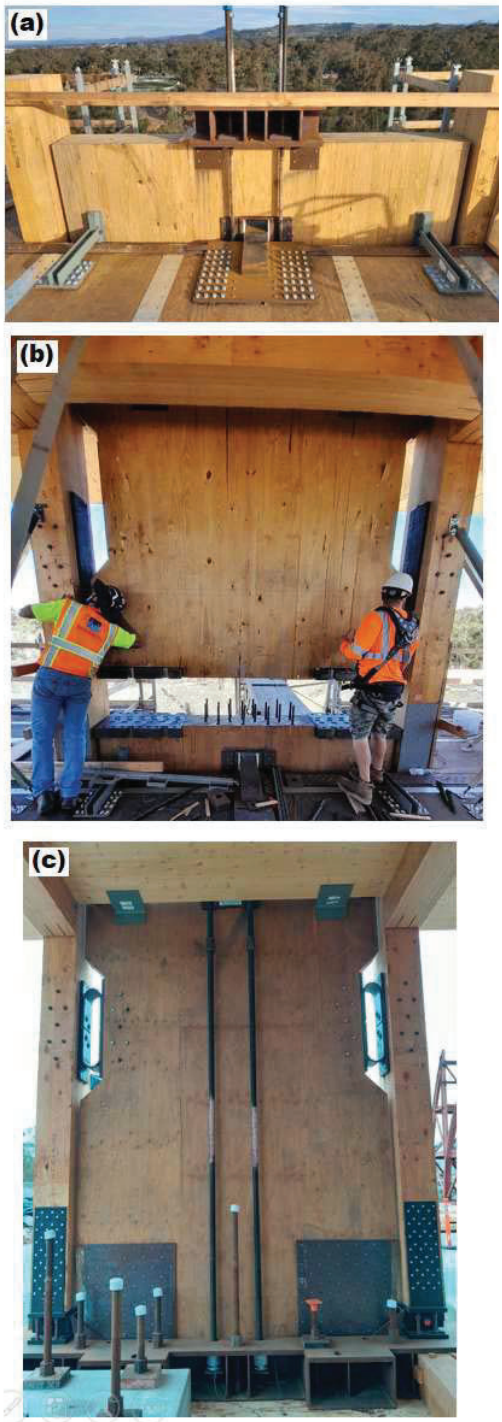

Figure 4: *Post-tensioned rocking wall system (a) PT anchor at wall top (b) Wall splice being installed (c) foundation level detail and UFP devices*

https://doi.org/10.52202/069179-0276

Figure 5: *Construction process of the test building*

The gravity system was erected along with the rocking wall segments. As shown in Figure 5, a modular stair and gravity columns were placed first, followed by the mass timber beam grid and floor panels. Once the gravity system reached the height of the rocking wall segment, the rocking wall panels were installed. This process was repeated 3 times during construction until the building was topped out. After that, the post-tensioning rods were extended to the top of the wall and stressed to complete the lateral force-resisting system. Once the design post-tensioning forces were applied (about 890 kN total post-tension force was applied to each wall), the construction of the structural system was complete.

In order to accurately evaluate repair time from non-structural system damage, the test specimen also included exterior façade subassemblies on the first three floors, interior partition walls, and a 10-story stair tower. Various low-damage deformation compatible details were implemented with the expectation of eliminating damage in small earthquakes and limited damage in design basis earthquakes. The details include horizontal slip joints fr walls, vertical joints at intersecting walls, and specialized joints for connecting stair stringers to mid-landings.

Figure 6: *Selected non-structural systems and components included in the test (a) Curtain wall (b) Exterior wall and windows (c) Interior partition walls.*

Figure 6 shows a few selected non-structural components, including a fire-rated curtain wall system, exterior stud wall with windows, and interior partition wall with low-damage joint details. Non-structural system construction is currently ongoing and is expected to be completed in February 2023.

4 INSTRUMENTATION PLAN

A comprehensive plan for instrumentation of the test building was developed and implemented. There are a total of over 700 instrumentation channels monitoring key aspects of the building response, namely overall building demands, rocking wall behavior, and non-structural system performances.

As shown in Figure 7, a 3D accelerometer was placed near the centre of mass of the floor diaphragm at each floor. String potentiometers will mainly be used to measure inter-story displacement, as well as absolute displacement for lower floors where they can be attached on the safety reference tower. The deformation of the rocking wall and building components are measured using LVDT sensors and tilt meters. Strain gauges were installed on key load-transferring components (e.g., tension straps and floor shear transfer keys) to monitor internal forces. Customized load cells were placed at the post-tensioning rod anchor to record rod forces. Examples of the installed sensors are shown in Figure 7.

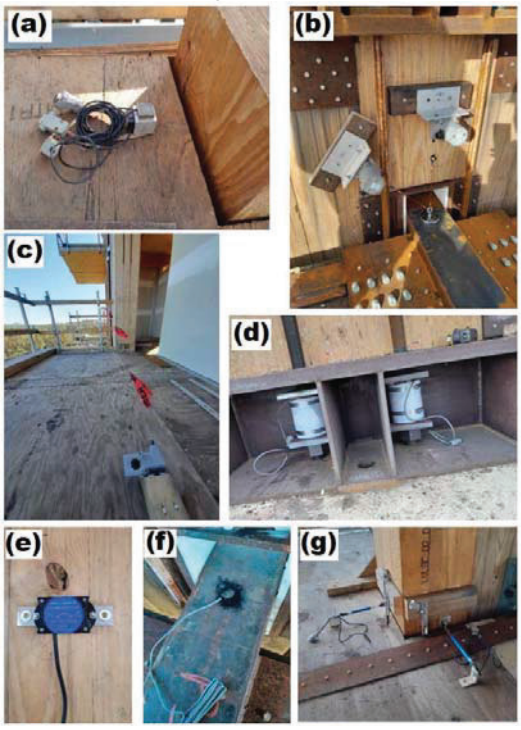

Figure 7: *A variety of sensors installed on the test building (a) Accelerometer on the floor (b) String potentiometer for small deformation (c) String potentiometer for inter-story displacements (d) Custom load cells for PT forces (e) Tilt angle sensor for rocking wall response (f) Strain gauge on key load transferring components (g) LVDT sensor for column rotation*

https://doi.org/10.52202/069179-0276

A summary of all sensors implemented on the test building is listed in Table 2. Data obtained from these sensors during the test will serve multiple purposes, including providing key safety limit information during testing, calibrating and validating numerical models developed by the research team and other engineers after the test, and helping support damage fragility models of structural and non-structural components within the building. The data obtained from the tests will be archived and made public on the DesignSafe-CI database following the end of the NHERI TallWood project.

5 TEST PROGRAM

The tests of the Tallwood building will be conducted on the newly upgraded 6-DOF high performance outdoor shake table at NHERI@UCSD in San Diego California. The research team plan to subject the building to a suite of ground motions selected and spectrally matched to represent seismic hazard at a site in Seattle WA, the location selected for the design of the building. Earthquake ground motions that will be used during testing have been selected and scaled to represent different hazard levels and sources affecting the site in Seattle, thus providing a realistic evaluation of the performance-based design for the building. The hazard levels include the 225 year, 475 year, 975 year and 2475 year return periods.

In order to achieve the desired range of hazards and sources, a total of 20 3D ground motions were selected, scaled and used to tune the shake table control before construction started. These inputs include recorded ground motions from historical earthquakes with different source types ranging from crustal earthquakes such as the Northridge Earthquake (1994) to interface subduction earthquakes such as the Tohoku, Japan Earthquake (2011). In particular, the interface subduction ground motion records contain significant amounts of excitation energy in long period ranges, which are believed to be especially detrimental to tall buildings. They also have long duration, resulting in many cycles of loading. All the ground motions at the Risk-Targeted Maximum Considered Earthquake (MCE_R) level which approximately corresponds to a 2,475 year return period, were used to tune the shake table. The test program will start at the lower hazard levels (i.e., lower levels of ground motion intensity). It will then continue with ground motions scaled to the larger and larger intensity levels. Numerical simulations will provide insight on the ground motions as the testing continues with decisions made dynamically as information is gathered following each test. The response spectra for the selected ground motions, scaled for different hazard levels, are shown in Figure 8 where the bold lines indicate averages at each hazard level. The ASCE 7 MCE_R spectrum used for design is also shown.

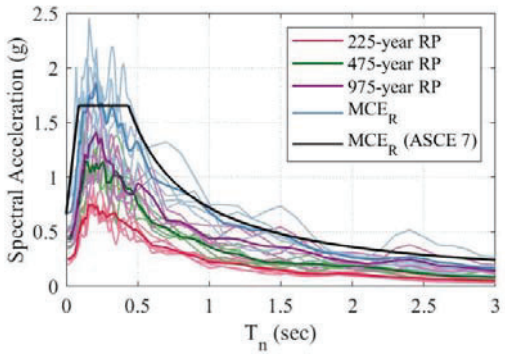

Figure 8: *Response spectra for all candidate ground motions at four representative hazard levels.*

Based on the schedule constraints, the test program will include 30 – 40 seismic tests over a period of about one month. White noise excitation will be implemented before and after each seismic test in order to gather data on the change in building dynamic characteristics. Since most of the practical design calculations currently required by the code do not consider biaxial or tri-axial excitation, the ground motion inputs were planned to first isolate the influence of multi-directional interaction. It is planned that the uniaxial ground motion components will first be applied. This will be followed by applying ground motion in the two horizontal directions and then by a full 3D motion. A typical testing sequence for one 3D seismic input at a given intensity level will include 5 tests and span over two to three days (See Table 3). This test program will help validate the design calculations/checks in a uniaxial configuration. The data from this test sequence will also be able to shed light on building response beyond code requirements in a biaxial and 3D excitation setting.

According to pre-test numerical simulation, the maximum inter-story drift during the planned test program will not exceed 3%, with the maximum drifts occurring in the MCE_R ground motions. Damage to non-structural systems at these drift levels is expected, while the structural system should experience negligible damage (except localized, expected component damage such as UFP energy dissipaters) throughout the test program. Comprehensive inspections of the test building will be conducted on both the structural and non-structural systems following significant testing events. The research team is planning for concluding the first phase of the test by April 2023.

https://doi.org/10.52202/069179-0276

Table 3: *As-planned typical testing sequence for a single seismic hazard level*

Test	GM record	Building direction	Comments
1	GM_H1	X	CLT wall response
2	GM_H1	Y	MPP wall response
3	GM_H2	Y	Biaxial comparison
4	GM_H1H2	XY	Biaxial test
5	GM_H1H2V	XYZ	Tri-axial test

Note: H1, H2 and V represent horizontal 1, horizontal 2 and vertical components of a ground motion.

6 KEY RESULTS

At the time of this writing, the building is still undergoing instrumentation, and no seismic tests have been conducted. The research team is expected to complete instrumentation of the structure by March 2023 and complete all testing by June 2023. It is expected that initial results from these tests will be presented in the conference presentation. It is envisioned that key testing results will include the dynamic response of the building and damage inspection outcome after large tests.

7 CONCLUSIONS

The ten-story Tallwood building test program planned in this study represents one of the most significant research efforts in recent years to experimentally validate tall wood building performance during earthquakes. Through extensive collaboration with the mass timber industry partners, the building archetype and construction details included in the test program are also readily implementable in realistic building projects for high seismic regions. While the test results are not available at the time of this paper, key details and the design methodology utilized in this project were introduced.

It is expected that the test building will have resilient performance, which corresponds to negligible damage under frequent earthquakes, negligible structural damage under design level earthquakes, and be quickly repairable under maximum considered earthquakes. The outcome from this test will help advance knowledge on mass timber structural system design and provide increased confidence to the mass timber market in regions with high seismicity around the world.

ACKNOWLEDGEMENT

The NHERI TallWood Project is a collaborative research project, supported under National Science Foundation (NSF) awards 1636164, 1634204, 1635363, 1635156, 1634628, carried out through collaboration with the U.S. Forest Service (USFS) through the Wood Innovation Fund program, Forest Product Laboratory and a large number of industry partners (see http://nheritallwood.mines.edu/collaboration.html). CONSTRUCTIVE REHABILITATION OF THE FLOOR STRUCTURES OF ZAGREB'S DOWNTOWN BUILT IN THE FIRST HALF OF THE 20TH CENTURY

Dean Čizmar[1], **Krunoslav Pavković**[2], **Marija Babić Tončić**[3], **Ivana Iljkić**[4]

ABSTRACT: The major damage to the buildings in Zagreb's Lower downtown caused by the earthquake is partly the result of the way the timber ceilings were built, which are mostly not connected to the masonry walls on which they rest. In this way, they do not have the properties of rigid diaphragms, which, due to the effect of an earthquake, leads to the loss of the integrity of the construction.

In the paper, we consider the possibility of strengthening timber ceilings with regard to the significant requirements of preserving cultural heritage, and present the results of selected types of reinforcement. The considered types of reinforcement are: reinforcement of the timber beams with a concrete compression slab, reinforcement of the timber beams with wooden elements - OSB boards, and reinforcement with steel elements.

Regarding the possibility of implementation, a conclusion was given on the chosen method that meets the given requirements in terms of horizontal stiffness and the preservation of the cultural and historical heritage of the downtown core.

KEYWORDS: Zagreb earthquake, timber ceilings, horizontal stiffness, seismic analysis

1 INTRODUCTION

Due to the earthquake in Zagreb on March 22, 2020, there was extensive damage to the downtown architecture. Damage is partly due to the way timber ceilings are built. Most of the damaged buildings were built in period 1900 and 1948. In that period, all buildings have deficiencies in terms of meeting the criteria of earthquake resistance, unconnected ceilings with walls, i.e., the inability to transmit horizontal forces, load-bearing walls made of unbounded masonry, and poor connections of basic assemblies and elements without the necessary load-bearing capacity and ductility [1].

Masonry buildings are structural systems of vertical and horizontal parts whose seismic response is the result of the interaction of wall with wall and wall with ceiling or roof. In order for the structure to meet the behaviour during an earthquake, it is necessary to realize the bearing capacity and rigidity of the walls in the plane and to prevent the collapse of the walls outside the plane [2].

In the paper we will analyse the possibility of strengthening the classic timber ceiling structures. These proposals for constructive rehabilitation will enable the strengthening of existing ceiling timber structures but also the preservation of cultural heritage, as damaged. buildings are individually or as an urban entity protected as Immovable Cultural Heritage.

2 CASE STUDY

The subject building is a residential building located in the downtown of the city of Zagreb, at the address Medulićeva street 16/3. The building was built in the first part of the 20th century (before 1920).

https://doi.org/10.52202/069179-0277

Figure 1: *The western façade (face) of the structure*

The vertical bearing structure consists of brick walls, while the ceiling structure is made of timber beams. The residential building has a basement, ground floor and 3 floors [3].

Figure 2: *The eastern façade (face) of the structure*

In the floor plan, we see a deficiency of walls in the x direction, and we can immediately establish that this is the weaker direction of our building.

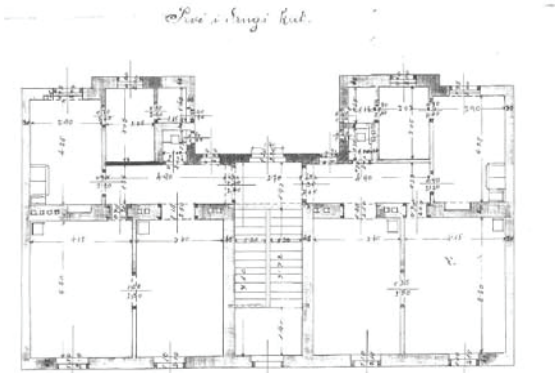

Figure 3: *Archival floor plan of the building (first and second floor)*

In this period [4], buildings are built that have predominantly timber ceiling structures, except for the basement ceilings, which are most often made in the structure of masonry vaults, arches, or Prussian ceilings. The extensive damage due to earthquakes is partly due to the way timber ceilings are built, which do not have the characteristics of rigid diaphragms, they cannot connect all the load-bearing elements into one whole. The consequence of this is the local failure of the walls.
Existing timber beams, meet the criteria of the final ultimate limit state of bearing capacity (ULS) while the limit states of serviceability are generally not met, mostly due to rheological phenomena (creeping). Furthermore, the connections of timber beams and walls are made by direct adhering the beams to the walls, as a rule, without anchoring. This type of design allows only reliable resistance to vertical actions, while resistance to horizontal actions is extremely low [3].

3 REHABILITATION METHODS

The possibility of rehabilitation, i.e., increasing horizontal and vertical stiffness is possible with concrete compression plate, OSB slabs or timber or wood-based elements and steel profiles. To achieve appropriate effect, it is necessary to connect the beams to the walls. In the case of reinforcement with the concrete compression plate [5], a pliable connection between concrete and wood is made.
Considering the weight of the rubble and the weight of the reinforced concrete slab, the own weight of the ceiling structure does not increase significantly. By placing the fasteners in the existing wooden beams, the structure is connected, and in this way, significantly greater load capacity and rigidity is achieved perpendicular to the plane, while inside the plane we get a rigid disc [1]. The pressure plate can be made of classic concrete C25/30 or light concrete EPS.

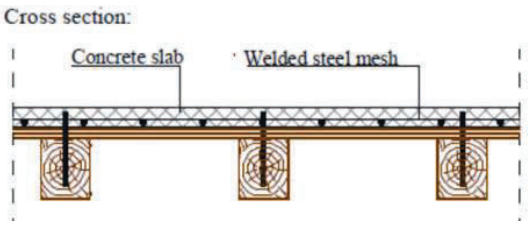

Figure 4. *Reinforcement of the timber beams with a concrete compression slab*

Figure 5. *Reinforcement of the timber beams with a concrete compression slab*

The disadvantages of this method of rehabilitation are changes in the stress state in the T-section and the action of two different materials of different stiffness and rheological characteristics [5].
Rehabilitation and reinforcement with OSB plates (possibly veneer plates or wooden boards) can be done

https://doi.org/10.52202/069179-0277

from the bottom or top side of the timber beam. This way of stiffening is a partially rigid diaphragm.
By placing wooden boards on the existing ceiling structure, i.e., timber beams, a double reinforcement effect is achieved. Reinforcement to vertical load, but also to horizontal action, is achieved if the elements that form the diaphragm are properly connected to each other to take the shear load.
The ceiling structures must be connected to the walls so that they do not separate during the horizontal effects of the earthquake force, but also to enable the proper distribution of the seismic force on the individual walls. Wooden panels made of OSB boards 22 mm thick is placed in two layers, the first layer is placed at an angle of 45° in relation to the beam, and the second layer is placed at an angle of 90° in relation to the first. The connection to the beams is made with self-tapping screws. Each joint is made with a minimum of 2 wood screws [1].
With the diagonal arrangement of the additional layer, we get better pressure resistance and stiffness in both planes [2].
To achieve continuity, it is necessary to adequately secure the joints with the walls.

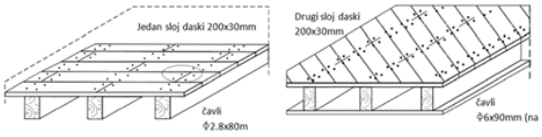

Figure 6. *Reinforcement with OSB boards on the top or bottom*

Rehabilitation and reinforcement with steel elements is usually carried out between the last two ceiling timber beams in such a way as to install steel sheets forming a lattice girder [4]. Horizontal stiffening of wooden ceiling structures with steel elements is carried out when no additional vertical bearing capacity of the structure is required, but only the absorption of horizontal forces [1].

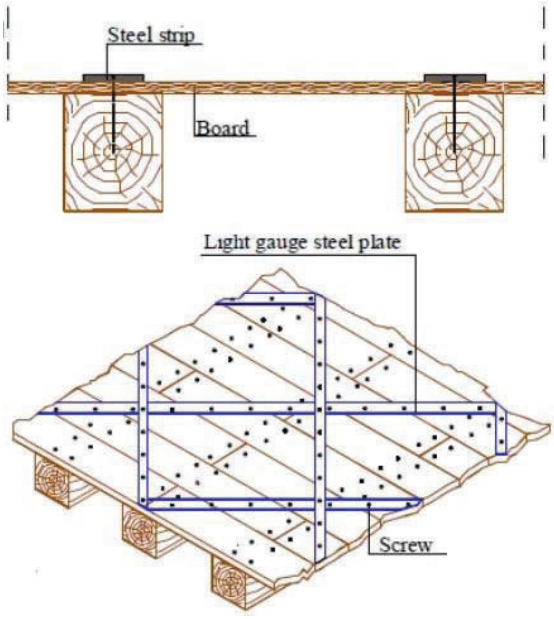

Figure 7: *Reinforcement with steel elements*

Figure 8: *Steel strip*

3.1 NUMERIC MODEL DESCRIPTION

For the purpose of the numerical modelling, an analysis of 3 cases was made – a timber beam without stiffening (existing condition) – model A, a timber beam with an 8 cm concrete plate - model B (composite timber-concrete), a timber beam with an OSB plate 24 mm – model C.
We describe the possibility of strengthening timber ceilings with steel elements, but we did not model it due to the complexity of creating such a model in the program for masonry structures.
Several models of the current state have been made, each of which has its own assumptions in modelling. A linear-elastic model was made. This model is acceptable for engineering practice. The following loads were considered:
LC1 - self-weight
LC2 – additional self-weight
LC3 – live load 2 kN/m2 in residential areas, 0.75 kN/m2 on an impassable roof and 3 kN/m2 on the staircase

https://doi.org/10.52202/069179-0277

LC4 - earthquake in X direction
LC5 - earthquake in the Y direction

A modal spectral analysis was made for the calculation, and the load was taken as if we wanted to strengthen the structure to meet level 2 of the seismic reconstruction. Among other data, soil type C, type 1 spectrum, soil acceleration coefficient 0.13 and behavioural factor 1.5 were assumed, which corresponds to the assumptions in Eurocode Standard for unbounded masonry. For each model, 30 different modes were considered [3].

In the model of the existing state, the beams are modeled so that they carry in the shorter direction, and in this way only the walls in the transverse direction take over the loads on the wall. (Model A). Due to the vertical/longitudinal direction of the earthquake in relation to the timber beam (in the direction of the timber beams), an orthotropic seismic response occurs, i.e., relative displacements of the beams and bending of the floor covering occur, while the load perpendicular to the direction of the timber beams causes bending of the beams and relative movements of the floor covering [2].
The second model is a model with a reinforced concrete pressure plate 8 cm anchored in the walls (model B).
The third model is stiffened using OSB panels on the upper side of the beams (model C). The thickness of the panels is assumed to be 24mm.

3.1.1 Seismic design in 3Muri

A 3D numerical model of the subject building was created using the 3Muri computer program. Seismic analysis of the observed structure was performed using a non-linear static calculation, i.e., a gradual pushover method with a constant gravity load and a monotonically increasing horizontal load.

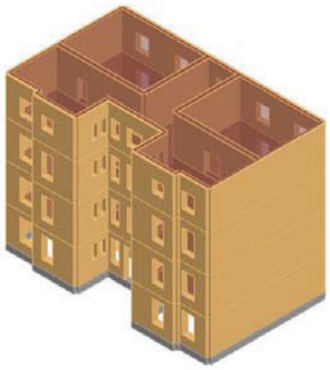

Figure 9: *3D building model - existing condition*

After the response of the structure to seismic excitation, i.e., the so-called capacity of the structure, which is independent of the seismic demand, is obtained, controls are carried out in accordance with the HRN EN 1998-3 standard according to the basic requirements related to the state of damage to the structure, which are defined by limit states.

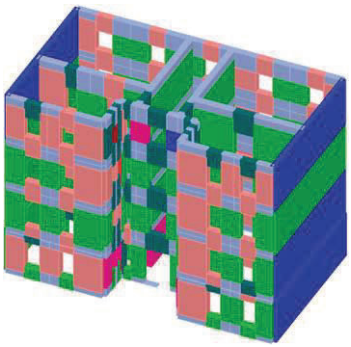

Figure 10: *3D Seismic model - existing condition (Model A)*

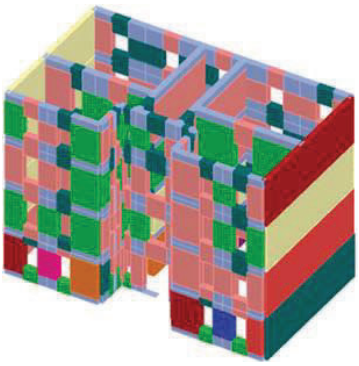

Figure 11: *3D Seismic model - reinforcement with a concrete compression slab (Model B)*

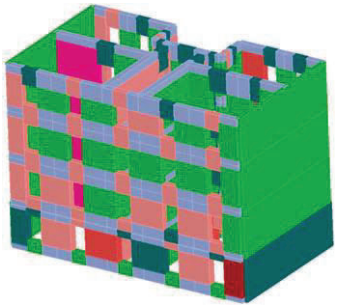

Figure 12: *3D Seismic model - reinforcement with wooden elements - OSB boards (Model C)*

https://doi.org/10.52202/069179-0277

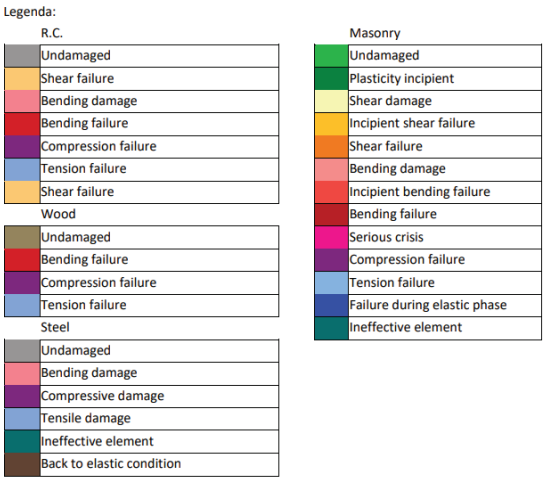

Figure 13: *Legend of structural damage*

The constructed 3D models represent the distribution of stiffness and masses, and thus all significant forms of deformation as well as inertial forces in the observed seismic action are taken into account. The analysis was performed according to Eurocode 8 [5,6].

For the method of gradual pushing, two forms of vertical distribution of lateral forces were used. These are a uniform distribution that is proportional to the mass of the structure on each floor, and a linearly increasing distribution in height that has the shape of an inverted triangle. The mentioned lateral forces act at the locations of the masses in the model. A random eccentricity of 5% was also considered, which takes into account possible uncertainties in the position of the masses. The result of the earthquake analysis is a capacity curve that gives the relationship between the transverse force at the footing and the control displacement.

4 RESULTS

The analysis for the existing condition shows the expected results - local failure of individual elements (walls are not horizontally connected). The largest displacements were achieved on the model of the existing state, where the horizontal stiffness of the timber ceiling is the least, and the smallest displacements are on the model of the reinforced concrete compression slab, which has the highest stiffness of the mentioned models.

Table 1: *Calculated construction shifts for individual models*

Model	Maximum displacement of the structure compared to model A [%]
Model A	100,00%
Model B	73,74%
Model C	65,42%

The tables below show the results of the pushover analysis for displacements under seismic loading for the X and Y directions:

The tables below show the results of the pushover analysis for the limit states of significant and limited damage under seismic loading for the X and Y directions:

Table 5: *Pushover analysis – limit states (Model A)*

Br.	Seismic load direction	Seismic load	α SD	α DL
1	+X	Uniform	0,735	0,394
2	+X	Modal distribution	0,059	0,155
3	-X	Uniform	0,790	0,345
4	-X	Modal distribution	0,064	0,169
5	+Y	Uniform	0,354	0,722
6	+Y	Modal distribution	0,249	0,525
7	-Y	Uniform	0,489	0,683
8	-Y	Modal distribution	0,339	0,657

Table 6: *Pushover analysis – limit states (Model B)*

Br.	Seismic load direction	Seismic load	α SD	α DL
1	+X	Uniform	0,758	0,416
2	+X	Modal distribution	0,335	0,367
3	-X	Uniform	0,820	0,366
4	-X	Modal distribution	0,463	0,433
5	+Y	Uniform	0,632	0,811
6	+Y	Modal distribution	0,614	0,847
7	-Y	Uniform	0,500	0,727
8	-Y	Modal distribution	0,514	0,754

Table 7: *Pushover analysis – limit states (Model C)*

Br.	Seismic load direction	Seismic load	α SD	α DL
1	+X	Uniform	0,917	0,403
2	+X	Modal distribution	0,944	0,404
3	-X	Uniform	1,137	0,361
4	-X	Modal distribution	1,050	0,417
5	+Y	Uniform	0,720	0,841
6	+Y	Modal distribution	0,772	0,719
7	-Y	Uniform	0,472	0,726
8	-Y	Modal distribution	0,599	0,624

According to the results of the calculation, the building model without reinforcement (model A) does not satisfy the deformability conditions in all analyses for the limit state of limited damage (DL) and for the limit state of significant damage (SD), with the most unfavourable analysis being 2 in the direction x for which the structure had the ability to withstand 5.9% of the designed peak ground acceleration for a return period of 475 years.
The result of the calculation of model B - the beam reinforced with a concrete compression slab does not satisfy the deformability conditions for any of the limit states, and in the most unfavourable analysis 2 in the x direction, the structure had the ability to withstand 33.5% of the designed peak ground acceleration for a return period of 475 years.

Results for the calculation model C - strengthening with OSB plates, shows that the building does not satisfy the deformability conditions for both limit states of damage, with the most unfavourable analysis being 7 in the y direction, for which the structure had the ability to withstand 47.2% of the designed peak ground acceleration for the return period from 475 years.

5 CONCLUSIONS

After conducting an analysis of various preliminary models of this structure, the best result in terms of increasing the horizontal stiffness of the structure is the use of concrete plate. But there is a problem with the influence of the stiffness of the compression plate on other structural elements, i.e., masonry, and the invasiveness of such a procedure.

However, the analysis showed that despite the high local stiffness of the slab, the calculated displacements of model B are about 11% higher than those of model C. This is explained by the relatively larger mass acting on the walls.

The advantages of strengthening with wooden elements are:

- execution speed,
- low self-weight,
- non-invasiveness
- stiffening in both planes
- can be used for both ceiling and roof systems [2].

Reversible strengthening techniques are preferred when strengthening historical heritage buildings. In this case model B represents an irreversible technique while model C is reversible therefore, option C is presented as the optimal solution.

EXPERIMENTAL RESEARCH ON THE SEISMIC PERFORMANCE OF WATTLE AND DAUB INFILLED CHUAN-DOU TYPE TIMBER FRAMES

Rui Xu[1], Yunyang Qi[2], Hao Huang[1,3]

ABSTRACT: In the southwest of China, the Chuan-Dou type timber structure is widely seen in traditional dwellings, temples and halls, among which the wattle and daub (W&D) infilled wall is a relatively common embedded wall. Based on a large-scale field investigation of 30 traditional wooden structures in Chongqing, this paper had conducted experimental research on the quasi-static loading test of one bare Chuan-Dou frame and two W&D infilled Chuan-Dou frames with different wall thickness. The damage characteristic, bearing capacity, stiffness, ductility and energy dissipation of each specimen were analyzed. The results had shown that, compared with bare frame, the W&D infilled frames had obvious better lateral performance; the thicker the infill wall, the higher the bearing capacity, stiffness and dissipated energy of the specimen while also the more intense the damage of the infills.

KEYWORDS: Chuan-Dou type timber frame, Wattle and daub, Seismic performance, Quasi-static

1 INTRODUCTION

Many scholars have carried out some research on the seismic performance of traditional bare timber frames, masonry or wood panel infilled timber frames [1–3]. Finite element simulation is also one of the key research directions, so as to check the failure mode of components in the test and analyse its seismic mechanism [4,5]. However, the W&D infilled timber structure (Figure 1), which is widely distributed in the southwest of China, still lacks adequate research, it is urgent to carry out relevant research to clarify the seismic characteristics of the W&D infilled Chuan-Dou timber frames.

Figure 1: *W&D infilled timber structure*

2 EXPERIMENTAL PROGRAM

2.1 DESIGN OF SPECIMEN

In order to study the effect of the embedded wattle and daub wall and the wall thickness on the properties such as lateral resistance and damage of the wood structure wall of the pierced bucket, a total of three elements were made as follows (Table 1).

Table 1: *Parameters of each specimen (Clay : Straw scraps refers to weight ratio)*

Parameters	CK-1	QH-50	QH-60
Wall Span/mm	1400	1400	1400
Brace spacing/mm	0	350	350
Wall thickness/mm	0	50	60
Clay : Straw scraps	0	130:1	130:1

The wood used in the test was southwest spruce from China, and all walls were full-scale specimens with single layer and single span. In order to fit the structure found during the actual investigation, the footing of the wooden column was floating and the bottom of the frame was in direct contact with the top of the concrete ground beam. The foot of the two wooden columns was actually the structure of the slot directly buckled at the top of the foot. The detailed structural parameters of the standard specimen (QH-50) and the dimensions of the beam and column elements are shown in Figure 2. The size of the pure frame is the same as that of the standard specimen except that there is no embedded wall.

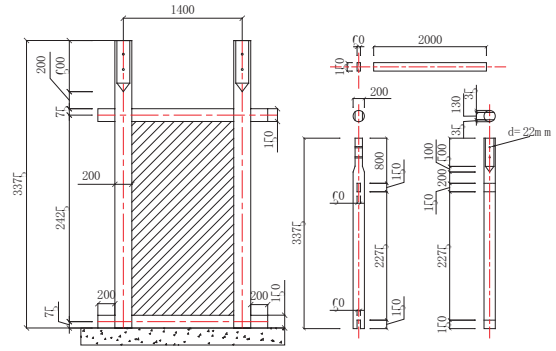

Figure 2: *Dimensions of standard specimen*

2.2 TEST SETUP AND LOADING PROTOCOL

The vertical load of the column is applied by the traditional method of hanging weights which are reinforced concrete columns for about 450kg each. It was decided to hang the weight in front of and behind each wooden column. The weights were lifted after the specimen and sensors were installed, and two weights of a column were lifted simultaneously to avoid a large out-of-plane tilt of the wall. The schematic diagram of the test piece after the overall installation is shown in Figure 3. The loading rate is also controlled at 25mm/min, and the wall cracks were plotted after all the single-cycle loading was finished and each three-cycle loading.

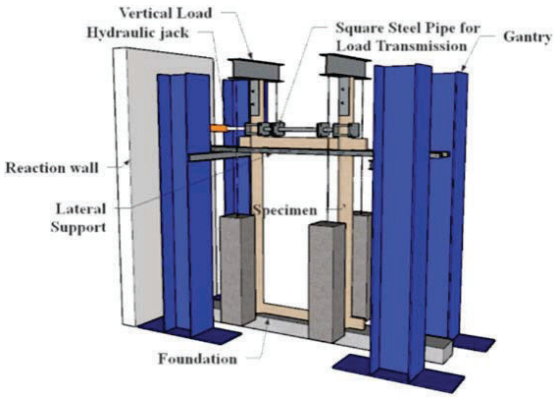

Figure 3: *Test model*

The design of the loading history referred to the international general standard, and the load-displacement curve of the static loading test of the corresponding wall is used to determine the control displacement of the structure under quasi-static loading. Finally, the loading history of pure frame and timber frame with embedded wall is determined as shown in Figure 4.

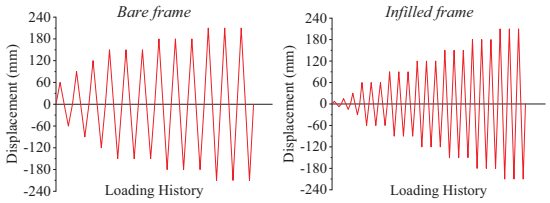

Figure 4: *Loading history*

For the unit wall of the traditional Chuan-Dou timber frame, the main horizontal displacement measurement is concentrated at the bottom of the frame and the load application site, and the vertical displacement is concentrated at the two column bases. In addition, the rotation angle and strain of each joint also need to be measured which is realized in this test with a pair of displacement gauges and strain gauges, respectively (Figure 5).

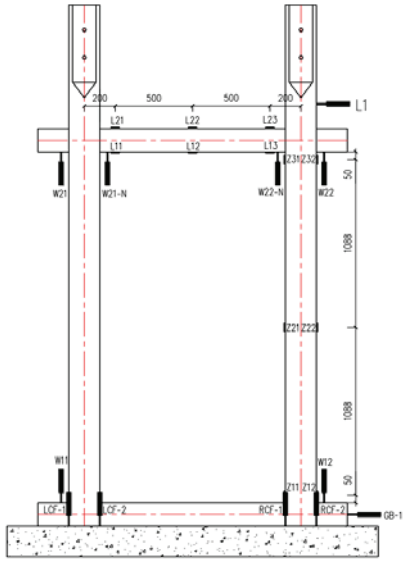

Figure 5: *Gauge arrangement*

3 TEST PHENOMENON

The embedded wall of the specimen is composed of wattle and daub and was finally finished in the form of putty smearing the surface layer. Therefore, there would be initial cracks caused by dry shrinkage cracking of the mud and specimen hoisting before the formal test. The main failure modes of the specimens are concentrated on the peeling off of the surface putty, the large area of the mud falling off, the bareness of the bamboo strips and the embedded wall separated from the frame. However, due to the variation in embedded wall and its thickness, there are differences in the stages of damage formation. The important failure process and the loading stage of each specimen are given in Table 2-4, and the crack development state and the specific failure mode are shown in Figure 6.

https://doi.org/10.52202/069179-0278

Table 2: *Summary of key experimental phenomena of specimen CK-1*

Loading stage	Key phenomena
150mm	The left and right column bases have unequal slip relative to the initial position
Third cycle of 180mm	The force transmission square steel pipe is partially pressed on the top surface of the wooden beam due to the loosening of the screw
First cycle of 210mm	The force transmission square steel pipe is all pressed on the top surface of the wooden beam. The steel parts rub violently against the wood
Second cycle of 210mm	The hysteresis curve does not show the load displacement path correctly and the test is terminated

Table 3: *Summary of key experimental phenomena of specimen QH-50*

Loading stage	Key phenomena
Before the test	Front surface fine cracks are distributed in the upper and lower part of the wall. Reverse surface cracks are spread all over the wall.
7.5-60mm	The new cracks continue to expand. The back putty is partially peeled. Some of the mud at the joints connected to the side of the column is stripped off.
120mm	When one side of the wall is pressed, the embedded wall is separated from the frame on the other side.
150-210mm	The shedding of mud material continues to develop. The embedded bamboo strips are partially exposed.

Table 4: *Summary of key experimental phenomena of specimen QH-60*

Loading stage	Key phenomena
Before the test	The initial cracks are long and thin, and the lifting process causes the putty to peel and fall off
90mm	Putty layer peeling keeps getting worse
120mm	Delamination of local surface mud and internal mud on the wall
150-210mm	Cracks are developing and large pieces of clay material are falling off more and more

Figure 6: *Test phenomenon*

4 ANALYSIS OF TEST RESULTS

4.1 HYSTERETIC LOOPS AND ENVELOPE CURVES

The comparison between hysteresis curves and envelope curves of different components are shown in Figure7.

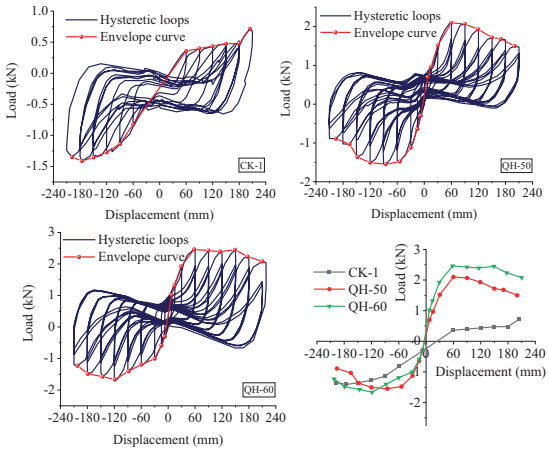

Figure 7: *Hysteretic loops and envelope curves*

Due to the initial existence of gaps in the mortise and tenon joints, the pure frame specimen showed slippage in the first loading level cycle, and the hysteresis curve showed anti-S shape. With the increase of loading level, the mortise and tenon joints exhibited more plastic deformation, and the slippage section of the hysteresis curve became longer and longer. with obvious pinching effect, the hysteresis loops of subsequent loading levels were Z-shaped. As the top force transmission square steel pipe fell on the top surface of the top beam, it was equivalent to become a part of the wall and was stressed together with the wall, so the stiffness and bearing capacity are steeply increased. It is the force transmission square steel pipe that was raised again in the back-tensioning process thus the bearing capacity began to drop at the end of the back-tensioning. It was no longer a part of the wall and the whole specimen exhibited a relatively large plastic deformation at this time which meant that the specimen began to enter yielding stage.

https://doi.org/10.52202/069179-0278

The hysteresis loops of the QH-50 specimen were shuttle-shaped at the loading level of 7.5 mm, and the load displacement was linear overall, indicating that the specimen was still in the elastic stage. With the increase of the loading level, the hysteresis loops gradually transitioned to Z-shaped, and the pinching effect became more and more obvious. The hysteresis loops of the standard specimens were obviously fuller than those of the pure frame specimens, reflecting the improvement of the energy dissipation capacity of the embedded wall with wattle and daub infill.

The development pattern of the hysteresis loop of QH-60 specimen is similar to that of QH-50, which is shuttle-shaped at 7.5 mm and Z-shaped at the subsequent large displacement loading level, and the pinching effect is intensified. The envelope curve of QH-60 specimen shows that the specimen reaches the extreme load of 2.46 kN in the positive direction at 60 mm loading level, but the obvious decrease of the load occurred after 150 mm. The drop of load before this is not significant, combined with the test phenomenon of QH-60 specimen, it can be inferred that the large area of mud shedding occurred at 180mm and afterwards caused a large discount in the bearing capacity of the specimen.

4.2 COMPARISON OF LATERAL RESISTANCE

For all loading specimens, the calculation of the lateral performance parameters is taken from the envelope curve. The calculation method is shown in Equation (1), Equation (2) and Equation (3):

$$K = \frac{0.3F_{\max}}{D_{0.4F_{\max}} - D_{0.1F_{\max}}} \tag{1}$$

$$G = \frac{F_{\max}}{2D_y} \times \frac{H}{L} \tag{2}$$

$$d = \frac{D_{\max}}{D_y} \tag{3}$$

where K = secant stiffness, F =force, D = displacement, G = shear stiffness, H = height, L = width, d = ductility.

The calculation results based on the above formula are shown in Table 5.

Table 5: *Comparison of lateral performance parameters between specimens*

Parameters	CK-1	QH-50	QH-60
K (kN/m)	9.850	55.350	88.618
G (kN/m)	10.063	102.560	171.127
d	3.41	3.47	4.79

It can be found that because there is no embedded wall, the mortise and tenon joints become the main part to resist the lateral force, and the role of the joint alone is relatively limited, so the embedded wall has a significant improvement in the bearing capacity. In terms of ductility, the two specimens (CK-1 and QH-50) also show different characteristics in the positive and negative directions. The ductility of the positive loading is similar, while the ductility of QH-50 is significantly larger than that of the pure frame. The embedded wattle and daub wall also significantly improves the initial stiffness and overall shear stiffness. In general, the bearing capacity, stiffness and ductility of the timber frame are obviously improved by the embedded wall. In terms of bearing capacity, the specimen shows that the thicker the wall, the higher the bearing capacity and the ductility of QH-60 is higher than that of QH-50 at the same time.

4.3 STIFFNESS DEGRADATION

The change in stiffness of a timber frame can reflect the magnitude of the frame's ability to resist deformation. The stiffness degradation reflects the cumulative damage to the joints of the timber frame which can be described by the secant stiffness K_i defined by Equation (4):

$$K_i = \frac{\left|+P_i\right| + \left|-P_i\right|}{\left|+\Delta_i\right| + \left|-\Delta_i\right|} \tag{4}$$

where P = peak load, Δ = displacement.

The comparison of the stiffness degradation between the wall thickness parameter specimens and the standard specimens with each other is shown in Figure 8. From the curve change, it can be found that the initial stiffness of the CK-1 specimen (l=60 mm) is 9.85 kN/m, and its stiffness decreases continuously during the loading process. Finally, it is only 4.91 kN/m which is a decrease of 50.2%.

The other two walls have much greater stiffness than the CK-1 specimen at the same loading level due to the presence of the embedded wall. Figure 8 shows that QH-60 has the largest initial stiffness of 88.13 kN/m, followed by QH-50 with 71.13 kN/m. During the subsequent loading, the stiffness of QH-60 is greater than the other two specimens from beginning to end.

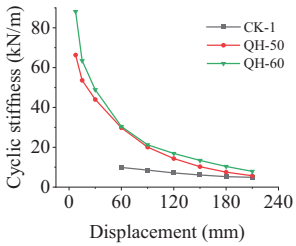

Figure 8: *Stiffness degradation*

The stiffness of all the specimens with embedded walls continuously decreased during the loading process, which was mainly caused by the accumulated plastic deformation of the mortise and tenon joints and the continuous development of the mud shedding in the walls. However, it can be found that the effect of increasing the wall thickness on improving the stiffness of the specimens is relatively obvious.

4.4 STRENGTH DEGRADATION

Strength degradation is caused by cumulative fatigue damage to structural specimens or joints, the magnitude of which determines whether the structure can maintain a good load bearing capacity under multiple cycles of lateral forces. Define R2/R1 as the ratio of the second

https://doi.org/10.52202/069179-0278

cycle peak load to the first cycle peak load at the same displacement control level, and R3/R2 as the ratio of the third cycle peak load to the second cycle peak load at the same displacement control level. These two parameters are used to quantitatively describe the strength degradation of the specimens. The R2/R1 and R3/R2 curves of all specimens are shown in Figure 9.

It can be found that the strength degradation curves of the three walls do not show an obvious rule, but the degradation occurs mainly in the second cycle. The steep increase in R3/R2 at 180 mm for CK-1 is due to the pressure of the force-transmitting square steel tube on the top surface of the top beam, which is mentioned in the test phenomenon before.

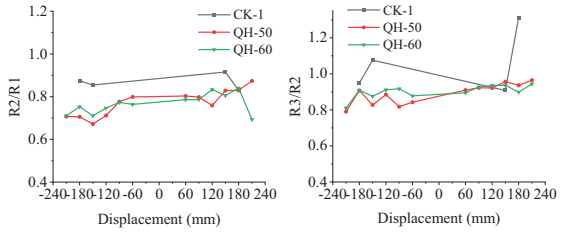

Figure 9: *Strength degradation*

4.5 ENERGY DISSIPATION

The energy dissipation ability of the structure is an important criterion to evaluate the seismic performance. The load-displacement hysteresis curve obtained by the test can calculate the energy dissipated by the structure at different loading levels, which is the area $S_{ABC} + S_{ACD}$ included in the hysteresis loop shown in Fig. 10. The energy dissipation of the structure is mainly manifested as the energy generated by the earthquake or cyclic loading is converted into heat energy or other forms of energy by the deformation and damage of the component or the whole wall.

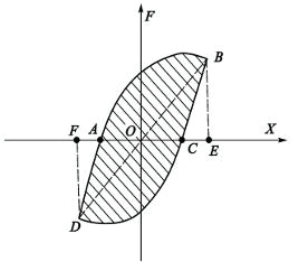

Figure 10: *The schematic diagram of the calculation of the area of hysteretic curve*

In order to better describe the energy dissipation ability of the structure, the equivalent viscous damping ratio (EVDR) is adopted as shown in Equation (5):

$$h_e = \frac{1}{2\pi} \cdot \frac{S_{ABC} + S_{ACD}}{S_{OBE} + S_{ODF}} \quad (5)$$

where h_e = EDVR, S = area.

For the specimens with different wall thickness, the energy dissipation curves and equivalent viscous damping ratio curves at each level are shown in Figure 11 and Figure 12, respectively.

.

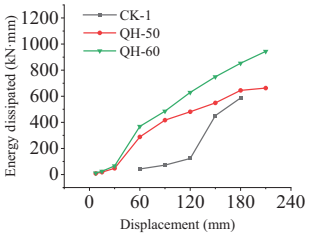

Figure 11: *The energy dissipation curve of all specimens*

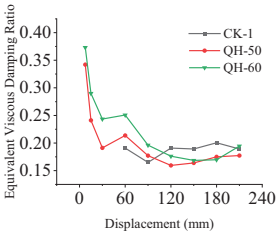

Figure 12: *Energy dissipation and equivalent viscous damping ratio (EVDR)*

It can be found that the pure frame has the lowest energy dissipation among all specimens at each loading level. When the loading displacement was small, the pure frame dissipated energy mainly through the extrusion of the mortise and tenon joints. With the loading displacement increasing, the whole specimen exhibited uncoordinated deformation due to the absence of the restraint of the embedded wall. In addition to the rotation extrusion at the joint of the pure frame specimen, the friction movement deviating from the initial position occurred and the bottom of the wall also rubbed back and forth with the surface of the floor beam during the cyclic loading process, which increased the energy dissipation of the pure frame to a certain extent, so the energy dissipation curve of the pure frame had a relatively obvious increase after 150mm loading displacement.

For both frames with embedded wall, during the whole loading process, the mud gradually dropped in blocks and the bonding between mud and the embedded bamboo strip mesh became worse. Under the large displacement loading section, the structural system cannot be formed between each other, so the energy dissipation ability decreased rapidly with the increase of displacement. In the single-cycle loading section, the energy dissipation of QH-60 was slightly higher than that of the other two specimens, but the overall difference was not significant. In the three-cycle loading section, the energy dissipation of QH-60 specimen was larger than that of QH-50. The comparison of the curves of QH-60 and QH-50 shows that the increase of wall thickness significantly improves the energy dissipation of the specimen.

The trend of the EVDR curve of the two embedded walls is similar, which is reflected in the continuous decline of the single cycle loading section. The curve has a rise when

https://doi.org/10.52202/069179-0278

entering the first three cycles, followed by a slow decline, and finally the curve has risen again. The phenomenon is related to the energy dissipation mechanism of the specimen. The small displacement loading section relied mainly on the nodal energy dissipation of the frame. With the increase of the loading stage, the hysteresis loop transformed from the shuttle shape to the longer anti-S shape of the slip section, and the energy dissipation efficiency was reduced. In the subsequent loading process, the mud wall began to have a relatively large extrusion with the wooden column, and the EVDR value of the specimen began to rise at l = 60mm due to the increase of the energy dissipation part, and the energy dissipation capacity was improved. Subsequently, the wall was damaged to varying degrees, and the EVDR value continued to decline due to the reduction of energy consuming parts. At the end of loading, friction energy dissipation began to occupy the main part, and the energy dissipation efficiency of each specimen was improved. The energy dissipation capacity of QH-60 is only slightly lower than that of QH-50 at 180 mm, while the other loading sections are higher than the standard specimen. It can be seen that the wall thickness improves the energy dissipation capacity.

The resistance of the traditional timber frame with wattle and daub infill mainly comes from the mortise and tenon joints, the mud wall itself and a large amount of frictional slip. The initial gap at the nodes and the wood joints have different effects on the lateral resistance and energy dissipation of the specimens. The main energy dissipation mechanisms of the traditional timber frame with embedded wall are shown in the following aspects. At the beginning of the test, the energy dissipation capacity decreased because the joints mainly provided resistance leading to the development of hysteresis loop pinching and shrinkage. In the middle of the test, the wall started to play more role in energy dissipation, but it decreased again with the increase of wall damage. In the later part of the test, various frictional effects had a greater impact on energy dissipation.

5 CONCLUSIONS

Based on the results of cyclic loading test, the main conclusions can be drawn as follows:

(1) Compared with bare frame, the W&D infilled frames had better bearing capacity and stiffness.
(2) The bearing capacity, stiffness and dissipated energy of W&D infilled frames can be obviously improved by increasing the wall thickness.

EVALUATION OF SEISMIC PERFORMANCE OF WOODEN HOUSES WITH SLIDING BASE BY FULL-SCALE SHAKING TABLE TEST

Ai Tomita[1], Yuji Miyazu[2], Takehiro Wakita[3], Takaki Tojo[4], Takashi Aoki[5], Masayuki Nagano[6]

ABSTRACT: For the purpose of validating the effectiveness of the sliding base for reducing the seismic response, we first conducted a shaking table test of a full-scale two-story wooden frame. In addition, we also propose an evaluation formula for the coefficient of friction and confirm its effectivenes though a time history response analysis that simulates the test results using the calculated friction coefficient. The test results show that the sliding base reduces the maximum story drift angle to 1/100 rad or less even for the input of ground motion that causes severe damage to conventional wooden houses. The analysis results indicated that the test results could be simulated by the time history response analysis using the friction coefficient calculated by the proposed evaluation formula of the friction coefficient.

KEYWORDS: Sliding base, Friction, Contact-pressure, Wooden house, Shaking table test

1 INTRODUCTION

Although research and development of seismic isolation and vibration control technology are being promoted as a method of improving the seismic performance of detached wooden houses, seismic isolation technology is not sufficiently widespread mainly because the installed cost is high. To resolve this situation, a sliding base that can be introduced at low cost has been proposed by Soda [1]. Previous studies have demonstrated the effectiveness of sliding base in reducing seismic response [2] [3]. However, full-scale shaking table test for two-story wooden frame has not yet been conducted. Therefore, in this paper, we conducted full-scale shaking table test of two-story wooden frame assuming a wooden house with standard specifications and examined the behaviour of the sliding base and the seismic response of the superstructure. We also propose an evaluation formula for the coefficient of friction and verify its validity by performing a time history response analysis that simulate the test results using the calculated friction coefficient.

2 OVERVIEW OF SLIDING BASE STRUCTURE

Figure 1 depicts the outline of the sliding base structure. The sliding base is a structure in which a sliding material is inserted between the reinforced concrete (RC) base and the base concrete. Subjected to a severe earthquake ground motion, the superstructure slides on the sliding material to reduce the seismic force acting on the superstructure.

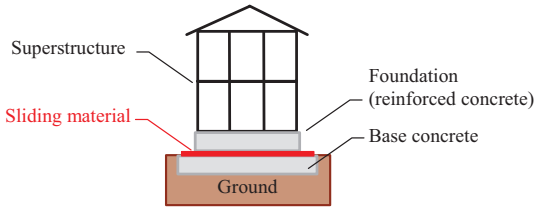

Figure 1: *Overview of sliding base structure.*

3 SHAKING TABLE TEST

3.1 OVERVIEW OF SHAKING TABLE TEST

Figure 2 shows the two-story wooden frame mounted on the shaking table installed in National Research Institute for Earth Science and Disaster Resilience (NIED), in Tsukuba, Japan. Figure 3 shows the elevation of both test frames, and Figure 4 shows the plan of each floor. There were two types of the base: Fixed Base (FB) [4] and Sliding Base (SB). Steel plate weights were installed on the second and the roof so that the mass of the superstructure was 2.61 t on the second floor and 1.73 t on the roof for both. The mass of the RC base of the SB was 6.81 t. There were two types of seismic elements: a 45×90 mm X-shaped brace wall and a structural plywood wall made by connecting 12 mm structural plywood with CN50 nails at a pitch of 150 mm. Figure 5 and Table 1 displays the details of the sliding base and the sliding materials. The base of the sliding base was an RC structure. A fluororesin sheet and a rubber mat as a protective material were laid between the RC base and the base concrete. The base concrete was fixed on the shaking

table around four circumferences using steel jigs. In order to constrain the in-plane rotation of the RC base during excitation, a guide rail was installed along the excitation direction on the side of the RC base. In order to reduce the frictional force generated by the contact between the guide rail and the RC base, a polypropylene sheet and a fluororesin sheet were inserted on the contact surface. In the FB, the base was fixed to the H-shaped steel with anchor bolts, and the H-shaped steel was fixed to the shaking table. The first-mode natural period of the superstructure under micro-vibration, which was evaluated by excitation using white noise, was 0.16 seconds for the FB and 0.19 seconds for the SB. Table 2 displays the information of input ground accelerations. An artificially synthesized motion 1 and 2 are the middle- and the large-scale earthquake ground motions defined in the Japanese Building Standards Act, respectively. The time history and pseudo velocity response spectrum of the input ground accelerations are shown in Figures 6 and 7.

3.2 CALCULATION METHOD OF THE FRICTION COEFFICIENT

Equation (1) shows the calculation method of the friction coefficient when the cumulative dissipated energy is equivalent, and the vertical ground motion is taken into consideration. The sign of the denominator in Equation (1) is the same as the sign of the slip velocity V defined in Equation (2).

$$\bar{\mu} = \frac{\sum_{t=0}^{T}(N_{t+\Delta t} + N_t)\,(L_{t+\Delta t} - L_t)}{\sum_{t=0}^{T} \pm m(2g + a_{t+\Delta t} + a_t)\,(L_{t+\Delta t} - L_t)} \qquad (1)$$

$$V = \frac{L_{t+\Delta t} - L_t}{\Delta t} = \frac{\Delta L_t}{\Delta t} \qquad (2)$$

where N_t is friction force of the sliding surface at time t, L_t is the sliding displacement at time t, a_t is vertical response acceleration of the sliding base at time t, T is earthquake duration, m is total mass of the structure and g is gravitational acceleration.

In order to eliminate the influence of noise contained in the measurement data, the sliding displacement L_t was subjected to moving average processing with an average interval of 0.02 seconds. In addition, when the value of ΔL_t is less than the threshold shown in Table 3, it was assumed that no sliding occurred during Δt ($\Delta L_t = 0$). The threshold was set for each excitation to be slightly larger than ΔL_t before the start of excitation.

Table 3: *Threshold for calculation of coefficient of friction.*

Name	Threshold (mm)
BCJ_Lv2	0.10

3.3 TEST RESULTS

Figure 8 compares the maximum response for each input ground acceleration. In the FB, first story drift angle of MSKf*0.75-1 increased sharply, and first story drift angle of KOBE-1 further increased. Whereas in the SB, the

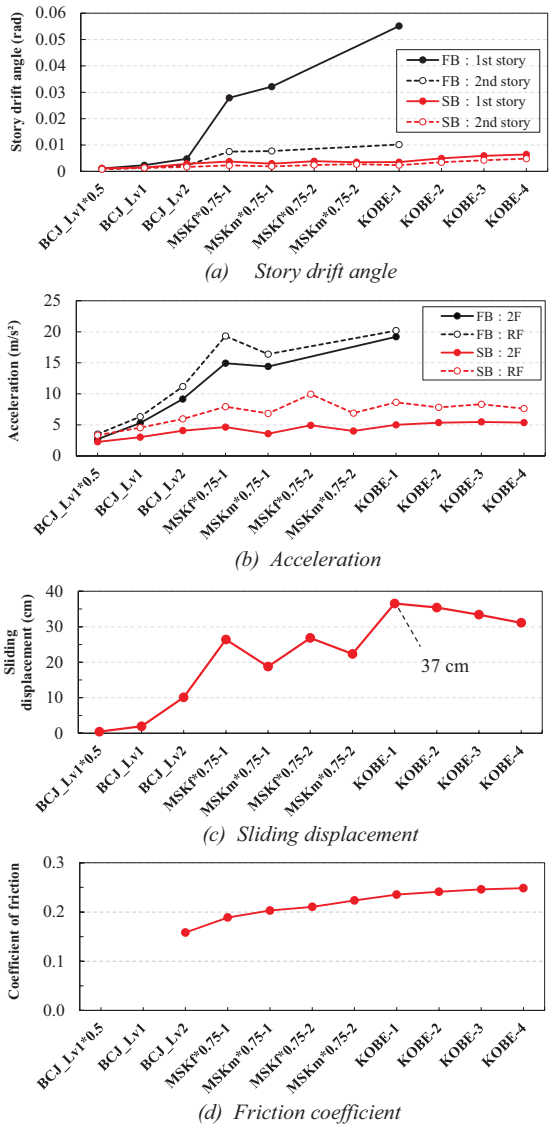

Figure 8: *Maximum response of FB and SB for each input ground acceleration.*

maximum story drift angle is reduced to 1/100 rad or less in all excitations. It is seen that the maximum response acceleration of each floor is also reduced by the sliding base. The maximum sliding displacement was 37 cm at KOBE-1. It can be seen that the coefficient of friction gradually increases with repeated excitation. In addition, it is found that the maximum sliding displacement decreases as the friction coefficient increases due to repeated excitation of KOBE. Figure 9 shows the values obtained by dividing the response values of the SB by those of the FB. By using a sliding base, it is possible to reduce the response, especially against strong ground motions. The maximum story drift angle of the first story was reduced to 13% with excitation of MSKf*0.75-1, 10% with excitation of MSKm*0.75-1, and 8% with excitation of KOBE-1. The maximum response acceleration on the second floor was reduced by 25% with excitation of MSKm*0.75-1, and the maximum response acceleration on the roof floor was reduced to about 40% by excitation of MSKf*0.75-1 to KOBE-1. From the acceleration response spectra on the first and second floors shown in Figures 10 and 11, it can be seen that the frequency characteristics have changed and the response value has been reduced by applying the sliding base. Figure 12 shows the force deformation relations of each story of the FB and the SB. It can be seen that the maximum force of first story can be reduced to about half by applying the sliding base.

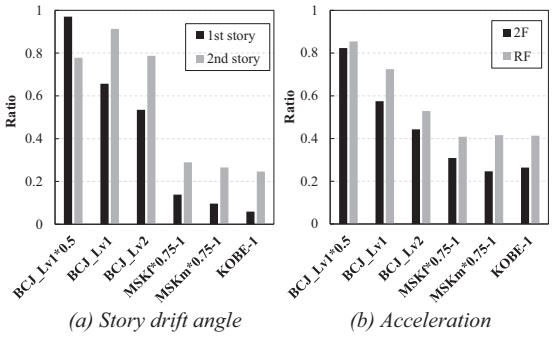

Figure 9: *Ratio of the response of SB to that of FB.*

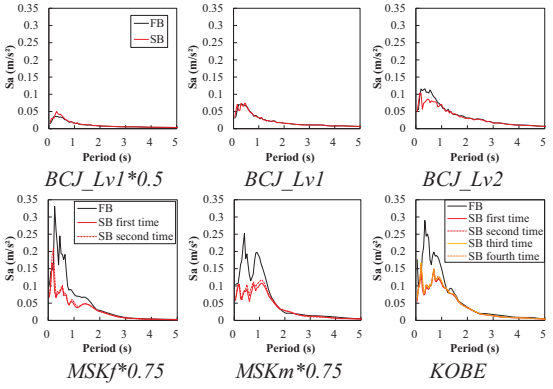

Figure 10: *Acceleration response spectra (h=5%) of the observed wave on the first floor.*

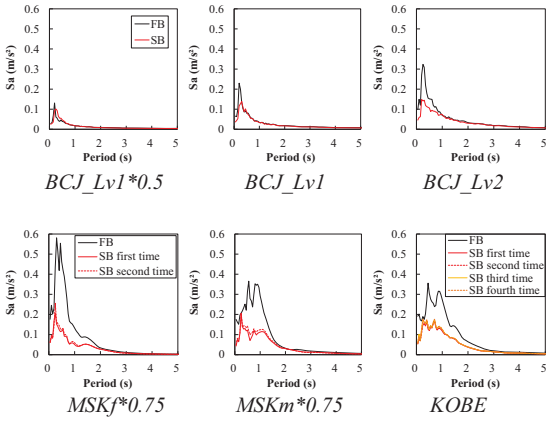

Figure 11: *Acceleration response spectra (h=5%) of the observed wave on the second floor.*

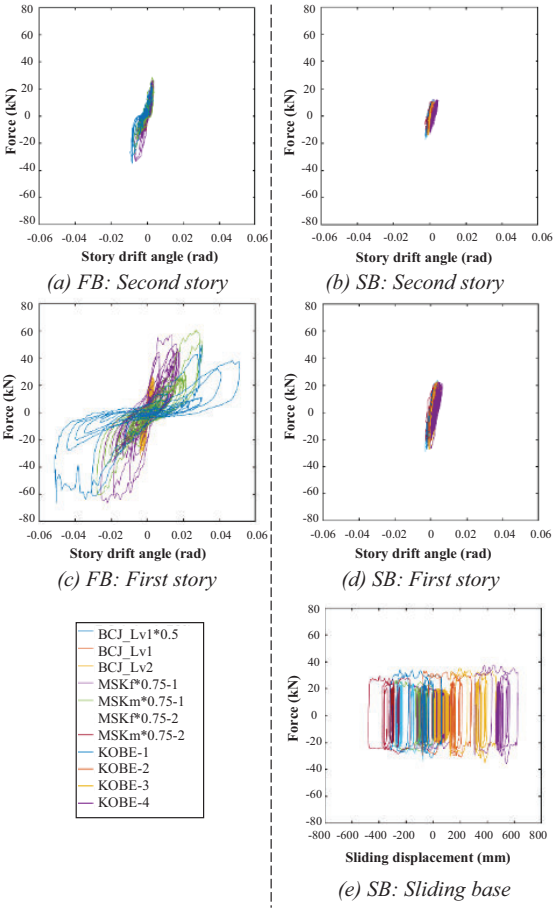

Figure 12: *Force-deformation relations of FB and SB.*

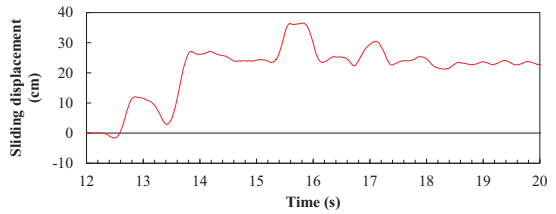
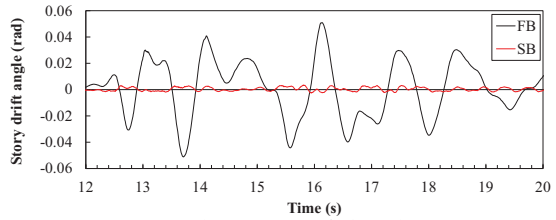
Time history of the sliding displacement, the story drift angle and the acceleration of the FB and the SB are compared in Figures 13 (a), (b) and (c), respectively. It can be seen that the base of the SB moved mainly in one direction and finally stopped with the residual displacement of about 20 cm. The residual displacement highly depends on the characteristic of the input ground motion; however, it is important to take it into

https://doi.org/10.52202/069179-0279

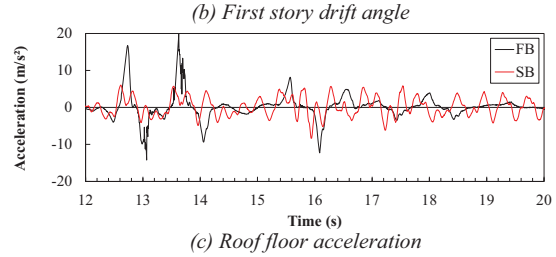
consideration at the design stage of the building with the sliding base. It can be confirmed in Figures 13 (b) and (c) that the story drift of the SB is lower than that of the FB in all the time, whereas the acceleration is reduced mainly during from 12 to 14 s and during from 15 to 16 s when the sliding of the base occurred.



(a) Sliding displacement



(b) First story drift angle



(c) Roof floor acceleration

Figure 13: *Time histories when input KOBE-1.*

The damage condition of the sliding material after all shakings is shown in Figure 14. It was confirmed that the sliding material was torn by about 1.3m after the end of all excitations. Considering this together with the results of maximum response, at least the increase in the friction coefficient and the decrease in the maximum sliding displacement after KOBE-2 can be attributed to damage to the sliding material.

(b) Enlarged photo in red frame

Figure 14: *The photograph of the damage condition of the sliding material after full excitation.*

4 TIME HISTORY SEISMIC RESPONSE ANALYSIS

4.1 OVERVIEW OF ANALYSIS

Each test frame was model in the multi-mass shear system depicted in Figure 15, and the simulation of the experiment was performed by time history response analysis. The mass of each floor was 6.81 t for the sliding base, 2.61 t for the second floor, and 1.73 t for the roof floor. An elastic-perfectly plastic model was used to model the sliding base. The yield force of the elastic-perfectly plastic model was obtained by multiplying the friction coefficient estimated from the test results by the total mass of the SB, 10.84 t. The coefficient of friction was set to 0.197, which is the average value from BCJ_Lv2 to MSKm*0.75-2, taking into account the effect of repetition. The initial stiffness of the elastic-perfectly plastic model was set to reach the yield force at 0.01 mm deformation. For the modelling of the superstructure, we used the ENCL model [5], which simulates the force deformation relations obtained from cyclic loading test on structural plywood walls and X-shaped brace walls. Figure 16 shows the force deformation relations of the ENCL model. The ENCL model for four structural plywood walls and the ENCL model for two X-shaped brace walls were placed in parallel on the first story, and the ENCL model for six structural plywood walls was installed on the second story. The damping of the superstructure was set to 1% of the initial stiffness proportional type, and no viscous damping was applied to the sliding base. The natural periods of the first mode of the FB and the SB are 0.282 s and 0.284, respectively. The input seismic motion was the acceleration measured on the shaking table, and the input acceleration was set to 0 between each excitation for 10 seconds, so that the free vibration after the excitation was sufficiently damped. OpenSees [6] was used to perform the time history analysis, and the Newmark β (β = 0.25) was used for the numerical integration. The step time of the calculation was 1/10000 seconds.

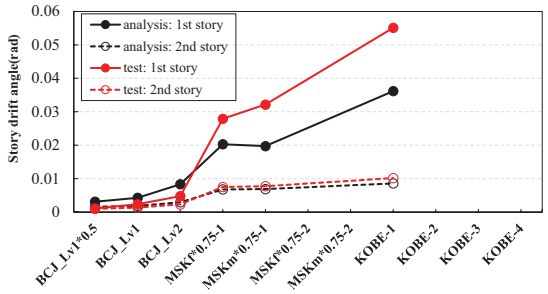
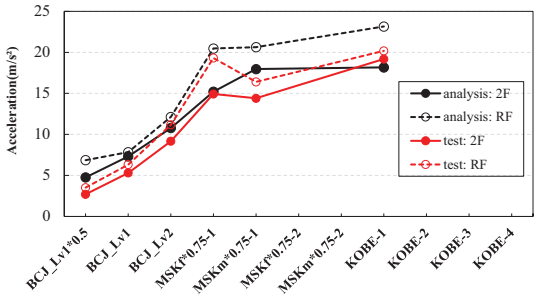
Figure 16: *Force-deformation relations of seismic walls.*

4.2 NUMERICAL ANALYSIS RESULTS

Figure 17 shows a comparison of the test results and analysis results for the FB, and Figure 18 shows a comparison of the test results and the analysis results for the SB. In the FB, the maximum story drift angle of the second story agree well with the test results. On the other hand, the analysis results for the first story were larger with excitation up to BCJ_Lv2, and smaller with excitation after the MSKf*0.75-1. Regarding the maximum response acceleration, the test results can be simulated on the second floor and the roof floor with the excitation up to MSKm*0.75-1. The maximum sliding displacement of the SB model generally simulates the test results. The maximum story drift angle is almost the same as the test results for the second story, but for the first story, there is a difference between the test results and the analysis results. As for the maximum response acceleration, the analysis results are excessive for both the second floor and the roof floor.

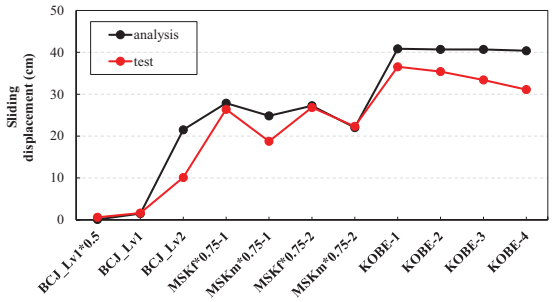


(a) FB: Story drift angle

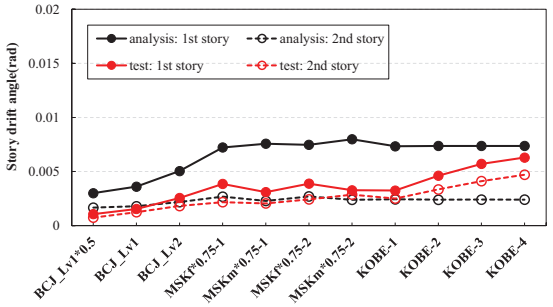


(b) FB: Acceleration

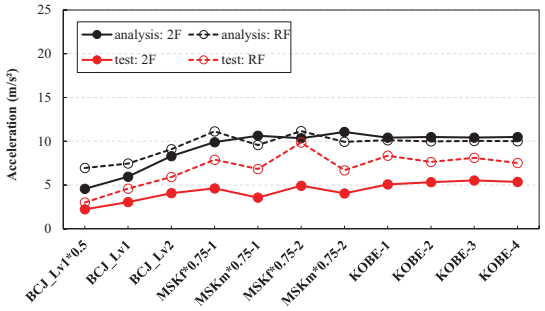
Figure 17: *Maximum response of analysis and test (FB).*



(a) SB: Sliding displacement



(b) SB: Story drift angle



(c) SB: Acceleration

Figure 18: *Maximum response of analysis and test (SB).*

Figure 19 compares the force-deformation relation between test and analysis results. In the test, tthe considerable degradation of the resistance occurred due to the buckling failure of the brace wall, which is not considered in the analysis model. It can be seen that both the maximum deformation and the maximum force of the superstructure of the SB are larger in the analysis results. From the force deformation relations of the sliding base, it can be seen that the difference in cumulative sliding displacement is large. Summarizing the maximum response results, the following two points are considered to be the factors for the difference between the analysis results and the experimental results. (1) Set low stiffness and yield strength of the analytical model in the small deformation region below about 1/100 rad. (2) In the region of large deformation above 1/30 rad, the analytical model does not consider the significant reduction of resistance due to the buckling failure of braces.

https://doi.org/10.52202/069179-0279

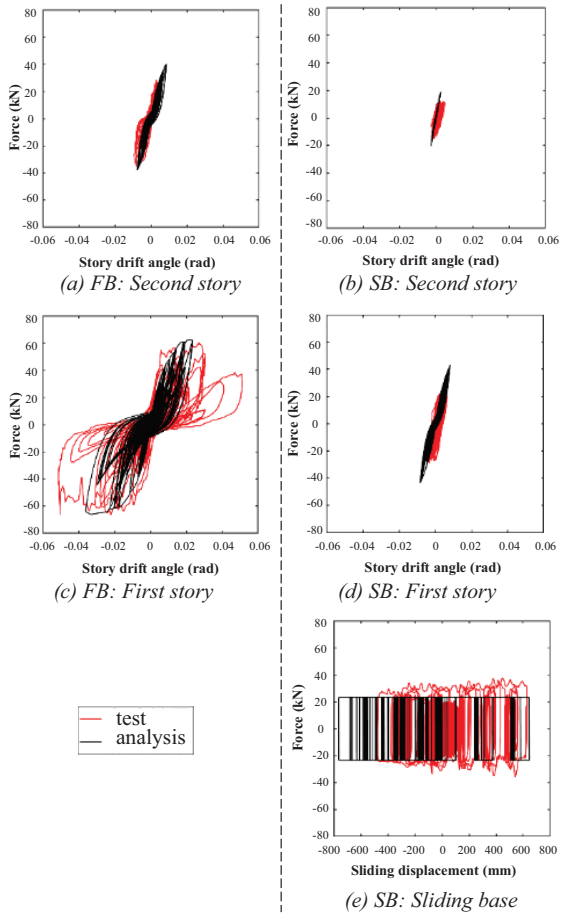


Figure 19: *Force-deformation relations of test and analysis.*

5 CONCLUSIONS

In order to understand the seismic response characteristics of a full-scale two-story wooden frame to which a sliding base is applied, a full-scale shaking table test and time history response analysis were carried out.

1) It is confirmed through the shaking table test that the maximum story drift angle can be reduced to 1/100 rad or less even under extremely strong ground motion by the applying of the sliding base.
The maximum sliding displacement of the sliding base was about 37 cm for the input of KOBE-1.
2) In the analytical study, even with a simple mass-shear system model in which the sliding base is represented by an elastic perfect plastic model, the analysis results shows good agreement with the test result. From this, it can be seen that the friction coefficient calculated by the proposed evaluation formula is appropriate.

CYCLIC TESTS OF INTERLOCKING CROSS LAMINATED TIMBER SHEAR WALLS

Wyatt Payne[1], Alex Winward[2], Johnn Judd[3]

ABSTRACT: Cyclic tests of interlocking cross laminated timber shear walls were conducted to determine hysteretic behavior under lateral load and the effect of anchorage on wall strength. Four 3.05-m tall by 2.44-m long by 288-mm wide shear wall specimens were constructed. Two types of let-in braces (rectangular and dovetailed) and two types of distributed anchor configurations (conventional and a withdrawal type connection) were examined. Shear walls without end anchorage (hold-downs) were compared to shear walls with 14-gauge and 12-gauge strap hold-downs. All specimens successfully resisted cyclic loading up to approximately 2.5% story drift without significant degradation in strength and stiffness. Walls with withdrawal type distributed anchorage increase the lateral strength compared to walls with the conventional configuration of distributed anchorage. The test results showed that hold-down straps increased the wall lateral strength by a factor of two compared to shear walls with only conventionally distributed anchorage.

KEYWORDS: Mass timber, seismic resistance, shear walls

1 INTRODUCTION

Many timber structures typically use high-grade building materials and often involve products that emit volatile organic compounds. The grade of dimensional lumber mainly depends on the slope of grain (fiber alignment relative to the edges of the member) and the size and number of knots (pieces of wood branches that intersect the cross section of the member) [1]. High-grade dimensional lumber has a low slope of grain, and few knots. Light frame construction in the United States often uses Grade No. 2 lumber. This grade of lumber has a low slope of grain and may contain moderate sized knots. In contrast, low-grade lumber has a higher of slope of grain and may contain larger knots. Lumber from trees killed by the Mountain Pine Beetle is an important example of low-grade lumber because it is plentiful in the United States. In Colorado alone, it has been estimated that nearly half of the forest areas have been infested [2]. If left standing, beetle killed trees pose a hazard for wildfires, but if employed as a building material, the wood has the potential to be a low-cost building material. As a result, there has been interest in utilizing beetle kill wood in mass timber systems, such as cross laminated timber, because the cost of the material can be much lower than high-grade materials.

Similar to other engineered wood products, the most common type of cross laminated timber relies on adhesives to bind the layers of wood. Commonly used adhesives include urea-formaldehyde, for interior use wood products, and phenol-formaldehyde, for exterior use wood products. Formaldehyde is a volatile organic compound that is emitted into the surrounding environment. In a building, the concentration of formaldehyde in the environment is increased when the air is refreshed low rates. In the United States, the Department of Housing and Urban Development sets limits on the amount of formaldehyde that may be emitted by building materials. Although formaldehyde emissions from wood products made with urea-formaldehyde or phenol-formaldehyde adhesives are less than the Department's limits, long-term exposure to volatile organic compounds may contribute to building occupants becoming sick proportional to the time spent inside the structure, without any specific illness or cause [3,4], a condition called "sick building syndrome" [5].

Interlocking cross laminated timber is a relatively new type of prefabricated mass timber panel structural system that has the potential to employ low-grade wood without volatile organic compounds [2]. Figure 1 shows an interlocking cross laminated timber structure under construction.

Figure 1: *Interlocking cross laminated timber structure under construction.*

[1] Wyatt Payne, Brigham Young University, USA, Wpayne397@gmail.com
[2] Alex Winward, Brigham Young University, USA, alex.winward@yahoo.com

https://doi.org/10.52202/069179-0280

Similar to conventional cross laminated timber, interlocking cross laminated timber is a panel that consists of orthogonal layers (plies) of wood. But unlike conventional cross laminated timber, interlocking cross laminated timber is assembled without adhesives. The plies in a panel can be interlocked using various methods [6]. One of these methods is to create a diagonal "let-in" brace within the panel.

Interlocking cross laminated timber was developed to be fabricated using low-grade wood material [7]. The orthogonal orientation of the plies minimizes the overall effect of the slope of grain on the strength. Thus, interlocking cross laminated timber systems can be sourced from local standing dead timber material, such as beetle-kill trees, and it can decrease the concentrations of pollutants in buildings.

Similar to conventional shear walls, interlocking cross laminated timber shear walls use distributed anchorage to resist sliding, and end anchorage to resist rocking. Figure 2 shows the distributed and end anchorage in a shear wall. The conventional type of distributed anchorage uses small-diameter self-tapping screws to fasten the wall to a wood sole plate that is bolted to the concrete foundation. For wide-segment shear walls with lower lateral demands, strap hold-downs are often used. Strap hold-downs are embedded in the foundation before the concrete hardens, and then later fastened to the face of the shear wall. For narrow segment shear walls, like the one shown in Figure 2, a larger-capacity hold-down is required.

Since interlocking cross laminated timber is relatively new, the structural strength and behavior of interlocking cross laminated shear walls is not yet fully understood. In the first study of the system [7], full-scale specimens of 2.44-m tall by 2.44-m long 340 mm wide five-layer interlocking cross laminated timber shear walls made with beetle killed wood were subjected to a monotonically applied lateral load in the plane of the wall. The lateral monotonic strength of the shear wall was 170 kN, approximately twice the unit shear strength of a comparable conventional shear wall.

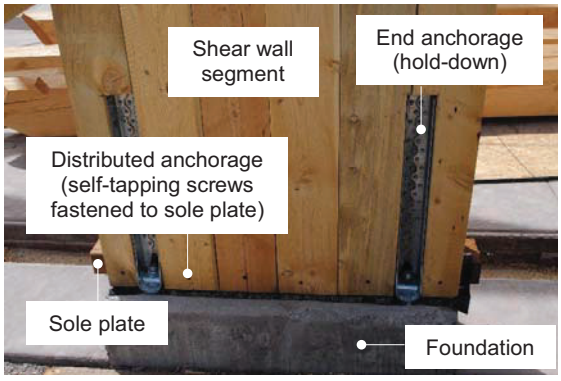

Figure 2: *Distributed and end anchorage in an interlocking cross laminated timber shear wall.*

In a subsequent study [8], 2.44-m tall by 2.44-m long 216 mm wide three-layer interlocking cross laminated timber shear wall specimens made with beetle killed wood were subjected to monotonic in-plane lateral load, and then, in a separate test, the wall was subjected to a monotonic load applied to the face of the wall. The in-plane lateral monotonic strength of the shear wall was 148 kN. Internal crushing of the dovetailed members in the layers of the wall led to ductile in-plane and out-of-plane behavior. In another study [6], 2.44-m tall by 2.44-m long 349 mm wide shear wall specimens using five vertically oriented layers of beetle killed wood were subjected to a monotonically applied in-plane lateral load. The average lateral monotonic strength was 147 kN for shear walls with dovetailed horizontal braces, and 246 kN for shear walls with horizontal and diagonal dovetailed braces.

The focus of the previous studies was on the monotonic lateral strength of the wall. Cyclic strength and behavior of interlocking cross laminated timber shear walls was not investigated. In the authors opinion, this is a significant gap in knowledge because cyclic strength and behavior are important in order to better understand how the shear walls will respond to seismic demands in an earthquake. Furthermore, in the previous studies the shear walls were secured directly to the test frame. No attempt was made to determine the effect on the lateral behavior of distributed and end anchorages that are used in the field. This is also a significant gap in knowledge because lateral behavior of a shear wall is known to be dependent upon anchorage.

In this study, four full-scale interlocking cross laminated timber shear wall specimens were constructed and tested under a cyclic loading sequence to determine hysteretic behavior under lateral load and to determine the effect of anchorage. Two types of let-in brace cross sections (rectangular and dovetailed) were used in this study. Distributed anchorage using medium-diameter self-tapping screws fastened to the wide face of the sole plate was compared to the typical configuration (small-diameter self-tapping screws fastened to the narrow edge of the sole plate). The effect of end anchorage was examined by testing two specimens without hold-downs, and two specimens with strap hold-downs.

2 METHODOLOGY

The shear wall specimens were 3.05-m tall by 2.44-m long by 288-mm wide. The specimens were manufactured by Euclid Timber Frames (https://euclidtf.com/), located in Heber City, Utah, using computer numerical control (CNC) milling machinery. Figure 3 shows a drawing of the shear wall. The wall used 102-mm thick Kiln-dried Douglas fir vertical interior plies, exterior tongue and grove (T&G) plies, and horizontal let-in braces. Specimens 1 and 2 used standard rectangular ("R") cross-section let-in braces (Figure 4a), and Specimens 3 and 4 used dovetailed ("D") braces (Figure 4b). The exterior T&G plies extended below the bottom of the wall to accommodate a rectangular wood sole plate.

https://doi.org/10.52202/069179-0280

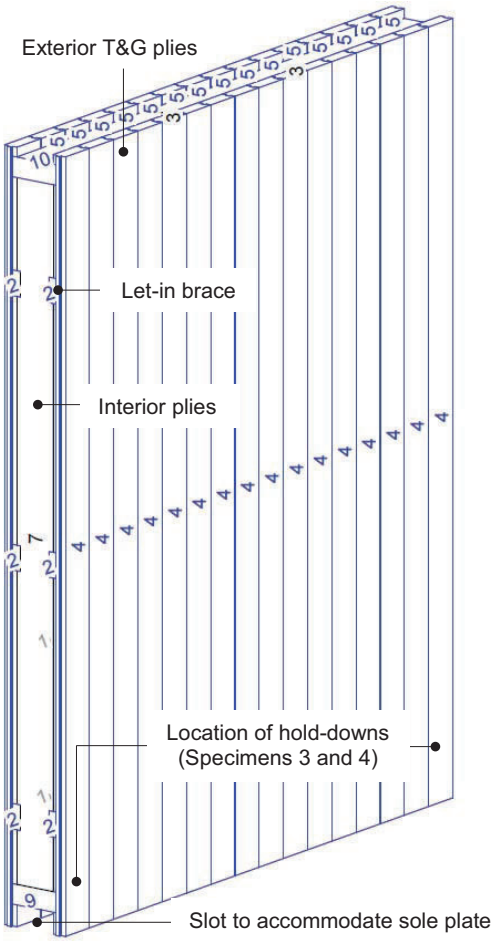

Figure 3: *Drawing of shear wall specimen.*

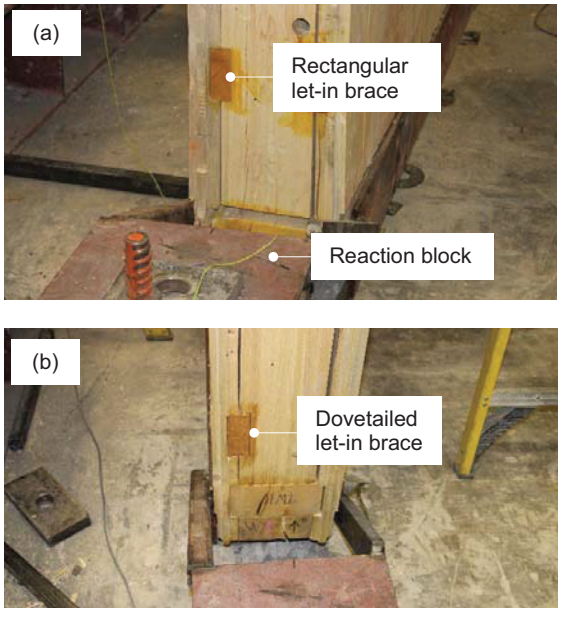

Figure 4: *Let-in braces: (a) rectangular, and (b) dovetail.*

Two types of distributed anchorage were used. For Specimen 1, the distributed anchorage consisted of two rows of 10-mm diameter by 215-mm long TCC self-tapping screws spaced every 76.2 mm. The face of the sole plate was fastened to the web of a steel beam below the wall. The screws passed through the sole plate and into the end grain of the interior plies of the shear wall. In this paper, this anchorage is referred to as type "W". For Specimens 2, 3, and 4, the distributed anchorage consisted of 4.8-mm diameter by 178-mm long OLYLOG self-tapping screws spaced every 203 mm. The screws were fastened through the exterior T&G plies of the shear wall to the narrow edge of the sole plate on both sides of the sole plate. Figure 5 shows the distributed anchorage. This type of distributed anchorage was intended to be representative current construction practices. In this paper, it is termed type "C".

Figure 6 shows the test setup. The top of the shear wall specimen was fastened to the web of a steel beam using 10-mm diameter by 215-mm long TCC self-tapping screws spaced every 76.2 mm. The beam was pin-connected to a spreader beam above. The pin allowed the wall to move vertically (rock). The spreader beam was connected to the end of a hydraulic actuator, and the actuator was mounted to a steel frame. Out-of-plane movement of the shear wall specimen was restrained by a surrounding steel framework. For Specimens 2, 3, and 4, the sole plate was fastened to the web of a steel beam below using 15.9-mm diameter anchor bolts spaced every 914 mm. The steel beam was secured to steel reaction blocks at each end (see Figure 3).

Figure 5: *Distributed anchorage (Specimens 2, 3 and 4).*

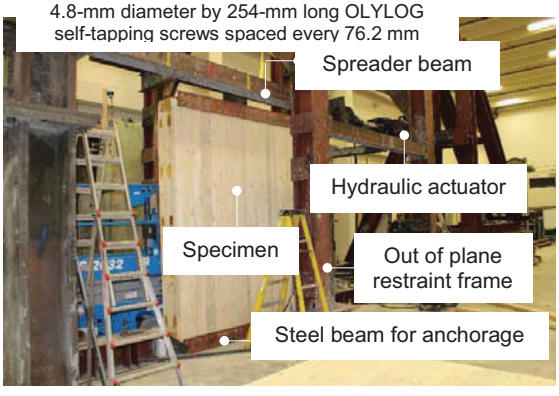

Figure 6: *Test setup.*

https://doi.org/10.52202/069179-0280

Specimens 1 and 2 were installed without hold-downs. Specimen 3 used a 14-gauge LSTHD8 strap hold-down at each end, and Specimen 4 used a 12-gauge STHD14 strap. The upper portion of the strap was fastened to the face of the shear wall according to manufacturer's instructions [9]. The lower portion of the strap is ordinarily embedded in concrete. For testing purposes, this portion was removed and the cut end of the strap was welded directly to the flange of the steel beam, as shown in Figure 7.

The shear wall specimen was subjected to a quasi-static cyclic loading sequence to determine lateral strength, ductility, and cyclic degradation of strength and stiffness. Figure 8 shows the loading sequence. The displacement-controlled loading sequence consisted of an initial two cycles at 1.67% target story drift, followed by two cycles at increments of 1.67% target story drift, continued until failure. The load rate was 50.8 mm/min.

The shear wall specimens were instrumented with string potentiometers (SPs) to measure in-plane and out-of-plane movement of the wall. Figure 9 shows the location of the instrumentation. The actuator internally measured its own displacement and force. The wall displacement was calculated by subtracting the sole plate movement from the displacement at the top of the wall.

Figure 7: *End anchorage placement (Specimens 3 and 4).*

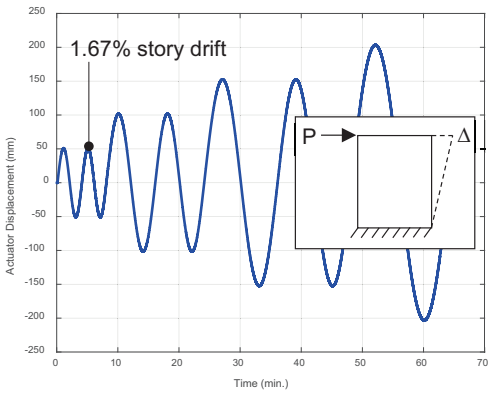

Figure 8: *Cyclic loading sequence.*

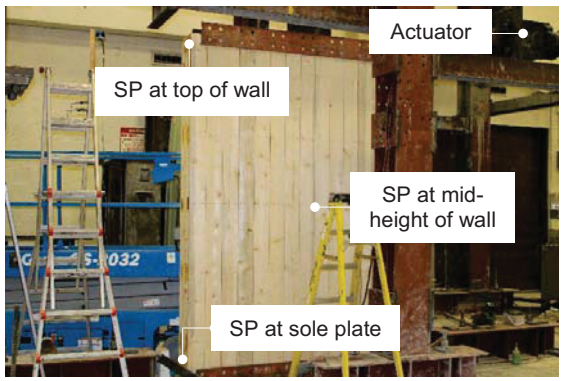

Figure 9: *Instrumentation.*

3 RESULTS

The lateral load versus wall displacement response of Specimen 1 is shown in Figure 10. No substantial damage was observed during the first cycles at 1.21% story drift. During the second cycle at 2.79% drift, vertical cracks initiated at the end of the shear wall. As loading increased, the bottom of the wall withdrew from the TCC self-tapping screws in the sole plate, as shown in Figures 11 and 12. The ultimate load achieved was 97.5 kN. Finally, at 4.39% drift, the sole plate failed in tension perpendicular to grain due to cross-grain bending.

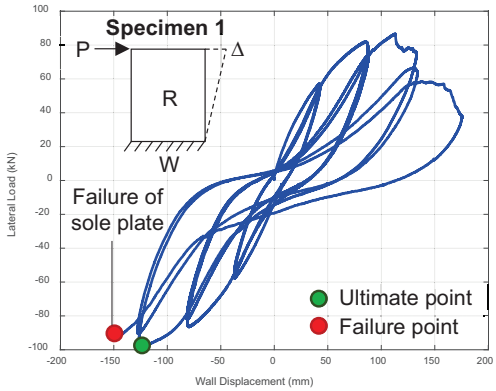

Figure 10: *Specimen 1: load versus displacement response.*

Figure 11: *Specimen 1: wall withdrawal from sole plate.*

https://doi.org/10.52202/069179-0280

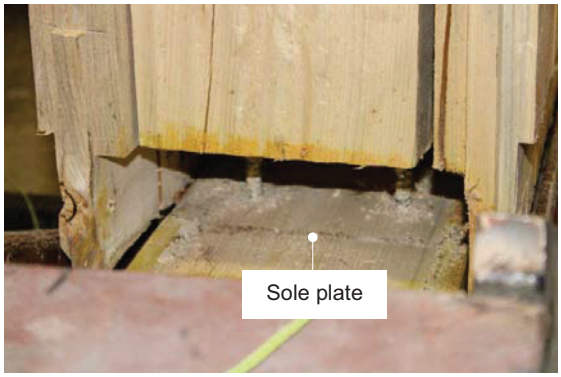

Figure 12: *Specimen 1: wall withdrawal from sole plate.*

Figure 13 shows the response of Specimen 2. As in the previous test, no substantial damage was observed during the first cycles. However, during subsequent cycles, the OLYLOG self-tapping screws tore through the exterior T&G plies, as shown in Figure 14. The ultimate load achieved was 32.8 kN. After completing the third set of cycles, the sole plate failed due to cross-grain bending.

Figure 15 shows the response of Specimen 3. The initial response was similar to the previous tests. As loading progressed, the hold-down straps buckled in compression.

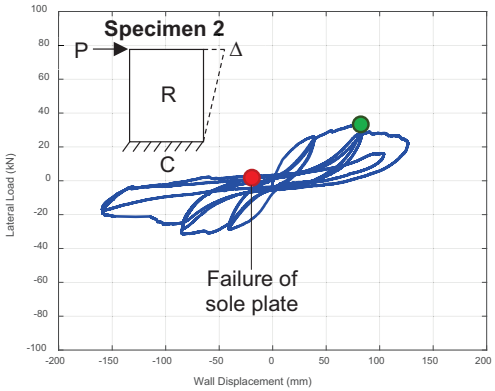

Figure 13: *Specimen 2: load versus displacement response.*

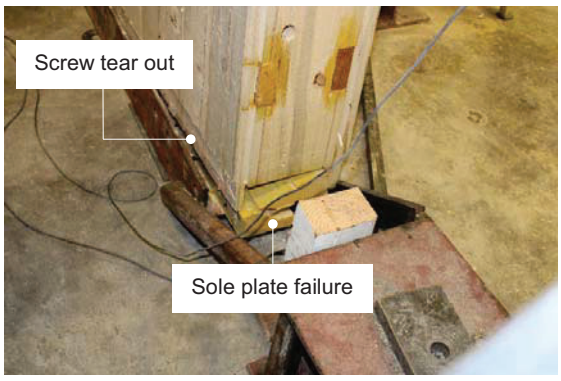

Figure 14: *Specimen 2: screw tear out and sole plate failure.*

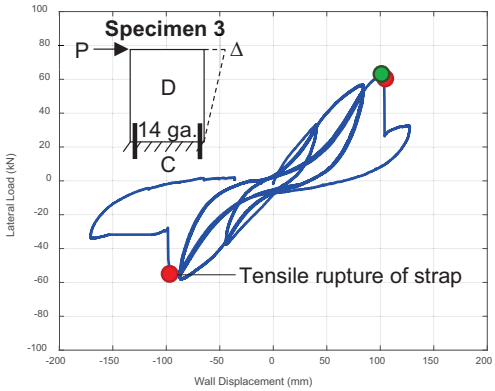

Figure 15: *Specimen 3: load versus displacement response.*

Figure 16a shows the buckled strap. At 3.34% drift, an ultimate load of 62.2 kN was achieved, and one of the straps ruptured in tension (Figure 16b). The loading continued in the reverse direction and the other strap ruptured at 3.23% drift. Finally, the sole plate failed due to cross-grain bending.

Figure 17 shows the response of Specimen 4. The response was similar to the previous test: the straps buckled in compression, then both straps ruptured in tension, and eventually the sole plate failed. The ultimate load achieved was 32.8 kN.at 4.36% drift.

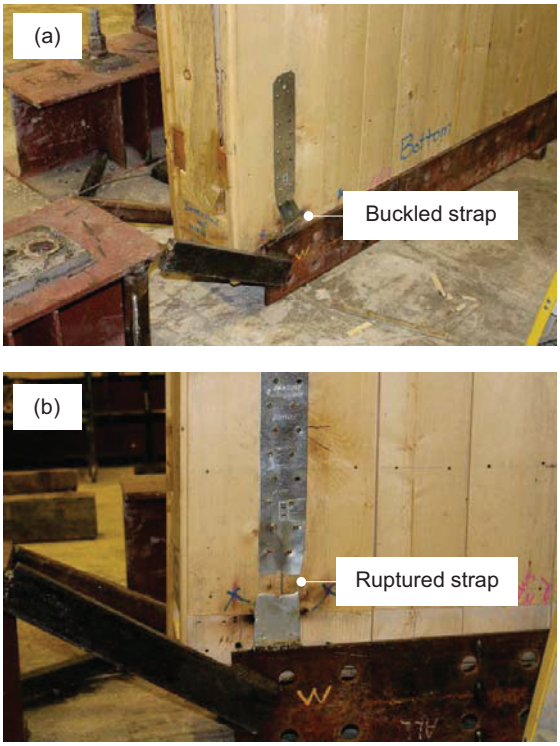

Figure 16: *Specimen 3: (a) buckled strap, and (b) ruptured strap.*

https://doi.org/10.52202/069179-0280

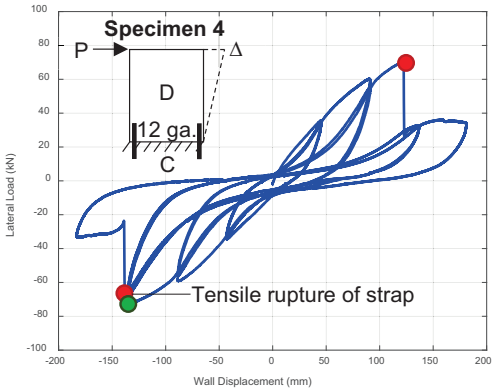

Figure 17: *Specimen 4: load versus displacement response.*

The test results are summarized in Table 1. All specimens successfully resisted cyclic loading up to at least 2.5% story drift without significant degradation in strength and stiffness.

The results indicated that rectangular versus dovetailed let-in bracing did not have a significant effect on the wall response. In contrast, distributed anchorage had a considerable effect. If hold-down straps were not installed, the ultimate strength of the wall with small-diameter self-tapping screws fastened to the narrow edge of the sole plate (Type C distributed anchorage) was a third of the strength compared to medium-diameter self-tapping screws fastened to the wide face of the sole plate (Type W distributed anchorage). The difference in lateral behavior can be attributed to the combined shear and uplift demands that are imposed on the self-tapping screws fastened to the narrow edge of the sole plate when end anchorage is not present to take the uplift loading.

The test results show that hold-down straps successfully resisted the uplift loads until the straps buckled and ruptured after repeated cycles. When the straps failed, the uplift load was transferred to the screws. For both types of distributed anchorage, the drift attained at the ultimate load was approximately 3%. The strength of the wall with Type C distributed anchorage increased by a factor of two if hold-down straps were installed, and the drift attained at ultimate load increased to over 4% drift.

Table 1: *Results of cyclic tests*

Spec.	Anchorage		Strength	
No.	Dist.	End.	P_u (kN)	Δ_u (%)
1	W	--	97.5	3.20
2	C	--	32.8	2.66
3	C	14 ga.	62.2	3.34
4	C	12 ga.	72.1	4.36

Although the results show that distributed anchorage fastened to the face of the sole plate effectively resisted uplift, this type of distributed anchorage configuration would require connecting the sole plate to the shear wall prior to connecting the sole plate to the foundation, which is not the normal construction sequence. Normally, the sole plate is fastened to the foundation wall first and the shear wall is installed later. Therefore, additional research is needed to determine the construction viability of using self-tapping screws fastened to the wide face of the sole plate as a means to anchor the base of the shear wall.

4 CONCLUSIONS

Four 3.05-m tall by 2.44-m long by 288-mm wide interlocking cross laminated timber shear wall specimens were tested under cyclic loads. The test results indicated that the distributed anchorage and the end anchorage have a significant effect on the load deformation response of the shear wall. The type of let-in brace was not significant based on the two cross sections examined. The results show that end anchorage was vital to resist the uplift demands at the base of the shear wall. The conventional configuration for distributed anchorage, using small-diameter self-tapping screws fastened to the narrow edge of the sole plate, led to a shear wall strength that was a third of the strength compared to fastening medium-diameter self-tapping screws to the wide face of the sole plate. However, it is recognized that fastening to the wide face may be challenging to accomplish in the field. In summary, the results suggest that interlocking cross laminated timber shear walls may be a viable lateral system in seismic areas provided sufficient distributed and end anchorages are provided.

ACKNOWLEDGEMENT

The shear wall specimens were generously provided and fabricated by Euclid Timber Frames. The authors also wish to recognize Mr. David Anderson, Lab Manager in the Civil and Construction Engineering Department at Brigham Young University, Rodney Mayo, Structures Laboratory Instrumentation Manager, and Ethan Brown and Micah Harley, Laboratory Assistants, for their help in the experimental tests. FATIGUE RESISTANCE OF ADHESIVE BONDED CONNECTIONS WITH AND WITHOUT INTERNAL STEEL PLATES IN LARGE TIMBER STRUCTURES

Robert Jockwer[1], Pierre Landel[2], Viktor Norbäck[3], Rune Ziethén[4], Erik Dölerud[5], Leo Anderson Naveda[6], Carl-Johan Åkerström[7]

ABSTRACT: A modular wooden wind turbine tower has been developed by the Swedish company Modvion AB, where the prefabricated modular elements are connected by glued timber-timber edge joints and by hybrid timber joints with bonded-in perforated steel plates. The application of wood-based products in such a demanding application and high-performance structure is challenging and a variety of questions had to be solved to ensure a reliable performance. The fatigue performance of the adhesive bonded connections has been evaluated in a research project and is presented in this paper. Test specimens of the fatigue resistance of the adhesive and the bond line has been developed. Different stress ratios with alternating loads and high numbers of load cycles have been tested. The results of the tests are presented in this paper.

KEYWORDS: Bonded-in steel plates, adhesive testing, butt-joints, fatigue strength

1 INTRODUCTION

The transition towards renewable energy supply is more urgent than ever. The need and demand for innovations that enable the construction of tall wind turbines (>150 metres hub height) is very high for Sweden and elsewhere to fully exploit the potential of wind power and reach 100% renewable electricity production.

A modular wooden wind turbine tower has been developed by the Swedish company Modvion AB [1] and a first 30 m tall demonstrator used for research of the Swedish Wind Power Technology Center (SWPTC) at the university of Chalmers has been built near Gothenburg, Sweden (Figure 1).

The tower developed by Modvion has a conical shape and is made of prefabricated modular elements made of LVL, that allow for easy transportation also on remote sites.

Building modular wind turbine towers enables further development towards higher wind turbines and contributes to a lower cost per kWh without logistical barriers. Modular towers made of wood with innovative joining solutions enable tall wind turbines at lower cost, lower weight and provide an efficient installation process. The LCA analysis carried out shows that the wood material contributes to 90% lower CO2 emissions than competing tower structures made of steel and stores Carbon for several years ahead. In addition, there is the possibility of reusing the wooden material in the tower as a construction material.

Nevertheless, the modularity requires strong connections that can be joined on-site. Butt-joints with bonded-in perforated high-strength steel plates are developed for the wooden wind turbine towers by Modvion. These joints are similar to other existing solutions [2].

2 DESIGN OF TIMBER TOWERS

2.1 GENERAL

Timber is so far mainly used in buildings and infrastructure applications. Consequently, the design parameters specified in design codes and guidelines, and material properties declared by producers are based on these applications.

Wind turbines made of steel and/or concrete elements can be designed in accordance with the International standard for the design of Wind turbines, IEC 61400 [3]. The design of timber structures follows the basic principles for structural design given in EN 1990, load cases in EN 1991 and specifications for timber materials in EN 1995 (Eurocode 5). These standards are based on similar methods with partial coefficients to achieve sufficient safety margins on both materials and loads. Wooden wind turbine towers can to a large extent be designed by combining these standards. However, there is a gap between innovation and existing design standards as this has not been done before on a large scale.

2.2 FATIGUE OF BONDED JOINTS

2.2.1 General

A good level of knowledge of the fatigue performance of the steel plates exists, however, there is a clear lack of basic and more detailed knowledge of the fatigue performance of the adhesive, its bond to the timber, and the timber itself.

In particular, knowledge and data are missing regarding the fatigue strength of the timber at very large numbers of cycles at low load levels. Current fatigue provisions limit the maximum number of load cycles to approx. $5 \cdot 10^7$. A fatigue threshold (or cut off limit) for wood has been mentioned in some research [4], but not in the design standard for timber bridges EN 1995-2. Existing tests on bonded timber joints [5] are typically below this maximum number of load cycles.

2.3 Fatigue design in Eurocode 5

In the 2004 version of Eurocode 5, the specification on fatigue design is given in the part for bridge structures EN 1995 – 2 (EC5-2) [6]. Kreuzinger and Mohr [7][8] derived the material parameters in the respective chapter based on the literature at the time of drafting.

The specification for the fatigue design of timber structures in the next generation of Eurocode 5 will be incorporated in the main part and can be found in prEN 1995-1-1 [9]. The specifications are based on the same theory and data as in the 2004 version but are slightly more extensive.

The design strength (or analogously the resistance) for the verification of fatigue $f_{fat,d}$ should be calculated from the characteristic strength f_k at static loading according to the following formula:

$$f_{fat,d} = k_{fat} \frac{f_k}{\gamma_{M,fat}} \qquad (1)$$

where k_{fat} is the reduction factor for fatigue and $\gamma_{M,fat}$ is the partial factor for the fatigue resistance, which may be considered as equal to the partial factor under static load unless other information is given in the National Annex.

The reduction factor k_{fat} can be calculated as follows:

$$k_{fat} = 1 - \frac{1 - R_T}{a_{fat}\left(b_{fat} - R_T\right)} \log\left(\beta n_{obs} T_{Life}\right) \qquad (2)$$

where R_T is the stress ratio, n_{obs} is the number of constant amplitude stress cycles per year, T_{Life} is the design service life of the structure expressed in years, and β is the factor based on the damage consequence which can have a value of 1 or 3.

The two coefficients a_{fat} and b_{fat} represent the type of fatigue action and are given in Table 1.

Table 1: *Values of coefficients* $\boldsymbol{a_{fat}}$ *and* $\boldsymbol{b_{fat}}$ *for timber members subjected to arbitrary state of stress*

	a_{fat}	b_{fat}
Timber members with $\sigma_{d,max}$ mainly being		
• compression, perp. or parallel to grain	2,0	9,0
• tension parallel to grain	9,5	1,1
• tension perpendicular to grain	4,7	2,1
Timber members mainly being subjected to		
• shear	6,7	1,3
Connections with		
• dowel-type fasteners with $d \leq 12\ mm$	6,0	2,0
• nails	6,9	1,2

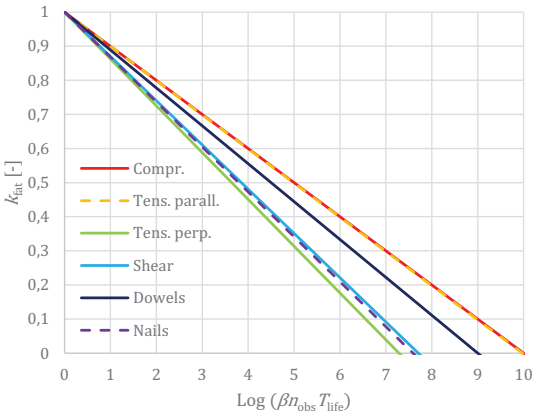

Figure 2: *Example of the reduction factor* $\boldsymbol{k_{fat}}$ *for different stress states and details with* $\boldsymbol{R_T = -1}$.

No specification or values of coefficients are given for the bond line or the glue line failure for different adhesives. The existing test methods for the fatigue testing of bonded joints, such as for glued-in rods when following EN 17334 [10], are not suited to evaluate and potentially classify the fatigue performance of the adhesive itself and the bond line strength. Instead, the steel member is often the element governing the fatigue resistance of the joint [11].

2.4 Impact of testing frequency on fatigue strength

The loading frequency can have an effect on the results of the fatigue tests. Typical frequencies reported in the

https://doi.org/10.52202/069179-0281

literature on connections with mechanical fasteners are in the range of approx. 1-3 Hz.
More detailed studies on the impact of testing frequency on the fatigue strength is reported in the literature for tests on wood-based materials. Bond and Ansell [12] state that at high frequencies adiabatic heating of the specimens may occur due to the hysteresis in the mechanical behaviour of the timber. The good insulation property of the timber limits the heat dissipation and may create heat build-up within the specimen. This can be a particular issue for connections with heat sensitive adhesives. In mechanical connections, also the frictional heating between shear surfaces should be considered. In addition, high frequencies might lead to longer fatigue life (in terms of number of cycles).
A very large range with frequencies from 1-100 Hz has been studied by Thompson et al. [13] on tests on chipboard. For this wide range, a clear impact of the frequency on the fatigue strength was observed: the fatigue strength was higher for the high frequencies of 10 and 100 Hz compared to 1 Hz.
Bonfield and Ansell [14] evaluated the fatigue properties of wood in tension, compression and shear in tests with frequencies of 5 Hz.
Hacker and Ansell [15] performed fatigue tests on wood-epoxy laminates with frequencies between 4 and 7 Hz. It is stated that these frequencies are low enough to avoid sample heating, moisture loss and change in mechanical properties.
Bond and Ansell [12] mention that the rate of stress application (RSA) is the relevant parameter to consider. Different stress levels at constant frequency result in different RSA, which in turn affect the fatigue life of the specimens. They used a constant RSA = 400 MPa/s in their tests resulting in variable frequencies for the different stress levels. Generally, all static and fatigue testing for a particular material should be carried out at the same rate.
Bond and Ansell [12] state that for frequencies exceeding 8 Hz, adiabatic heat generation may cause changes in the properties of the wood.
The frequency of the actual loading in the wooden wind tower is very complex as it is a stochastic phenomenon. For the present case, however, it can be derived that a variable load with $5 \cdot 10^7$ cycles during 20 years' service life has a period of approx. 10 sec (0.1 Hz). It is of course impossible to perform laboratory tests with such low frequency and large number of cycles. Hence, it was decided to perform a first explorative series with different frequencies at high stress ratios and low fatigue life, in order to determine an adequate high frequency.

3 EXPERIMENTS

3.1 OVERVIEW

Different static tension and cyclic fatigue tests of the adhesive bonded joints by Modvion have been carried out at the laboratories of the Swedish institute RISE in Borås, Sweden, between Mars 2022 and January 2023.
The purpose of the experiments was to investigate the fatigue life capacity (curve).
Within the tests, the different stress ratios (-1 < R < 0,1) and loading-ratios have been varied to study the number of cycles to fatigue in the range of approx. $10^4 - 10^7$.
In order to reach the desired high number of cycles in reasonable time, a relatively high loading frequency of up to 10 Hz is desired. In a preliminary test campaign, the static performance of the specimen and the impact of loading frequency were analysed.
It was confirmed that no impact of frequency on the fatigue resistance was observed in the desired range of frequencies between 1-10 Hz.

3.2 MATERIALS

The objective of the test campaign is to study the fatigue performance of the adhesively bonded joints with polyurethane adhesive in the timber tower by Modvion. In particular the bond line fatigue strength between timber and adhesive in the timber-timber edge joints and the glue dowel fatigue strength in the hybrid timber joints shall be evaluated.
The walls of Modvion's timber towers are made of several layers of special Laminated Veneer Lumber (LVL). First, the thick, curved LVL modules are glued together from thinner, special LVL panels. The precise cutting of the LVL modules is done by a CNC-robot. Four of these modules are assembled on-site to build a tubular section of the tower. The sections are then stacked on top of each other to build the tall conical timber tower.
Two different types of joints are present in the tower:

1. the longitudinal (lap) shear joints between LVL modules in the vertical direction of the tower.
2. the transversal, hybrid butt-joints with perforated steel plates between the tower sections in the horizontal direction of the tower.

The test specimens were developed and chosen accordingly, and are denoted as:

1. *Strong Enough Longitudinal* joint or SEL joint
2. *Strong Enough Transversal* joint or SET joint

The dimensions of the joints are carefully calibrated in order to achieve the desired failure in the bond line or in the adhesive dowels going through the perforated steel plates for the SET joint.
In the tests, the mean density of the LVL was 510 kg/m^3. The LVL veneer layup in the specimens was representative of the layup in the final application in the tower.

3.2.1 The edge joint (SEL)

The edge joint technology with a 3 mm thick 2-component polyurethane adhesive is utilized in Modvion's tower to connect two modules along the length.
All specimens were carefully produced in the factory of Modvion AB as solid specimens with an internal thick glue line (Figure 3 top). At the moment of testing at RISE, Borås, two cuts in transversal direction at a distance of 30 mm were cut using a band saw in order to create the bond surface for the shear tests (Figure 3 bottom). The test

was inspired by the lap joint test specimen in EN 302-1 [16].
Steel plates were glued into the specimens in order to clamp the specimens with the same equipment as the SET-specimens. In this case, the glued joint between the steel plate and the LVL was sufficiently overdesigned to prevent failure.

Figure 3: *SEL-specimen without the cutting (top) and with the two cuts for testing (bottom)*

3.2.2 The hybrid timber joint (SET)

The hybrid timber joint is an adhesive connection using a thin perforated steel plate to join two timber members. It is similar to other bonded connections between steel and timber such as glued-in rods for glued structural timber products or the connection system described in [2].
In Modvion's application, a thick steel plate with a large amount of holes are inserted in slots in the LVL members. Then a 2-component polyurethane adhesive is injected between the LVL and the steel plate. When the adhesive cures, bond to the wooden members is established and "glue-dowels" penetrating the steel plate are formed, which lock the steel plates in place and provide strength and stiffness to the connection. These hybrid joints are utilized in Modvion's timber tower to connect two sections on top of each other's to reach the desired height of the tower. The steel plates have a specific hole pattern in order to avoid stress concentrations.

The dimensions of these specimens were carefully designed to achieve the desired failure mode in the adhesive or the bond line. Hence, the steel plates used in the SET samples have small number of holes for the glue dowels to create the connection. An illustration of the specimens is shown in Figure 4. The desired failure mode with bond line failure was confirmed in static tests.

Figure 4: *Illustration of the SET-specimen*

A variety of different configurations of SET-specimens have been tested as shown in Table 2. The configurations include: two different methods for manufacturing the holes of the steel plates, different adhesion inhibitors applied on the steel plates (SET 200 and 400) , a variation of the glue line thickness, and the number of holes in the steel plate have been varied.

Table 2: *The different sets of SET samples*

SET series	# of samples	Hole manufacturing	Slot thickness [mm]
000	13	Laser-cut	6
200	6	Punched	6
400	12	Laser-cut	6
500	8	Laser-cut	9
Double # holes	8	Laser-cut	6
no hole	4	-	6

3.3 METHODS - TESTING EQUIPMENT

3.3.1 Static tensile tests

The static tensile tests aim to evaluate the tensile strength of the samples. The tensile tests have been performed on a universal testing machine (Instron 1253) with a hydraulic cylinder of 50 kN capacity in both compression and tension. The load was recorded using a load cell with a capacity of 50 kN. Before testing, the samples were stored for several weeks in a conditioned climate of 20 °C and 65% relative humidity.
Special grips were designed and manufactured to secure a stiff and strong connection between the steel plates of the specimens and the test machine and to avoid bending stresses in the specimens.

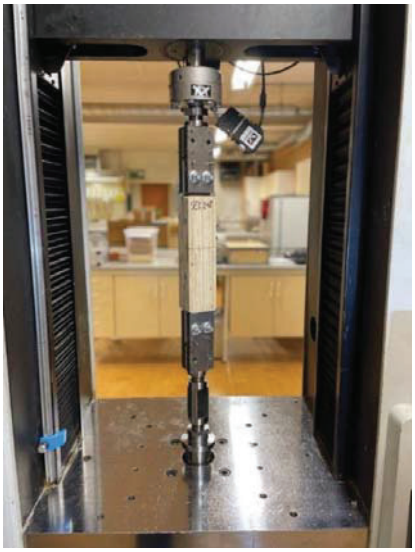

Figure 5: *Test machine Instron 1253 and set-up with SEL sample*

3.3.2 Fatigue tests

In the cyclic fatigue tests the connection's fatigue strength was determined, i.e. the number of loading cycles the connection can withstand for certain loading conditions

https://doi.org/10.52202/069179-0281

before failure. Sinusoidal cyclic loading was applied at frequencies of 5, 6, 8, and 10 Hz.
The loading amplitudes and the mean load values varied, and three different stress ratios $R = \sigma_{d,min}/\sigma_{d,max}$ were tested:

- $R = -1$, the loading is pulsating, e.g. the load varies sinusoidally between -5 kN (compression) and 5 kN (tension), for an example of a load record see Figure 6.
- $R = 0.1$ in tension, e.g. the load varies sinusoidally between 1 kN and 10 kN, an example of a load record see Figure 7.
- $R = 0.5$, e.g. the load varies sinusoidally between 5 kN and 10 kN.

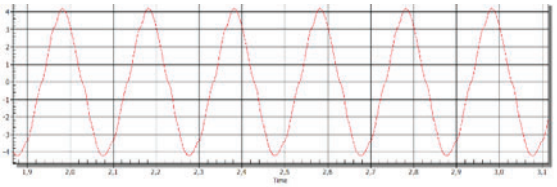

Figure 6: *Example of a load record in machine Instron 1253 during a fatigue test at 5 Hz and R = -1, with pulsating load varying sinusoidally between +4.2 kN and – 4.2 kN. The time in [s] is on the horizontal axis, and the load in [kN] is on the vertical axis.*

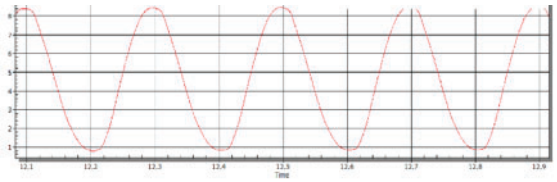

Figure 7: *Example of a load record in machine Instron 1253 during a fatigue test at 5 Hz, and R = 0.1, with load varying sinusoidally between +8.5 kN and +0.85 kN. The time in [s] is on the horizontal axis, and the load in [kN] is on the vertical axis.*

Two machines were used for the fatigue tests at RISE in Borås. The Instron 1253 and a special machine for long-term testing with a hydraulic cylinder (capacity 100 kN) called the Blå-Rigg, (Figure 7). Before testing, the samples were stored for several weeks in a conditioned climate of 20°C and 65% relative humidity. However, the ambient climate during the fatigue testing was not controlled and varied between 19-23ºC and 40-70 % RH.

Figure 8: *Fatigue test machine **Blå-Rigg** and set up with a SET sample*

4 TEST RESULTS

4.1 The edge joint specimens (SEL)

4.1.1 SEL static tests

Ten SEL samples were tested in the Instron 1253 machine. The load was applied at a constant displacement rate of 0.5 mm/min until failure. The mean value of the bonline shear strength is approx. 6 MPa and the CoV is 5.2%.

4.1.2 SEL fatigue tests

For the fatigue tests, 34 samples were tested to failure at different load levels and frequencies. One loading ratio $R = -1$, i.e. pulsating loading from tension to compression, has been studied in this test series.
In Figure 9, the results are presented in a log-linear diagram with the number of cycles to failure with respect to the applied (sinusoidal) stress level in the glue line (SEL Fatigue in blue), and the relative results from the static tests (SEL Static in red).

https://doi.org/10.52202/069179-0281

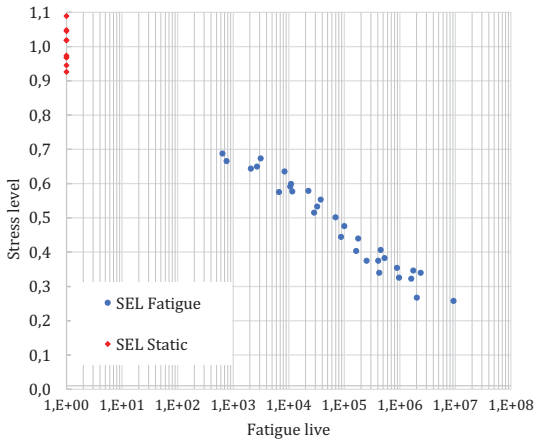

Figure 9: *Results of the SEL fatigue tests*

4.1.3 The SEL failure mode

For both static and fatigue tests the failure mode was similar and happened in both the adhesive, in the wood and/or at the bond line interface between both materials. From visual inspection, the mean value of the surface share with wood failure is approximately 60 %, i.e. about 40 % failure at the adhesive or at the bonding interface. However, a large variation of the surface share ratio can be observed. Some examples of the failure surfaces SEL specimens are shown in Figure 10.

Figure 10: *Examples of failure surfaces of three tested SEL specimens*

4.2 The hybrid timber joint (SET)

4.2.1 SET static test

Results from the static tests on the SET specimens are presented in Table 3 for the different sets of SET configurations summarized in Table 2. The static tests on the specimens with special steel plates show considerable different resistance: the specimens with steel plates of double amount holes (SET double) show an almost double resistance whereas the specimens with steel plates without any holes (SET no hole), i.e. with smooth steel plates show slightly smaller resistance.

Table 3: *Comparison of the relative mean resistance from the test results for the different sets of SET samples*

SET series	Mean max. load [kN]	CoV max. load [%]
SET 000	100%	13.5%
SET 200	101%	6.7%
SET 400	101%	3.1%
SET 500	102%	3.9%
SET double # holes	193%	16.0%
SET no hole	87%	14.6%

4.2.2 The SET fatigue tests

For the fatigue test of series SET 000 at $R = -1$, a preload of 10 kN was applied in tension to all the samples. This simulates the load of a storm with 50-year return period right after erection the tower. No preload was applied to the other series in the fatigue tests.

The results are presented in Figure 11, in a log-linear diagram with the number of cycles to failure with respect to the applied (sinusoidal) stress level for all specimens.

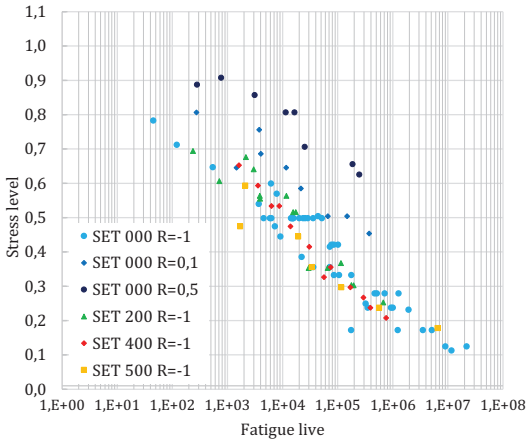

Figure 11*: Results of the SET fatigue tests*

4.2.3 The SET failure mode

For both static and fatigue tests the failure mode is similar and common to most of them: failure always occurred in the glue dowels (100%). But also failures of the bonding at the interface between the steel plate and the adhesive (60-80%), and failures of the bonding at the interface between the wood surface and the adhesive or in the wood material (20-30%) were observed. However, the visual estimation of the ratings is subjective and rough. Figure 12 shows some examples of pictures of tested SET samples and the failure mode.

https://doi.org/10.52202/069179-0281

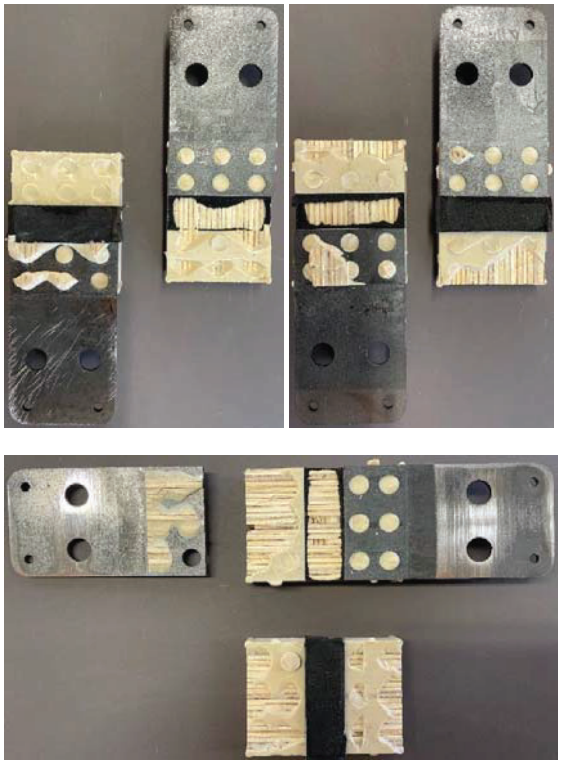

***Figure 12**: Examples of failure surfaces of three tested SET specimens.*

5 CONCLUSIONS

The results of the project described in this paper provide the basis for the design and verification of advanced timber structures for wooden wind turbine towers and allow a better understanding and further development of fatigue-loaded bonded joints in timber construction.

TESTING OF STRONG MULTI-LAYERED WOOD FRAME SHEAR WALLS WITH NON-STRUCTURAL LAYERS

Diego Valdivieso[1] , Diego Lopez-Garcia[2], Jairo Montaño[3], Pablo Guindos[4]

ABSTRACT: In areas of high seismic activity it is important to provide Light Frame Timber Buildings (LFTBs) with enhanced levels of lateral stiffness and strength, as well as to prevent excessive levels of non-structural (NSC) damage. Chilean wood-frame shear walls are usually sheathed at both sides with OSB and covered by one/two-ply type X gypsum wallboard (GWB) fastened to the frame with narrow patterns of nails or screws. The result is a multi-layered strong shear wall (MLSSW), which is not considered as such by design codes and mechanical models. The objective of this paper is to report an experimental evaluation of typical Chilean MLSSWs, with emphasis on the influence of NSCs. Connection-level and assembly-level of 1:1 aspect ratio shear walls were evaluated through experimental tests. Results showed increments of 53% and 160% in elastic stiffness and maximum capacity, respectively, while keeping virtually the same deformation capacity and energy dissipation of equivalent bare (non-GWB finished) shear walls. It is postulated that such increases may arise from the high embedment strength of the GWB, and that the deeply screwed GWB may prevent nails from pulling out during hysteresis cycles. It is concluded that GWBs have a significant structural influence on MLSSWs, and such influence should be taken into account in structural design.

KEYWORDS: Wood frame construction, light-frame shear walls, multi-layered, non-structural, gypsum wallboard.

1 INTRODUCTION

Light Frame Timber Building (LFTB) is one of the structural systems currently evaluated by the Chilean construction industry, public authorities, and academia to enhance the sustainability of the Chilean building inventory. Since Chile is subjected to strong earthquakes, it is essential to provide LFTBs with enhanced levels of lateral stiffness and strength. Equally important is the prevention of excessive levels of non-structural damage, as significant costs of damage repairs (i.e.,gypsum wallboard replacement) after earthquake events have been reported [1]. In Chile, wood-frame shear walls usually have a strong structural configuration, consisting of 41 mm × 185 mm (2×8) framing members, sturdy end studs (typically comprising 4 or more members), conventional or continuous holdown devices, wood structural panels (WSPs) -typically OSB on both sides- and closely spaced nails for attachment of sheathing to wood-frame members [2]. On the other hand, the non-structural sheathing customarily consists of one or two layers of Type X gypsum wallboard (GWB) at both sides, fastened to the framing with screws or staples through the OSB. These features cast multi-layered strong shear walls (MLSSWs), as exemplified in Figure 1, whose characteristics have neither been thoroughly investigated nor explicitly considered by design codes or mechanical models. More precisely, although previous investigations have reported a distinct behavior for these types of strong walls (i.e., more prevalence of the rocking effect [2-4]), the influence of the non-structural finishes is rather unknown, and no adequate modeling procedures are currently available. The structural effect of the GWB has been mainly studied in conventional light-frame shear walls (the term conventional was introduced by Estrella et al. [2]), hence a brief summary of the experimental testing of conventional walls with non-structural finishes is presented next.

1.1 EXPERIMENTAL EVALUATION OF THE EFFECT OF NON-STRUCTURAL GWB FINISH LAYERS

GWB is the most common interior wall sheathing material for fire protection used in residential construction [5]. Due to the brittle nature of its core material and its supposedly low stiffness and strength relative to that of wood-based panel materials, the structural contribution of GWB to the lateral response of light-frame buildings is rarely recognized [5]. For this reason, manufacturers have focused on the characterization of GWB for acoustic and fire protection purposes rather than on the mechanical properties that influence the lateral response of a shear wall, such as the shear modulus [6-8]. However, previous research has evaluated the contribution of GWB finish layers to the lateral response of different configurations of

conventional shear walls where the OSB and GWB sheathing layers are installed at opposites sides of the frame. For example, the effect of the GWB finish layer on the lateral response of wood-frame shear walls was experimentally evaluated in [9]. A 12% and 60% increase in lateral strength and stiffness, respectively, was found, but also a 31% reduction in deformation capacity due to significant strength degradation. Moreover, GWB impacted the failure mode of the shear walls by limiting the twisting in the stud caused by the eccentricity due to sheathing placed at only one side. In [10] the effect of GWB on a full-scale two-story wood-frame townhouse was evaluated. A reduction of up to 9% of the fundamental period was found because of a 21% increase in the lateral stiffness of shear walls, which was attributed to the incorporation of GWB in the interior side. Also, contrary to other findings [9], when the finish layer was incorporated the lateral stiffness degradation was smaller than that of bare shear walls. The study highlighted the need to develop a seismic design method that takes into account the effect of wall finishes materials.

Even though the aforementioned research results were promising, the experimental evaluation of the MLSSW configuration typically used for mid-rise buildings in highly seismic-prone areas was not considered. In this context, a first approach was given in [11]. Improvements in the performance of GWB in wood-frame shear walls were investigated, motivated by the fact that the configuration typically used in houses (i.e., OSB and GWB panels installed on opposite sides of the frame) tended to trigger substantial damage to the GWB, mainly because of the different lateral stiffness of OSB and GWB. A promising solution was to install the GWB at the top of a shear wall sheathed on both sides with OSB, which resulted in improvement of the GWB performance (i.e., reduction of earthquake damage) due to minimization of the difference in lateral stiffness between both sides of the wall. However, the effect of the finish layer on the lateral behavior of the shear wall (which is of great interest for MLSSWs and mid-rise LFTBs) was not quantified. Recently, in [12] the contribution of Type X GWB to the racking strength of wood-frame shear walls with representative multi-story details (i.e., the racking restraint system was a continuous rod system [13]) was evaluated experimentally. GWB and OSB were installed on opposite sides of the frame, as in previous research [9, 10]. Results showed that Type X GWB increased the peak strength by 3% and the initial stiffness by 11% when shear walls were tested cyclically and monotonically, respectively, compared to bare shear walls. Contrary to previous research, the study reinforced the traditional practice that ignores the contribution of GWB in the seismic design of LFTBs.

In summary, even though several studies have demonstrated the benefits of non-structural finish GWB layers, the experimental evaluations have been limited to wall assemblies that are different from those typically used in mid-rise LFTBs located in highly seismic-prone areas (i.e., MLSSWs). Hence, it becomes important to quantify experimentally and/or numerically the effect of GWB layers in strong shear wall assemblies, particularly in the context of development of tall timber buildings in seismic areas.

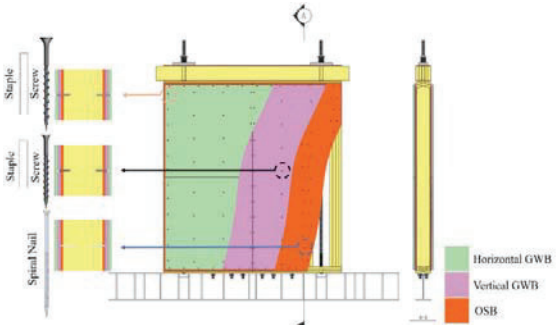

Figure 1: *Typical Chilean MLSSW configuration*

2 SCOPE

In this paper, the contribution of Type X GWB finish layers to the lateral response of multi-layered strong shear walls (MLSSW) is evaluated through reverse cyclic tests on 2.44 m x 2.44 m full-scale MLSSWs and comparisons with previous findings on bare shear walls [3,4].

3 METHODOLOGY

An experimental program was developed to characterize the behavior of multi-layered sheathing-to-frame connections and full-scale shear walls under monotonic and/or cyclic loading.

3.1 CONNECTION-LEVEL TESTS

Three different configurations of multi-layered sheathing-to-frame connections were assembled considering the typical fasteners used for attaching OSB and Type X GWB to wood frames. As shown in Figure 2, the connection-level specimen consisted of a frame of 41 mm x 185 mm (2 x 8) dimensional Chilean radiata pine lumber mechanically graded as C16 according to NCh1198 [14] and attached to different sheathing materials and fastener types (see Table 1). For each configuration, four specimens were considered (i.e., one and three specimens for monotonic and cyclic test, respectively).

Table 1: *Connection-level specimens (all dimensions in millimetres)*

ID	Wood Structural Panel (OSB)		Type X Gypsum Wallboard (GWB)		
	Thick	Nail	Thick.	Type	Fast.
A	11.1	2.9x80	-	-	-
B	11.1	-	15	Screw	4.0x63.5
C	11.1	-	(2) 15	Screw	4.0x76.2

Notes:
a) OSB sheathing layer attached to frame with pneumatically driven wire coil spiral nails (80 x 2.9 x 6.5 mm) according to EN14592:2008+A1:2012 [29].

https://doi.org/10.52202/069179-0282

b) Type X GWB sheathing first layer attached to frame through the OSB with type "W" screws (63.5 x 4.0 x 8.0 mm)
c) Type X GWB sheathing second layer attached to frame through the 1st Type X GWB and OSB with type "W" screws (76.2 x 4.0 x 8.0 mm)

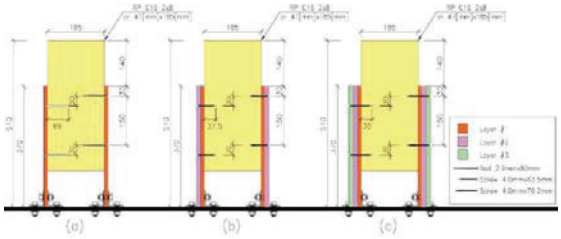

Figure 2: *Multi-layered connection specimen for: (a) Test Group A, (b) Test Group B, and, (c) Test Group C. All dimensions in millimeters*

The test setup is shown in Figure 3. The reaction steel frame is anchored to a concrete floor. A heavy-duty steel beam is installed on the frame at a suitable location to accommodate the specimen, which is attached to the heavy-steel beam through bolted L-shape elements (Figure 3). The load was applied by a double-action cylinder of +/- 86 kN and +/- 75 mm of force and displacement capacity, respectively, which transfers the vertical load to the specimen through a load-transfer system. All specimens were instrumented with two displacement transducers (LVDTs) and one double-effect load cell to capture the slip and shear force between the frame and sheathing multi-layers.

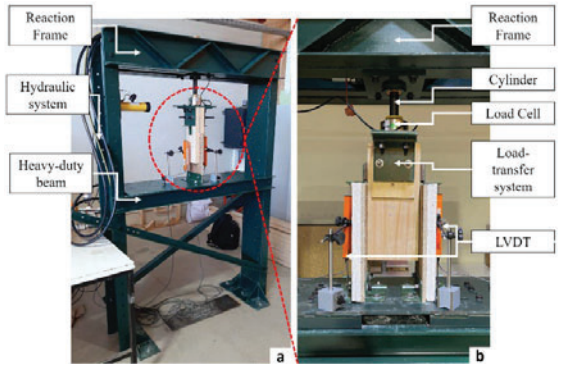

Figure 3: *Connection-level test set-up: (a) general view of the reaction steel frame and (b) detailed view of the specimen set-up*

The loading protocol was established according to ASTM E564-06 [15] and ASTM E2126-19 [16] for the monotonic and cyclic tests, respectively. The ultimate displacement observed in the monotonic test (i.e., the maximum displacement at which the strength has not yet dropped below 80% of the peak strength) was used to compute the reference displacement for the simplified CUREE-Caltech cyclic testing protocol [17] according to method C of ASTM E2126-19 [16]. The loading protocol was displacement-controlled and applied until failure of the specimen.

3.2 ASSEMBLY-LEVEL TESTS

Specimens are representative of typical ground-level walls of a 7-story building designed per the Chilean seismic design code NCh433 [18] (see Figure 4). Four of them are MLSSWs, whereas the remaining one (i.e., the control wall) is a bare strong shear wall. As shown in Figure 4, the walls had a 1:1 aspect ratio (i.e., 2481 mm in height and 2440 mm in length). Wood-frame consisted of eight studs distributed along the length every 400 mm center-to-center distance. Due to the high levels of overturning moments, each sturdy end-stud consisted of four members mechanically joined and located symmetrically with respect to the continuous rod system. Double plates at the top and bottom of the wall were nailed to the studs with ϕ3.0 mm x 80 mm nails. All framing elements were 41 mm x 185 mm (2 x 8) C16 Chilean RP dimensional lumber, with a nominal modulus of elasticity E = 7900 MPa according to NCh1198 [14]. The walls were sheathed on both sides with 11.1 mm thick APA-rated OSB panels [19] with G = 1307.5 MPa (measured in previous studies [3]), and pneumatically driven to the frame with ϕ2.9 mm x 80 mm helical nails. The edge and field nails were installed at 100 mm and 200 mm center-to-center, respectively. According to SDPWS prescriptions [20], edge-nailing at the end studs should be uniformly distributed among the four framing members and spaced at a maximum of 300 mm. The walls were sheathed on both sides with two-ply 15 mm thick Type X GWB panels [6] with a measured G = 1177.9 MPa according to the ASTM D3044-16 [21] prescriptions. The first Type X GWB layer was vertically oriented and attached to the frame through the OSB with ϕ4.0 mm x 63.5 mm (i.e., Nº 8 x 2-½") drywall screws, whereas the second Type X GWB layer was horizontally oriented and attached to the frame through the first GWB layer and OSB with ϕ4.0 mm x 76.2 mm (i.e., Nº 8 x 3") drywall screws. The edge screws and field screws were installed at 200 mm and 300 mm center-to-center, respectively, according to the NCh1198 [14] fire prescription draft. In order to transfer the lateral load to the wall, a built-up collector beam of 205 mm x 207 mm (i.e., five members of 41 mm x 185 mm C16 RP plus an 11.1 mm thick OSB layer on top and bottom) was mechanically attached to the top sole plate through 38 Simpson Strong-Tie's SCDP221100 screws. The MLSSW racking restraint system consisted of a continuous rod system (i.e., Strong-Rod® system [13]) fabricated in Pleasanton, CA, USA. High-Strength ASTM A193 Grade B7 (i.e., ultimate strength equal to 125 ksi) fully threaded steel rods of ϕ38.1 mm were installed on both sides of the specimen. The rods were attached to the walls by a reaction system over the collector beam that consists of (from bottom to top) a 31.75 mm thick bearing plate (i.e., Simpson Strong-Tie PL16-5x12), a take-up device (i.e. Simpson Strong-Tie ATUD14), a 9.5 mm thick bearing plate (i.e. Simpson Strong-Tie BP 1-1/2), and a finger tightened double heavy hexagonal nut ASTM A563 Grade DH. To avoid sliding between the specimen and the reaction beam, 14 ϕ32 mm x 220 mm ASTM A193 Grade B7 anchor bolts were used to attach the bottom double sole plate to the top flange of the reaction steel beam.

https://doi.org/10.52202/069179-0282

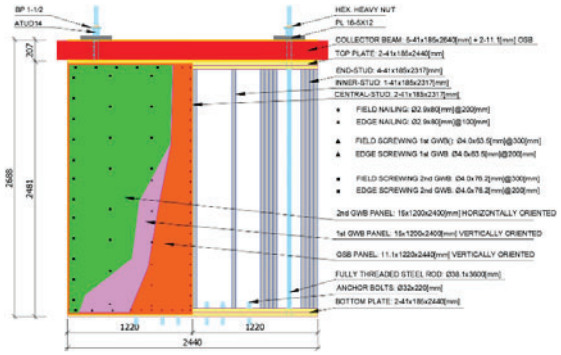

Figure 4: *Monotonic response of connection-level groups*

A cantilever reaction wall, a strong floor, and a reaction steel beam were used to perform the assembly-level tests. As shown in Figure 5, the reaction steel beam was attached to the strong floor by two transversal steel beams attached to the strong floor by four high-strength fully threatened steel rods with a post-tensioned force of 120 kN each, avoiding possible sliding of the reaction beam. The specimens were attached to the reaction beam through a rod-to-steel beam connector (i.e. Simpson Strong-Tie ATS-SBC10H connector) and 14 ϕ32 mm x 220 mm ASTM A193 Grade B7 anchor bolts to prevent overturning and sliding, respectively. The lateral load was applied by a hydraulic bidirectional actuator of +/- 245 kN and +/- 250 mm of force and displacement capacity, respectively, which transfers the lateral load to the specimen through the collector beam. To prevent out-of-plane displacements, the specimens were laterally braced by two steel A-frames which allowed in-plane displacements. To capture the lateral displacement and shear force along the axis of the collector beam, the slip of the wall with respect to the steel reaction beam, the diagonal (shear) deformation, uplift in the exterior edge of the wall, the relative displacement between the multiple layers of the wall, the relative displacement of the steel reaction beam with respect to the strong floor, and the compressive deformation under the bearing plate of the strong-rod system, all specimens were instrumented with thirteen displacement transducers (LVDTs), one laser displacement transducer, and one load cell and displacement transducers (LVDT) incorporated into the actuator. To measure the tension in the rods of the continuous holdown, two unidirectional strain-gauges were attached to the rods.

In order to characterize the in-plane cyclic behavior of specimens, the CUREE-Caltech cyclic testing protocol proposed by Krawinkler et al. [17] was applied. The reference displacement was based either on: a) previous monotonic tests conducted by Guiñez et al. [4] on bare shear walls of comparable specimens features for the case of discrete hold-downs; or b) the shear walls investigated by Estrella et al. [3] for the case of continuous rod systems. The maximum limit for the reference displacement Δ = 61 mm was set for the specimens (i.e. 0.0025 times the wall height) as established in method C (i.e. the simplified CUREE-Caltech protocol) of ASTM E2126-19 [16]. The loading protocol was displacement-controlled and applied until the specimens reached a safe minimum capacity after the peak strength.

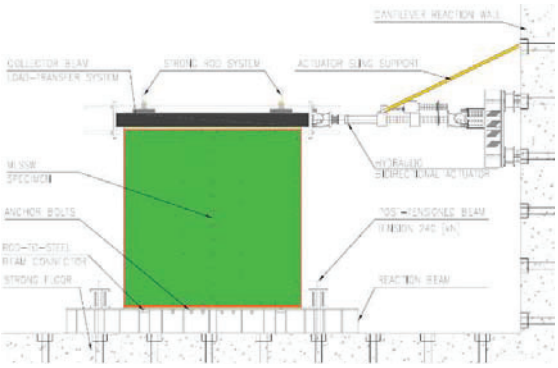

Figure 5: *Front view of the test set-up for assembly-level specimens.*

4 RESULTS

In this section, test results and a discussion of the findings are presented. Failure mode, hysteresis shape, and six engineering parameters were established for connection-level and assembly-level test results: (1) elastic stiffness (K_e); (2) yield displacement (Δ_y); (3) yield force (F_y); (4) ultimate displacement (Δ_u); (5) ultimate force (F_u); and, (6) ductility (μ). Moreover, the lateral behavior of MLSSWs is compared with that of bare SSWs used in this study as reference.

4.1 CONNECTION-LEVEL TESTS

The specimens were inspected after each cyclic test in order to evaluate typical failure modes. On the nailed OSB-to-frame connection (i.e., test group A) two failure modes were identified: (i) excessive bend in the nail leading to shearing-off of the fastener; and (ii) pull out or pull-through of the nail from the OSB-to-frame joint, leading to detachment of the OSB. In both cases, crushing in the wood and OSB panel and fiber tear in the OSB panel were observed. On the screwed 1-ply type X GWB+OSB-to-frame connection (i.e., test group B) two failure modes were identified: (i) excessive bend in the screw leading to shearing-off of the fastener; and (ii) pull-through of the screw from the 1-ply type X GWB+OSB-to-frame joint, leading to detachment of the GWB and OSB sheathing. In both cases, crushing in the wood and panels and tearing in OSB and GWB panels were likewise observed. Finally, on the screwed 2-ply type X GWB+OSB-to-frame connection (i.e., test group C), one failure mode was identified: (i) excessive bend in the screw leading to shearing-off of the fastener. Wood crushing and tearing in OSB and GWB panels were observed.

https://doi.org/10.52202/069179-0282

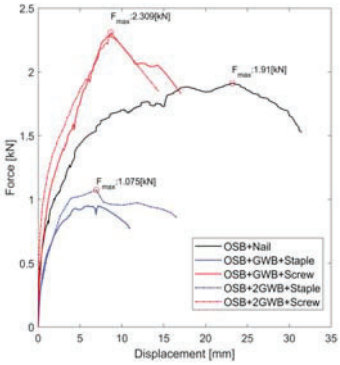

Figure 6: *Monotonic response of connection-level groups*

Table 2: *Engineering parameters from monotonic connection-level test results*

Test Group	K_e kN/mm	Δ_y mm	F_y kN	Δ_u mm	F_u kN	μ
A	0.91	1.87	1.69	31.51	1.53	16.9
B	0.91	2.15	1.94	17.05	1.83	7.9
C	1.89	1.01	1.91	14.39	1.85	14.3

The monotonic force-displacement test response for all the tested groups is presented in Figure 6, in which the reported displacement is the differential slip between the wood frame and the multi-layer sheathing, and the force is that taken by only one fastener along a single shear plane. In specimens with two Type X GWB, two screws are needed (one for each GWB), but results reported in this section refer to either one nail (for bare connections) or one screw, regardless of the number of Type X GWB. This makes possible a direct evaluation of the use of only one fastener in different configurations. Six engineering parameters are summarized in Table 2, where the Equivalent Energy Elastic-Plastic (EEEP) [22] approach was used to estimate the parameters according to ASTM E2126-19 [16]. Monotonic test results indicate that connections A (OSB+nail) and B (OSB+Type X GWB+screw) exhibited almost the same elastic stiffness, even though connection B has multiple layers of sheathing. In contrast, connection C (OSB+(2)Type X GWB+screw) was about twice stiffer than connections A and B. Results for connections A and C were consistent with the analytical stiffness expressions reported in [23]. However, connection B exhibited smaller stiffness than the analytical prediction, attributable to installation defects that tend to leave a gap between the sheathing layer and the wood-frame due to difficulties in screwing throughout the finish layers. Regarding capacity (strength), the screwed connections B and C exhibited stronger capacity than the nailed connection A. The screwed connection takes advantage of the axial capacity of the fastener, whereas the nailed connection is easily pulled out. From a ductility point of view, connection A performs better than all other GWB-sheathed connections. Ductilities of connections B and C were expected because screws are typically less ductile than nails and the reinforcing effect of the Type X GWB produced a more prominent strength degradation and a reduction of the inelastic ultimate displacements. However, the behavior of connection C is similar to the one reported in concrete-to-wood hybrid connections [24] in terms of elastic stiffness (i.e., elastic stiffness is almost twice that of connection B), but the peak strength and the ultimate displacement are similar to the ones of connection B. That is why the ductility of connection C is 80% higher than that of connection B. Likewise, it was found that even when all connections showed comparable yielding displacements of about 1-2 mm, the ultimate displacement of the bare connection A was about twice larger than that of the other connections, indicating that GWB-sheathed connections can clearly undergo lesser inelastic displacements.

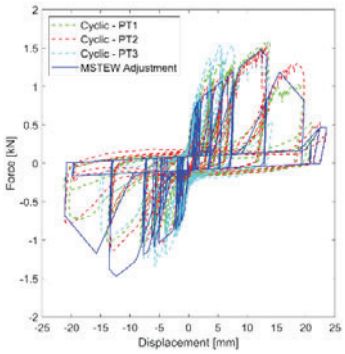

Figure 7: *Force-displacement response of test group A (i.e., nailed OSB-to-frame)*

The cyclic force-displacement test response for all the tested connections is presented in Figures 7 to 9. Again, results are expressed in terms of differential slip per fastener/shear plane. Cyclic test results for all tested connections depict a strong pinching effect due to wood frame and OSB crushing at the shear planes. Moreover, an abrupt strength degradation after repeated cycles at the same target displacement was found in all tests. A markedly asymmetric hysteretic response was found for bare OSB connections (group A), which was not consistent with previous findings [2, 25-27]. This asymmetric response could be attributed to: (1) the threaded portion of the nail is located at its end rather than distributed along the whole length (as in previously reported tests [2]), which would affect the rope effect in the connection [25]; and/or (2) an installation effect (i.e., the use of a pneumatic nail gun). This asymmetric response behavior of full-scale MLSSWs should be analyzed with more detail in the future. Apart from the response asymmetry, cyclic test results were consistent with monotonic test results: larger strength and stiffness of screwed connections, and a significantly larger ultimate displacement capacity of nailed connections.

https://doi.org/10.52202/069179-0282

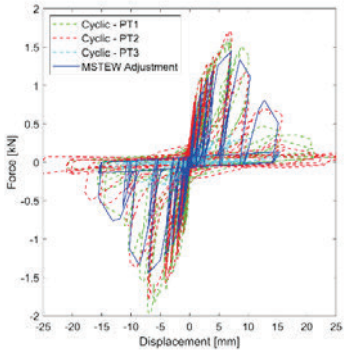

Figure 8: *Force-displacement response of test group B (i.e., screwed one layer Type X GWB+OSB-to-frame).*

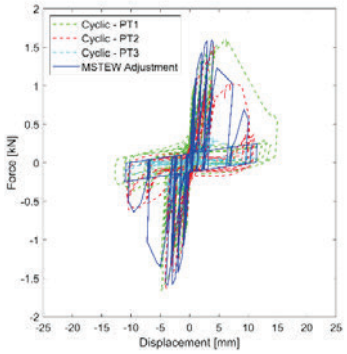

Figure 9: *Force-displacement response of test group C (i.e., screwed two layers Type X GWB+OSB-to-frame).*

4.2 ASSEMBLY-LEVEL TESTS

The wall specimens were inspected after each test in order to evaluate typical failure modes. In all four specimens (all of them had a 2-Type X GWB screwed configuration) five failure modes were identified: (i) pulling out of the nails and screws; (ii) pulling out of the nail and screw heads through the OSB or Type X GWB panels; (iii) shear-off of nails and screws due to excessive fastener bending; (iv) local embedding failure (crushing) in the OSB and Type X GWB panels attributable to an excessive stress concentration around the fastener; and, (v) detachment (out-of-plane unsheathing) of the OSB and GWB panels from the wood-frame because of failure of the fasteners (i.e. nails and screws). In all cases, excessive and moderate crushing in the wood and in the OSB and Type X GWB panels were observed, respectively. The fasteners failure was initiated at the center studs of the walls and propagated to the edge of the walls at the final stages of the loading protocol. This phenomenon is consistent with findings of previous researchers for continuous rod hold-downs [3], and can be explained by the concentration of fasteners in end studs around the continuous rod, which typically initiates failure at interior sheathing edges.

It is remarkable that double shear failure, pull-out, and pull-through of fasteners, along with local embedding of sheathing, were found as failure modes. However, there was no evidence of shear Type X GWB failure, and apparently, there was no reduction of the shear wall racking deformation capacity. Typically, the failure of non-structural finishes has been a cornerstone in restraining the design inter-story drift limit because it is commonly thought that it has much less deformation capacity and is more brittle than OSB. In MLSSWs, however, there was neither evidence of GWB failure nor shortening of the deformation capacity. This behavior is attributed to the fact that OSB sheathing offers protection to GWB [11], preventing brittle failure modes if OSB and GWB are located on both sides of the frame (i.e., the GWB always has a protective OSB layer beneath. Moreover, failure of the nails and detachment of the OSB occurred only at the ultimate stages of the loading protocol because of the minimal reinforcing effect of the GWB after the general failure of the GWB-screwed connections.

Figure 10: *Main failure modes observed in MLSSW specimens: (1) nail and screw failure pattern; (2) and (3) failure of the screwed* Type X GWB+*OSB-to-wood frame connection (in orange) for the 2nd layer and 1st layer, respectively; (4) and (6) pulling out of screws and nails; (5) and (9) local failure of the* Type X GWB *panels and OSB, respectively; (7) pulling through of nails and screws;(8) sheathing layers detachment from the wood-frames; and, (10) double shear failure of the screws.*

The wood frame showed moderate to low damage in all cases. Damage was concentrated mainly on the double central (interior) stud of the specimens and its connection to the top and bottom double plate, and was not as excessive as observed in previous tests on specimens with denser nailing patterns of 50 mm [3]. At the final stages of the loading protocol, detachment between the end studs located at the edge of the specimen and the bottom double plate was observed due to failure of the nailed OSB-to-bottom plate connection.

As expected, the rocking restraint system showed no damage in all the wall tests (it was designed to behave elastically even at the peak strength of the MLSSW specimens). The top-bearing steel plates were not

damaged, as no crushing into the OSB of the collector beam was observed. This was also attributable to the overstrength factor used to design the specimens, which led to predominant nail and screw ductile failures.

The backbone hysteretic curves of the four MLSSW specimens (CT-MLSSW-0i, all comprising 2 screwed Type X GWB) and the control wall (CT-100-38, only with bare OSB without any GWB sheathing) are shown in Figure 10. The reported displacement is the effective displacement of the wall measured at the collector axis where the actuator was located. The effective displacement is the measured lateral displacement at the collector of the wall minus the displacement measured at the specimen-to-reaction beam relative to the reaction beam-to-strong floor. The overall shape of the hysteresis loops was consistent with that reported in previous research [3, 4, 28]. The MLSSW specimens showed elastic response up to a drift of about 1.0%, and then a nonlinear response was observed, attributable to the multilayer sheathing-to-wood frame connection. After the specimens reached the peak strength, progressive and smooth strength and stiffness degradation was found. As expected, high redundancy was evident in the specimens because of the multiple screwed and nailed connections at multiple layers, resulting in high drift levels with no brittle failures. Hence, as the lateral behavior of the MLSSWs was governed by the connection-level response, the MLSSW hysteresis was markedly pinched because of the non-reversible crushing effect of the fasteners (i.e., nails and screws) over the wood-frame components, which leads to a gap between the wood and the fasteners.

The engineering parameters of the backbone curves were estimated according to the Equivalent Energy Elastic-Plastic (EEEP) approach [22] per ASTM E2126-19 [16]. The resulting mean values are summarized in Table 3. All the shear walls tested in this research had a panel edge nail spacing of 100 mm and an anchoring rod of 38 mm in diameter.

Table 3. *Engineering parameters from cyclic MLSSW and control wall test results*

Test Group	K_e [kN/mm]	Δ_y [mm]	F_y [kN]	Δ_u [mm]	F_u [kN]	F_{peak} [kN]	μ
MLSSW	5.9	28.6	157.5	93.6	139.6	174.5	3.5
CT-100-38*	3.8	15.4	58.6	90.2	54.0	67.5	5.9

* CT -NP-AD: CT = cyclic test; NP = nail spacing pattern (i.e., 100 = 100[mm]); AD = anchorage diameter (i.e., 38 = 38[mm]).

The MLSSW specimens showed a mean peak strength of 174.5 kN, which is up to 160% higher (i.e., almost 3 times) than the peak strength (67.5 kN) observed in the equivalent bare strong shear wall specimen (CT-100-38), see Table 3. These surprising results confirm that double sheathing and screwing Type X GWB in timber shear walls can make an enormous structural difference, as it may have an even stronger influence than denser nailing patterns or stronger anchorages (these two parameters are currently among the most important design parameters to increase the capacity of timber shear walls). This enormous increase is thought to be generated not only by the "parallel spring" action of the screws but also because of the axial strength of the screws and their axial sheathing fixing may also reinforce and benefit the nailed OSB-to-wood frame connection, which is believed to control the strength of bare shear walls. This is related to the fact that in MLSSWs the evident pulling-out of OSB-to-wood frame connections took place at the final stage of the testing protocol, whereas in the CT-100-38 specimen the same phenomenon started right after the peak strength was reached.

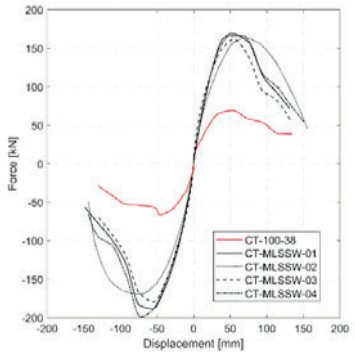

Figure 10: *Comparison between backbone curves of all tested specimens.*

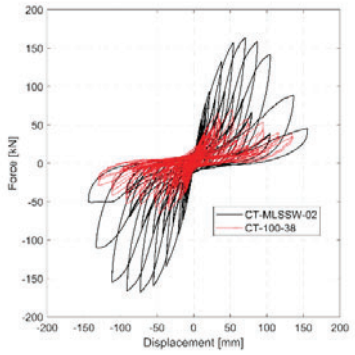

Figure 10: *Comparison between force-displacement hysteretic response of MLSSW sample CT-MLSSW-02 and control wall (i.e., bare strong shear wall) CT-100-38.*

The elastic stiffness of the MLSSWs, CT-100-38 and other research specimens are reported in Table 5. MLSSW specimens show a mean elastic stiffness of 5.854 kN/mm, which is up to 53% higher than the elastic stiffness observed in the control specimen CT-100-38 (3.821 kN/mm). All specimens show a clear stiffness degradation as the lateral drift increases, presenting a residual stiffness between 0.5 kN/mm to 1.5 kN/mm. At 0.1% to 4% lateral drift the MLSSWs exhibit the highest levels of secant stiffness, and the degradation is linear rather than quadratic as observed in bare shear walls. Finally, at lateral drifts smaller than 0.1%, specimen CT-100-38 present a secant stiffness that is 99% smaller than that of the MLSSWs. These results confirm that the actual

https://doi.org/10.52202/069179-0282

elastic and secant stiffness of MLSSWs are greater than those based on the assumption of bare shear wall.

In bare wood-frame strong shear walls the ductility is governed mainly by the nailed sheathing-to-frame connection. MLSSWs, on the other hand, have multiple sheathing-to-frame connections and each of these has a different ductility level, hence the overall ductility of MLSSWs depends on the combined effect of all connections. Values of ductility μ are reported in Table 3. They were computed according to ASTM E2126-19 [16] as the ratio of ultimate to yield displacement: $\mu = \Delta_u/\Delta_y$. MLSSW specimens show a mean ductility of 3.5, which is 42% smaller than the observed ductility in the control specimen CT-100-38 (5.929). This reduction in ductility could be attributed to the screwed 1st/2nd layer GWB+OSB-to-frame connection, which contributes mainly to stiffness and strength rather than to deformation capacity because screws tend to fail first as the lateral drift of the MLSSW increases. In other words, the screwed connections themselves are less ductile than the nailed connections. However, once the screwed connections fail in MLSSWs, a rapid failure of the nails is expected as they are unable to take all the load previously taken by the screws. Therefore, the ductility of the screws (rather than that of the nails) is thought to govern the MLSSW ductility as was reported by previous researchers [3, 4], the nail spacing in OSB-to-frame connection controls the ductility of bare shear wall.

5 CONCLUSIONS

Findings of this investigation reinforce the idea of taking advantage of the effect of the finishes layer on the lateral response of MLSSWs to achieve a cost-effective structural design. Such approach would cast a paramount criterion in the context of targeting earthquake-prone tall timber buildings, and traditional design practices that ignore the contribution of GWB finish layers should be discouraged. Further research is needed to elucidate the potential contributions of the finishes layer on seismic performance factor of light-frame timber buildings.

TESTING THE INFLUENCE OF 3D COUPLING EFFECTS ON THE LATERAL RESPONSE OF NON-PLANAR T-SHAPE WOOD FRAME SHEAR WALLS

Diego Valdivieso[1], Diego Lopez-Garcia[2], José Luis Almazán[3], Jairo Montaño[4], Pablo Guindos[5]

ABSTRACT: Cumulative shear wall overturning (CSWO) is a common response of structural models of multi-story Light-Frame Timber Buildings (LFTBs) under lateral loads. Governed by holdown uplift and shear wall (SW) bending, large CSWO occurs in LFTBs due to the light self-weight of wood and the dominant rocking flexibility of stiff SWs. Even though CSWO is paramount in seismic design because of its effect on the flexibility of LFTBs (making hard to achieve the inter-story drift limits), this phenomenon is not incorporated into the structural models of LFTBs. For instance, in the design of LFTBs for lateral loads it is assumed that SWs behave as planar isolated elements. However, CSWO may be influenced by 3D coupling effects (3D-SWCE) in non-planar SWs such as T or L assemblies. This paper describes a large full-scale experiment of a 7.32 m x 5.1 m assembly, performed to gather insight into 3D-SWCEs through the cyclic evaluation of a non-planar T-shape SW. Results showed an asymmetric behaviour of the T-shape SW with increments of 20% and 98% in elastic stiffness and maximum capacity, respectively, with respect to those of a planar SW. It is concluded that 3D-SWCEs have a significant structural influence on the response of LFTBs.

KEYWORDS: Wood frame construction, light-frame shear walls, non-planar, T-shape, 3D-SWCE.

1 INTRODUCTION

Light frame timber building (LFTB) is one of the alternatives evaluated by the Chilean construction industry to eventually replace concrete and steel mid-rise buildings, reducing the housing deficit and the contribution of the construction industry to the global greenhouse gas emissions [1].

A LFTB is the result of the assembly of several components with repetitive members such as walls, floors, and roof systems connected by intercomponent connections forming a three-dimensional highly indeterminate structural system. Then, gross simplifying assumptions are made (e.g., walls assumed as in-plane resistant components) for its design and analysis [2]. When LFTBs are subjected to earthquake loads, cumulative rotation effects are presented when the shear walls are assumed to behave as isolated cantilever components due to the hold-down elongation and bending deformation of the wall [3]. However, full-scale test results [4-8] showed that current mechanical models [3,9,10] suffer from several limitations as the system effects are not captured. In this paper system effect refers to the interaction between the components of a building (i.e., shear walls, floor, or roof systems) which modifies the response of isolated components. It is then important to experimentally evaluate the mechanism that controls the system effect considering component-level specimens, as the experimental campaigns in light-frame structures that identified the system effect had been done based on building-level specimens [4-8].

1.1 NON-PLANAR TIMBER SHEAR WALLS

For mid-rise buildings in highly seismic-prone areas, such as Chile, wood-frame shear walls usually adopt a strong structural configuration (i.e., strong shear wall or SSW), consisting of 41 × 185 mm (2×8) framing members, sturdy end studs (typically comprising 4 or more members), strong hold-down, wood structural panel (WSP) - typically OSB on both sides-, and closely spaced

edge and field nailing patterns [11-13]. In the layout of a building, SSWs are typically assembled in T-shape, L-shape, and/or U-shape non-planar SSWs based on the architectural project. These non-planar shear walls have been deeply studied in concrete structures [14, 15], identifying coupling effects (i.e., the effect of transverse shear walls on the in-plane response of a wall) that need to be addressed in SSWs. In this paper, the coupling effect presented in non-planar SSWs is denoted 3D shear wall coupling effect (3D-SWCE).

In light-frame timber structures, 3D-SWCE has been identified as one of the key factors to be evaluated for a better understanding of LFTBs [16]. The 3D-SWCE has been evaluated experimentally in conventional shear walls [17, 18] (i.e., the term conventional shear wall was introduced in [11] for referring to wood frame shear wall consisting of a 1.2–2.4 m long wood frame with 38 × 89 mm (2×4) interior studs spaced at 400 mm on center, double end studs, single members for the top and sole plate, and discrete holdowns to prevent overturning of the wall) and partitional walls [19, 20] as an alternative for replacing the installation of hold-downs. Experimental results showed that transverse shear walls have the potential to increase the racking stiffness of a wall to the point where no hold-down is needed. An analytical procedure was introduced in [21] for computing the tying-down effect of transverse walls on the load-carrying capacity of partially anchored conventional shear walls. The procedure demonstrates that transverse shear walls have the potential to increase the lateral in-plane load-carrying capacity of a shear wall. That increment reduces as the aspect ratio of the wall reduces as well (i.e., up to 100% of increment in lateral load for shear walls with a 1:2 aspect ratio, from up to 32% for walls with a 1:0.5 aspect ratio). Even though this procedure is a starting point for the evaluation of 3D-SWCE, it considers only the effect of transverse shear walls by their uplift strength/stiffness, neglecting the out-of-plane strength/stiffness component. Further experimental evaluation is needed in the case where SSWs are used (i.e., as the in-plane/out-of-plane stiffness and strength are higher in SSWs than in conventional shear walls). To the best of the authors' knowledge, no previously published studies have described the cyclic behavior of non-planar SSWs.

The 3D-SWCE has been studied in cross-laminated timber (CLT) shear walls experimentally and numerically [22, 23]. The effect of the out-of-plane walls on the in-plane strength and stiffness of an I-shape CLT non-planar shear wall was reported in [22]. A positive influence on the initial lateral stiffness (i.e., increment of up to 155%) and peak strength (i.e., increment of up to 60%) was found because of the added out-of-plane walls with respect to an isolated wall assembly. Furthermore, the 3D-SWCE seems not to affect the failure mechanism and deformation capacity of the system. The study highlights that a key component for achieving 3D-SWCE is a properly detailed connection between transverse and in-plane walls in order to use them as an uplift restraint system.

2 SCOPE

This investigation aims at evaluating experimentally the lateral cyclic response of a non-planar T-shape wood frame strong shear wall as a way to represent part of the system effects found in LFTBs. Also, as previous studies identified that the wall-to-wall perpendicular connections are crucial for achieving 3D-SWCEs, two alternatives were evaluated experimentally.

3 METHODOLOGY

Connection-level and assembly-level tests were carried out under monotonic and/or cyclic loading according to ASTM E564-06 [5] and ASTM E2126-19 [6], respectively. The loading protocol was displacement-controlled and applied until failure of the specimen.

3.1 CONNECTION-LEVEL TEST

Two different configurations of wall-to-wall perpendicular connections were assembled. Both connections (i.e., screwed and slotted) were selected to facilitate wall installation considering off-site construction techniques. The connection-level specimens are representative of an end-stud-to-end-stud perpendicular connection (i.e., for a wall-to-wall perpendicular connection, end-studs are connected). Specimens consider two lateral elements and one central element manufactured with 41 mm x 135 mm (2x6)

https://doi.org/10.52202/069179-0283

dimensional Chilean radiata pine (RP) lumber mechanically graded as C16 according to NCh1198 [26]. As SSWs are sheathed with OSB, a layer of OSB is attached at both sides of the central element. Screwed connection considers two pairs per shear plane of four crossed screws in an X-position installed at 45°. Slotted connections consider one slot connector per shear plane. Details of each specimen are summarized in Table 1. Each configuration consists of 3 specimens: 1 for monotonic testing, and 2 for cyclic testing.

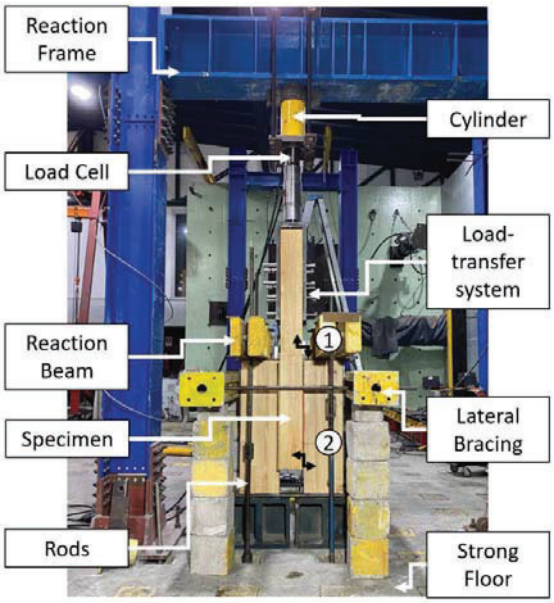

Figure 2: *Connection-level test setup*

A reaction steel frame was used to perform the connection-level tests. As shown in Figure 2, the reaction steel frame is anchored to a strong floor. Two heavy-duty steel beams are installed at each side of the specimen reacting against the strong floor through four high-strength rods (Figure 2). The load was applied by a double-action cylinder of +/- 588 kN and +/- 75 mm of force and displacement capacity, respectively, which transfers the vertical load to the specimen through a load-transfer system that consists of two steel plates attached to the specimen through bolts. As shown in Figure 2, all specimens were instrumented with four (i.e., two per shear plane) displacement transducers (LVDTs) for measuring the slip of the connection (labelled as 1 in Figure 2), two (i.e., one per shear plane) LVDTs for monitoring the rotation of the lateral end-studs (labelled as 2 in Figure 2) and one double-effect load cell to capture the shear force between end-studs.

Table 1: *Connection-level specimen details*

Connection Type	Lateral Element[b]	Central Element[b]	Fast.or Conn. Type
45XSc[a]	(4)41x135	(10)41x135	ESCRFTZ 8.0X300[c]
Slot90	(6)41x135	(12)41x135	SLOT90[d]

Notes:
a) Screw is abbreviated as Sc
b) For assembling each element, wood-frames are glued together following NCh2150 [27] prescriptions.
c) ESCRFTZ 8.0X300 per ETA-13/0796 of 12/15/2017 manufactured by Simpson Strong-Tie.
d) SLOT 90 per ETA-19/0167 of 04/05/2019 manufactured by Rothoblaas.

3.2 ASSEMBLY-LEVEL TEST

Specimens used for the planar and non-planar T-shape walls are representative of typical ground-level walls of a 7-story building designed per the Chilean seismic design code NCh433 [28]. Details of the wall specimens are summarized in Table 2. Double plates at the top and bottom of the wall were nailed to the studs with ϕ3.0 mm x 80 mm smooth shank nails that conform to ASTM F1667 [29]. All framing elements were 41 mm x 185 mm (2x8) C16 Chilean RP dimensional lumber, with a nominal modulus of elasticity E = 7900 MPa according to NCh1198 [26]. The walls were sheathed on both sides with 11.1 mm thick APA-rated OSB panels [30] with G = 1307.5 MPa (measured in previous studies [11]), and pneumatically driven to the frame with ϕ2.9 mm x 80 mm spiral nails. OSB sheathing layers were installed at both sides of the specimens and attached to the lower top plate and to the upper bottom plate as illustrated in Figure 3. According to the SDPWS [31], edge-nailing at the end studs should be uniformly distributed among the four framing members and spaced at a maximum of 300 mm. In order to transfer the lateral load to each specimen, a built-up collector beam of 205 mm x 207 mm (i.e., five members of 41 mm x 185 mm C16 RP plus an 11.1 mm thick OSB layer on top and bottom) was mechanically attached to the top plate through 38 Simpson Strong-Tie's SCDP221100 screws. For assembling the non-planar T-shape SSW, one type A (i.e., for the web) wall and two type B (i.e., for the flange) wall were used. For the wall-to-wall perpendicular connection (i.e., for attaching each flange to the web of the T-shape wall), six SLOT90 connector are used. The connectors are installed into the walls and fixed using two (i.e., one screw for wall) Simpson Strong-Tie's SDCF22614 screws (Figure 3). The planar SSW is a type C wall.

Table 2: *Wall type configuration*

Wall Type	n	Wall size (L by H)	Wood Structural Panel (WSP)		
			Thickness	Sheathing Nails[d]	Spacing edge/field
A[a,c]	1	2440x2481	11.1	ϕ2.9x80	100/200
B[b,c]	2	2440x2481	11.1	ϕ2.9x80	100/200
C[b,c]	1	2440x2481	11.1	ϕ2.9x80	100/200

Notes:
a) Wall framing consisted of 41mm x 185 mm (2x8) C16 Chilean RP [26] studs at 400mm o.c., (2) 41mm x 185 mm used as a central stud, (4) 41mm x 185 mm studs mechanically joined and located symmetrically with respect to the rod and (5) 41mm x 185 mm studs mechanically joined are used as end-studs.
b) Wall framing consisted of 41mm x 185 mm (2x8) C16 Chilean RP [26] studs at 400mm o.c., (2) 41mm x 185 mm used as a central stud, (4) 41mm x 185 mm studs mechanically joined

https://doi.org/10.52202/069179-0283

and located symmetrically with respect to the rod are used as end-studs.
c) Wall shear anchorage consisted of ϕ32 mm x 220 mm ASTM A193 Grade B7 anchor bolts (14 and 15 for wall type A and B, respectively) with ϕ80 mm x 4.0 mm Grade A36 washers. Overturning restraint provided by ϕ38.1 mm ASTM A193 Grade B7 rods with 31.75 mm thick bearing plate (i.e., Simpson Strong-Tie PL16-5x12), a take-up device (i.e., Simpson Strong-Tie ATUD14), a 9.5 mm thick bearing plate (i.e., Simpson Strong-Tie BP 1-1/2), and ASTM A563 Grade DH double hexagonal nut.
d) nails installed considering a minimum of 20/40 mm of end/edge distance, respectively. According to EN14592:2008+A1:2012 [32].

Figure 3: *(a) sliding restrain system for wall type A and B, and, wall-to-wall connection detail; (b) slot disposition; and (c) installation of the SLOT90 connector*

An L-shape cantilever reaction wall, a strong floor, and a T-shape reaction steel beam were used to perform the assembly-level tests following ASTM E2126-19 [25] prescriptions (Figure 4). As shown in Figure 3, the specimens were attached to the reaction beam through 43 ϕ32 mm x 220 mm ASTM A193 Grade B7 anchor bolts to prevent sliding in the T-shape SSW. In order to prevent sliding and to measure the shear force during the cyclic test in the planar SSW, a couple of cylinders reacting against a L-shape connector were installed at each side of the wall (element 9 in Figures 5 and 6). The walls continuous rod system reacts against the top flange of the reaction beam through a system of double hexagonal nuts. Out-of-plane support was provided to the 2D SSW in such a way that in-plane displacements were not affected. In order to capture the 3D response of the T-shape non-planar shear wall, a bidirectional cyclic test was performed according to FEMA 461 [33]. The hexagonal protocol from FEMA 461 [33] consider as a base the test protocol per ASTM E2126-19 [25] method C where a 100% and 50% of the target displacement were applied in the longitudinal and transverse direction. The lateral load was applied by a hydraulic bidirectional actuator of +588 kN/-294kN and +/- 200 mm of force and displacement capacity, respectively, in the longitudinal direction, and by a hydraulic bidirectional actuator of +588 kN/-294kN and +/- 50 mm of force and displacement capacity, respectively, in the transverse direction. Both actuators transfer the lateral load to the specimen through the collector beam. The T-shape non-planar SSW and the planar SSW are connected by a steel pinned-beam, allowing the in-plane loading transferring and decoupling the racking response of the specimens (Figure 4).

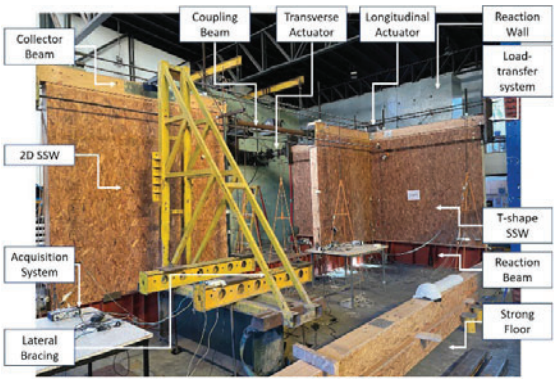

Figure 4: *Assembly-level test setup*

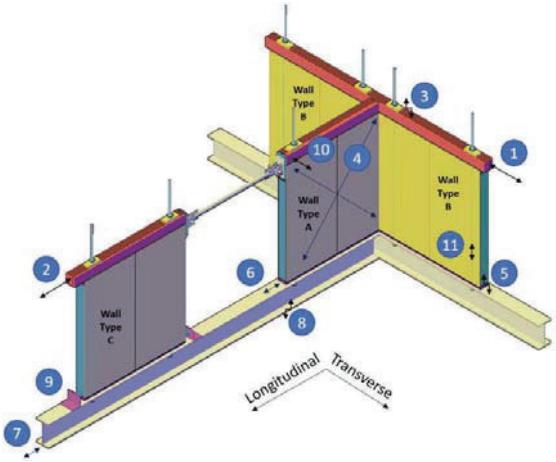

Figure 5: *Assembly-level specimen and instrumentation detail*

The specimen were instrumented with 41 displacement transducers (LVDTs), two cell load at the reaction cylinders (element 9 in Figures 5 and 6), and two load cell and displacement transducers (LVDT) incorporated into the actuator to capture the lateral displacement and shear force along each axis of the specimens (elements 1 and 2 in Figure 5), the slip of the wall with respect to the steel reaction beam (elements 6 and 8 in Figures 5 and 6), the diagonal (shear) deformation (element 4 in Figures 5 and 6), uplift in the exterior edge of the wall (element 5 in Figures 5 and 6), the out-of-plane displacement of the T-shape SSW web (element 10 in Figures 5 and 6), the relative displacement of the steel reaction beam with respect to the strong floor (element 7 in Figure 5), and the compressive deformation under the bearing plate of the strong-rod system (element 3 in Figures 5 and 6). To measure the tension in the rods of the continuous hold-down, seven unidirectional strain-gauges were attached to the rods (element 11 in Figures 5 and 6).

4 RESULTS

Failure mode, hysteresis shape, and six engineering parameters were established for connection-level and assembly-level test results: (1) elastic stiffness (K_e), calculated as the secant stiffness between zero and 40% of maximum load F_{max}; (2) yield displacement (Δ_y); (3) yield force (F_y); (4) ultimate displacement (Δ_u), defined as the displacement after post-peak load where the load dropped to $F_u = 0.8\ F_{max}$; (5) ultimate force (F_u); and, (6) ductility (μ), defined as the ratio of Δ_u to Δ_y. Moreover, the lateral behavior of the T-shape SSW is compared with that of the 2D SSW used in this study as reference.

4.1 CONNECTION-LEVEL TESTS

The slotted connection (i.e., connection type Slot90) shows two failure modes: (i) compression parallel to the grain crushing at the wood studs; and (ii) local yielding in the SLOT90 connector. The screwed connection (i.e., connection type 45XSc) shows two failure modes: (i) excessive bend in the screws, wood crushing and tearing in OSB sheathing layer; (ii) withdrawal failure of at least one screw of the group; (iii) pull-through of the screws head; and (iv) tension failure of at least one screw of the group. Note that in failure modes (ii) to (iv) pulling out of the connected wood members was present.

Monotonic results for each connection-level test are shown in Figures 7 and 8, in which the reported displacement is the differential slip between the wood frames, and the force is that taken by only one SLOT90 or group of four inclined ESCRFTZ 8.0X300 screws along a single shear plane. Based on monotonic test results, engineering parameters are summarized in Table 3. Both connections showed almost the same peak load and higher elastic stiffness which is attributable to the wood parallel to the grain stiffness/strength and axial stiffness of fully threaded screws for the case of connection type Slot90 and 45XSc, respectively. From a ductility point of view, connection type 45XSc showed almost four times higher values than the Slot90 connection. However, this tendency was not evidenced in cyclic test results were the 45XSc and Slot90 connection types show almost the same deformation capacity (Figures 9 and 10). Finally, based on preliminary numerical models, for achieving 3D-SWCE in a T-shape non-planar SSW the wall-to-wall

perpendicular connection needs to have a stiffness equal to 40% of that of the 2D SSW. When 3D-SWCE is achieved, the numerical model predicted a 20% reduction in the lateral displacement of a 1-story SSW. Based on previous evaluation, both connection types are good candidates as wall-to-wall perpendicular connections.

Table 3: *Engineering parameters from monotonic connection-level test results*

Connection Type	K_e kN/mm	Δ_y mm	F_y kN	Δ_u mm	F_u kN	μ
45XSc	156.0	0.59	92.4	6.74	84.5	11.4
Slot	39.2	2.64	103.6	7.72	92.65	2.9

The cyclic force-displacement test response for both connection types is presented in Figures 9 and 10. Again, results are expressed in terms of differential slip per connector or group of fasteners per shear plane. Cyclic test results for all tested connections depict a strong pinching effect due to the wood frame crushing at the shear planes. Moreover, strength and stiffness degradation after repeated cycles were found in all tests. In particular, in the 45XSc connection type, an abrupt reduction of the stiffness and strength was found after reaching the peak load as the withdrawal failure tends to be more brittle than the parallel to the grain crushing evidenced in the Slot90 connection.

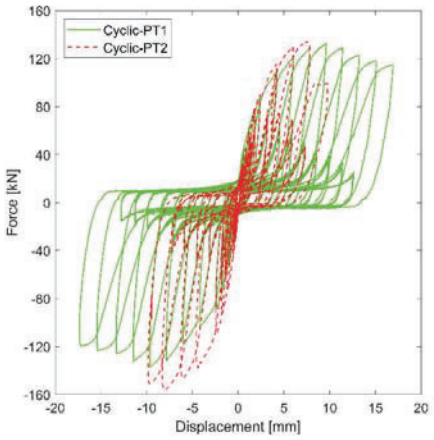

Figure 9: *Cyclic test results of Slot90 wall-to-wall perpendicular connections.*

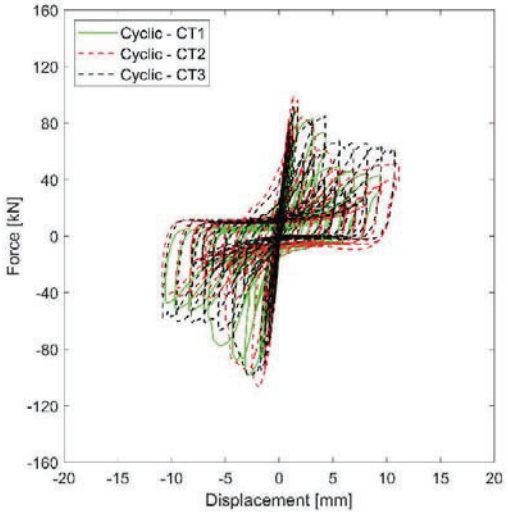

Figure 10: *Cyclic test results of 45XSc wall-to-wall perpendicular connections.*

4.2 ASSEMBLY-LEVEL TESTS

A comparison between the backbone curves obtained from bidirectional cyclic loading on the assemble-level full-scale tests is presented in Figure 11. Based on backbone curves results, engineering parameters are summarized in Table 4. Assembly-level tests showed an asymmetric behaviour of the T-shape SSW with increments of up to 19% and 98% in the elastic stiffness and maximum capacity, respectively, compared to those of a 2D SSW. However, a mean reduction of 44% in ductility was also observed.

The hysteretic curves of the T-shape SSW and the control wall (i.e., 2D SSW) are shown in Figures 12 and 13, respectively. The reported displacement is the effective displacement of the wall measured at the collector axis where the actuator was located (i.e., longitudinal collector). The effective displacement is the measured lateral displacement at the collector of the wall minus the displacement measured at the specimen-to-reaction beam relative to the reaction beam-to-strong floor. The overall shape of the 2D SSW hysteresis loops was consistent with that reported in previous research [12, 13]. However, the T-shape SSW cyclic response was asymmetric (i.e., 44% difference in peak strength) with a faster degradation of strength and stiffness in the flange side of the specimen (i.e., the negative branch of the cyclic response in Figure 13), which is attributable to the premature detachment of the OSB sheathing (i.e., nailed OSB-to-wood frame connection failure) close to the flange of the wall. The 2D SSW and the T-shape SSW specimens showed elastic response up to a drift of about 0.6% and 0.8%, respectively, and then a nonlinear response was observed, attributable to the nailed OSB-to-wood frame connections. After the specimens reached the peak strength, progressive strength and stiffness degradation was found. As expected, high redundancy was evident in the specimens because of the nailed connections, resulting in high drift levels with no brittle failures. Hence, as the

https://doi.org/10.52202/069179-0283

lateral behavior of the specimens was governed by the nailed connection response, the hysteresis was markedly pinched because of the non-reversible crushing effect of the nails.

Table 4: *Engineering parameters from cyclic backbone curves of the assembly-level test results*

Wall Conf.	K_e kN/mm	Δ_y mm	F_y kN	Δ_u mm	F_u kN	μ

5 CONCLUSIONS

Findings of this research reinforce the idea of taking advantage of the 3D-SWCE on the lateral response of LFTBs. The ultimate objective is to achieve a cost-effective structural design and to better understand CSWO, so that traditional pseudo-3D design practices be discouraged. The next steps of this research program include the calibration of analytical and numerical models for non-planar timber shear walls. Further research is needed to elucidate potential 3D effects on other non-planar walls such as U- or L-shape assemblies.

DATA-DRIVEN APPROACH FOR ASSESSMENT OF SEISMIC DAMAGE IN WOOD BUILDINGS

Sifat Muin[1], Asif Iqbal[2], John W. van de Lindt[3]

ABSTRACT: Advances in modern computing techniques and capabilities have been utilized in development of new structural health monitoring techniques that utilize a significant volume of data from instrumentation. These data-driven methods open new possibilities for the damage assessment of wood (or any) buildings. A method known as feature engineering is a key step in developing such tools. This paper presents a feature engineering procedure for wood buildings based on data recorded during seismic events and utilizes a full-scale wood shake table test data set and damage inspection results to illustrate the procedure.

KEYWORDS: Data-driven Damage Assessment, Seismic Performance, Resiliency, Wood Buildings, Feature Engineering, Cumulative absolute velocity

1 INTRODUCTION

Over the past decade, significant progress has been made in structural health monitoring through the application of data-driven damage assessment. Data-driven seismic damage assessment evaluates the potential damage to structures or infrastructure caused by earthquakes using data and analytical techniques. Advances in computing technologies, remote sensing, and data science paved the way for new and improved damage assessment tools, many of which are machine learning algorithm-based [1-3]. These ML-SHM techniques, which utilize structural vibration response as the primary data type, have four stages: *health definition*, *data acquisition*, *feature engineering*, and *machine-learned damage assessment*. Arguments for the damage prediction power of ML have been made in several studies [4-7]. These studies have focused on addressing feature engineering through extracting and selecting features that result in more effective ML model training. This feature engineering step is particularly crucial for ML-based seismic damage assessment as data from the damage class is sparse. Hence, a dataset that provides vibration data from damaged structures is extremely valuable for the development of data-driven damage assessment tools. In this study, feature engineering concepts are applied to a dataset acquired from a series of shake table tests of a four-story full-scale soft-story wood-frame building model. The study's primary goal is to identify the most suitable features for damage assessment of such buildings so that ML-based algorithms would provide the most accurate predictions.

2 FEATURE ENGINEERING

In feature engineering (FE), domain knowledge and data mining techniques are used to identify the most useful features from the data to enhance the performance of ML models. For seismic damage assessment, classifiers or regression models may be used with these features to predict the extent of damage caused to the structure. The data required for the FE are acceleration response histories (RH) and corresponding damage states (DS), or RH-DS pairs. Through *feature extraction*, *exploratory data analysis* ((EDA), and *feature selection*, a vector of damage features is selected that is most suitable for damage classification and localization.

Feature extraction is the process of transforming the measured data into a helpful alternative form. In this step, the RH-DS dataset is transformed into a feature-DS dataset. This transformation reduces the dimension of the dataset keeping the most informative and salient features for damage assessment from the raw data. The extracted damage features include vibration characteristics that have been studied as structural damage indicators by researchers in the past [3]. Past work has shown that these features, referred to as "intensity measures" or "engineering demand parameters" in earthquake engineering, are related to the structural response and are thus likely correlated to damage from a physics-based perspective. Examples of these damage features include peak ground acceleration, peak ground velocity, peak ground displacement, peak responses, cumulative absolute velocity (CAV) [8,9], standardized CAV (CAV_{STD}) [10], Arias Intensity (AI), etc.

Exploratory data analysis (EDA) is the process of studying the *feature-DS* dataset in detail. EDA aims to gain insights into the underlying structure, patterns, and relationships in the data and to identify any potential problems or outliers. EDA often involves visualizing the data using graphs, plots, histograms, and running summary statistics. By exploring the data this way, researchers can make informed decisions about which features and models to use for further analysis. Figure 1 shows an example of EDA where CAV shows a clear pattern with ductility. This set of data was collected using a finite element model of a building and the displacement ductility was used as a measure of damage. Consequently, it was successfully used as a damage indicator for concrete and steel buildings.

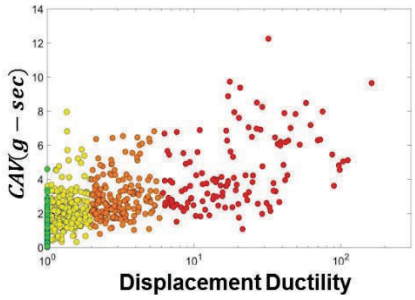

Figure 1. *EDA of CAV showing distinct pattern with increasing ductility (damage) for a reinforced concrete structure. [8]*

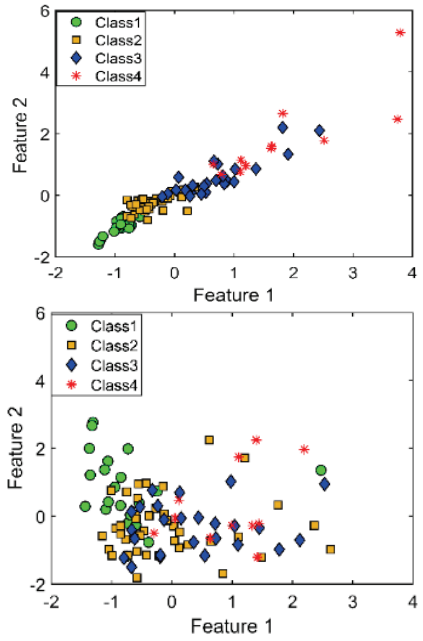

Figure 2. *Discrimination ability of features with high (top) and low (bottom) Fisher scores.*

Feature selection is the process of identifying a subset of the original feature set, which increases the learning efficiency without compromising the classification performance. A filter-based feature selection method is chosen herein called the Fisher Score (FS) because it is computationally inexpensive.). FS determines the relative ability of features to discriminate between categorical classes in a classification model. A larger Fisher score indicates that the feature is more discriminative (Figure 2). Although the Fisher score is known to have limitations as it considers each feature separately and therefore cannot reveal mutual information between features, it is widely used as a heuristic algorithm for feature selection [11].

In this study, the classification model aims to determine which class of DS is indicated by the feature vector. The DSs are ordered in this problem, i.e., if DS0 refers to undamaged and DS1 refers to minor damage, then DS1 is ranked higher than DS0. Due to the ordering of the classes in this model, feature selection that considers *ordinality* is preferred. Thus, an ordinal variant of the Fisher score, the *Ordinal Fisher Score*, is used for feature selection [12]. The ordinal Fisher score (F_{OR}) for the i^{th} feature, x_i is computed following a specific procedure. First, the class discrimination term, $F_O(x_i)$, is defined as follows,

$$F_O(x_i) = \sum_{k=1}^{K}\sum_{j=1}^{K}|k-j|\cdot d^i(C_k,C_j)/\{(K-1)\sum_{k=1}^{K}(\sigma_k^i)^2 \qquad (1)$$

where the class C_k indicates data from one of the K classes, $k,j \in \{1,2,\ldots,K\}, \sigma_k^i$ is the variance of the i^{th} feature in class k, and $d^i(C_k, C_j)$ is the distance between classes C_k and C_j. It is computed using the Hausdorff distance which allows for use of nonlinear, multimodal, or non-normal data, and shown in [12] to perform best for ordinal classification. Second, an ordinality term, $O_R(x_i)$, incorporating the relative distance between classes, is defined as follows,

$$O_R(x_i) = \sum_{k=1}^{K-2}\sum_{j=k+1}^{K-1}\sum_{h=j+1}^{K} I(d^i(C_k,C_h) - d^i(C_k,C_j) > 0)/\sum_{j=2}^{K-1}(K-j) \qquad (2)$$

where $I(\cdot)$ is the indicator function (1 if the inner condition is true & = 0 otherwise). This $O_R(x_i)$ score measures the number of ordinal requirements fulfilled for the i^{th} feature. Finally, the two terms $F_O(x_i)$ and $O_R(x_i)$ are combined in a weighted sum as follows,

$$F_{OR}(x_i) = \alpha \cdot F_O(x^i) + (1-\alpha)\cdot O_R(x_i), \alpha \in (0,1) \qquad (3)$$

The candidate damage features are evaluated using Equation (3) with $\alpha = 0.1$ to identify which features best discriminate between the different classes of DS. Selecting features that can identify ordinality is crucial for accurate damage assessment. Hence, the ordinality term, $O_R(x_i)$, is given a higher weight ($1 - \alpha = 0.9$) compared to the class discrimination term, $F_O(x_i)$. The features with the highest Ordinal Fisher Scores constitute the final damage feature set.

3 FULL WOOD BUILDING APPLICATION

The methodology described above is applied to data acquired from a shake table test program on a four-storied full-scale wood building (Figure 3) tested at the University of California San Diego in 2013 under the project titled "Seismic Risk Reduction for Soft-Story Woodframe buildings (NEES-Soft)" [13, 14]. The model represents many thousands of buildings throughout California, and the United States, generally built before 1970 and many as early as the 1920s, following conventional construction practices of the time which are no longer satisfactory by today's seismic codes and standards. The NEES-Soft project included a major testing program to validate performance-based seismic retrofit methodology developed for these buildings. The penultimate experiment of this program was a collapse test sequence. Data from the collapse test is utilized in this investigation as the structure experienced increasing levels of damage.

Figure 3. *NEES-Soft model building*

3.1 MODEL DESCRIPTION AND TESTING

The building in this study was a 370 m^2 (4,000 sqft) four-story light wood-frame building with a "soft-story" archetype most common in San Francisco Bay Area. It had a plan dimension of 7.3 m x 11.6 m and a total height of 10.9 m. The first story (soft story) mainly serves as a parking area with big wall openings for parking doors. The other three upper stories facilitate two typical two-bedroom apartment units [15]. In order to monitor the behavior of the building during testing, the building was instrumented with two string potentiometers and four accelerometers on the first floor, and three accelerometers on the roof. Moreover, six video cameras monitored the movement of the building. Figure 4 presents the location and details of the instrumentation used in the series of tests leading to the collapse of the test building.

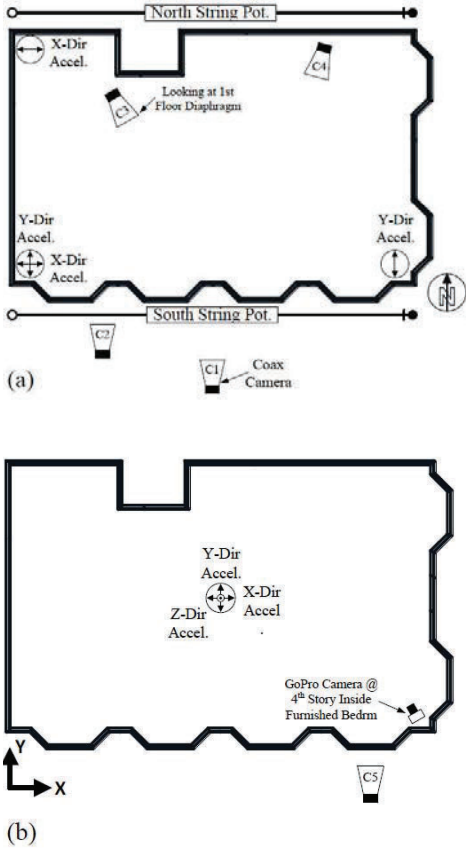

Figure 4. *Instrumentation plan a) first story b) fourth story*

To study the collapse mechanism and behavior of this type of at-risk building, the building was subjected to a range of ground motions with different scaling. Three different ground motions with different intensities were selected. The selections were such that they would provide a range of earthquake records based on differences in ground displacement, even if the seismic intensities as determined through spectral acceleration were similar. The ground motions were then scaled to spectral accelerations ranging from Sa = 0.4g (33% of the design-based earthquake level) to Sa =1.8g (maximum credible earthquake (MCE) level). Table 1 presents the ground motions and test sequences with the corresponding peak ground acceleration (PGA) and peak ground displacement (PGD) for each test.

3.2 DEVELOPMENT OF RH-DS DATABASE

The RH-DS database is created from the acceleration response histories of the eight tests and their corresponding observed damage conditions. The RH data is acquired from the six accelerometers that measured the horizontal responses of the first story and roof. The ground motion RHs were computed from the feedback of the shaketable.

The DS data is based on damages reported during the testing. Due to safety regulations, no damage inspection

https://doi.org/10.52202/069179-0284

and repair was conducted between each consecutive test; therefore, the structural and non-structural damage accumulated during the entire collapse test program. However, building period calculation and residual displacement measurements indicated the level of damage after each test. It was observed that the period of the building increased significantly after Test-4 due to permanent structural damage [16]. But no residual displacements were observed even after Test 5. Test 6 led to extensive permanent damage to the building, bringing it to the verge of collapse with a residual displacement of 350 mm. Then, it was subjected to the same ground motion scaled to Sa=0.9g to evaluate the aftershock performance of the building (Test 7); however, the building did not collapse even with about 406 mm (16 in.) residual drift and 2.3 degrees of residual rotation. The building was then subjected to Test 8, which led to the collapse of the building. Based on these observations, the damage states are classified into four categories, shown in Table 1. These are:

i. DS0 when no damages are reported.
ii. DS1 when the period increase is reported.
iii. DS2 when residual displacement is observed.
iv. DS3 when the building collapsed.

Table 1: *Testing details and damage states*

Seismic Test ID	Eq record	Sa (g)	PGA (g)	PGD (mm)	Damage State
1	Cape Medocino - Rio	0.40	0.21	13.1	DS0
2	Cape Medocino - Rio	0.90	0.44	29.4	DS0
3	Cape Medocino - Rio	1.20	0.56	39.2	DS0
4	Cape Medocino - Rio	1.80	0.90	58.8	DS1
5	Loma Prieta - Gilroy	1.80	0.98	72.1	DS1
6	Superstition Hills	1.80	0.86	277	DS2
7	Superstition Hills	0.90	0.42	138	DS2
8	Superstition Hills	1.80	0.86	277	DS3

4 RESULTS AND DISCUSSION

4.1 FEATURE EXTRACTION:

In the feature extraction phase, the RH-DS database is transformed into a feature-DS database. Six individual features are computed from the RHs. Table 2 shows the feature name and their mathematical definition. For each test, these six features are calculated for the ground response, first story response, and the roof response making the total number of features 18. These 18 features are studied in the EDA phase and utilized in the feature selection phase with corresponding DS shown in Table 1 as their respective class.

Table 2: *Description of candidate damage features*

Feature	Definition
Peak acceleration (PA)	$max(\lvert\ddot{u}(t)\rvert)$
Peak velocity (PV)	$max(\lvert\dot{u}(t)\rvert)$
Peak displacement (PD)	$max(\lvert u(t)\rvert)$
Arias intensity (AI)	$\frac{\pi}{2g}\int_0^T [\ddot{u}(t)]^2 dt$
Cumulative absolute velocity (CAV)	$\int_0^T \lvert\ddot{u}(t)\rvert dt$
Standardized CAV (CAV_{std})	$\sum_{i=1}^{N} H(PA_i - 0.025)\int_{i-1}^{i} \lvert\ddot{u}(t)\rvert dt$ $H(x) = Heaveside\ function = \begin{cases} 0\ , x < 0 \\ 1,\ otherwise \end{cases}$ N: $non-overlapped$ 1 sec $intervals\ with\ PA_i$

4.2 EXPLORATORY DATA ANALYSIS

In this phase, the extracted features are studied to understand their relationship to damage and to point out any outliers. Two different tasks were performed as EDA. Firstly, the relationship between CAV profiles and damage states is investigated. Then all 18 features and their progression with damage are studied.

Figures 5 and 6 show each test's CAV time series and Normalized CAV time series. The normalized CAV is computed by dividing the CAV values by the final CAV, making the ultimate value 1. The responses are calculated from acceleration data of X-direction from the first floor. Figure 5 shows that the damage-inducing tests (4,6,8) have high CAV values (>0.8 g-sec). The normalized CAV plots (Figure 6) show a baseline behavior for tests 1, 2, 3, 4 and a departure from this baseline pattern for tests 5,6,7,8. In previous studies, such deviations coincided with damage [8]. Similar behavior is observed for roof response as well. The figures show that CAV-based

features should be considered as candidate damage features.

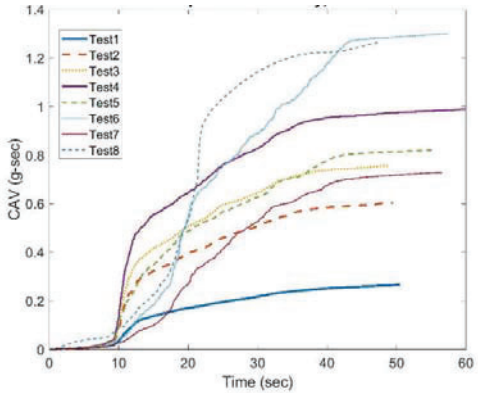

Figure 5. *CAV profile at first floor for X-dir response*

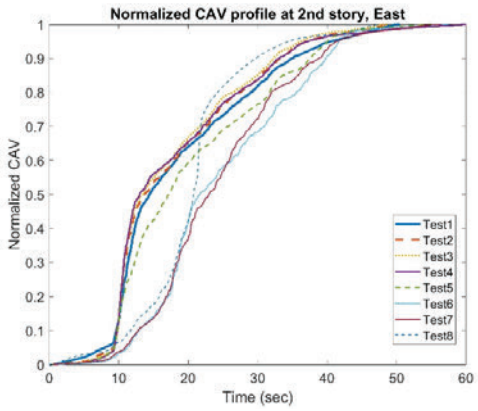

Figure 6. *Normalized CAV profile at first floor for X-dir response*

Figures 7, 8, and 9 show the relationship of the features with the damage states for ground, first floor, and roof response respectively through box plots. The ends of the box plots indicate the quartiles and the line in the middle is the median. The cross inside the box represent the mean. The whiskers (if any) indicate outliers. All ground motion features (Figure 7) depict some trend with increasing damage states. However, for the first floor (Figure 8) and roof responses (Figure 9) the trend is unclear due to the excessively high feature values of DS3. Moreover, the box plots in Figure 8 shows outliers for DS3. Such data, if used in feature selection will produce undesirable outcome. Therefore, DS3 data was not utilized in the feature selection phase following the findings of EDA.

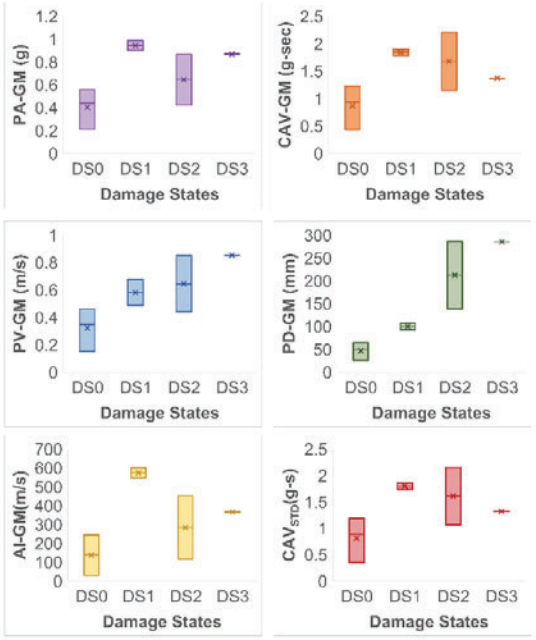

Figure 7. *Features vs damage states computed from the shake table response (ground motion)*

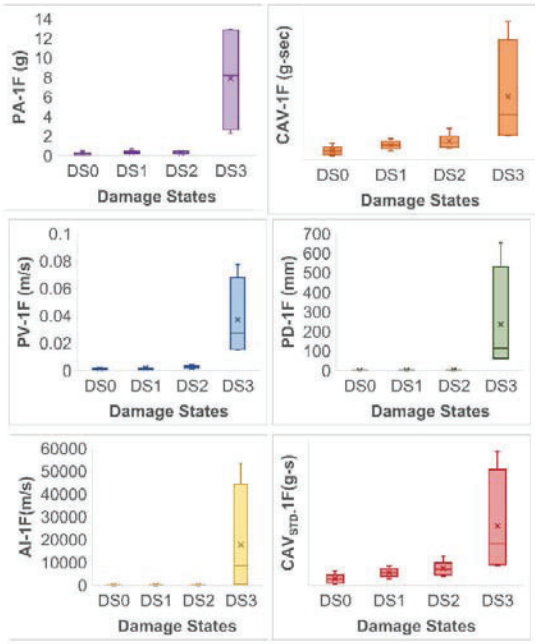

Figure 8. *Features vs damage states computed from the first floor response*

https://doi.org/10.52202/069179-0284

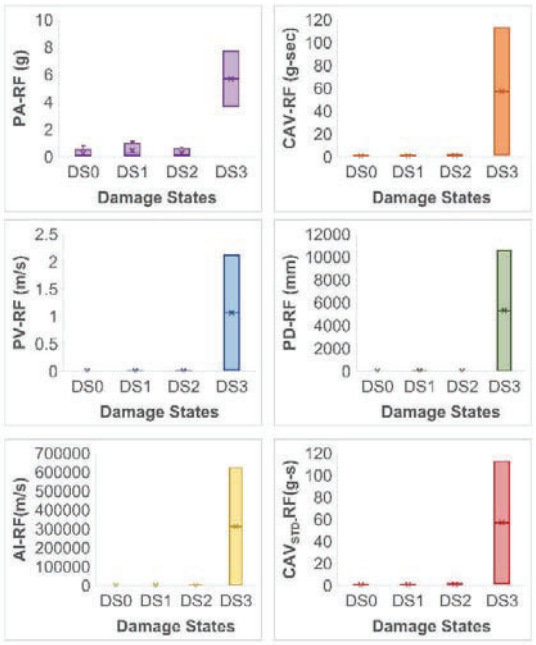

Figure 9. *Features vs damage states computed from the roof response*

4.3 FEATURE SELECTION

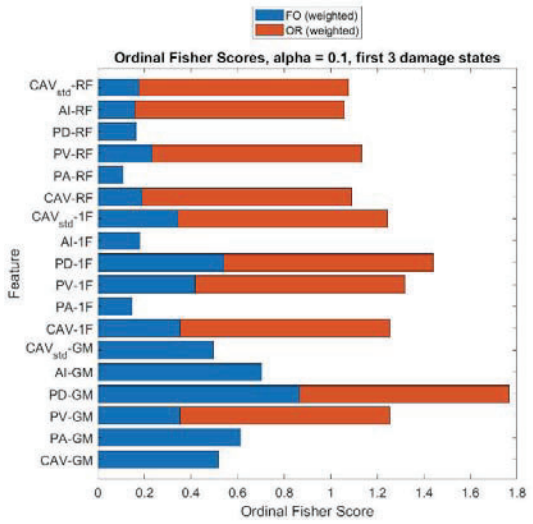

Figure 10. *Ordinal Fisher Scores of the candidate damage features*

In feature selection phase, Fisher score is calculated for all 18 features using Equation 1, 2, and 3. Three damage classes were considered (DS0, DS1, and DS2). Figure 10 shows the ordinal fisher score (F_{OR}). The blue portion is weighted the class discriminatory part and red is the weighted ordinality term. Higher weight is given to the ordinality term so that the features that can identify order of the DS scores higher.

Table 3: *Ordinal Fisher score of the candidate features*

Features	Fisher Score
PD-GM	1.77
PD-1F	1.44
PV-1F	1.32
PV-GM	1.25
CAV-1F	1.25
CAVstd-1F	1.24
PV-RF	1.13
CAV-RF	1.09
CAVstd-RF	1.08
AI-RF	1.06
AI-GM	0.70
PA-GM	0.61
CAV-GM	0.52
CAVstd-GM	0.50
AI-1F	0.18
PD-RF	0.16
PA-1F	0.15
PA-RF	0.11

Table 3 lists the F_{OR} from highest to lowest. Peak displacement of the ground scores the highest among all the features. The high correlation of ground displacement and damage is a well-established observation in the literature. The first floor's peak displacement and peak velocity are the second and third-highest-scoring features. CAV and CAVstd of the first floor, along with the peak velocity of the ground motion, are ranked next with almost the same values. This higher ranking of the CAV features agrees well with Figure 5 and Figure 6 observations. Overall the first-floor features ranked higher than the roof features. This behavior may be due to the "soft-story" mechanism of the structure. One interesting observation is that even though some features (PA-GM, AI-GM) showed a specific trend to damage (Figure 7), their $F_{OR}$was low. Figure 10 shows that these features have high discriminatory terms but very low ordinality terms bringing down the overall score. Therefore, these features would not be suitable for damage classification.

The results imply that for damage assessment of “soft-story” wood-frame buildings, peak displacement and peak velocity of the ground motion are crucial indicators. Moreover, peak displacement, peak velocity, CAV, and CAVstd of the first-floor response will improve the overall performance of an ML model developed toward damage classification. It should be noted that computing displacement values from acceleration by double integrating can sometimes produce erroneous peak values, particularly for low signal-to-noise ratio measurements. CAV values, CAVstd specifically by definition, avoid such noise levels. Therefore, having these features with the peak values will provide a more reliable outcome.

https://doi.org/10.52202/069179-0284

5 CONCLUSIONS

In this study, feature engineering is applied to a dataset acquired from a series of shake table tests of a soft-story wood-frame building. The building was subjected to increasing levels of ground motion until it collapsed, providing a valuable RH-DS dataset. All three phases of feature engineering have been applied to the data set. During the feature extraction phase, peak values of acceleration, velocity, and displacement, and energy representing features such as CAV and AI are extracted. In the exploratory data analysis phase, CAV-based features of the first floor have shown an obvious pattern with increasing damage states. In this phase, all the features are studied for the ground, first floor, and roof in order to identify any outliers. It was discovered that the DS3 values were outliers compared to other DSs. Therefore, in the feature selection phase, DS3 data was left out.

In feature selection, the ordinal Fisher score is used as identifying the order of the DSs is essential to accurate damage assessment. The analysis showed that the peak displacement of the ground and first floor are the most important features. Peak velocities of the ground and the first floor were also critical. Moreover, CAV and CAVstd of the first floor were also identified as important. Therefore, when developing an ML model for damage assessment of a wood-frame soft-story building, these six features should be used.

EFFECT OF SMALL OPENINGS ON SHEAR CAPACITY OF PLYWOOD SHEATHED SHEAR WALLS

Yuta Sakai [1] , Kenji Aoki[2]

ABSTRACT: In plywood shear walls used for interior walls, small openings are provided for the installation of piping. With the increase in the number of medium and large wooden buildings, it is necessary to accurately calculate the earthquake resistance of each member, as the requirements for the earthquake resistance of elements have increased. The purpose of this study is to verify the effect of small openings on the shear capacity of plywood shear walls. 1820 x 910 mm plywood shear walls with small 350 mm wide square openings were used as a preliminary element test. The results indicate that the location of the opening affects the shear failure behavior of the plywood and its ability to resist loads after maximum load. Based on the results of the element tests, full scale plywood shear walls with small openings were developed with the same performance as those without the opening.

KEYWORDS: small opening, racking test, plywood sheathed shear wall, medium- and large-sized wooden buildings

1 INTRODUCTION

In order to prevent global warming and realize a sustainable society, the use of wood is being promoted worldwide. In recent years, the expansion within medium and large scale wooden buildings has received much attention. However, the change from residential scale to medium and large scale brings challenges in various aspects, such as changes in building design methods and preparation of codes. Small openings in plywood shear walls, which are the subject of this study, are one such example. Small openings are made in interior walls to install ducts, outlet boxes, switch boxes, etc. In the past, for small residential buildings, it was not a problem to consider shear walls with small openings as non-shear walls. This was because the entire building had a surplus of earthquake resistance. In fact, in general wooden houses, openings as small as ventilation ducts were allowed in shear walls at the discretion of the building control officer. Therefore, there was almost no research on shear walls with small openings, and no theory for calculating the shear capacity of walls was established. However, as buildings have become larger, the required earthquake resistance has increased. There is no longer a margin for the earthquake resistance of the entire building, and it is necessary to verify the loss of performance due to small openings. In addition, the current standards for small openings have no experimental or theoretical basis, and their applicability to high-strength shear walls is also unclear. It is dangerous to apply the current standards, which are designed for residential buildings, to medium and large timber buildings. It is urgent to establish a new method to accurately calculate the performance of shear walls with small openings in order to promote medium and large wooden buildings and create a sustainable society. Therefore, the purpose of this study is to verify the effect of small openings on the shear capacity of plywood shear walls and to propose small opening size, location, and reinforcement method for a plywood sheathed shear walls with small openings to have the same performance as those with no openings.

2 PRELIMINARY ELEMENT SPECIMEN

2.1 SPECIMENS

Figure 1 and Table 1 shows the preliminary element test specimen and members, a plywood shear wall. The thickness of the plywood is 24 mm, the density is 0.57g/cm^3, and seven layer. The wall size was 1820 mm in height and

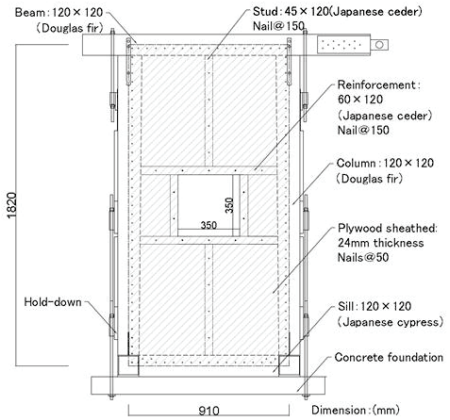

Figure 1: *Preliminary element test specimen*

[1] Yuta Sakai, Yayoi 1-1-1, Bunkyo-ku, Tokyo, Japan. Department of Biomaterials Sciences, Graduate School of Agricultural and Life Sciences, The University of Tokyo, nimajneb1119@g.ecc.u-tokyo.ac.jp

https://doi.org/10.52202/069179-0285

910 mm in width, with a small 350 mm square opening, assuming that the pipes used in medium and large wooden buildings have an outer diameter of about 300 mm. When making small openings, holes are drilled at the four corners and then cut in straight lines. The principle of specimen naming and a simplified diagram of each specification are shown in Figure 2. The first half of the specimen name was named after one of the four types of small opening locations (MM, EE, EM, ME), and the second half was named after the reinforcement method (-N, -S, -HS, -SH). The parameters were the location of small openings and the method of reinforcement, and a total of 12 specimens were made, one for each of the 12 specifications. The nails and screws used are shown in Table 2 and Figure 3.

Table 1: *Members of specimens*

Member	Species	Cross-sectional Area(mm)	Dencity (kg/m^3)	Moisture Content(%)
Beam	Douglass fir	120×120	555	13.3
Column			510	15.6
Sill	Cypress		534	16.8
Stud	Ceder	45×120	390	17.0
Reinforcement		60×120	458	19.4

Common 75 mm long nails were used to join the plywood to the framing at 50 mm pitch and for the studs and opening reinforcement at 150 mm pitch. The studs and opening reinforcement were fastened with two 100 mm long structural screws for each joint. Beam-to-column connections were made with mortise and tenon, foundation-to-column connections were fastened with box-type column leg hardware, and foundation-to-base connections were fastened with hold-down connectors.

2.2 TEST METHODS AND EVALUATION

The static load test was conducted according to the racking test in "Wood Frame House Construction in Japan"[1]. The deformation angle was provided by the horizontal displacement height of the specimen. And the three-time cyclic test was conducted at each deformation angle of 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50, and 1/30. The envelope curve was determined using the load-displacement test data of cyclic loading. Yield strength (P_y) was obtained from the intersection of the line connecting 0.1 P_{max} point and 0.4 P_{max} point and the tangent line to the envelope curve parallel to the line connecting 0.4 P_{max} point and 0.9 P_{max} point. The stiffness (K) was obtained by dividing the yield strength by the yield displacement (δ_y). Ultimate displacement (δ_u)was obtained from the point where the load dropped to 0.8 P_{max} after P_{max}. Ultimate strength(P_u) was obtained from the point where the area of the trapezoid is equal to the area bounded by the envelope curve and the ultimate displacement. P_y, K, P_u are obtained as shown in Figure 5. Displacements of the test were measured by transducers shown in Figure 4.

2.3 TEST RESULTS AND DISCUSSION

Figure 5 shows the load-deformation angle relationship and Table 3 shows the results. Out-of-plane buckling of the plywood did not occur even in the specification with the lowest ability to suppress buckling. The cause of the decrease in strength in the small opening specifications was shear failure of the plywood, as shown in Figure 6. Cracks started at the corners of the small openings at 1/50 rad and expanded with increasing deformation, reaching the edges of the plywood at about 1/30 rad. In the case where the distance from the opening corner to the plywood edge was short as shown in Figure 7, the cracks starting from the opening corner reached the plywood edge relatively early, but the other parts of the plywood were not damaged and the load continued to increase slowly because the shear force was transferred to the column assembly through the opening reinforcement. On the other hand, when the distance was long as shown in Figure 8, it took time for the crack to reach the plywood edge, so the wall deformation proceeded, but after the crack reached the plywood edge, the plywood was damaged more and the load was maintained while the shear failure zone was crushed.

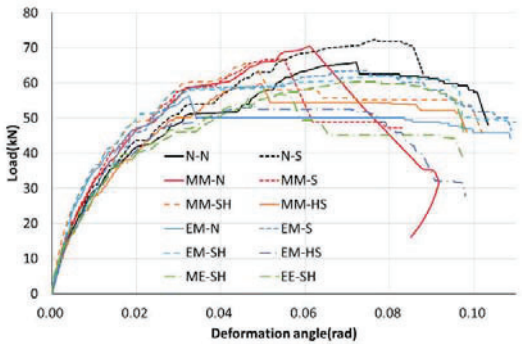

Figure 5: *Load deformation angle relationship of preliminary element test*

Comparing the specification with no openings and those with openings and no reinforcement, it was assumed that the performance of the specification with openings and no reinforcement was lower because of the openings in the plywood. In fact, this trend was confirmed for the EM specification, but the MM-N specification had the highest maximum load of all specifications, an unnatural result that was thought to be due to variation. Therefore, the following discussion is based primarily on the trends in the EM specifications. In comparing the specifications with and without reinforcement, the performance of the specifications with reinforcement was better, confirming the usefulness of the reinforcement. Comparison of the specifications without openings and those with openings and reinforcement indicated that the performance of the specification with openings would be lower, but no significant decrease in stiffness was observed. This is due to the increase in the number of joints because the plywood and the opening reinforcement were fastened with nails, and the opening reinforcement and the frame were fastened with screws. On the other hand, the strength of the plywood was lower because all the openings were

https://doi.org/10.52202/069179-0285

due to shear failure of the plywood, while those without openings were due to failure at the nail joints. Regarding the method of reinforcement, the -SH specification performed better. It was expected that the short reinforcement would carry the stresses more efficiently. However, contrary to expectations, an extra stud was placed, increasing the number of nails and thus improving the performance of the wall.

3 ANALYSIS

3.1 ANALYSIS MODEL

The analysis was performed to verify the effect of variation in the preliminary test and to confirm the detailed stress state. The analysis was conducted using the SNAP analysis software and the analysis model is shown in Figure 9. The Multi Shear Spring(MSS) model was used for the nails. The restoring force characteristics of the nails were obtained from the results of the nail single shear test, which was carried out as an elementary test through the monotonic loading test of the rocket type shown in Figures 10. As shown in Figure 11, four lines were substituted, including the negative slope after the maximum load. The evaluation of the nail shear test was in accordance with the Wood Frame House Construction in Japan. Each point was set as follows for the average of three specimens based on the element test results.

First point: (P_y, δ_y)
Second point: (P_u, displacement of an arbitrary upper point coinciding with the envelope)
Third point: (P_{max}, δ_{Pmax})
Fourth point: (0.8 P_{max}, δ_u)

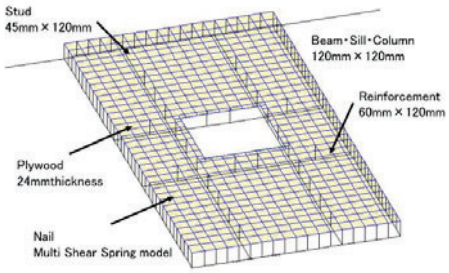

Figure 9: *Analysis model*

Figure 10: *Monotonic loading test of the rocket type*

The boundary conditions were pin supported on one side of the foundation and roller supported on the other. All joints between members were pin joints. The cross sections and nail positions were the same as in the preliminary tests, and only the nails on the four perimeters of the plywood were placed at the edges of the plywood. Physical properties were obtained from the literature. Forced displacement was applied in the positive direction of the x-axis of the beam, with a target displacement of 182 mm and a displacement increment of 0.2 mm per step, for a total of 910 incremental analysis steps.

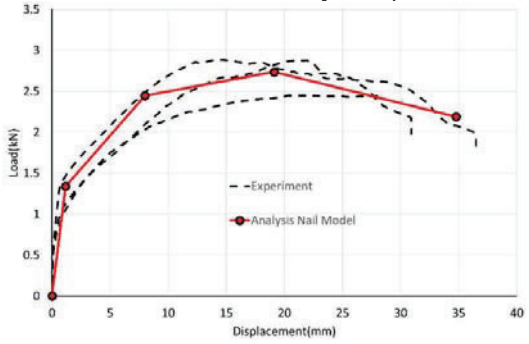

Figure 11: *Load displacement relationship of loading test*

3.2 ANALYSIS RESULT AND DISCUSSION

The load-deformation angle relationships obtained from the analysis are shown in Figure 12, and Table 4 compares each of the analytical values obtained from the analysis with the experimental values. The outline of the curves and the ratio of experimental to analytical values in Table 3 show that, although there are a few large deviations, the overall trend is generally captured.

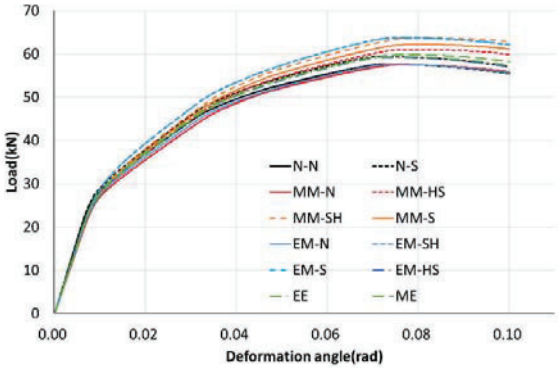

Figure 12: *Load deformation angle relationship of analysis*

The analysis results showed that the specimens with openings and reinforcement had the highest maximum loads, followed by those without openings, and those with openings and no reinforcement had the lowest loads. With no reinforcement, the specimens with openings, which are weak points, had the lowest load capacity. In the case with reinforcement, the load was higher with more nails, supporting that the nails were the main factor in the resistance mechanism.

Ratio* means 'Ratio to experimental value' (analsis value/experimental value)

The behavior after yielding was considered to be improved by adding appropriate rotational stiffness to the ends of each member in the analytical model instead of pin joints. The plasticity factor tended to have a large error due to its small value. On the other hand, this analytical model does not consider the shear failure of the plywood, so a new method that can estimate the behavior after the end of the phase is needed to predict the overall behavior.

4 FULL SCALE TEXT

4.1 SPECIMEN

To verify the applicability of the preliminary element test results to the actual building, eight 24 mm plywood sheets, four on the front and four on the back, were attached together for a full-scale test of a 3340 mm height and 1820 mm length shear wall as shown in Figure 13. Beam connectors and hold-downs were used for column head connections. Lag screws (ϕ45, 600 mm) was used for the column legs. 110 mm screws were used to fasten the reinforcement to the frame. As in the preliminary test,

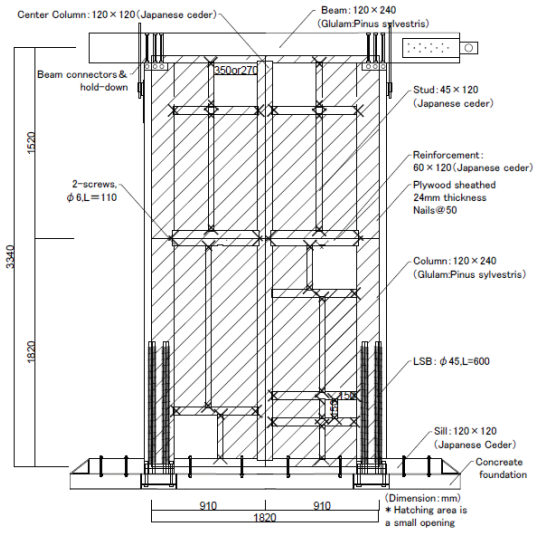

Figure 13: *Full scale test specimen*

a small 350 mm square opening was made in each faceplate. The number of specimens tested was three for the specimen with no opening and four for the specimen with openings including the preliminary test. The small openings were located at the four corners where performance was estimated to be lowest based on the preliminary element test results, assuming actual construction. An additional 150mm opening for a switch box was provided in the bottom plywood to make the specifications similar to actual installation. Based on the preliminary test results, the size of the small openings in the full-scale test was reduced to 270mm square when small openings are provided at the same height, and the nail pitch to the studs and opening reinforcement was modified from 150mm to 100mm.

4.2 TEST RESULTS AND DISCUSSION

Figure 14 shows the load-deformation angle relationship. The experimental values calculated from them are shown in Table 5. The failure of the preliminary test and the main test are shown in Figure 15 for the entire and in Figure 16 for the upper opening(Left:preliminary,Right:main). Preliminary test results showed that the performance similar to that of the no-opening specification could not be achieved because the center columns failed in bending and the load dropped rapidly. The bending failure of the columns was caused by stress concentration on the columns because the plywood could not resist the shear stress after the cracks from the opening corners reached the plywood edges as in the preliminary test. In this test,

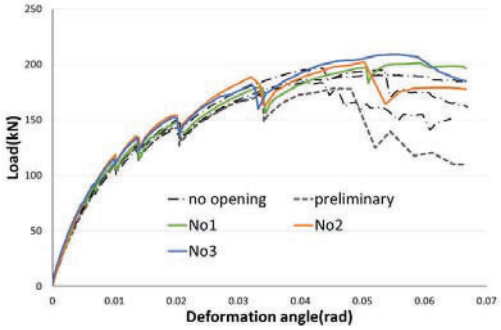

Figure 14: *Load deformation angle relationship of full scale test*

https://doi.org/10.52202/069179-0285

crack propagation from the opening corner was suppressed and brittle failure did not occur up to 1/15 rad, confirming that the performance was equivalent to that of the no opening specification. The failure behavior at the end of the test was that the plywood around the opening on the column leg side failed as shown in Figure 17 and the plywood could no longer bear the load, resulting in collective failure of the LSB on the column leg on the tension side and buckling failure of the columns on the compression side as shown in Figure 18 and 19.

5 CONCLUSIONS

Preliminary element tests were conducted on a plywood bearing wall 1820 mm high and 910 mm wide with a small 350 mm square opening for a piping. The results indicate that the location of the opening changes the degree of damage to the plywood and may subsequently affect the shear capacity of the wall. In combination with the results of the analysis, it was estimated that the opening positions with the lowest performance were those closer to the four corners. Based on these results, full-scale tests were conducted on an actual medium- to large-sized wooden shear wall. Preliminary tests revealed that shear walls with small openings did not perform as well as walls without openings. When the small openings were horizontally connected, the nail pitch to the opening reinforcement was narrowed by setting a limit based on the opening size. As a result, it was confirmed that the performance of the wall with small openings was equivalent to that of the wall without openings. In this study, the size, location, and reinforcement method of small openings were proposed to ensure that plywood sheathed shear walls with small openings perform as well as those with no openings.

ACKNOWLEDGEMENT

This research was carried out with the cooperation of Maeda Corporation and supported by Grant-in-Aid for JSPS Research Fellow Grant Number JP 22J12027 I would like to thank all those involved.

CYCLIC TESTING AND NUMERICAL MODELING OF A THREE-STORY MASS-TIMBER BUILDING WITH A PIVOTING MASS PLY PANEL SPINE AND BUCKLING-RESTRAINED ENERGY DISSIPATORS

Gustavo A. Araujo R.[1], Barbara G. Simpson[2], Tu X. Ho[3], Gustavo F. Orozco O.[4], Andre R. Barbosa[5], and Arijit Sinha[6]

ABSTRACT: Mass timber panels are emerging as an innovative alternative for the design of elastic spines due to their high stiffness- and strength-to-weight ratio, among other factors. Recent research has shown that mass timber panels used in conjunction with steel energy dissipators are promising solutions for enhanced seismic performance. However, the available experimental data at the building scale is still minimal, which limits the understanding, adoption, and development of effective seismic design guidelines for these systems. This research addresses this gap through full-scale quasi-static cyclic testing of a three-story mass timber building. Lateral loads are transferred through Mass Ply Panel (MPP) diaphragms to an MPP spine with vertically-oriented unbonded steel buckling-restrained braces (BRBs) as energy dissipating boundary elements in the first story. The only elements designed to dissipate energy in the inelastic range are the BRBs. The building specimen achieved low-structural damage and enhanced-performance goals, being able to reach a 4% roof drift ratio with little loss of strength and stiffness. The proposed pivoting detail was effective in mitigating compressive damage at the wall toe. To support the experimental campaign and future design procedures, a high-fidelity numerical model of the building was developed using OpenSees.

KEYWORDS: buckling-restrained braces, experimental testing, mass timber, numerical model, pivoting spine

1 INTRODUCTION

The emergence of mass timber as a novel construction material poses new opportunities for the development of innovative seismic force-resisting systems that are designed for enhanced-performance goals beyond the scope of prescriptive codes [1]. For example, mass timber walls can be designed as structural spines. A spine is a stiff and strong vertical element or portion of the structure that is designed to remain essentially elastic in every vibrational mode, thereby imposing a more uniform drift distribution with building height [2], [3], mitigating story mechanisms [4], [5], and enabling the designer to bypass potential geometric or mass irregularities [6]. If detailed properly and combined with supplemental energy dissipators, mass timber spines are capable of deforming well into the inelastic range during strong ground shaking with stable energy dissipation and, in some cases, low-damage seismic performance [7]–[19].

Despite efforts to standardize mass timber wall design in the United States [20]–[23], alternative means and methods, e.g. performance-based design methods [24]–[28], are often needed to design systems employing mass timber spines, since mass timber seismic force-resisting systems frequently fall outside prescriptive clauses [29]–[32]. However, such methods rely on numerical models grounded on extensive experimental data and can be computationally expensive, thereby limiting the design of mass timber spines in practice. Consequently, experimental testing and numerical validation are necessary to support the development of more practical design methods that better reflect the existing seismic design philosophy in the U.S. to facilitate the use of mass timber systems, including those with spines.

This research contributes to existing experimental data through full-scale quasi-static cyclic testing of a three-story mass timber building featuring a seismic force-resisting system employing a Mass Ply Panel (MPP) pivoting spine with vertically-oriented unbonded steel buckling-restrained braces (BRBs). The specimen was tested in October 2022 at the A.A. Red Emmerson Advanced Wood Products Laboratory at Oregon State University as part of ongoing research on low-damage mass timber seismic force-resisting systems. A numerical model was developed to support the experimental campaign and aid in the development and validation of future design procedures.

2 EXPERIMENTAL PROGRAM

2.1 TEST SPECIMEN

The test specimen consisted of a two-bay by two-bay three-story building segment selected from a case-study building archetype; see Figure 1 through Figure 3. The building segment had a square floor plan with an area of approximately 12.2 m x 12.2 m = 149 m^2 (1,600 ft^2). The first story was slightly taller than the others, with a height of 3.15 m (10.3 ft); the remaining stories had a typical story height of 2.75 m (9 ft).

The gravity system featured four frames made of simply-supported laminated-veneer lumber (LVL) beams and LVL columns. Beams and columns were connected using customized Simpson Strong-Tie column caps with vertically-slotted holes at the column ends to allow for rocking at the beam-to-column interface with minimal moment restraint, effectively accommodating large story drift demands [16]. The gravity connections were braced against lateral-torsional buckling using a L-shaped cross-section steel members. Diaphragm panels were also MPP supported by the LVL beams.

The building specimen was subjected to two separate phases of experimental testing. Phase 1, which is the object of this paper, featured an MPP wall designed as a pivoting spine, supplemented by two-vertically oriented BRBs attached to the wall boundaries in the first-story; see Figure 2(a). The spine is located between two collar beams. In comparison to a rocking wall, the proposed pivoting wall does not impact the foundation during shaking, which alleviates potential crushing at the toe at the base of the wall [33], [34], which might render repairs impractical. Other methods of mitigating crushing at the wall toe have also been proposed [8]. Uplift at the base is restrained by two steel threaded rods connected to a steel plate screwed to the MPP wall at both sides and the external energy dissipators. The base shear is transferred from the spine to the foundation through cross-ply bearing of the MPP on two stiff shear key plates located at the edges of the wall panel. The proposed seismic force-resisting system takes inspiration from previous research on pin-supported reinforced concrete walls [35]–[41] and steel braced frames [42]–[45].

The BRBs are bolted at both ends to gusset plates. The top gusset plate is ultimately connected to the MPP wall through steel side plates and 45-deg inclined, fully threaded screws; see Figure 2(b). The design detail takes advantage of the high strength and stiffness of inclined screws in tension [46], [47], while compressive forces are transferred through bearing of the MPP on top of the timber-to-BRB connection.

To ensure torsional stability of the building specimen during unidirectional cyclic testing, a series of platform-construction MPP walls, termed herein out-of-plane walls, were installed around the perimeter of the building in the perpendicular-to-loading direction. The out-of-plane walls were connected to the MPP floors using standard angle brackets [22] designed to resist 10% of the expected in-plane capacity of the spine.

General dimensions and material properties of the different elements in the specimen are shown in Table 1.

***Table 1**. General dimensions and material properties.*

Element	Material	Dimensions
Floor panels	Freres F16-7 MPP	181 mm thick
Columns	Boise Cascade Douglas-fir LVL	178 mm × 178 mm cross section
Beams	Boise Cascade Douglas-fir LVL	133 mm × 559 mm cross section
Spines	Freres F16-8 MPP	207 mm thick
BRBs	CoreBrace bolted brace	A = 1,290 mm^2 L_{core} = 2.03 m L_{brace} = 3.05 m
Foundation beams (spine and gravity system)	ASTM A992	W12×136 [in×plf]
	Boise Cascade Douglas-fir LVL	178 mm × 356 mm cross section
Beam-to-column connections	Simpson Strong-tie column cap	Customized to project

2.2 SEISMIC DESIGN

The building was assumed to be representative of an office building archetype located in Seattle, WA, USA (47.58227 N, 122.33111 W). The building specimen was designed following traditional prescriptive seismic design principles from ASCE 7-16 [48], with additional stiffness and strength considerations to include enhanced-performance goals under multiple hazard levels, including seismic demands associated with the Risk-Targeted Maximum Considered Earthquake (MCE_R), in addition to the Design Earthquake (DE). The design method was broken into three major components: (i) design of the BRBs, (ii) design of the spine, and (iii) design of the diaphragm and connection details.

The BRBs were designed to resist the entirety of the overturning moment resulting from the design lateral forces, which were obtained using $R = 8$, consistent with the design of buckling-restrained braced-frames. This value of R will be validated in the future. The yield length of the BRB was selected to keep strain demands in the core at the MCE_R level below 2.5% to mitigate fracture due to low-cycle fatigue and $10\varepsilon_y$ (where ε_y is the yield strain) to target Life Safety per ASCE 41-17 [49].

The spine was proportioned to limit inelastic story drift ratios to 2.0% at the DE level following a displacement-based design approach [49], [50]. In this approach, an equivalent single-degree-of-freedom system is used to estimate the maximum-allowed structural period of the system based on the demands from the DE spectrum. In addition, the MPP spine was designed to remain elastic up to 4.0% roof drift ratio under a first-mode loading pattern to target enhanced performance beyond the MCE_R. Design forces were derived from the expected inelastic forces delivered by the BRBs to the spine at a 4.0% roof drift ratio and the near-elastic demands expected in the higher modes. The seismic design of the spine and the BRBs are covered in detail in ref. [51].

Diaphragms and their components, including splines, coiled straps, collectors, and the shear transfer mechanism, were preliminary designed using the alternative design method from ASCE 7-16 §12.10.3, with timber and fastener strength per NDS 2018 [52] and manufacturer recommendations, respectively. The design was then adjusted for the estimated capacity of the spine at a 4% roof drift ratio. More details on the design and expected performance of the diaphragms can be found in refs. [53], [54].

2.3 TEST SETUP AND INSTRUMENTATION

Lateral cyclic loads were applied to the structure at each floor level using three actuators, one per level, connected through stiff reaction steel beams to an L-shaped, 7.70-m (25.25-ft) tall reaction wall; see Figure 3. The concentrated load from the actuators was distributed across the MPP diaphragm panels using an assembly of load-transfer steel beams at the south side of the building and LVL beams spanning along the north-south direction. The LVL beams are connected to the MPP diaphragm using screwed steel angle plates and brackets.

The instrumentation layout was designed to measure the global load-displacement behaviour of the system and the local deformations in the spine, BRBs, diaphragm panels and connections. Applied loads at each level were recorded using the corresponding actuator load cells. Lateral displacements of the system in the direction of loading were determined using string potentiometers connected to fixed points in the perimeter of the laboratory. LVDTs were used to measure the tilting behaviour of the MPP spine at the base and the axial deformation of the BRBs. Strain gauges were installed in the elastic regions of each BRB and in the pivot-support rods to estimate axial forces in these elements.

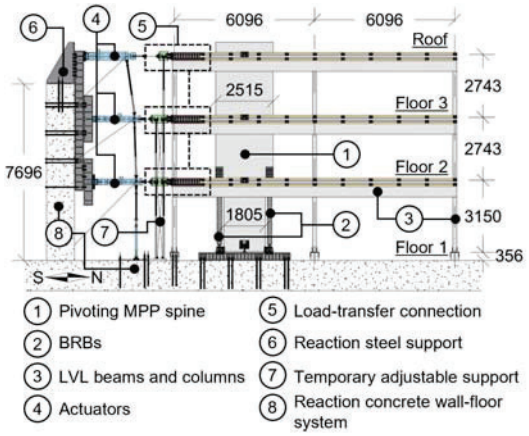

Figure 3: *Test setup. Units: mm.*

2.4 LOADING PROTOCOL

The specimen was subjected to two types of loading protocols:

(i) **First mode:** a quasi-static cyclic loading procedure derived from CUREE [55] to assess the behaviour of the spine subjected to a first-mode loading distribution up to 4% roof drift ratio, which was the displacement demand targeted in the design for enhanced performance; see Figure 4 and Figure 5(a).

(ii) **"Higher mode":** a quasi-static half-cycle procedure following a "higher-mode"-like loading distribution up to a base shear of 178 kN (40 kip) to verify the spine remained elastic in the higher modes; see Figure 5(b). The load distribution was selected to satisfy modal orthogonality assuming uniform mass distribution.

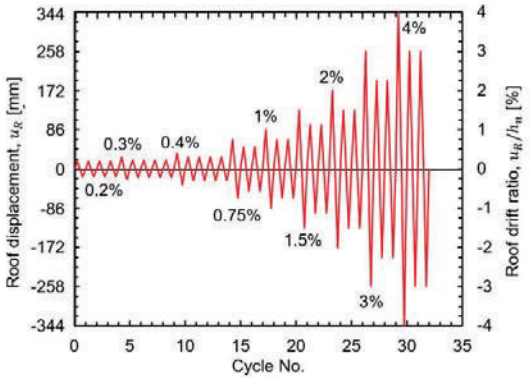

Figure 4: *First-mode displacement protocol with primary-cycle amplitudes labelled.*

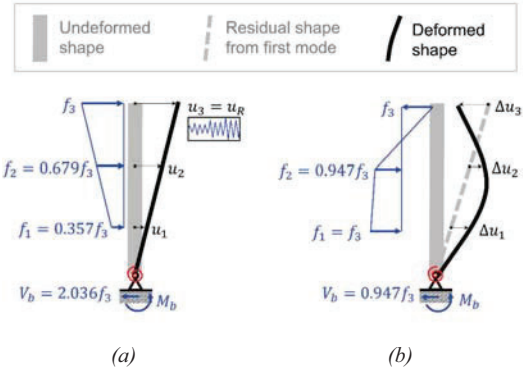

(a) (b)

Figure 5: *Testing load distributions: (a) first mode and (b) "higher mode".*

3 EXPERIMENTAL RESULTS

3.1 GLOBAL FIRST-MODE BEHAVIOUR

Figure 6 shows the global base shear-roof displacement hysteretic behaviour of the building specimen when subjected to a first-mode loading distribution; Figure 7 breaks down the experimental results by primary and trailing cycles of different peak cyclic amplitudes. The specimen performed as intended, maintaining a nearly uniform distribution of lateral drifts across all stories for the entire loading protocol; see Figure 8. The building exhibited a full and stable global hysteretic behaviour, including a complete cycle at the target enhanced-performance drift of $\theta = 4.0\%$ and two subsequent cycles at $\theta = 3.0\%$, without observed loss of lateral strength. In general, the behavior of the system was comparable to the observed in previous tests on steel and concrete pivoting spines supplemented by BRBs [33], [44].

Observed residual drifts significantly increased after yielding of the BRBs due to the absence of a self-centering mechanism in the structure and accumulated residual deformations in the BRBs. After the cycles to $\theta = 2.0\%$ (the target drift at the DE level), the observed residual roof drift ratio was 1.38%. Similarly, the residual drifts after the cycles to $\theta = 3.0\%$ and 4.0% were 2.3% and 3.3%, respectively. Such level of residual drift may result in increased repair costs and downtime after an earthquake event. A plausible solution for this issue would be the use of self-centering BRBs [56]–[58], post-tensioning or other similar devices.

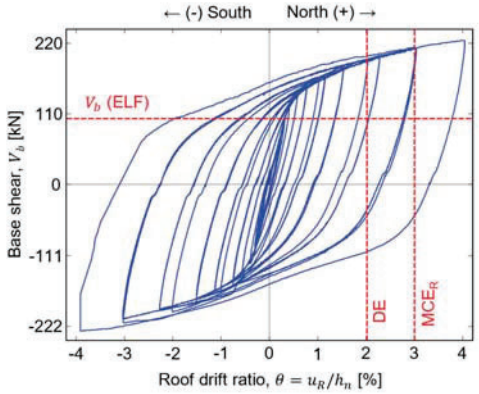

Figure 6: *Global hysteretic behaviour of the specimen subjected a first-mode loading distribution.*

https://doi.org/10.52202/069179-0286

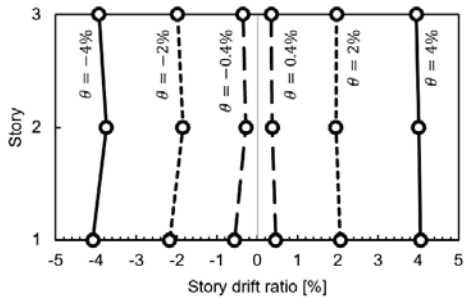

Figure 8: *Story drift profiles at different roof drift levels θ.*

3.2 BRB BEHAVIOUR

Damage investigation after the primary cycles and post-processed instrumentation data were used to assess the behaviour of each of the components of the test specimen, including the BRBs, the MPP spine and connections, MPP diaphragms and the gravity system.

Inelastic behaviour was observed in the BRBs at low drift levels ($\theta > 0.40\%$). After yielding, the BRBs started to exhibit significant residual elongation or shortening of the yielding core when unloaded in tension or compression, respectively. Figure 9(a) shows photographical evidence of the state of the BRBs before testing and after completion of the loading procedure. The BRBs were able to sustain the axial deformation demands imposed by the tilting mode of the spine without fracture or the core or instabilities at the connection regions. Due to inelastic deformations in the BRBs, the BRB-MPP spine system remained tilted towards the south direction at the end of the test, resulting in a residual roof drift ratio of 3.2% after the last cycle; see Figure 9(b).

Both BRBs exhibited similar axial deformations in tension and compression, as shown in Figure 10(a), due to the rod preventing uplift at the pivot support. By vertical equilibrium, without the addition of the rod detail, the wall would have uplifted at the middle and the deformation demands in the BRBs would have been greater in tension than in compression. Deformation demands in the BRBs at the cycles up to $\theta = 4\%$ were in the order of 40 mm (1.57 in), resulting in strains of nearly 2% in the yielding core.

Figure 10(b) presents the estimated hysteretic axial force-deformation behaviour of the BRBs. Axial forces were estimated using the average of the data recorded by four strain gauges installed near the ends of the BRBs, while axial deformations were measured using LVDTs oriented lengthwise on either side of the BRB (assuming deformations occurred primarily in the yielding region of the core). The strain gauges installed in the transition region were expected to remain elastic. In the test, however, flaking at the BRB end connections was observed during damage inspections after the 3.0% cycles, and this strain gage data is suspect. For this reason, the estimated hysteretic behaviour shown in Figure 10(b) is separated into cycles before and after 2.0%. The recorded data suggest that the BRBs exhibited kinematic and isotropic strain hardening after yielding, which is consistent with previous observations on systems employing BRBs [44], [47], [59]–[65]. However, the effects of isotropic hardening were not evident in the observed global behaviour of the system. It is suspected that other sources of softening in the system could have overshadowed the effect of isotropic hardening in the system.

(a) *(b)*

Figure 10: *Experimentally-observed behaviour of BRBs:(a) axial deformation vs roof drift ratio for both BRBs and (b) hysteretic force-displacement behaviour.*

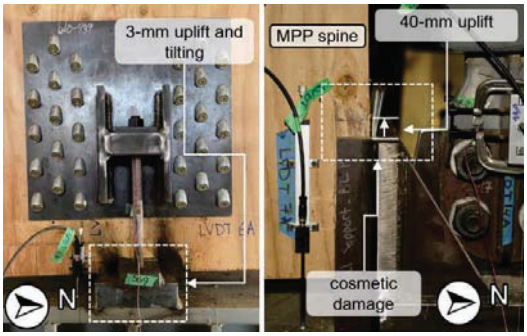
3.3 MPP SPINE AND CONNECTIONS

The MPP spine remained essentially elastic throughout the entire testing protocol. The midpoint pivot support behaved as intended, limiting uplift due to the unbalance force between the two BRBs acting in tension and compression (i.e., by vertical equilibrium). Small southward sliding of the MPP spine with respect to the

foundation was observed from low-amplitude cycles; see Figure 11(a).

Minimal, cosmetic damage was observed in the spine at the location of the base shear keys, as shown in Figure 11(b). The observed damage was attributed to a combination of bearing stresses in the cross-ply direction of the MPP and friction between the steel and the outer MPP plies in the vertical direction.

No visible damage was observed in the MPP spine above the first floor. The BRB-to-MPP connections did not show any signs of slip of the steel plates or splitting/crushing in the MPP boundaries at the screwed connections.



(a) (b)

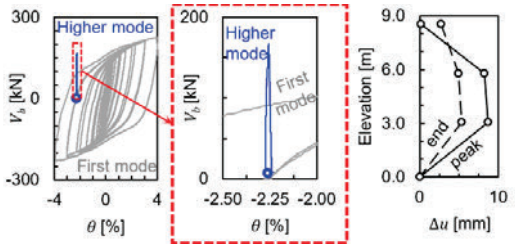
Figure 11: *Damage observation in the MPP spine after the test: (a) midpoint pivot support, and (b) north base-shear key.*

3.4 DIAPHRAGMS AND GRAVITY SYSTEM

The MPP diaphragms remained essentially elastic throughout the entire test. No visible signs of slip in the plywood splines or openings between the diaphragm panels was observed. Similarly, the beam-to-column connections in the gravity system were able to accommodate story drift demands up to $\theta = 4.0\%$ through rocking, without inducing visible damage to the LVL columns.

3.5 GLOBAL HIGHER-MODE BEHAVIOUR

Figure 12 summarizes the global behaviour of the building when subjected to the "higher-mode"-like loading distribution. The testing procedure started after the full first-mode loading protocol was applied, with the building tilting southwards with a residual drift of $\theta = -2.25\%$. The specimen behaved near-elastic, as is intended for the spine design, under the higher-mode loads. The load-displacement relation reached the maximum targeted base shear in a near-linear way, with high stiffness and little increase in lateral displacements; see Figure 12(a-b). Under this force distribution, the behaviour of the spine resembled that of a simply-supported deep beam under a four-point loading distribution, as shown by the incremental displacement profile in Figure 12(b). No visible damage in the connections or MPP spine was observed at the end of the test. Deformation and force demands in the BRBs did not vary significantly throughout the "higher-mode"-like testing procedure.



(a) (b)

4 NUMERICAL VALIDATION

4.1 MODELING SCHEME

The cyclic behaviour of the test specimen was estimated using a two-dimensional nonlinear numerical model in OpenSees [66], as shown in Figure 13. The numerical model included the LVL beams and columns, pivoting MPP spine, BRBs, and foundation beam for the spine. The BRB-to-spine, diaphragm-to-spine, and foundation connections were also modelled. Material properties were based on existing test data at the component level [44], [62], [67]–[69]. More details on the numerical model can be found in ref. [51], [70].

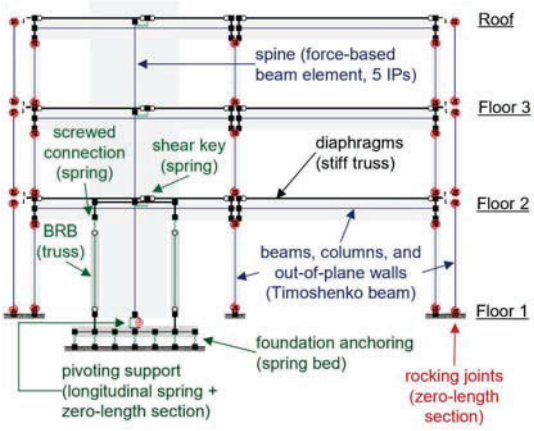

Figure 13: *Two-dimensional numerical model of the building specimen.*

4.2 SIMULATED BEHAVIOUR.

Figure 13 compares the experimentally-measured cyclic behaviour of the building specimen and the BRBs under a first-mode loading distribution against the numerical estimates. At the system level, the simulation results agree well with the observed behaviour of the specimen; see Figure 13(a). At the BRB level, the simulation approximates the experimentally-measured behaviour for cycles up to $\theta = 2.0\%$. For larger values of θ, the simulation significantly diverges from the BRB experimental data, particularly on the tension side. It should be noted that this discrepancy is likely due to the strain gage data used to estimate the axial force in the

https://doi.org/10.52202/069179-0286

BRBs becoming corrupted after $\theta = 2.0\%$. In general terms, the proposed numerical model estimates well the behaviour of the specimen and is suitable for extensive numerical analyses typical in performance and collapse assessment.

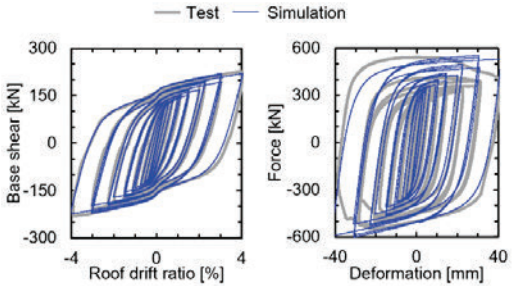

Figure 14: *Experimentally-measured vs simulated behaviour: (a) system level and (b) BRBs.*

5 CONCLUSIONS

This study introduced a seismic force-resisting system employing a mass timber pivoting spine supplemented by BRBs as energy dissipators. The behaviour of the system was studied through experimental quasi-static cyclic testing of a three-story full-scale building specimen and numerical modelling. The study illustrates that mass timber walls can be effectively designed as structural spines with the addition of BRBs as energy dissipators. The specimen achieved low-structural damage and enhanced-performance goals. The proposed pivoting detail was effective in mitigating compressive damage at the wall toe. The behaviour of the system was significantly influenced by the inelastic and strain-hardening behaviour of the BRBs, resulting in high residual drifts due to the absence of self-centering mechanisms.

These findings can be useful for improving the design and evaluation of mass timber structures in future studies. Future work should explore the addition of self-centering devices that help to reduce residual drifts and assess the seismic performance of the system through nonlinear dynamic analysis.

ACKNOWLEDGEMENTS

The authors would like to thank graduate students Steven Kontra, Patricio Uarac, and undergraduate students Kristian Walker, and Tanner Field for their help with instrumentation and testing. In addition, the authors would like to thank the laboratory technicians Byrne Miyamoto, Phil Mann, and Mark Gerig of the Tallwood Design Institute for their support throughout the experimental program.

This project was executed under the USDA Agricultural Research Service Award No. 58-0204-9-165. Part of the work was also supported by the National Science Foundation under awards #2120683, #2120692, and #2120684. Special thanks to our industry partners, KPFF, Holmes, Fortis Construction, Carpenters Union, CoreBrace, Boise Cascade, Simpson Strong-Tie, and Freres Engineered Wood, for supporting this experimental program. The findings, opinions, recommendations, and conclusions in this paper are those of the authors and do not necessarily reflect the views of others, including the sponsors.

HYSTERESIS - A PYTHON LIBRARY FOR ANALYSING STRUCTURAL DATA

Christian Slotboom[1]

ABSTRACT: Researchers studying the design of timber structures are often required to generate and process a large amount of data from experimental and numerical studies. Hysteretic data coming from seismic tests is particularly challenging to work with, because the x/y curve will change direction through testing. This paper provides an overview of Hysteresis, a software library written in the Python programming language that can be used to quickly process and analyse structural data, including hysteretic curves.
The main structure and algorithms used in the software package are presented, including a summary of how data is represented in the package, and how it can be used. Two case studies are then presented where data is processed using the Hysteresis package. In the first, experimental and numerical data from tests on a shear wall are processed and compared in a variety of ways. The second, Hysteresis is used in an optimization analysis, where a genetic algorithm is used to fit non-linear material data to a structural element.

KEYWORDS: Hysteresis, Connection Testing, Data Analysis, Genetic Algorithm.

1 INTRODUCTION

In seismically active areas, wood structural elements and connections will be exposed to repeated loading. For these elements it's important to understand not just the initial behaviour of the specimen to load, but how the response of the system change over repeated loading in a force deformation hysteresis. Experimentalists testing structural elements and connections will often have to apply load protocols, such as the CUREE method proposed in Krawinkler et al. [1], to their test specimens to understand this behaviour. Common tasks may include finding the area under a curve, finding the back-bone curve of a hysteresis, or fitting a new curve to a back bone, such as in the Equivalent Energy Elastic-Plastic procedure outlined in ASTM E2126 [2]. These data processing tasks are often very time consuming and take away time from high level research.
Structural researchers are also frequently working with hysteretic data coming from a finite element numerical analysis. In addition to processing this data, there are many common tasks that require researchers compare output data a numerical model to those from experiment to see their similarity. Researchers also may want to fit parameters of a non-linear material model, for example Steel02 [3] or pinching4 [4] from the OpenSees [5,6] library, to their experimental data. These tasks are often completed manually, due to the difficulty in matching different hysteresis.
To address these challenges in processing experimental and numerical data, a library in the Python programming language has been developed. This library can be used to work with simple x/y curves, as well as hysteretic data that changes direction in cycles. The following paper describes the Hysteresis library, its main features, and showcases several key use-cases.

2 HYSTERESIS PACKAGE SUMMARY

2.1 BACKGROUND

Data from structural tests is generally represented by a series of (x,y) points, commonly force vs. deformation. In the case of structural data, it can be useful for curves to be divided into regions where the y values are "mostly" increasing or decreasing monotonically. For a CLT wall loaded in shear loaded may have a force deformation curve that increases to a peak value, then decreases after this value. Figure 1 demonstrates this, using the final cycle from a force deformation hysteresis tested by Drexlar et. al. [7], where the cycle has been split into regions of interest.

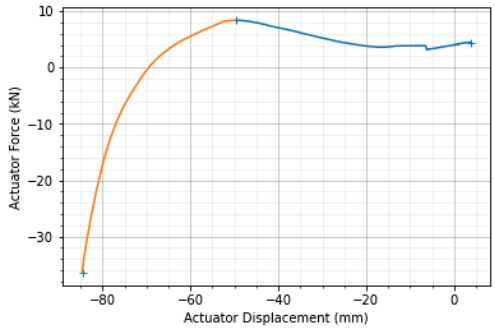

Figure 1: *A data from a shear wall split into regions that are mostly increasing (orange) or decreasing (blue).*

[1] Christian Slotboom, Graduate Engineer, Fast+Epp, cslotboom@fastepp.com

https://doi.org/10.52202/069179-0287

Structural data will also occur in cycles, where the x axis values are either increasing or decreasing monotonically. This commonly occurs in reverse cyclic loading for seismic testing. Figure 2 shows a hysteresis of the same shear wall in Figure 1, highlighting distinct regions where the x values are mostly unchanging. Similar to the monotonic load case, it's often useful to determine where these cycles occur in data.

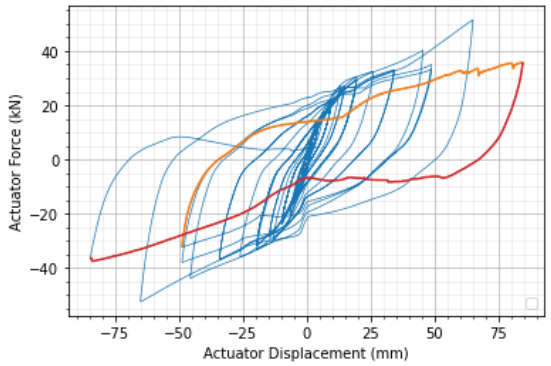

Figure 2: *A positive cycle (orange), and negative cycle (red) noted in a shear wall hysteresis.*

In both Figure 1 and Figure 2, there are small regions where the graph will decrease slightly in a roughly increasing zone. These irregularities are often not important to the data but can complicate finding data.

2.2 ABSTRACTIONS AND CLASS STRUCTURE

To represent x/y curves of structural data, the hysteresis Python package contains three main classes of curve objects:

- The "MonotonicCurve", where the x/y curve does not change in in its vertical axis and its horizontal axis.
- The "SimpleCycle", where data changes only in the y axis only.
- The "Hysteresis", where data in the x/y curve can change in both the both the x and y direction.

The structure of each curve object is nested, so that Hysteresis objects can be broken up into SimpleCycle objects, and SimpleCycle can be broken up into of MonotonicCurve objects.

Hysteresis and SimpleCycle objects divide themselves into sub-curves by finding reversal points in either the x data, or peaks in the y data. Signal filtering functions from the Python library Scipy [8] are used to find these local extreme values in the data. These functions also allow peaks/reversals to be selected based on various criteria, such as number of data points between extremes, or the prominence of the peaks/reversals from other lower points. Providing a method of filtering out smaller peaks in the data allows the main objects to ignore minor irregularities within the input data.

MonotonicCurve, SimpleCycle, and Hysteresis objects all inherit from a common "CurveBase" class that provides functionality to all objects. Included in this base class are a number of methods that can be used to numerically find properties like the curve, such as slope, cumulative change in x, arclength, or area under the curve. Figure 3 showcases some of these properties for a SimpleCycle object. By default, slope and area is calculated with second order finite difference schemes.

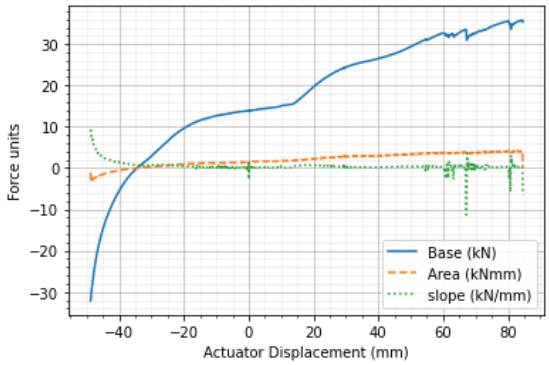

Figure 3: *A SimpleCycle object cycle with its numerically calculated slope, and area under the curve.*

The CurveBase class also includes a number of methods that allow for the curve to be easily plotted. Built in methods include: making a x/y plot of the curve, plotting the cumulative area under the curve, or plotting a curves x value against the index. Plots can also be made to show peak values or reversal points. All plots produced by the hysteresis module make use of the Matplotlib Python library [9] and can be modified with well-known commands. Figure 4 shows two of the plot functions, for the hysteresis in Figure 2 with reversal points highlighted, and the same data with x values plotted against index.

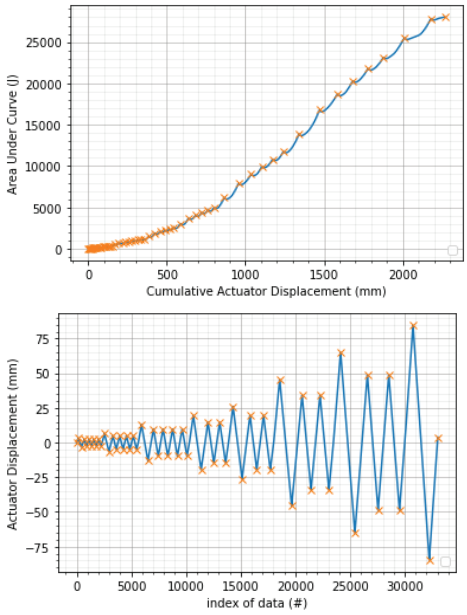

Figure 4: *Top, experiment hysteresis with reversal points highlighted. Bottom, the x displacement plotted against the index used, with reversal points highlighted.*

The Hysteresis package was designed to allow users to customize the behaviour of its key objects. At the time of object creation, functions are assigned to each object. For

https://doi.org/10.52202/069179-0287

example, the "areaFunction" is set, reading from a environment object that contains the default functions used by all objects. The stored areaFunction will then be called later when a request is made to calculate area. Users can implement custom behaviour by either directly overwritten the desired function in individuals object, or by setting a new function in the environment variable. Changing the environment will affect the behaviour of all objects created afterwards.

Figure 5 summarizes the main classes used in the Hysteresis package, and some of their key methods. Arrows represent inheritance relationships, where one class is a subclass of another class, while diamonds represent composition where objects are stored in other objects. Hysteresis classes will contain SimpleCycles in a list of "cycles", and similarly SimpleCycles contain MonotonicCurves in a list of subcycles.

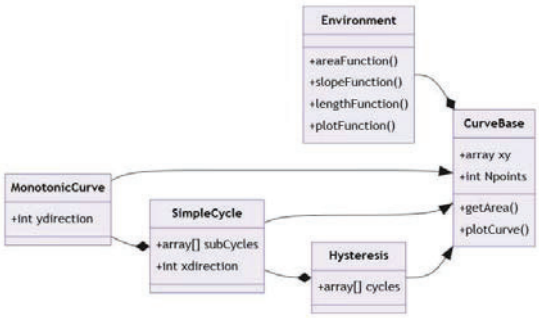

Figure 5: Class diagram for the Hysteresis package's main abstractions, and some key methods for each class.

2.3 BASIC FUNCTIONS

In addition to the basic numerical analysis and plotting functionality provided by the CurveBase class, there are a number of functions in the Hysteresis package that allows users to operate on hysteresis objects. Different object types can be combined can be combined with the "concatenate" function. This allows for more complex objects, such as the SimpleCycle or Hysteresis, to be built up from its component curves, or lists of x/y data.

Another desirable feature is the ability to take an input curve and resample it, which allows for data to be compressed or expanded. The Hysteresis package has a "resample" function, which allows for the number of x axis points to be increased or decreased using linear interpolation. When called on the MonotonicCurve or SimpleCycle Object, resample will change the total number of points in the curve, while when Hysteresis objects are resampled the number of points in each sub-curve is changed. This highlights a major benefit of the class structure used, because complex objects such as the Hysteresis are broken into simpler objects, it's possible to easily resample entire hysteresis by resampling its components. Resampling can be done based on a number of increments between the maximum and minimum x value or based on a sample change in x direction distance. Figure 9 shows the final cycle shown in Figure 1, where the curve has been resampled to only include 5 segments.

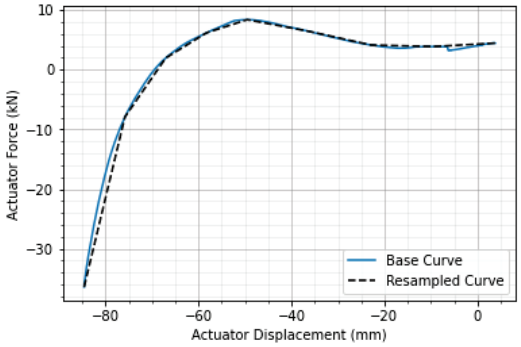

Figure 6: *The x/y curve shown in Figure 1, and a resampled version of that curve.*

A feature enabled by the resample function is the ability to various Curve objects of the same type. Two curves can be compared using the "compare" function by resampling each curve, then summing the Euler distance over all the resulting set of points. Equations (1,2) below overview this calculation for a SimpleCycle and Hysteresis respectively, where: "j" is an index that counts the number of sample point; and "i" is an index that counts the number of SimpleCycles that make up a hysteresis object. While the actual sum of the two curves is not physically significant, it's size will indicate how similar two curves are, and reduce to zero when curves coincide. Like resampling, Hysteresis curves are compared by summing the comparison between the monotonic cycles of each object. Figure 7 showcase the process comparison process, where the final output is the average distance between each point on the curve.

$$\varepsilon_0 = \frac{\sum_j^{N_j} \sqrt{\left(y_j - y_{j-1}\right)^2 + \left(x_j - x_{j-1}\right)^2}}{N_j} \quad (1)$$

$$\varepsilon_{hys} = \sum_i^{N_i} \frac{\sum_j^{N_j} \sqrt{\left(y_j - y_{j-1}\right)^2 + \left(x_j - x_{j-1}\right)^2}}{N_j} \quad (2)$$

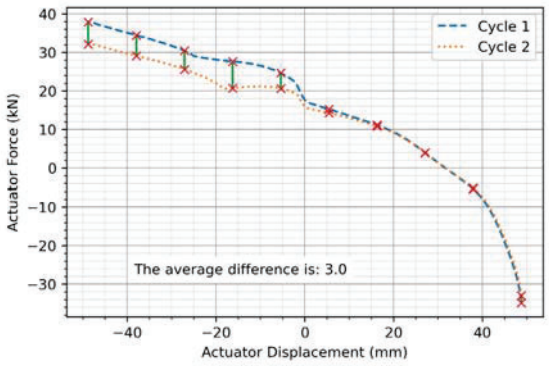

Figure 7: *The average difference in the x/y space between each point for the resampled curves.*

2.4 ENVELOP FUNCTIONS

The Hysteresis library also has functions that can be used to extract data from the envelop of a Hystersis class. A

common task researchers will face is finding the backbone of a hysteresis. Because the reversal points in an input Hysteresis are automatically stored, the Hysteresis library can be used to quickly extract the backbone of data coming from a numerical or experimental hysteresis. A function "getBackbone" can be applied to the curve in question to extract the correct points from an input Hysteresis. Figure 8 shows a backbone curve extracted from a numerical model of a seismic damper [11]. By default the getBackbone function will return all reversal points, but the user can provide the number cycles each step in the load protocol has to the function to skip certain points, for example return only the first cycle.

In addition to the getBackbone function, a second function called "getBackboneAvg" can be used. This function extracts the positive and negative backbones of a Hysteresis objects, takes the absolute value of each x/y points, then an averages to the two curves.

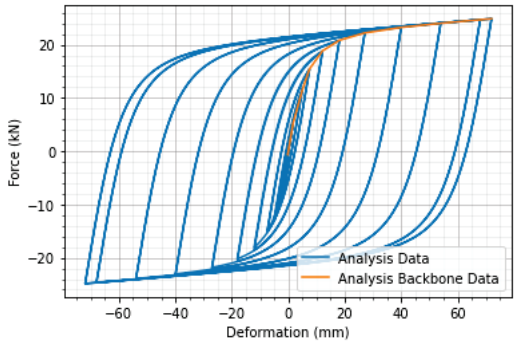

Figure 8: *The extracted backbone curve from a hysteresis.*

A specialized feature of the Hysteresis package is automatically fit an Equivalent Energy Elastic-Plastic (EEEP) Curve to a Hysteresis. In this process, the backbone of the hysteresis is first extracted using the average backbone function and rules outlined in ASTM 2126 [2]. Figure 9 shows a typical use case, where a EEEP curve is fit to the shearwall data from Figure 2.

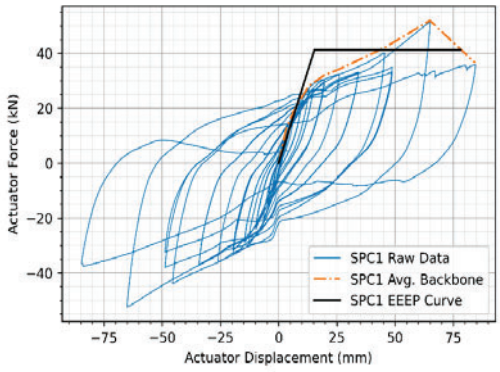

Figure 9*: Raw data from a shearwall test SPC1, overlayed with the calculated back-bone curve and fitted EEEP curve.*

3 CASE STUDIES

3.1 POST PROCESSING OF SHEAR WALL DATA

In the following example, experimental data from a self-centring CLT shear wall is postprocessed, then compared to data coming from numerical models of the shear wall. The CLT wall was approximately 4.5m tall, and a post-tensioned steel tendon was used to apply an initial compression force to the wall. Lateral force was applied to the system in a number of cycles, and the force-deformation of the wall was recorded. A detailed discussion of the experimentation can be found in Ganey [10], where it is labelled as TS1. Data for the numerical model is generated in OpenSees [5] using a models similar to those presented in Slotboom [11]. Figure 10 below shows both models, where both data sets have been "cropped", so they both end at approximately 0.15m of drift.

First the experimental data will be checked to see if reversal have been correctly extracted properly. The "plotLoadProtcol" method is used to clearly see which peaks have been picked up, and can be seen in figure XX. It's noted that that not all of the reversal points alternate between positive and negative, and one of the peaks has a value similar to the prior peak. This incorrectly detected point is removed by recalculating the reversal points using a prominence filter that will removes reversal points which do not change much compared to other points. The updated plot can be seen in Figure XX.

Often data from numerical and experimental studies are compared by plotting directly on top of each other, similar to Figure 12. While this can be used to understand general trends in the data, it is often difficult to tell how each curve compares at different points in the analysis. Using the hysteresis package, it's possible easily extract specific cycles of the curve for comparison. Two other metric can easily be employed to see how similar each curve is at different points:

- Cumulative energy observed by each model.
- A direct comparison of the "error" between each curve.

Figure 13 shows a cycle of the produced by the Hysteresis package, while Figure 14 and Figure 15 overview the cumulative energy and error of each cycle respectively. Looking at the Figure 14 it easily be observed that the experimental model absorbed much more energy per cycle than the numerical model did, something which would have been difficult to observe from Figure 12 alone. Through Figure 13, it can be concluded that the experimental hysteresis was asymmetric, and had an open hysteresis that was absorbing energy, while the numerical model was symmetric and had a purely elastic behaviour. Noting quickly noting these differences could allow the researcher make changes to their experimental setup or numerical model if needed.

3.2 PARAMETER FITTING USING GENETIC ALGORITHMS

A second case study is presented where a nonlinear numerical models are calibrated to match experimental data using a genetic algorithm and the Hysteresis package. As part of a testing program on self-centring shear walls, Ganey tested a number of U-shaped Flexural Plate (UFP) steel dampers. These dampers showed a stable response with a full hysteresis until failure. It's desired to make numerical models of this damper, which can be applied to model of the wall system.

The numerical models of the damper were developed in with the Python implementation of OpenSees, OpenSeesPy [6-7]. A zero-length element was used to model the damper, with a steel02, a Giuffre-Menegotto-Pinto steel material, applied to the element. Force was applied to one of the zero length element's nodes, and the load protocol used matched the testing from Ganey's experiment. To match the damper to experimental results, the OpenSees analysis was first parameterized to take in set of values about the zero-length damper. The significant parameters chosen to be varied were: F_y, the yield strength; E_0, the slope of the elastic tangent; b, the strain hardening ratio between the elastic and plastic tangent lines; and R_0, C_{R1}, and C_{R2}, which are parameters influence how the material transfers from it's elastic to plastic tangent lines.

Once the function was parameterized, the genetic algorithm was set up to iterate through possible values until an optimum was reached. The genetic algorithm used a scheme where a pool of 30 genes was tested over 100 generations. Each gene consisted of the six parameters used to . Initially parameters were randomly generated, with the bounds for the parameters defined in Table 1.

During each generation, all genes in the population were tested by running a OpenSeesPy with those values, then using the Hysteresis Compare function to quantify how similar the experimental and analysis hysteresis was. In each generation, 8 pairs of genes are chosen to pass on their genes to the next round, and results that closely matched experiment were more likely to be chosen. The remaining 14 genes were filled up by randomly generated values within the range of Table 1. Both crossover, where information is swapped between pairs of genes, and mutation, where genes are randomly changed were considered. After 100 generations the analysis was ended, and the optimal value was taken, and is presented in Table 1.

Table 1: *Genetic algorithm parameters and solution.*

Parameter	Minimum	Maximum	Solution
F_y (kN)	0	32	23
E_0 (kN/m)	0	$4x10^6$	$2.9 x10^6$
b	0	0.023	0.002
R_0	0	29	4
C_{R1}	0	1.4	0.57
C_{R2}	0	.23	0.15

Figure 16 compares results from the experimentally tested damper to the solution chosen by the genetic algorithm, showing a close fit between the two hysteresis curves. The Hysteresis package is small part of this process, but it provides a crucial comparison between experiment and numerical data, needed to tell which parameters are good, and which are bad.

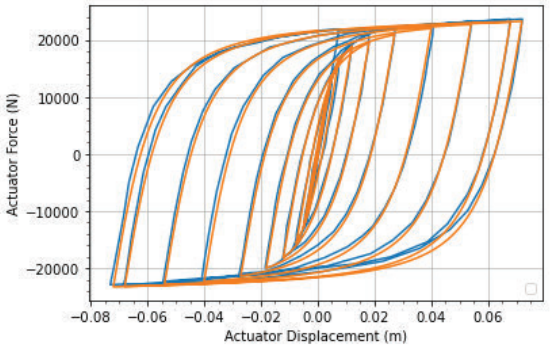

Figure 16: *Experiment (blue) vs. Optimal solution (orange) for the chosen genetic algorithm.*

4 CONCLUSIONS

The Hysteresis Python package can be used to quickly post process structural data, with an emphasis on hysteretic data. The main structure and algorithms used in the package was overviewed, highlighting the three key types of curves (Monotonic, SimpleCycle, and Hysteresis) used to represent structural data. These curve classes all have built in functions for plotting and doing numerical analysis on their data. These classes were designed with customization in mind, and the user can modify these methods by changing the underlying functions in the environment. In addition to the basic functionality, there also exists a number of functions that can be used to extract parameters from an envelop of a Hysteresis object, with some key functions being "getBackbone", and "compare".

Two case studies are then presented, showing how the hysteresis python package can be used to speed up data processing, and enable different types of analyses. The Hystersis package can be used to quickly compare numerical and experimental data in a number of ways. Also, by enabling two hysteresis curves to be compared, the Hysteresis package allows for advanced algorithms or machine learning models to work with Hysteresis dat.

MONOTONIC TESTS ON BEAM-TO-COLUMN JOINT WITH STEEL LINK FOR TIMBER SEISMIC RESISTANT STRUCTURES

Giacomo Iovane[1], Leonardo Rodrigues[2] , Jorge Branco[3], Beatrice Faggiano[1]

ABSTRACT: For the design of dissipative heavy timber frame structures, in the context of modern seismic design approach based on the mechanical triad of strength, stiffness and ductility, brittle timber failure modes can be avoided by integrating modern timber connection technology into hybrid timber-steel system. The overall seismic performance can be improved, entrusting the dissipation function to ad hoc conceived devices, as an alternative to connections. Steel links located at the ends of the beams are very promising solutions, which can develop plastic hinges, thus providing a ductile behaviour, with a significant dissipative capacity. Besides timber members, as well as connections, to be designed with an adequate over-strength, can remain in elastic field. In this perspective, the paper illustrates the mechanical characterisation through monotonic tests of two different configurations of timber beam-to-column joint with steel link for heavy timber frames, consisting of a timber element connected to a steel link by means of a steel end-plate and glued-in steel rods. The experimental results indicate a satisfactory agreement with the theoretical ones, therefore the suitability of the system and of the design criteria.

KEYWORDS: Seismic resistant timber structures, beam-to-column joints with steel link, monotonic test on joint.

1 INTRODUCTION

Timber material has an elastic and fragile behaviour up to failure, so that, the present anti-seismic regulations, like the European Eurocode 8 [1], indicates that for the seismic design of dissipative timber structures, joints should dissipate a part of the seismic energy through plastic deformations of steel connectors. However, joints are primary structural elements, with a crucial role in bearing the design loads, so that their integrity should be preserved [2]. By integrating modern timber connection technology into hybrid timber-steel system, brittle wood failure modes can be avoided and overall seismic performance improved.

With specific reference to the structural type of Moment Resisting Frames (MRF), recently, some authors have proposed different solutions for dissipative timber structures, by coupling a ductile material like steel to timber [3 - 9].

In particular, Montuori and Sagarese [6] and Montuori [7] have applied to timber beams the steel reduced beam sections, commonly proposed for steel MR frames; as well as Gohlich et al. [10] studied hybrid steel-timber structures, such as buckling restrained braced frame (BRBF) and moment resistant frame (DMRF) with steel links; Yang et al. [11] have delegated the dissipative capacity to a steel box connected to the beam and column by glued bars; Tomasi et al. [8] and Andreolli et al. [9] focused on a beam-column timber joint equipped with steel links for dissipative MR frames.

The paper deals with the latter type of device, such as a timber beam-to-column joint with steel link located at the ends of the beam. It is designed so that the plastic hinge forms in the steel link, achieving a ductile behaviour and a significant dissipative capacity, while timber members and steel connections, having an adequate over-strength as respect to the dissipative links, remains in elastic field. Such connection system, further to an advantageous mechanical performance, has some other interesting properties, like versatility and prefabrication [2, 12, 13].

As regard the design criteria of the study joints, the capacity design method was applied to ensure the collapse hierarchy between the connection subcomponents [12, 13]. The joints behaviour was preliminary studied through numerical analyses, by means of the software ABAQUS FEA [14], in terms of key parameters, like ultimate strength, stiffness, rotation capacity and failure mode [13]. Then the ductile joint system and the proposed design criteria were validated through an experimental campaign carried out in 2019 at the Department of Civil

Engineering (DECivil) of the University of Minho, in Guimaraes (Portugal), in cooperation with the Department of Structures for Engineering and Architecture of the University of Naples Federico II. 2 monotonic and 2 cyclic tests up to collapse were performed for 2 types of specimen.
In particular, in this work the monotonic tests on the two beam-to-column joints with steel link are presented.

2 SPECIMEN FEATURES AND MANUFACTURING PROCESS

The specimens (Figs. 1, 2a; [13]) are made of a laminated timber beam (GL24h) with a 140x320mm rectangular cross section, 850mm long, equipped at one end with a steel link, HE100A or IPE100 profiles 250mm long (steel grade S355) with two welded end-plates (120x230mm, steel grade S275), with 20mm thickness for the HE100A, 15mm thickness for the IPE100 specimens.

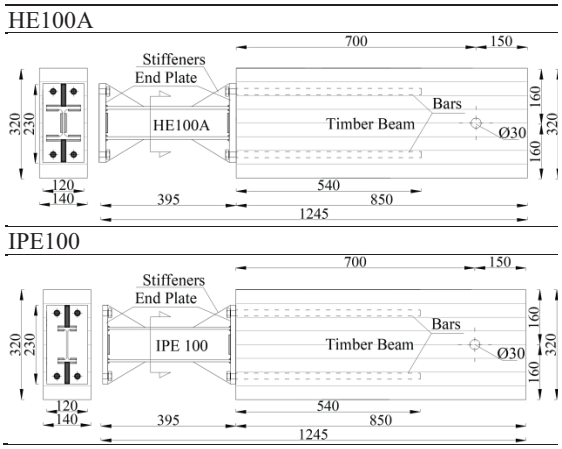

Figure 1: *Specimens geometrical features [mm].*

For both specimens, the link is connected at one side to the timber beam by 4 glued threaded bars (M16, 10.9, 540mm long), at the other side it is rigidly connected to a steel endplate (300x300mm and 40mm thickness) by 4 bolts (M16, 10.9 steel grade, 60mm long). The endplates have four triangular stiffeners (110x67mm for HE100A and 110x65mm for IPE100, with 15mm thickness).
With regards to the insertion of the bars within the timber beam the following manufacturing procedure was applied. On the timber element (Fig. 2b) 4 notches, 49x18mm and 540mm long, were realized guaranteeing an adequate bars anchorage. To ensure the bars centering within the notches, 2mm thick wire was wrapped around each bar, as spacer between bars and internal surface of notches (Fig. 2c). A two-component epoxy resin (Xepox F-liquid, by Rothoblaas) was poured into the notches (Fig. 2d), then the 4 threaded steel bars were inserted. At the end, notches were closed through additional timber elements (31x18mm and 540mm long), previously obtained by the timber rods cut from the timber element for realizing the notches (Fig. 2e, f), ensuring a 18x18mm cavity around the bars. The closing timber elements were sealed using structural timber glue. After gluing, the timber beam was left to dry for 4 days (Fig. 2g).

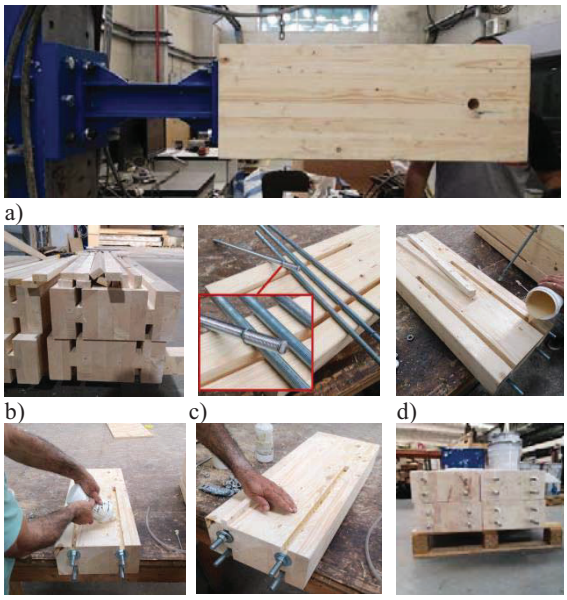

Figure 2: *Manufacturing steps: a) assembled joint; b) notches realization; c) wire spacer around the bars; d) epoxy resin pouring into the notches; e) and f) gluing of additional timber elements; g) timber specimen;.*

3 TEST SET-UP AND EQUIPMENTS

For the tests, a cantilever configuration (Fig. 3a) is realized. At one end, the link is rigidly connected to the reaction steel column of the retaining frame by means of 6 bolts (M12, 10.9 steel grade, 60mm long, Fig. 3b). At the timber beam free-end the load is applied through a pin, inserted in a hole with 30mm diameter drilled at the free-end of the beam. A steel fork connected to the pin ends is used to transfer the load by an hydraulic jack, having a maximum stroke of 200mm (Fig. 3c).

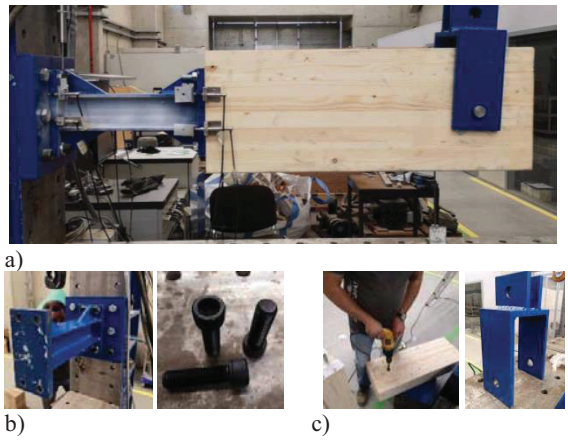

Figure 3: *Test set-up: a) overall set up; details: b) connection of the joint to the retaining frame; c) steel fork.*

The displacements of the specimen during the test are measured by using different types of linear variable displacement transducers (LVDTs). The displacement ranges required to each LVDT were estimated through the preliminary numerical analyses [13]. The LVDTs were installed on the specimen by using aluminium brackets screwed at the timber beam and glued at the steel elements.

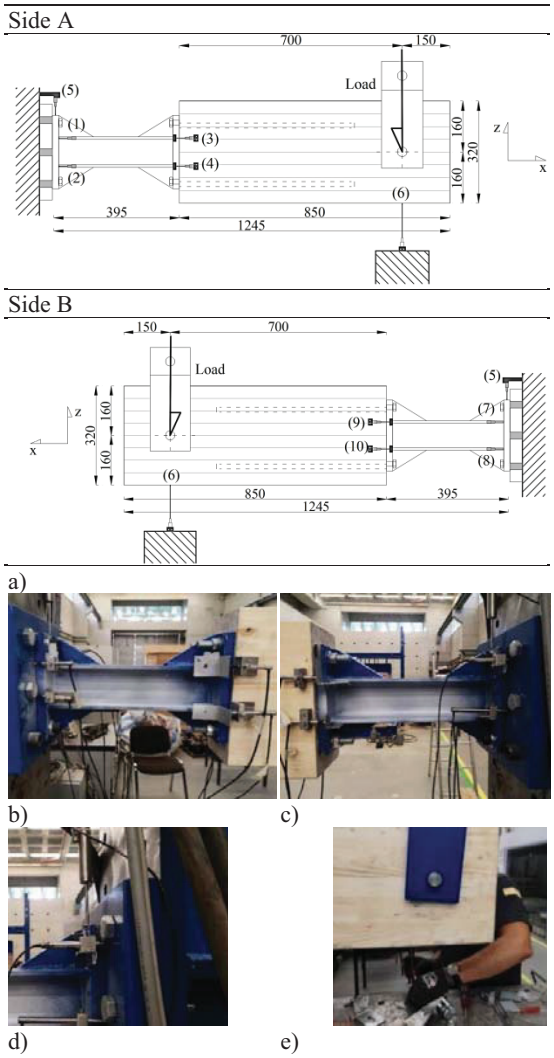

Figure 4: *Displacement transducers position: a) LVDTs on sides A and B [mm]; b) LVDTs nr.1, 2, 3, 4 on side A; c) LVDTs nr.7, 8, 9, 10 on side B; d) LVDT nr.5 at the upper side of the right end-plate; e) LVDT nr.6 at the loading beam section.*

In Figure 4 the position of the LVDTs is shown, they are:

- 4 LVDTs, 2 for each side of the specimens (nr.1 and 2 on side A, Figs. 4a, b; nr. 7 and 8 on side B, Fig. 4a, c) to measure the horizontal displacement between the fixed steel end-plate and the retaining frame;
- 4 LVDTs, 2 for each side of the specimens (nr. 3 and 4 on side A, Fig. 4a, b; nr. 9 and 10 on side B, Fig. 4a, c) to measure the horizontal displacement between the steel link and the timber beam;
- 1 LVDT (nr. 5) placed over the joint end-plate connected to the fixed end-plate to evaluate the possible vertical displacement at the fixed-end of the specimen (Fig. 4a, d);
- 1 LVDT (nr. 6) placed under the hydraulic jack to measure the vertical displacement of the joint at the free-end of the cantilever (Fig. 4a, e).

The LVDTs were calibrated using a large micrometre over a range of ±6 mm. The core of the device is set as close as possible to the zero locations.

The applied force (F) is measured by a load cell (max load: 200kN).

In Figure 5 the overall view of the test set up including the retaining frame is shown.

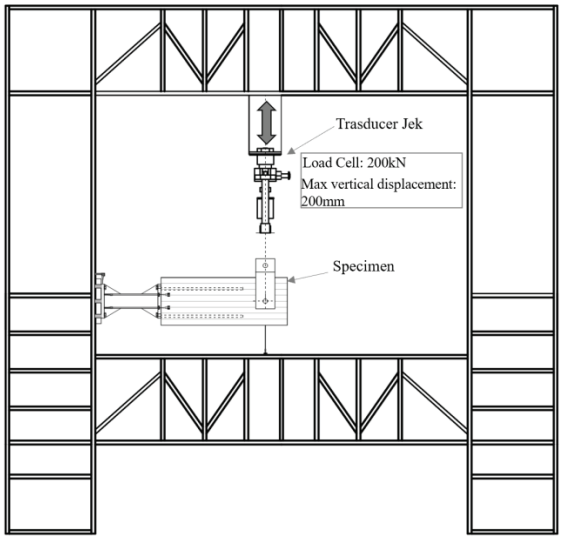

Figure 5: *Overall view of the test set up with the retaining frame.*

4 TEST PROCEDURE AND PERFORMANCE CURVES

The vertical load is applied under displacement control at a constant rate of 0.1mm/s, according to the European standard EN 12512 [15], in order to study the specimen response in elastic-plastic field. Therefore, considering the maximum stroke of the actuator of 200mm, the test end is achieved in about 30 minutes.

The test outputs are provided in terms of force-displacement (F-u) curve. Then, the bending moment-rotation (M-θ) curve is analytically obtained, evaluating the bending moment (M; Eq. 1) and the corresponding rotation (θ; Eq. 2) at the mid-section (M_L point) of the link, according to the following equations (Fig. 6):

$$M = F \cdot L \quad (1)$$

$$\theta = \theta_{Tot} - \theta_A - \theta_B \quad (2)$$

where L is the distance of the mid-section of the link M_L from the load point (L=1020mm); θ_{Tot} is the global rotation of the joint as respect to the retaining frame, θ_A is the rotation of the link left end-plate with respect to the retaining frame, θ_B is the rotation of the link right end-

https://doi.org/10.52202/069179-0288

plate with respect to the timber beam. In particular, the above defined rotations are calculated as it follows with reference to Figure 6:

$$\theta_A = \frac{\delta_{1,7} + \delta_{2,8}}{h_A} \quad (3)$$

$$\theta_B = \frac{\delta_{3,9} + \delta_{4,10}}{h_B} \quad (4)$$

$$\theta_{Tot} = \frac{u_{Tot}}{L_A} \quad (5)$$

where $\delta_{1,7}$ and $\delta_{2,8}$ are the horizontal displacements detected at point A section, evaluated as mean value between the displacements measured with the LVDTs nr. 1, 7 and 2, 8 and h_A is the distance between the LVDTs (Fig. 6b); $\delta_{3,9}$ and $\delta_{4,10}$ are the horizontal x-direction displacements detected at point B section, evaluated as mean value between the displacements measured with the LVDTs nr. 3, 9 and 4, 10 and h_B is the distance between the LVDTs (Fig. 6c); u_{Tot} is the total displacement in vertical z-direction, evaluated at the applied force (F) section by using the LVDT nr. 6 and L_A is the whole length of the joint.

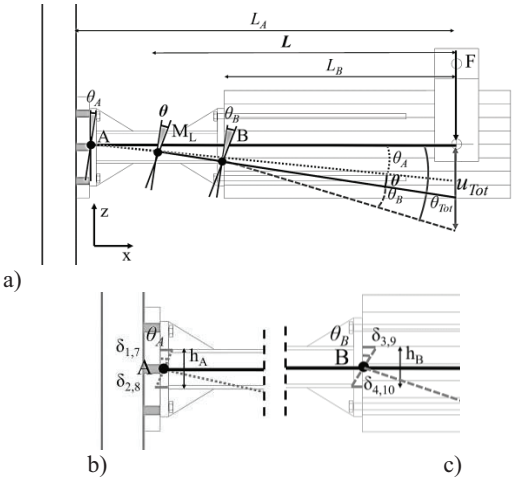

Figure 6: *a) Schematic deformation of the joint and relative rotations between the joint components; b) Rotation between link left end-plate and retaining frame; c) Rotation between link right end-plate and timber beam.*

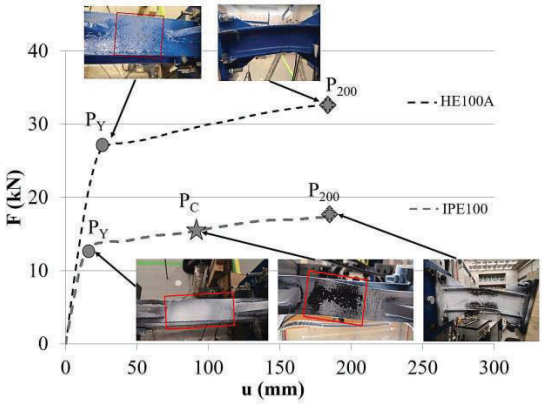
5 MONOTONIC TEST

In Figure 7, the force-displacement (F-u) curves and the failure modes achieved through the experimental tests are presented. In particular, outputs are noticed at specific selected performance points, defined at the yielding of the steel link (P_Y), the collapse of the specimen (P_C) and a total displacement equal to 200mm (P_{200}), which corresponds to the maximum stroke of the loading actuator.

Both joints show a ductile behaviour with the plastic deformation of the link, achieving the formation of the plastic hinge. HE100A joint reached the maximum stroke of 200mm (coinciding with the end of the test) before the failure (P_C), while IPE100 joint failed (P_C) through the buckling of the link flange, before the achievement of the 200mm total displacement.



Joint	HE100A		IPE100	
Performance points	**F [kN]**	**u [mm]**	**F [kN]**	**u [mm]**
P_Y	27.11	17.73	12.89	14.96
P_C		-	15.40	97.32
P_{200}	32.71	184.97	17.81	184.97

Figure 7: *Experimental F-u curves of the joints; performance points: Y-yielding, C- collapse, 200-Actuator stroke.*

6 ANALYSIS OF RESULTS

The tests results are discussed in terms of initial stiffness $S_{j,ini}$ (eq. 1), plastic field stiffness $S_{j,pl}$ (eq. 2, 3) and resistance $F_{j,Y}$ at yielding point (P_Y), as well as ductility capacity D_j (eq. 4, 5), evaluated as it follow:

$$S_{j,ini} = \frac{M_{j,el}}{\theta_{j,el}} \quad (1)$$

$$S_{HE100A,pl} = \frac{M_{j,Rd,200}}{\theta_{j,pl,200}} \quad (2)$$

$$S_{IPE100,pl} = \frac{M_{j,Rd,C}}{\theta_{j,pl,C}} \quad (3)$$

$$D_{HE100A} = \frac{u_{200}}{u_Y} \quad (4)$$

$$D_{IPE100} = \frac{u_C}{u_Y} \quad (5)$$

where $M_{j,el}$ and $\theta_{j,el}$ correspond respectively to the elastic bending moment, not exceeding 2/3 $M_{j,Rd}$ ($M_{j,Rd}$ being the design bending strength of the j-joint, [16]), and the rotation at the elastic limit; $M_{j,Rd,C}$ and $\theta_{j,pl,C}$ correspond respectively to the design bending strength and the rotation of the IPE100 at collapse point (P_C); $M_{j,Rd,200}$ and $\theta_{j,pl,200}$ correspond respectively to the design bending strength and the rotation of the HE100A at 200mm vertical displacement (P_{200}); u_{200} is the displacement at P_{200} point, u_C is the displacement at P_C point and u_Y is the displacement at P_Y point.

In particular, HE100A and IPE100 joints performances are compared through the Capacity Ratios (CRs), defined in terms of initial stiffness $S_{j,ini}$ (CR-S_{ini}=$S_{IPE100,ini}$/$S_{HE100A,ini}$), plastic field stiffness $S_{j,pl}$ (CR-S_{pl}=$S_{IPE100,pl}$/$S_{HE100A,pl}$), yielding strength $F_{j,Y}$ (CR-F_Y=$F_{IPE100,Y}$/$F_{HE100A,Y}$) and ductility capacity D_j (CR-

$D_j=D_{IPE100}/D_{HE100A}$). The mechanical parameters are given in Table 1. Observing the experimental results, IPE100 joint shows lower initial and plastic field stiffnesses, strength and ductility, as respect to HE100A, with CR-S_{ini}=75%, CR-S_{pl}=85%, CR-F_Y=48%, CR-D=75%.

***Table 1**: Joints initial stiffness $S_{j,ini}$, plastic field stiffness $S_{j,pl}$, resistance F_j and ductility capacity D_j for study joints: preliminary numerical and experimental values.*

Joint	**HE100A**		**IPE100**	
Performaces	**Test**	**Num.**	**Test**	**Num.**
$S_{j,ini}$ [kN/rad]	1227	1546	936	1054
$S_{j,pl}$ [kN/rad]	38	16	28	17
$F_{j,Y}$ [kN]	27.11	26.50	12.89	11.61
D_j [-]	10.43	11.48	6.51	7.85

With regards to rotations, it has to be noticed that, in both joints, the maximum θ_B and θ_A rotations are negligible compared to the overall rotation θ_{Tot}, being θ_B/θ_{Tot} equal to 2.2% and 2.3% for HE100A and IPE100 respectively, θ_A/θ_{Tot} equal to 0.5% and 0.7% for HE100A and IPE100 respectively (Tab. 2). This also confirms the efficiency as rigid connections of the link end joints.

***Table 2**: Joints rotations θ_B, θ_A and θ_{Tot} in P_{200} and P_C points respectively for HE100A and IPE100.*

Joint	**HE100A**		**IPE100**	
Points	**P_{200}**		**P_C**	
	[rad]	**θ_i/θ_{Tot}** [%]	[rad]	**θ_i/θ_{Tot}** [%]
θ_B	0.004	2.2	0.002	2.3
θ_A	0.0009	0.5	0.0006	0.7
θ_{Tot}	0.18		0.084	

In Figure 8, the experimental force-displacement (F-u) and the analytically moment-rotation (M-θ) curves are given in comparison with the preliminary numerical ones [13]. In particular, further to the previously defined performance points (P_Y, P_C, P_{200}), on the numerical curve also the point, corresponding to the link full plasticization (P_{PN}), is evidenced.

It is apparent that the experimental and numerical curves are very close in the elastic field, while the post-elastic branches differs. This means that the preliminary model perfectly caught the elastic behaviour, while it has to be calibrated after the laboratory tests. This is also quantified through the Capacity Ratios (CRs) evaluated at the selected performance points (P_i, where i is Y, 200, C), in terms of strength $F_{j,i}$ (CR-$F_{j,i}=F_{j,n,i}/F_{j,t,i}$), displacement $u_{j,i}$ (CR-$u_{j,i}=u_{j,n,i}/u_{j,t,i}$), initial stiffness $S_{j,ini}$ (CR-$S_{j,ini}=S_{j,n,ini}/S_{j,t,ini}$), plastic field stiffness $S_{j,pl}$ (CR-$S_{j,pl}=S_{j,n,pl}/S_{j,t,pl}$) and ductility capacity D_j (CR-$D_j=D_{j,n}/D_{j,t}$; Tab. 3).

With regards to the collapse modes it is worth noticing that the preliminary numerical analysis of HE100A joint reached the failure, beyond the test limit of 200mm (P_{200t}), corresponding to the buckling of the link web (F_{Cn}=29.35kN; u_{Cn}=242mm). Besides the same collapse condition is evidenced for IPE100 in both preliminary numerical analysis and test, corresponding to the buckling of the link flange before P_{200}.

It is not possible to evaluate the collapse hierarchy of the joint sub-components through the experimental tests, however by superimposing the images deriving from the numerical analysis with the photos taken at the end of the test (at P_C for IPE100 and P_{200} for HE100A), a very good approximation of the ultimate deformed configuration of the joints is worth noticed (Fig. 9).

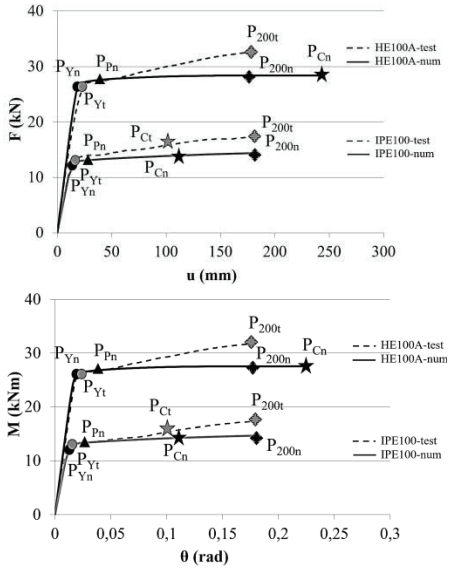


***Figure 8:** Experimental vs preliminary numerical F-u and M-θ curves of the joints; performance points: Y-yielding, C-collapse, 200-Actuator stroke.*

***Table 3**: Joints Capacity Ratios (CRs) in terms $F_{j,i}$, $u_{j,i}$, $S_{j,ini}$, $S_{j,pl}$, and $D_{j,i}$ in P_Y, P_{200} and P_C points for HE100A and IPE100.*

Joint	**HE100A**			**IPE100**		
[%]	**P_Y**	**P_{200}**	**P_C**	**P_Y**	**P_C**	**P_{200}**
Cr-F	98	87	/	90	81	91
Cr-u	98	108	/	89	108	108

7 CONCLUSIVE REMARKS

The paper focuses on beam-to-column joints with dissipative steel link in the timber beam for seismic moment resistant heavy timber framed structures. In

https://doi.org/10.52202/069179-0288

particular, monotonic experimental tests on two joints are presented.

The HE100A and IPE100 joints structural performance was preliminary investigated through monotonic incremental non-linear analyses on refined FE models, examining the key parameters, such as strength, stiffness, rotation capacity and failure modes. Then, the mechanical behaviour of the joints was studied through the capacity curves, F-u and M-θ, obtained through the monotonic tests. The joints performance is evaluated at specific points, corresponding to the link yielding (P_Y), full plasticization of the link (P_P), ultimate strength (P_C) and strength at the actuator stroke equal to 200mm (P_{200}). Results showed that HE100A joint, as respect to IPE100, has higher initial stiffness, plastic field stiffness, strength and ductility. With regards to the collapse conditions, for HE100A joint, the 200mm stroke (P_{200}) occurs before the joint failure, while for IPE100 joint, the failure is achieved before, corresponding to the buckling of the link flange. For HE100A the collapse was attained through the preliminary numerical analysis, corresponding to the buckling of the link web.

Therefore, the experimental results are compared with those of the preliminary numerical analysis. The experimental and numerical curves are coincident in the elastic field, up to the yielding point, while the post-elastic branches are different, evidencing the need to opportunely calibrate the FE models, specially on the basis of the laboratory tests on the materials.

Definitely the tests have validated the theoretical and numerical predictions, confirming the formation of the plastic hinge in the link, which dissipates the energy through plastic deformation, avoiding brittle failures, as well as proving the efficiency of the system and of the proposed design criteria.

The work is in progress toward the development of seismic resistant dissipative timber structures, focusing on the dissipative device design, toward the calibration of the refined numerical model, the extension of both the numerical analyses and test campaigns, to evaluate the cyclic behavior and the dissipation capacity of the beam-to-column joint with steel link. At the same time, the global behavior of seismic resistant timber structure with dissipative links is going to be investigated.

ACKNOWLEDGEMENT

MODELLING SEISMIC ISOLATION BEARING FOR WOOD BUILDINGS

Asif Iqbal[1], Angelo Aloisio[2] and Massimo Fragiacomo[3]

ABSTRACT: This paper discusses the details of modelling a type of seismic isolator, named RoGlider, suitable for wood buildings. An analytical model of the bearing and estimate the parameters of a classical Bouc-Wen model representative of this device is presented. RoGlider is found to be useful for seismic protection and the proposed model can represent the isolation system with sufficient accuracy.

KEYWORDS: Seismic Isolation, Bouc-Wen Model, Wood Buildings

1. INTRODUCTION

The RoGlider, shown in Figure 1, is a sliding bearing which includes an elastic restoring force [1,2]. The actual configuration is dependent on the details of the structure being isolated and the expected earthquake. It consists of two flat steel plates with a puck between the plates. The puck consists of alternating layers of rubber and sheet steel, similar to the arrangement used in elastomeric bearings and Lead Rubber Bearings. The sliding elements such as PTFE are mounted at the ends of the puck. The two rubber membranes are attached to the puck with each being joined to either the top or the bottom plates thereby making a sealed unit. When the top and bottom plates slide sideways with respect to each other diagonally opposing parts of the membrane undergo tension or compression. The tension components provide the restoring force between the plates.

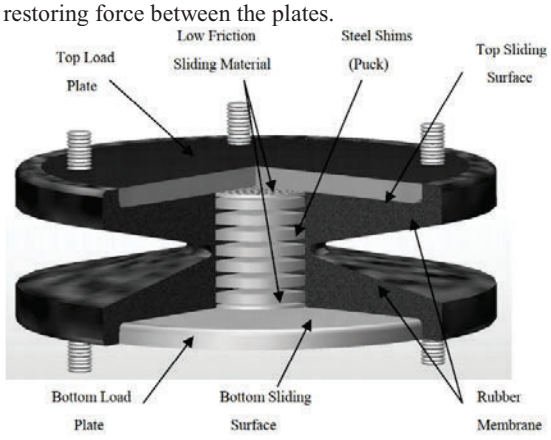

Figure 1: *Sectional view of RoGlider.*

With the special arrangement (Figure 3) and geometry (Figure 4), RoGlider is characterized by a lower lateral stiffness compared to classical elastomeric isolators. This feature enables the RoGlider to be used for isolating lightweight structures. The lower lateral stiffness guarantees the attainment of higher natural periods of vibration. Figure 2 shows a typical hysteresis plot.

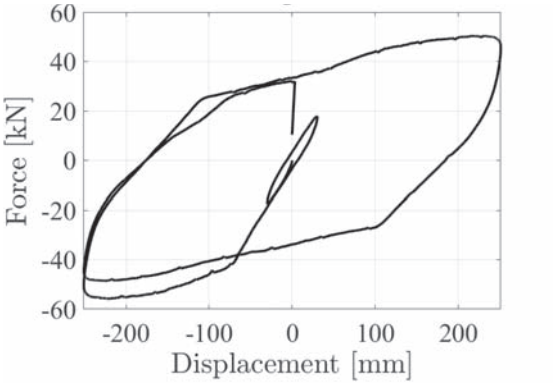

Figure 2*: Hysteresis of RoGlider*

2. ROGLIDER PROPERTIES

RoGlider bearings went through extensive testing by the developers and also during a research project at BRANZ in New Zealand [3]. Robinson et al. tested the bearing at their facility (Figure 4) under a range of vertical loads and displacement range [1]. It is visible that the bearings can carry significant vertical load at design-level (Figure 6) and large displacements (Figure 7). The force displacement plot (Figure 8) shows significant energy dissipation under design-level displacements. The energy dissipation is less under large displacements, but the loading cycles produce very stable loops (Figure 9).

https://doi.org/10.52202/069179-0289

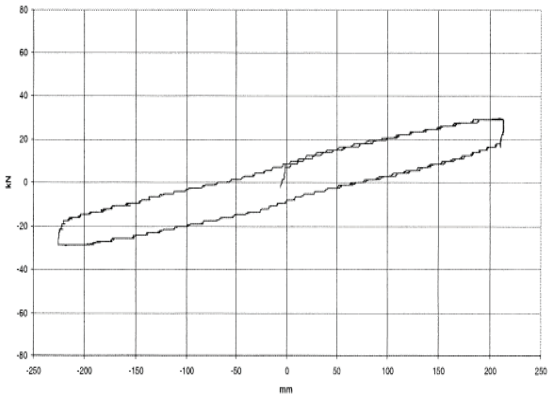

Figure 9: *Force-displacement plot of RoGlider, under 110 kN vertical load [1]*

The bearings also exhibit stable behaviour under sinusoidal loading cycles at slow (Figure 10) and high speeds (Figure 11). The coefficients of friction vary with speed (Figure 12) but the trend is consistent between slow and high speeds.

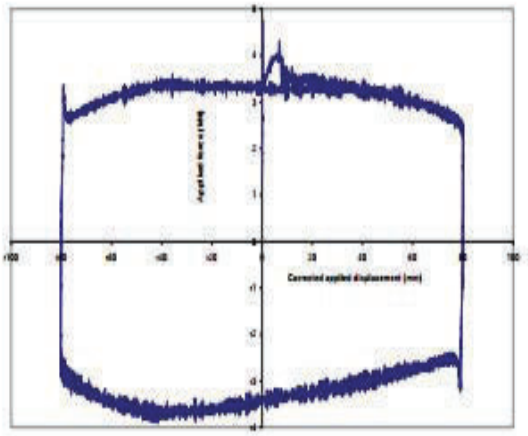

Figure 10: *Hysteresis loops of RoGlider, under sinusoidal displacement to 80 mm at 0.01 Hz [3]*

3. ROGLIDER APPLICATION

Figure 13: *Wanganui Hospital Building in New Zealand [2]*

RoGlider have been used to isolate a hospital building in Wanganui (Figure 13) in the North Island of New Zealand [2]. The bearings have been placed under the steel structure of the building (Figure 13). The load-displacement plots of the bearings used (Figure 14) again show very stable loops with significant energy dissipation capacity.

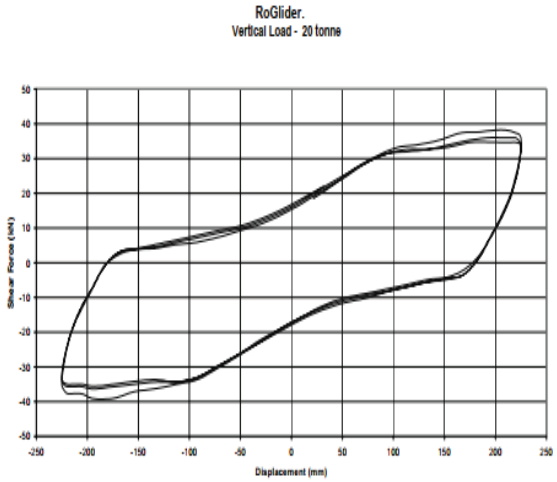

Figure 14: *Hysteresis loops of RoGlider, bearing used in Wanganui Hospital building [2]*

4. HYSTERESIS MODELLING

The authors describe the hysteresis curve of the RoGlider using a classical Bouc-Wen model. For a structural element described by a Bouc–Wen class model, the resisting force is written as

$$f_s(x, \dot{x}, z) = \alpha k_0 x + (1 - \alpha) k_0 z \qquad (1)$$

Where

fs	Resisting force
x	Displacement
x	Derivative of x with respect to time
z	Auxiliary variable representing inelasticity
α	Post- to-pre-yield stiffness ratio
k_0	Initial stiffness

The evolution of z is determined by an auxiliary ordinary differential equation, which can be written in the form

$$\dot{z} = \dot{x}[A - |z|^n \psi(x, \dot{x}, z)] \qquad (2)$$

Where

z	Derivative of z with respect to time;
A	Parameter controlling scale of hysteresis loops;
n	Sharpness parameter of hysteresis loops, n>0;
ψ	Other shape features of the hysteresis loop;

The ψ functions of the original Bouc–Wen model used in this paper is

$$\psi_{Bouc-Wen} = \gamma + \beta sgn(\dot{x}z) \qquad (3)$$

Where

$\psi_{Bouc-Wen}$ Shape parameter, $\gamma > 0$, $-\gamma < \beta < +\gamma$;

5. MODEL VALIDATION AND DETAILS

Comparison between the simulated and experimental data in terms of hysteresis curve, force-time and energy-time functions are shown in Figures 15, 16 and 17, respectively.

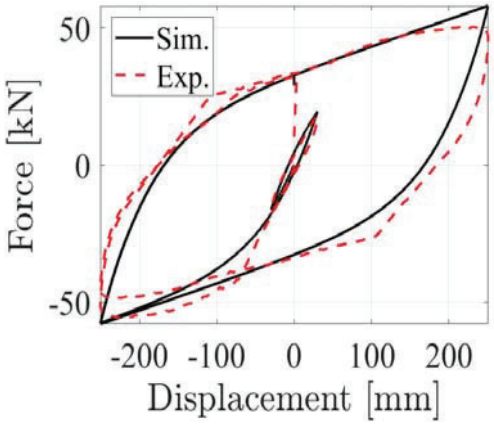

Figure 15: *Hysteresis comparison*

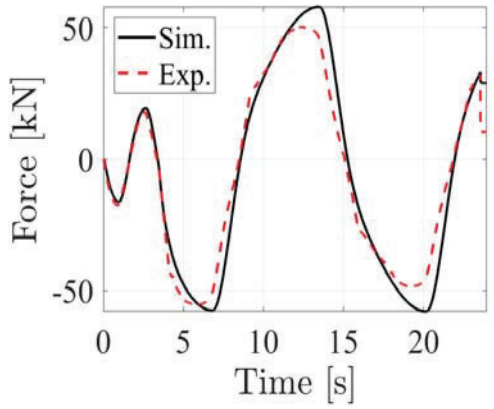

Figure 16: *Comparison of force vs. time*

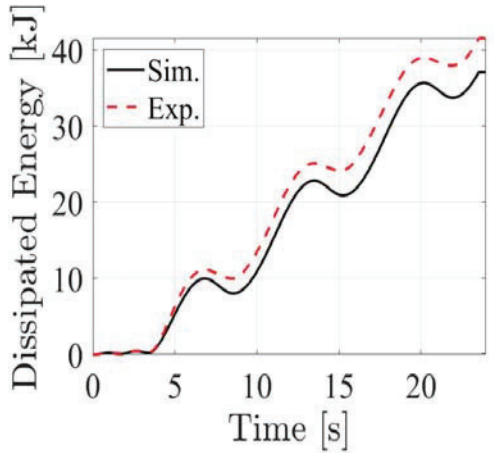

Figure 5: *Energy vs. time functions*

Hysteresis curve parameters in Figures 3, 4 and 5 estimated using Ordinary Least Square Operator [5,6] are:

Table 1: *Estimated classical Bouc-Wen model parameters*

Parameters	RoGlider
α	0.15
k_0	0.65
n	1.08
β	20.5
γ	0.1

6. RESULTS

The paper discusses the effect of variable mass on the gain spectra of a SDOF oscillator, whose restoring force is represented by the Bouc-Wen model in Figure 3. The gain spectra are defined as:

$$\mathcal{G}(T,\xi) = \frac{\max(|x_1(t)|}{\max(|x_2(t)|} \tag{4}$$

where $\mathcal{G}$ is the gain spectrum, ξ is the viscous damping ratio, $x_1(t)$ is the seismic response of a SDOF oscillator with restoring force described by the Bouc-Wen model, $x_1(t)$ seismic response of a viscoelastic SDOF system with damping ξ. If $\mathcal{G} < 1$, the use of the RoGlider is advantageous. The inelastic restoring force contributes to the equilibrium of a single-degree-of-freedom oscillator (SDOF), which is representative of the dynamic response of the RC frame. The analysis focuses on the behavior of a SDOF system neglecting all aspects related to the practical scenario of a full-size building. The equilibrium of a lumped mass above the frame yields the following ordinary differential equation (ODE) under earthquake excitation:

$$m\ddot{x} + f_t = -m\ddot{x}_g \tag{5}$$

where m is the mass equal to 20 t, x is the displacement, $\ddot{x}$ is the double derivative of x with respect to time, f_t is the resisting inelastic force, and $\ddot{x}_g$ is the ground acceleration. Fig.4 shows the comparison between the seismic response of a specific SDOF with mass equal to 20ton, under the El-Centro earthquake.

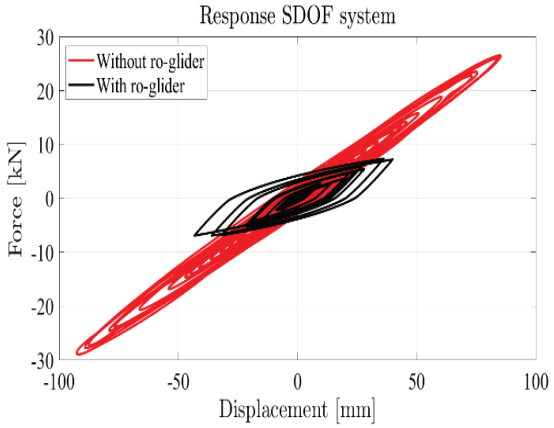

Figure 17: *Response of a SDOF system with mass M=20ton to the El Centro earthquake*

Figure 18 plots the inelastic gain spectra, defined in Eq.(4) estimated using earthquake records listed in Aloisio et al. [6].

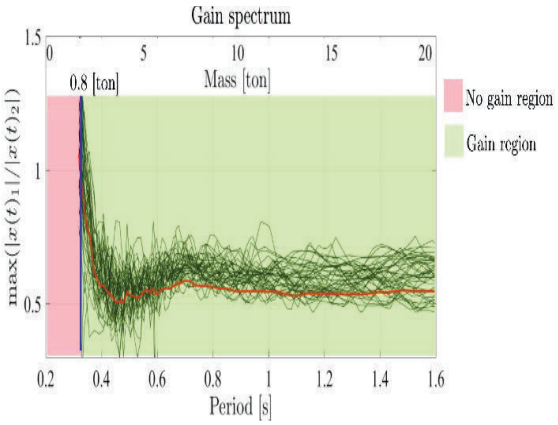

Figure 18: *Gain Spectra*

The averaged gain spectrum, in red, exhibits a peculiar shape. If the lumped mass is lower than 0.8 ton, the maximum displacement attained by the two systems with and without the Ro-glider are equal. This mass value corresponds to a natural period equal to 0.35s. There is a region of minimum between 0.4 and 0.6s, where the gain spectrum attains 0.5. For natural periods higher than 0.6s, the gain spectrum stabilizes at 0.55.

7. CONCLUSIONS

The proposed model promises to represent the isolation system with sufficient accuracy. It also demonstrates usefulness of RoGlider as a practical option for seismic design of lightweight structures. Further work on applicability and seismic performance of the system in multi-story timber buildings is currently underway.

EXPERIMENTAL MONOTONIC AND CYCLIC TESTING ON GLULAM BEAM-TO-COLUMN CONNECTIONS

Erica C. Fischer[1], Haley Madland[2], Sujit Bhandari[3], Arijit Sinha[4]

ABSTRACT: During seismic events, mass timber gravity connections must be able to accommodate the induced lateral deformations while still maintaining their load bearing capacity. Large-scale experimental testing can demonstrate and provide data for different connection configurations and numerical simulations can further inform the behaviour of these connections under lateral demands. However, there is a lack of experimental testing on glue laminated (glulam) beam-to-column connections, which presents a lack of data available for benchmarking numerical modelling. This paper will summarize a comprehensive large-scale testing regime performed at Oregon State University on five glulam beam-to-column connections, three custom designed connections and two pre-engineered connections. Each connection was tested under both monotonic and cyclic loading demands and the data from one of the connection tests was used to develop preliminary numerical modelling techniques for glulam beam-to-column connections. The tests demonstrated that all of the connections were able to be tested to 7.2% drift in the monotonic test and 4% drift in the cyclic test without losing load bearing capacity. The experimental testing regime developed data on maximum force demands in the connections, connection rotations, and connection stiffnesses that were used to characterize the connections on a scale of pinned to fixed connections.

KEYWORDS: Mass timber, Beam-to-column connection, Deformation compatibility, Monotonic, Cyclic

1 INTRODUCTION

Gravity beam-to-column connections in a building are designed to transfer shear forces, to be capable of rotation, and to have some small resistance to lateral forces. During a seismic event, where lateral forces are applied to a building, the entire building will also be subjected to deformation demands. Because of this, every member in the structure, including the gravity connections, must be capable of deforming along with the rest of the structure. Loss of load carrying capacity of gravity connections can occur when the connection components do not have sufficient ductility or strength to deform with the remainder of the building under lateral demands. This could potentially have cascading effects leading to a partial or complete collapse of the structure itself. Therefore, it is extremely important that the ductile behaviour of gravity connections under lateral loading is understood and promoted in design. This behaviour is referred to as deformation compatibility.

To better understand the deformation compatibility behaviour of beam-to-column connections, they are tested under monotonic and cyclic lateral loading. The experimental data from these tests informs connection characteristics such as the force-deformation (F-δ) and moment-rotation (M-θ) relationships of the connection. However, there is minimal research on deformation compatibility behaviour glulam beam-to-column connections. Because of this, the deformation compatibility behaviour of glulam beam-to-column connections is not well understood.

Glulam beam-to-column connections typically fall into one of two categories: custom designed connections or pre-engineered connections. For custom design connections, the responsibility of designing the connection is placed on the engineer of record. However, pre-engineered connections are proprietary connections that have been designed, tested, and rated for certain loading by a supplier. This means that once the required capacity of a connection has been determined by the engineer, a pre-engineered connection can be selected using design aids developed by the supplier of the connection. Therefore, while custom connections can be specifically designed to meet the necessary capacity requirements most efficiently, more time spent designing is required of the engineer. Conversely, pre-engineered connections can reduce the design time for the engineer,

https://doi.org/10.52202/069179-0290

but limited options may force the engineer to use an over-designed connection.

The design of custom glulam beam-to-column connections is prescribed by relevant standards, such as ASCE 7-16 [1] and the National Design Specification for Wood [2]. The required lateral capacity of a gravity connection is defined in Section 1.4 of ASCE 7-16 as no less than 5% of the supported members weight, and no less than 5% of the reaction imposed on the supporting member due to the unfactored dead and live loads [1]. Although gravity connections are not intended to resist large lateral forces, these integrity provisions in Section 1.4 ensure that there is some connection between members capable of withstanding a minimum prescribed lateral force. However, although custom connections are designed for this lateral force there is no correlation between this lateral force demand and the deformations or rotations of the connection. Therefore, the behaviour of connections exposed to large deformations is not addressed.

To demonstrate the capacity of pre-engineered connections and provide design aids to the engineer for choosing pre-engineered connections, suppliers must perform experimental testing [3] to establish allowable loads in the connection. This testing prescribes how connection characteristics such as the limiting strength and deflection should be determined but does not address the deformation compatibility behaviour of the connection. Testing such as this creates substantial barriers to the development of pre-engineered connections because of the large time and financial investments that must be spent to perform experimental testing.

The research presented and discussed in this paper serves to develop a fundamental understanding of the behaviour of glulam beam-to-column connections exposed to lateral monotonic and cyclic loading. Monotonic and quasi-static cyclic testing of both custom and pre-engineered glulam beam-to-column connections involving combined lateral and gravity loading were performed, from which quantitative data was collected and qualitative observations were made. From the experimentally collected data, the force-displacement (F-δ) and the moment-rotation (M-θ) relationships were compared between connections. Connection characteristics such as initial and secant stiffness and energy dissipation were calculated and compared across custom and pre-engineered connections. The data developed from the experimental testing regime was used to develop and benchmark a finite element method model and explore numerical modelling methods for glulam beam-to-column connections. Specifically, the objectives of this research are to: (1) quantify the deformation compatibility behaviour of glulam beam-to-column connections under lateral loading demands, (2) compare the deformation compatibility behaviour of custom and pre-engineered beam-to-column connections, and (3) explore numerical modelling methodologies for simulating glulam beam-to-column connections under lateral demands.

2 MATERIALS AND METHODS

2.1 TESTING SETUP

The testing setup (Figure 1) consisted of a 3.66 meter tall 24F-V4 glulam Douglas Fir (DF) column, connected at its base to a pin connection. The beam, a 24F-V4 DF glulam, extended approximately 4.27 meters from the face of the column, at mid-height in all connection types. The beam was 311 mm (W) x 610 mm (D). The column width was 311 mm in all connections, but depth varied on connection type. The end of the beam was supported by a roller support. A 1.2 meter wide, 4.27 meter long, and 175 mm thick SPF CLT (5-ply) deck was connected to the top of the beam. A hydraulic ram applied a constant gravity load throughout the tests.

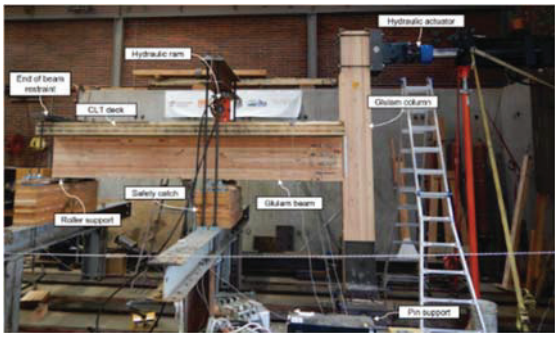

Figure 1: *Testing setup*

2.2 SPECIMEN DESCRIPTIONS

Five connections were investigated. Three connections were designed at Oregon State University per relevant standards [1, 2] and two connections were pre-engineered connections, designed by MTC Solutions. Specimen designations include the connection number, a shortened descriptor of the connection, and loading type (M for monotonic and Cyc for cyclic). For example, C1-KP-Cyc1 refers to connection 1 (C1), the connection uses a knife plate (KP), and the first cyclic test performed (Cyc1) on that connection type. For brevity the connections are referred to only by their designation. Connection C1-KP was a bracketed knife plate connection (Figure 2a). Connections C2-N and C3-N2 were bearing connections where the beam was inserted into a notched column (Figures 2b and 2c). Connection C4-MEG was a MEGANT 450x150x50 concealed beam hanger (Figure 2d), and connection C5-MTCP was a prototype connection designed by MTC (Figure 2e). Both MTC connections involved two interlocking aluminium plates, one screwed to the beam, and one to the column. A more comprehensive description of the connections is provided in [4, 5].

https://doi.org/10.52202/069179-0290

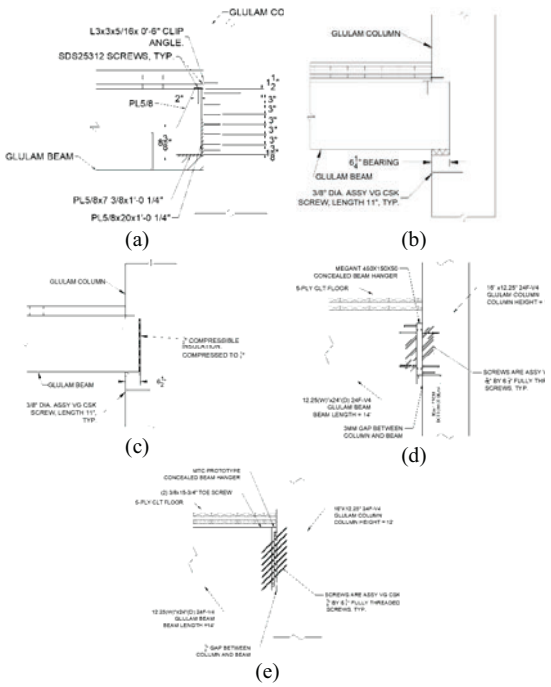

Figure 2: *Glulam beam-to-column connections*

2.3 LOADING PROTOCOL

For monotonic tests, displacement was applied through a hydraulic actuator at a rate of 0.51 mm/second to a target drift of 7.2%. The abbreviated CUREE basic loading history [6] with a target reference deformation of 1.9% drift and maximum displacement of 3.8% drift was used for the cyclic tests (Figure 3). The cyclic test began at a rate of 0.25 mm/second and increased to 0.64 mm/second after the cycle with the reference deformation. The cyclic loading protocol was altered for connections C4-MEG-Cyc2, C5-MTCP-Cyc1, and C5-MTCP-Cyc2, such that the cycle of maximum displacement was increased to 4% drift (from 3.8%), and the following trailing cycle was increased to 75% of the 4% drift cycle.

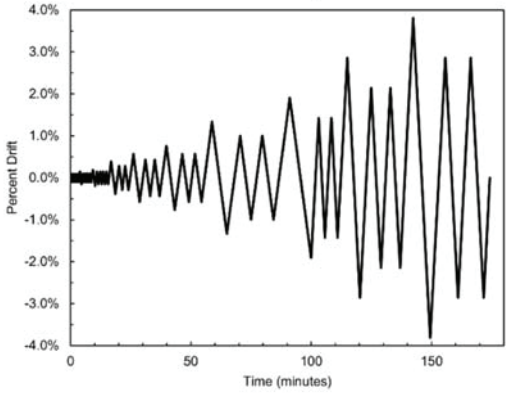

Figure 3: *Cyclic loading protocol per CUREE [6]*

The design shear demands for connections C1-KP, C2-N, and C3-N2 were calculated using an archetype office building with glulam beams spaced at 3.66 m, columns spaced at 8.53 m, and a live load of 2.39 kPa [1]. The design lateral demand were calculated per Section 1.4 of ASCE 7-16 [1]. To resist this lateral demand, and to have a mechanical connection between the glulam beam and column, each of these connections used an L3x3x5/16x152 mm section connected to the beam and column with two SDS25312 screws each. To install this clip angle on the top of the beam, a small portion of the CLT was chipped out to not conflict with the clip angle. The design shear demands for connections C4-MEG-M and C5-MTCP-M were prescribed by the supplier, MTC Solutions. Additional information on these demands can be found in [4, 5]. A summary of these demands and capacities is shown in Table 1.

Table 1: *Summary of gravity and lateral loading demands on connections*

Connection designation	Design shear demand [kN]	Design lateral capacity (demand) [kN]
C1-KP	49.1	6.09 (2.4)
C2-N	49.3	
C3-N2	49.3	
C4-MEG	98	14.5
C5-MTCP	179	17.3

2.4 INSTRUMENTATION LAYOUT

For both the monotonic and cyclic testing, seven linear variable differential transformers (LVDTs) and three load cells were utilized to measure the displacement and calculate the behaviour of the connections (Figure 4). In addition, the hydraulic actuator head displacement and a string potentiometer were utilized to measure the movement of the column. These measurements were used to calculate story drift throughout the test. LVDTs #1 – 4 were utilized to calculate the rotation of the connection assuming rigid body rotation of the column. These connection rotations were then compared with the base connection rotations calculated using LVDTs #5 and #6 to confirm the assumption of rigid body rotation. LVDTs #5 and #6 measured vertical displacements throughout the duration of the test and were centred on the column such that the recorded data could be used in combination with the known distance between the two LVDTs to calculate the column base rotation. Lastly, LVDT #7 was used to measure the differential movement between the top of the CLT and the column itself.

The load cells under the beam end, the ram, and the column base were utilized to calculate the shear in the connection throughout the test (Table 1). Connection moment was calculated throughout the test by multiplying the measured actuator force by the distance between the actuator force and the mid-height of the beam.

https://doi.org/10.52202/069179-0290

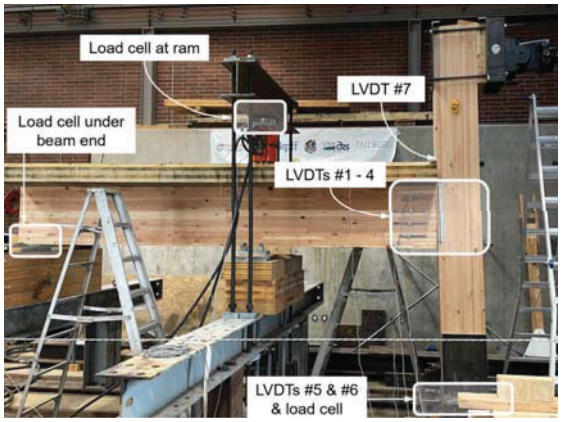

Figure 4: *Instrumentation layout for connection tests*

2.5 NUMERICAL MODELING METHODOLOGY

A three-dimensional finite element method (FEM) model of C2-N-M was developed in the commercially available software, Abaqus CAE, to explore the methodology for simulating glulam beam-to-column connections and to further understand the experimental test. The dimensions of the glulam beam, column, and CLT deck matched those tested in the laboratory at Oregon State University. An additional part was added to the base of the column such that the point of rotation for the column base matched that experimentally tested. Steel material properties were applied to this part to limit deformations. In addition, rather than applying boundary conditions to the beam end directly, an end of beam support was simulated to explore if friction contributed to the stiffness of the connection. Deformations were applied through a displacement-controlled loading protocol at the same rate as described in Section 2.3 at where the centroid of the actuator was located. The FEM model is shown in Figure 5.

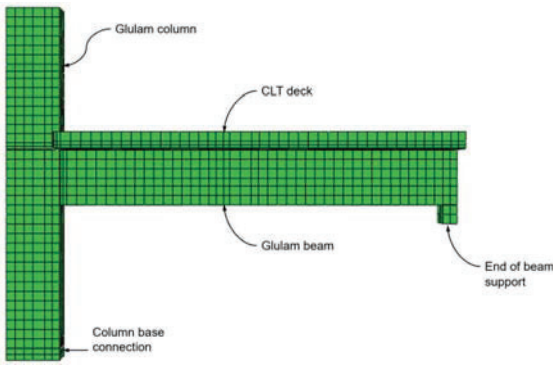

Figure 5: *FEM model of C2-N-M*

The column base was restrained from rotation in the out-of-plane direction and movement in all directions, but allowed to rotate about the base. The beam end was restrained from vertical displacement and rotation but was allowed to move horizontally.

As an anisotropic material, wood's stiffness and strength properties vary in different directions. Usually, the property of wood is defined in three directions: longitudinal (L), radial (R), and tangential (T). The strength and stiffness properties are typically higher in the longitudinal direction compared to radial and tangential directions. The stress-strain relationship for wood is typically linear until brittle failure for tension and shear loading in all directions while the stress-strain relationship is typically nonlinear and ductile in compression. For the FEM model described within this paper, wood has been modelled as orthotropic material with elastic-perfectly plastic behaviour [7, 8]. The stiffness properties for 24F-V4 DF glulam are from NDS and Wood Handbook [2] while the properties for SPF E1 CLT are taken from PRG 320 [9].

The coefficient of friction between the glulam column and beam was assumed to be 0.5 and the coefficient of friction between the glulam beam end and end support was varied to explore the degree of "frictionless" the authors were able to attain.

3 EXPERIMENTAL RESULTS

3.1 MONOTONIC TESTING

The yield load, yield displacement, and initial stiffness were calculated per EN12512 [10] and are summarized in Table 2. Specimen C2-N-M was the only specimen to have post-peak behaviour during monotonic testing. The remainder of the specimens reached maximum load (F_{max}) at maximum displacement.

Specimens C1-KP-M and C2-N-M had the lowest of the F_{max} with F_{max} increasing by 260% between C2-N and C3-N2 connections. The addition of the compressible insulation increased the capacity of the connection. The pre-engineered connections had larger F_{max} than the custom connections, even with the application of larger shear demands throughout the test.

Table 2: *Calculated properties for connections under monotonic loading*

Connection designation	Max. load [kN]	Yield load [kN]	Yield displ. [mm]	Initial stiffness [N/mm]
C1-KP	8.72	4.84	10.9	446
C2-N	11.97	8.87	15	595
C3-N2	21.42	18.46	28.4	649
C4-MEG	29.17	15.82	33.8	467
C5-MTCP	36.48	25.16	27.7	913

A small yield displacement (d_y) can indicate less ductility within the connection whereas a larger d_y, particularly coupled with a larger yield force (F_y) can indicate more ductility within the connection. In addition, higher values of initial stiffness can potentially indicate that the connection has more rotational rigidity. This type of behaviour is more evident in the initial stiffness

https://doi.org/10.52202/069179-0290

calculations where C4-MEG connection has lower initial stiffness than some of the custom connections (C2-N and C3-N2). C5-MTCP-M had the largest initial stiffness, 105% greater than the initial stiffness of specimen C1-KP-M. Connections C3-N2-M, C4-MEG-M, and C5-MTCP-M all had considerably larger d_y values than C1-KP-M and C2-N-M, ranging between 28 – 34 mm.

The design-level drift demand for buildings is 2% drift [1]. The actuator force at a lateral displacement corresponding to 2% drift for each test was compared to the design lateral capacity for each connection. For every connection, the actuator force exceeded the design lateral capacity at a drift of 2%. Table 3 summarizes the ratio of the actuator force at 2% drift ($P_{2\%}$) to the design lateral capacity of connection (P_n). However, failure of the connections (loss of load carrying capacity) was not observed during any of the tests. Therefore, although the lateral capacity of the connection was exceeded, force transfer continued through the connection for the duration of the tests.

Table 3: *Ratio of actuator force at 2% drift to design lateral capacity of tested connections*

Connection designation	$\frac{P_{2\%}}{P_n}$
C1-KP	1.13
C2-N	1.56
C3-N2	3.54
C4-MEG	1.22
C5-MTCP	1.79

During monotonic testing of the connections, screw fracture occurred in the C4-MEG connection, and fracture of the column connection plate occurred in the C5-MTCP connection. In the C2-N and C3-N2 connections, withdrawal of the screws connecting the clip angle to the column was observed.

3.2 CYCLIC TESTING

Backbone curves of all cyclically tested specimens, constructed from the peak actuator force and corresponding story drift in each primary cycle, are plotted in Figure 6. Connections C2-N and C3-N2 had similar forces during pulling cycles, but C3-N2 connections had substantially larger forces during pushing cycles, indicating greater capacity. Overall, custom connections generally had lower actuator forces than pre-engineered connections.

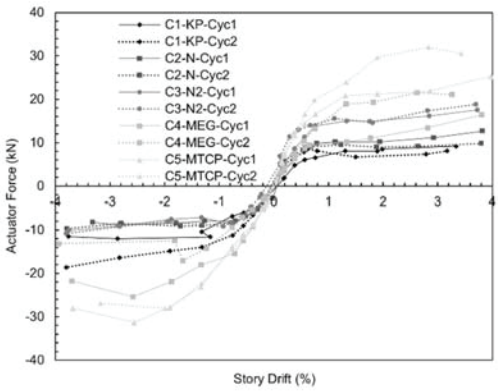

Figure 6: *Backbone curves of cyclic tests*

In Figure 7, the connection moment-rotation relationship is plotted for all cyclically tested specimens, with backbone curves (shown in black) constructed from peak connection moments and corresponding rotations in each primary cycle. The same trends were also observed for actuator forces due to the nature of how connection moments were calculated. As such, pre-engineered connections generally demonstrated larger connection moments than custom connections. The large drop in moment during the pushing cycle of the largest amplitude primary cycle for C5-MTCP-Cyc2 corresponds to the fracture of the column connection plate pocket (Figure 7).

The secant stiffness for each primary cycle was calculated for each connection, similar to previous research [11, 12], and plotted against connection rotation. These plots (Figure 8) show the calculated secant stiffness of the specimens decreases throughout the test. The secant stiffness is the ratio of the summation of the absolute value of the maximum ($+M_i$) and the minimum ($-M_i$) connection moment attained during a primary cycle to the summation of the absolute value of the rotation that corresponds to $+M_i$ ($+\Delta_i$) and the absolute value of the rotation that corresponds to $-M_i$, ($-\Delta_i$). The secant stiffness degraded with increasing connection rotation for each specimen. The secant stiffness decreased 74 – 91% from the first to the last primary cycle. The decrease of secant stiffness can indicate damage accumulating in a connection. While damage is expected, rapid decreases in secant stiffness indicate more brittle behaviour while gently decreasing slopes indicate more ductile behaviour. Although lateral force demands on connections are lower in early primary cycles, it is in these early loading cycles that the greatest stiffness degradation occurred. Greater secant stiffness indicated greater rotational rigidity in the connection as a larger force, or moment, is required to achieve the same connection rotation.

https://doi.org/10.52202/069179-0290

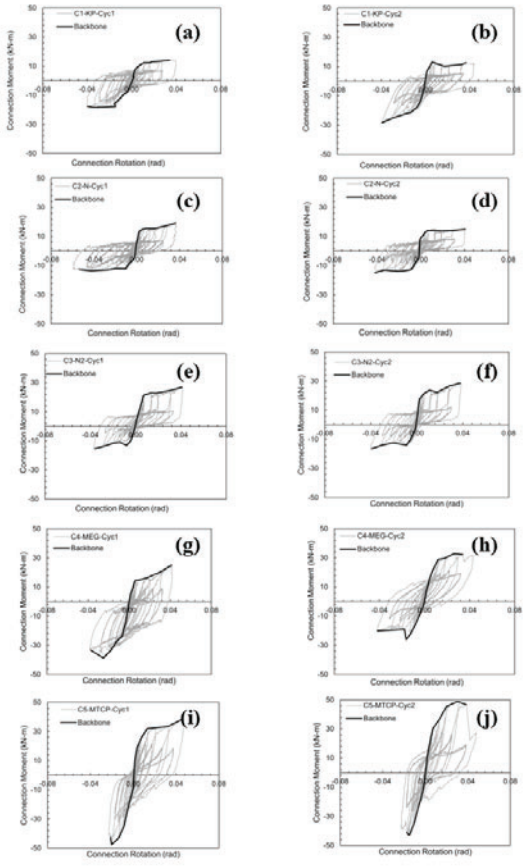

Figure 7: *Connection moment rotation relationship for cyclic tests (a) C1-KP-Cyc1, (b) C1-KP-Cyc2, (c) C2-N-Cyc1, (d) C2-N-Cyc2, (e) C3-N2-Cyc1, (f) C3-N2-Cyc2, (g) C4-MEG-Cyc1, (h) C4-MEG-Cyc2, (i) C5-MTCP-Cyc1, (j) C5-MTCP-Cyc2*

An increase in secant stiffness was observed between the first (0.075△) and second primary cycles (0.1△) except for C1-KP-Cyc2, C3-N2-Cyc1, C4-MEG-Cyc1, and C4-MEG-Cyc2. After the 0.1△ primary cycle, as damage accumulated, specimens demonstrated a non-linear decrease in secant stiffness from one consecutive primary cycle to the next. The largest rate of decreasing secant stiffness occurred between the 0.1△ and 0.2△ primary cycles except for connections C1-KP and C4-MEG. These specimens had the largest rate of decreasing secant stiffness either between primary cycles 0.075△ and 0.1△ (C1-KP-Cyc2, C4-MEG-Cyc1, and C4-MEG-Cyc2), or primary cycles 0.2△ and 0.3△ (C1-KP-Cyc1). Both C2-N specimens exhibited the largest percent degradation of secant stiffness from the first to the last primary cycle (91% in each case). Pre-engineered connections had the largest secant stiffnesses, displaying more rigidity than custom connections. However, C4-MEG specimens had lower rates of decreasing secant stiffness than the C5-MTCP specimens, indicating more ductile behaviour.

To compare the per-cycle energy dissipated, equivalent viscous damping ratio (EVDR) was used. This ratio is the energy enclosed in the moment-rotation hysteretic loop (Figure 7) divided by the corresponding energy that a linear system undergoing the same maximum rotation and corresponding moment would have dissipated. This ratio is then divided by 2π. A higher EVDR indicates that the connection has better energy dissipation. Between the 0.075Δ and 0.1Δ primary cycles, specimens C2-N-Cyc1, C2-N-Cyc2, and C5-MTCP-Cyc1 had large increases (between 54-203%) in EVDR while all other connections tested exhibited either much smaller increases or even decreases in EVDR. These sharp increases indicate damage occurring within the connection due to energy being dissipated. All of the C2-N and C3-N2 connections tested exhibited a small peak in EVDR during the 0.7Δ primary cycle (1.33% drift). During these cycles, the authors observed screw withdrawal of C2-N-Cyc1, and deformation of the clip angle during testing of C2-N-Cyc2. The EVDR of the custom connections either plateaued or decreased between the final primary cycles (1.5Δ to 2.0Δ); however, the EVDR of the pre-engineered connections increased with increasing connection rotation. This behaviour indicates that pre-engineered connections exhibited improved energy dissipation compared to custom connections, with larger total energy dissipation, and increasing EVDR values throughout testing.

4 NUMERICAL MODELING RESULTS

The authors compared the results from the FEM model with the experimental data for only C2-N-M testing to explore modelling methodologies for glulam beam-to-column connections. The authors found that the numerical model and the experimental data had good agreement for drift levels less than 1.4% drift (Figure 8). The comparison of energy differential between the experimental data and the FEM model was less than 20% and reduced substantially throughout testing. The results shown in Figure 8 used a coefficient of friction of 0.1 between the beam end and beam end support. The difference in the experimental data and the numerical modelling resides in the material model. While the behaviour of the FEM model and experimental data at maximum drift look similar (Figure 9), there is crushing of the glulam beam at the top of the connection pocket. The nature of the material model that was utilized within the FEM model described in this paper did not implement simulating crushing of the glulam.

https://doi.org/10.52202/069179-0290

Previous researchers have tried to implement damage and crushing material models into FEM simulations to simulate crushing of timber. However, many of these simulation techniques requires the researcher to know where localized crushing will occur prior to the simulation and therefore are limited for predictive modelling of untested connections. Hill yield criterion, sometimes with modifications, has been used to simulate the post-peak behaviour of wood for modelling of timber connections [13 -16]. To simulate the crushing around the steel members in connections, a so-called "foundation" modelling approach based on the theory of a beam on a nonlinear foundation has been used [15, 17, 18]. In these simulations, a material model with lower strength and stiffness was applied where localized crushing was expected. Crushable foam material model has also been used to simulate the crushing of wood in numerical models [19]. While this model simulated crushing at the bearing surfaces and the numerical model provided comparable results to the experiment, this isotropic material model doesn't consider the orthotropic behaviour of wood.

User subroutines incorporating different behaviour of wood have also been used in numerical modelling. Modified Hashin-Hill yield criterion implemented in a user subroutine has been used to model a bolted glulam beam-to-column connection. The model was able to simulate the cracking of wood similar to that seen in the experiment [13]. A more sophisticated constitutive model combining a number of sub-models, including orthotropic elasticity, Yamada-Sun failure criteria, softening, and hardening, was incorporated into a user subroutine for Abaqus [20]. The behaviour of wood in compression was modelled using strain-based damage evolution, plastic-flow, and hardening law. This model was able to reasonably simulate the mechanical as well as thermal behaviour of wood in bending and connections; however, creates a large burden on the researcher to write the subroutine and validate the subroutine against experimental data prior to predictive modelling.

5 CONCLUSIONS

Seismic events can create both force and deformation demands on a building. Beam-to-column connections must be capable of deforming with the rest of the structure during these events while maintaining load-carrying capacity. This behaviour is referred to as deformation compatibility and can be quantified through experimental testing. Because of the novelty of mass timber as a structural material, very limited experimental data has been produced on the deformation compatibility behaviour of glulam beam-to-column connections, therefore this behaviour is not yet well understood. To meet this demand of experimental data, five different connection designs were investigated. Three were custom connections (C1-KP, C2-N, and C3-N2), and two were pre-engineered connections (C4-MEG and C5-MTCP).

Large scale monotonic tests were performed on connections to a target deformation of 7.2% drift. Larger lateral forces were present in connection C3-N2 than C2-N, indicating the addition of compressible insulation increased capacity in the connection. Connection C5-MTCP had the largest initial stiffness and secant stiffness, while C4-MEG had the had the second lowest initial stiffness, and the largest yield displacement, indicating more ductile behaviour.

In cyclic tests, the cycle of maximum displacement corresponded to a target story drift between 3.81 - 4.0%. The hysteretic force-displacement and moment-rotation behaviour of the connections were analysed, and initial stiffness, secant stiffness, and energy dissipation of the connections was compared. Pre-engineered connections had larger total energy dissipation when compared to the custom connections. The EVDR of pre-engineered connections generally increased throughout testing, while custom connections showed a decrease or plateau of

https://doi.org/10.52202/069179-0290

EVDR in the final primary cycles. As damage accumulated, all specimens experienced a degradation of secant stiffness throughout testing. By the final primary cycle of the cyclic testing protocol, all pre-engineered connections had the largest remaining secant stiffness, however, connection C4-MEG demonstrated a much gentler degradation of secant stiffness than the C5-MTCP connection, indicating more ductile behaviour. Similar to the monotonic testing, all connections maintained load carrying capacity throughout the testing protocol.

The data collected within this research is representative only of the five connection designs tested, therefore continued testing and investigation into the behaviour of a wider variety of beam-to-column connections is recommended. Additionally, increasing the cycle of maximum displacement to larger amplitudes would be recommended for future testing, so that the post-peak behaviour of connections could be observed. Examination of the post-peak behaviour of connections would allow for the calculation of connection ductility, as well as comparisons of post-peak degradation of strength and stiffness between different connection designs.

Additional research on numerical modelling methodologies for simulating these connections is necessary to expand the body of knowledge on the behaviour of glulam beam-to-column connections. Specifically, research on the development of material models that simulate crushing of timber in compression is necessary to perform predictive modelling of mass timber connections.

SEISMIC CONNECTIONS FOR CLT STRUCTURES WITH TUBULAR ELEMENTS AND UNCOUPLED TENSION-SHEAR INTERACTION

Luca Marchi[1], Davide Trutalli[1], Luca Pozza[2], Roberto Scotta[1]

ABSTRACT: Cross Laminated Timber (CLT) panels possess high in-plane stiffness, and traditional earthquake resistant connections, originally designed to counteract separately rocking and sliding phenomena, are subjected to a combined tension-shear interaction. Detailed models involving tension-shear interaction may be considered unpractical to apply by designers with the dilemma of simpler ones not representative of the real behaviour of the panels. This work presents the mechanical response of a novel connection system which limits tension-shear interaction aiming to contribute towards the reliability of capacity design of CLT shear wall assemblies. Such connection system extends the concept of rocking shear-walls with shear keys used for high-rise CLT buildings to the case of low-to medium rise buildings. Latest results from monotonic and cyclic-loading experimental tests of the connection device are presented and the design implication of this solution is analysed via a comparative analysis adopting non-linear numerical simulations of a CLT structure.

KEYWORDS: Earthquake resistant connections, Cross-laminated Timber, Aluminium, Shear test

1 INTRODUCTION

Cross Laminated Timber (CLT) are large factory-manufactured panels commonly used in mass timber construction as both horizontal and vertical structural elements due to their flexibility in interpreting challenging architectural solutions. The high-level of prefabrication ensures a reduced time for the erection of such systems. Their high performance/weight ratio justifies their acceptance in several high-seismicity areas such as Mediterranean European countries, North American territories, Japan and New Zealand.

The seismic response of these structures is strongly dependent on the cyclic behaviour of connections between panels and to foundation because CLT panels behave almost elastically under in-plane forces. In particular when large-sized panels are used where the density of connections is drastically decreased [1]. Although a great effort of the research is toward the developing of novel dissipative connection/damping systems to be used for the realization of tall buildings, CLT is still mostly used to realize low-to medium rise buildings, e.g., residential dwellings and public buildings (schools, community centers). Here, traditional hold-downs and angle brackets, initially designed for intrinsically ductile and dissipative platform-frame structures, are still the most employed fastening systems.

As CLT panels possess high shear stiffness [2], these traditional connections, originally designed to counteract separately rocking (uplift) and sliding (shear) phenomena, are subjected to a combined tension-shear interaction [3, 4]. Furthermore, application of capacity design principles requires the shear connection to be over designed for strength and stiffness [5]; this may inevitably lead to an even higher tension-shear interaction of the connections. This can result in lower-dissipative cyclic response and often unpredictable connection failure; hence conservative behaviour factors are adopted in various International Seismic Codes [6, 7] and revision proposals [8].

Detailed models involving tension-shear interaction may be considered unpractical to apply by designers [9] with the dilemma of simpler ones not representative of the real behaviour of the panels. Therefore, a high number of fasteners are generally required as shear connectors to fulfill capacity design resulting in economically inefficient solutions. From a practical point of view novel connection systems able to simplify and speed up the realization of wall-floor-wall nodes in CLT structures are of paramount relevance.

This paper presents the mechanical response of a novel connection system which limits tension-shear interaction aiming to contribute towards the reliability of capacity design of CLT shear wall assemblies. The idea is to exploit metallic tubular elements inserted edge-wise into predrilled holes operating as shear-keys. They can also operate as tension-resistant connection (such as hold-downs) if the tubular connectors are connected to CLT with screws or dowels. Such connection system extends the concept of rocking shear-walls with shear keys used for high-rise CLT buildings [10] to the case of low-to medium rise buildings. Latest results from monotonic and cyclic-loading experimental tests of the connection device are presented. The obtained mechanical parameters are

compared in terms of stiffness, strength, and ductility to that of traditional connection systems and to analytical and numerical models.

2 DESIGN AND CONCEIVING

2.1 OVERVIEW OF THE CONNECTION

The investigated connection system exploits tubular elements realized from extruded steel or aluminium inserted into pre-drilled holes at the edge of the timber panels (Figure 1). The location of the tubes along the wall is equivalent to standard hold-down and angle brackets connections, with the elements on the wall edges contrasting the wall rocking and the inner ones opposing to the horizontal slip. While the outer tubes are connected to the wall with dowel-type fasteners to provide a vertical restraint, the inner tubes are meant to work as traditional shear-keys thus restraining the horizontal displacements. The complex tension-shear interaction is almost completely avoided by simply increasing the diameter of the holes on the floor panel where the outer tubes are placed, i.e., forcing the transmission of the shear force by contact of the inner tubes only (Figure 2).

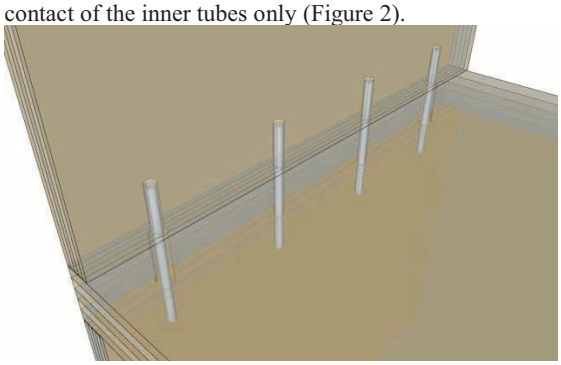

Figure 1: *Conceptualization of the analysed connection system*

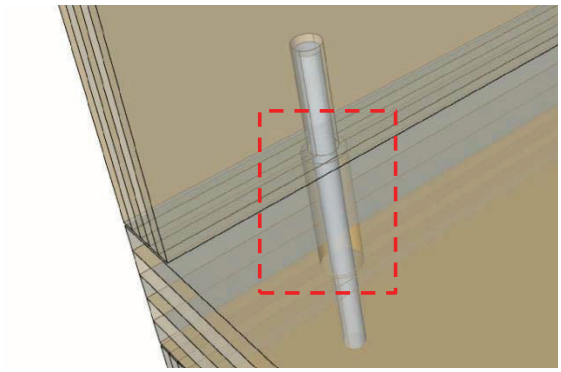

Figure 2: *Gap of the floor panel for the edge connections*

The material properties of the tube are of utmost importance in this application. Aluminium is already being successfully applied as good medium to realize other timber joints thanks to its lightness and good mechanical performance [11, 12]. In this case, its use as tension-resistant connection would benefit for the types of screws or dowels as less drilling force is required to pass through the tube walls. On the contrary, its lower stiffness compared to steel may provide reduced performance as a shear-key connector.

2.2 ANALYTICAL DESIGN

The conceiving phase started with the analytical determination of the load-carrying capacity of a dowel-type fastener drilled into the tube and locking it to the CLT panel. This was mandatory to overdesign the tube cross-section, namely diameter and thickness that guarantee a sufficient overstrength to the element.

The CLT panel thickness and layer arrangement implicitly define the possible failure modes of the dowel-type fasteners used to fasten the tube to the wooden element. Considering that the connection was purposely designed to be used into a low-rise structure (up to two-three storey high), the reference CLT wall panel thickness can be figured in the range of 100-140 mm in a 3-to-5-layer configuration.

Within the 3-layer configuration it is likely possible that the tube will exploit the whole inner layer and therefore the possible failure modes for this condition are already included in the Eurocode 5 [13] for the case of steel plates of any thickness as the central member of a double shear connection:

$$F_{v,Rk} = min \begin{cases} f_{h,k} t d & (f) \\ f_{h,k} t\, d \left[\sqrt{2 + \frac{4 M_{y,Rk}}{f_{h,k} d t^2}} - 1 \right] + \frac{F_{ax,Rk}}{4} & (g) \\ 2{,}3 \sqrt{M_{y,Rk} f_{h,k} d} + \frac{F_{ax,Rk}}{4} & (h) \end{cases}$$

For a 5-layer configuration the failure modes can be reconstructed by following the approach of [14] starting from the Johansen model. In summary, the possibility to obtain one or two plastic hinges is split into two sub-cases as reported in the equations below.

Mode 1 - wood embedment:

$$F_{v,Rk} = f_h \cdot d \cdot t \tag{1}$$

Mode 2.1 - one plastic hinge:

$$F_{v,Rk} = f_h \cdot d \cdot t \left(\sqrt{2} \sqrt{\beta \left[\beta (1-\psi)^2 + \psi (2-\psi) + \frac{M_{y,Rk}}{f_{h1} \cdot d \cdot t^2} \right]} + \beta (\psi - 1) - \psi \right) \tag{2}$$

Mode 2.2 - one plastic hinge:

$$F_{v,Rk} = f_h \cdot d \cdot t \left(\sqrt{2} \sqrt{2 + \psi (\psi - 2) - \beta (1-\psi)^2 + \frac{M_{y,Rk}}{f_{h1} \cdot d \cdot t^2}} + \beta (1-\psi) + \psi - 2 \right) \tag{3}$$

Mode 3.1 - two plastic hinges:

$$F_{v,Rk} = \sqrt{2} \sqrt{2 M_{y,Rk} \cdot f_{h1} \cdot d \cdot \beta} \tag{4}$$

Mode 3.2 - two plastic hinges:

https://doi.org/10.52202/069179-0291

$$F_{v,Rk} = f_h \cdot d \cdot t \left(\sqrt{\left[(1-\psi)^2(1-\beta) + 4\frac{M_{y,Rk}}{f_{h1} \cdot d \cdot t^2} \right]} + \beta(1-\psi) + \psi - 1 \right) \quad (5)$$

The tensile strength of the tube could be easily calculated following provisions from Eurocode 3 [15] or 9 [16], whether steel or aluminium is used.
Main outcomes from the analytical approach suggested that a 4-mm thick extruded profile of aluminium alloy equal to EN AW 6082 [17] with an external diameter equal to 40mm could be used for the purpose. The fastening of the tube shall be entrusted to self-drilling dowels with nominal diameter equal to 7 mm realized with steel grade S275.

3 TENSION-RESISTING JOINT: EXPERIMENTAL TESTS

Monotonic tests were performed to assess the main mechanical parameters of the joint if exploited as tension-resistant element.

3.1 SPECIMEN CHARACTERISTICS

The joint in the tension-resisting configuration was tested according to a simple compression setup using a universal testing machine (Figure 3). The CLT specimens were cut from a 5 layer 100-mm thick CLT panel (20-20-20-20-20) with dimension sufficient to respect actual edge distance provisions valid for the chosen connections. The resistance of the self-drilling was evaluated in two distinct configurations:

- a single dowel with length equal to 93mm placed orthogonally to the CLT panel face;
- a single dowel with length equal to 133mm placed at an angle of 45° to the CLT panel face.

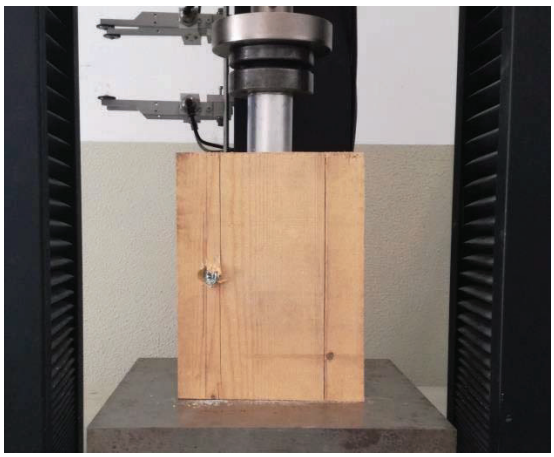

Figure 3: *Tensile test*

3.2 RESULTS

Preliminary tests were conducted to assess the contribution of friction between tube and CLT by pushing the tube into the hole without the insertion of the dowels. Results shows a resistance of about 500N to be reached before the triggering of the slippage phenomena. Force increased up to 1450N at 20mm of insertion.

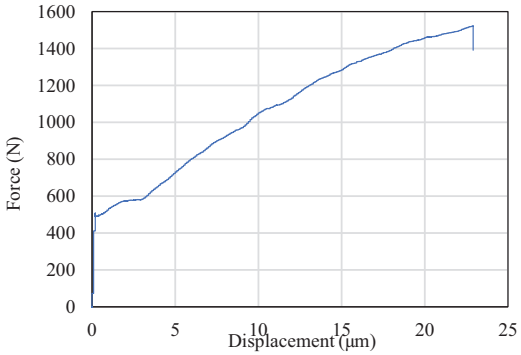

Figure 4: *Frictional contribution between tube and panel*

All monotonic tests returned a combined wood embedment failure coupled with the formation of two plastic hinges, technically the most ductile failure mode achievable for a dowel-type fastener (Figure 5).

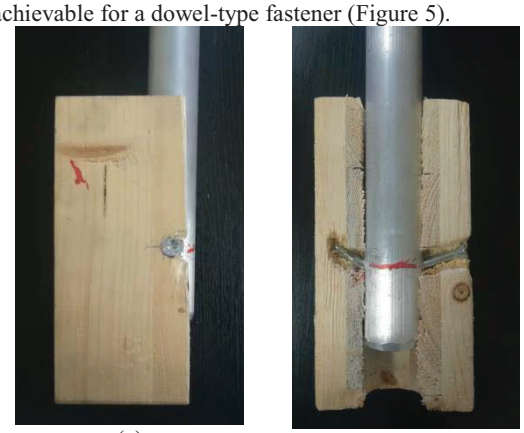

Figure 5: *Specimen inspection at failure*

Table 1 summarize the mechanical parameters calculated from the force displacement curves, for which average trends are reported in Figure 6 and Figure 7.

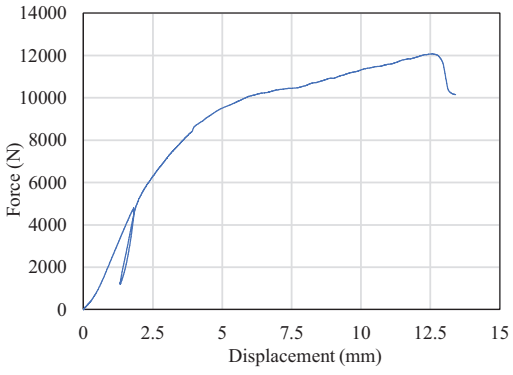

Figure 6: *Average force-displacement curve of a single dowel orthogonal to the panel (90°)*

https://doi.org/10.52202/069179-0291

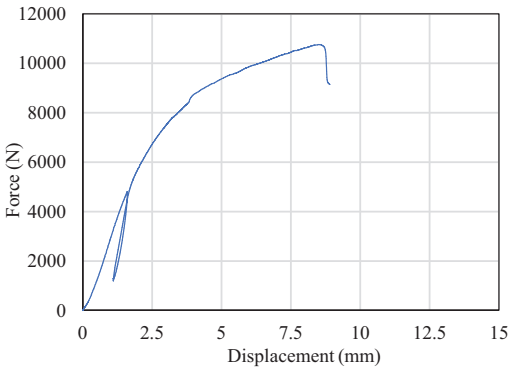

Figure 7: *Average force-displacement curve of a single dowel orthogonal to the panel (45°)*

dowel; iii) elastic-plastic orthotropic response for the timber element.

Large deformations and frictional contact laws were used to simulate the interaction (i.e., force transfer) between the different elements. The CLT panel was discretized according to the different composing layers. A bonded contact was applied between the different layers.

The simulated timber elements were a 200-mm thick CLT panel working as a floor, and a 100-mm thick CLT panel as a wall. A 5-layer configuration was chosen for both elements with 20 mm and 40 mm of thickness for the floor and wall respectively. Symmetry planes were adopted to reduce the computational costs of the models (Figure 8).

Firstly, a parametric analysis was performed to evaluate the changes of the mechanical performance by varying three key parameters defining the aluminium tube: strength class (yielding and ultimate strength in detail),

Table 1: *Summary of tensile tests between the two tested fastening configurations*

	F_{MAX} [kN]	d_{FMAX} [mm]	F_Y [kN]	d_{FY} [mm]	K_{el} [kN/mm]	K_{pl} [kN/mm]	μ [-]	Ductiliy class [-]
Angle 90°								
Mean	12.01	14.80	8.99	2.15	4.60	0.24	7.53	H
Dev.St.	0.62	4.72	1.01	0.13	0.61	0.03		
5% Fractile	10.46		**6.48**					
COV	5.20%	31.88%	11.21%	6.21%	13.33%	10.54%		
Angle 45°								
Mean	11.15	9.95	9.63	2.42	4.93	0.21	5.05	M
Dev.St.	1.09	1.68	1.25	0.31	0.88	0.10		
5% Fractile	8.44		6.53					
COV	9.80%	16.84%	12.98%	12.78%	17.85%	48.84%		

The two configurations show comparable values of the yielding point, expressed by the resistance F_y and displacement d_y (evaluated according to EN 12512 method b [18]). A more pronounced post-elastic response of the dowels placed at 90° allows to reach a greater static ductility value. This returns that only the first configuration can be assigned to the highest ductility class according to [8].

Considering an average load bearing capacity at yielding of about 6.5 kN it results that about 6 to 8 dowels should be fastened to the same tube to obtain an overall capacity comparable to traditional hold-downs fastened with annular ringed-shank nails.

4 SHEAR-RESISTING JOINT: NUMERICAL SIMULATIONS

Given the high complexity and effort of designing a test to investigate in deep the behaviour of the tubular element when used as a shear-resisting connection, a 3D finite element model of the joint was developed with the commercial software Ansys Mechanical Workbench to test the performance of the joint. The analyses included material non-linearities for all the components: i) multilinear Ramberg-Osgood law [19] for the aluminium element; ii) bilinear elastic-plastic constitutive law for the

external diameter and thickness. This becomes important not to overdesign the tube but also to obtain a cost-efficient solution.

A parametric analysis was performed to assess the different response to be obtained when the floor panel is oriented parallel or perpendicular to the wall. Additionally, the contribution of the frictional forces that can develop at the wall-to-panel contact interface and at the CLT-tube interface was also included in the parametric analysis.

4.1 RESULTS

Sections 4.1.1 and 4.1.2 summarize the results obtained by considering the CLT panel representing the floor oriented parallel or perpendicular to the wall respectively. By comparing Figure 8 to Figure 11 it emerges the different location of the plastic hinge that is the consequence of the different stiffness of the external layer of the floor panel (light shaded elements on the left of the figure).

Considering a reference displacement of 15 mm and frictionless boundary conditions, it results in an important difference between the two panel orientations with an applied force equal to 93.5 kN for a parallel layout and 76.6 kN (-18%). Introducing friction at both interfaces raise the force level up to 113.9 kN and 91.1 kN respectively (-20%).

https://doi.org/10.52202/069179-0291

The contribution of the frictional phenomena can also be appreciated from the superposition of the force-displacement curves obtained from the parametric analysis. Such occurrence, to be neglected in the design phase, can produce an increase of the total shear force between 8 to 10% attributed to the panel-to-panel interface and an additional 10% to the tube-to-CLT interface.

By adopting the same bilinearization method of the tensile-resisting configuration the yielding force F_y can be estimated between 50 to 70kN; within this range of shear load bearing capacity, a single tube can easily provide similar or higher performance of the last generation of angle-brackets.

VARIABILITY OF THE CROSS-LAMINATED TIMBER (CLT) SINGLE-PANEL SHEAR WALLS' RESPONSE UNDER IN-PLANE LATERAL LOADS

Vincenzo Rinaldi[1], Igor Gavrić[2], Massimo Fragiacomo[3]

ABSTRACT: In the past, several studies analysed the seismic response of Cross-Laminated Timber (CLT) shear wall systems using experimental tests and numerical analyses. Usually, these analyses were based on the average mechanical properties of connections, which have the largest effect on the non-linear response of CLT shear walls. This paper investigates the non-linear in-plane response variability of single-panel CLT shear walls accounting for the actual scatter of the connection's mechanical properties. Based on previously obtained experimental results of traditional hold-downs and angle brackets, the response of CLT shear walls subjected to in-plane lateral loads is analysed considering the main engineering parameters variability, such as strength, deformation, and ductility through a simulation approach based on random sampling. The study considers three different shear walls width-to-height aspect ratios (1:3, 1:1, 3:1) analysed by changing the vertical loads. For each scenario, one thousand of numerical analyses are carried out by varying the experimental mechanical properties of every single connection. The outcomes of this study show the variability of the non-linear numerical response of single-panel CLT shear walls, which was found to decrease with an increase in the length of the shear wall, while the engineering parameters varied in a range of 1% to 17%.

KEYWORDS: Cross-Laminated Timber, shear wall, variability, non-linear response, mechanical connections.

1 INTRODUCTION

The numerical modelling of Cross-Laminated Timber (CLT) shear wall behaviour under lateral loads is still a subject of research. Among the proposed modelling strategies [1], several authors implemented the so-called component-level (CL) modelling approach since it allows a detailed analysis of the non-linear behaviour. The CL strategy considers each structural system component (i.e. CLT panels, connections) with linear/non-linear behaviour calibrated through experimental tests or analytical equations. Although significant efforts have been made to investigate the CLT shear walls' behaviour [2,3], no research has been conducted to estimate the variability of the non-linear response due to the variability of the connections' actual behaviour.

The average experimentally obtained properties are commonly used to perform non-linear numerical analyses when adopting a CL approach [4,5,6].

This approach is obviously correct when assessing a CLT shear wall's performance. However, for all structural systems, the seismic response of CLT shear walls is ruled by physical aspects of each structural component, including the deformation mechanisms (CLT shear and bending deformations, sliding and rocking) and the variable behaviour of the structural components.

In the case of CLT shear walls without openings, the total lateral deformation of a shear wall [7] is mostly influenced by the connections' flexibility instead of the panel deformability.

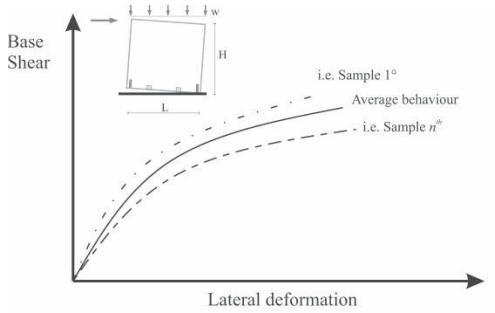

Figure 1: *Different response scenarios due to the connections' variability for the same CLT shear wall configuration*

Due to this phenomenon, the response of a CLT shear wall is predominantly affected by the connection's behaviour [8]. As shown in Figure 1, a CLT shear wall could result in different force-displacement responses due to the variability of the connections' mechanical properties.

In most experimental programmes on timber connections [9-11], a well-defined connection is tested several times to investigate the actual behaviour and the variability of the connection's response. It should be highlighted that mechanical timber connections are prone to a high scatter of results due to the natural variability of the timber as a material [12]. In fact, the fasteners of a connection may be fixed into a quite defective part of the wood (i.e. knot) or layer with less strength which can completely influence the overall behaviour of a connection.

In this paper, several CLT single-panel shear wall setups are numerically analysed to investigate the effects of the mechanical variability of traditional CLT connections.
A parametric analysis is carried out by examining three different shear wall aspect ratios (1:3, 1:1, 3:1) varying the levels of applied vertical loads and modifying the experimental backbone curves of each connection of the shear wall through a simulation approach based on random sampling. According to this procedure, each configuration is analysed in terms of aspect ratio and vertical load. The specific objectives of this study are to investigate:

- the variability of CLT shear walls response under different conditions (aspect ratios and vertical loads);
- the variability of the main engineering output parameters, such as strength, deformation and ductility.

2 METHODOLOGY

The randomness and the response variability of single-panel CLT shear wall are investigated through a non-parametric stochastic simulation approach.
The study is based on four main phases: *i)* collection of the experimental data of the mechanical connections and calibration of the numerical parameters, *ii)* definition and validation of a numerical model, *iii)* definition of the shear walls configurations in terms of geometry, vertical loads and number of connections, and *iv)* random sampling generation and analyses of a thousand different CLT shear walls for each configuration.
Non-Linear Static Analyses (NLSA) are used to estimate and compare the variability of strength, deformation, and ductility of each shear wall. The pushover curves are linearised according to EN 12512 [14]. Figure 2 shows the adopted nomenclature.

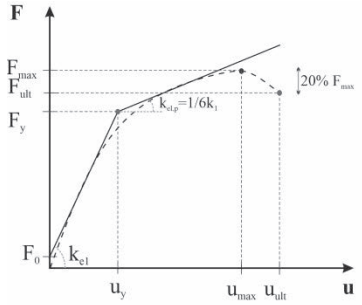

Figure 2: *Linearisation and definition of the parameters according to EN 12512 [14]*

F_0 is the intercept between the elastic branch representing elastic stiffness k_{el} and the y-axis; k_{el} is defined as the secant stiffness between 10% and 40% of the maximum strength F_{max}; $k_{el,pl}$ is the post-elastic branch tangent to the experimental curve and inclined by 1/6 k_{el}. The points (F_y, u_y), (F_{max}, u_{max}) and (F_{ult}, u_{ult}) represent the conventional yielding, maximum strength and ultimate capacity, respectively, where the last one is estimated at the strength drop equal to 20% of F_{max}.

2.1 EXPERIMENTAL DATA AND NUMERICAL CALIBRATION

Traditional timber-to-steel connections such as Hold-Downs (HD) and Angle-Brackets (AB) are considered in this study. The backbone curves of the HD and AB are based on existing experimental data [9]. HD type WHT540 with twelve 4×60 mm annular shanked nails and AB type BMF 90 × 116 × 48 × 3 with 11 annular shanked nails are used (Figure 3).

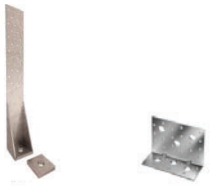

Figure 3: *(a) hold-downs (HD) and (b) angle brackets (AB)*

Several specimens were tested for each configuration of HDs and ABs during the experimental programme (tension and shear tests). Results are available for seven samples of HDs in tension, six samples of AB in tension and six samples of AB in shear and were implemented in this work.
A uni-directional vertical-uplift behaviour is assumed for HD since they do not provide a significant contribution in horizontal-shear direction and assuming a bi-directional behaviour would yield too conservative results [7]. A bi-directional behaviour is considered for AB due to the comparable load-bearing capacity in both directions, shear (horizontal-shear) and tension (vertical-uplift).
The "SAWSMaterial" [13] OpenSees numerical model was implemented in the FE model to reproduce the connections' behaviour. All nineteen experimental curves (seven HDs in tension and six ABs in shear and tension) were calibrated based on a fitting procedure. Figure 4 displays the experimental and numerical curves of the analysed connections. The curves are derived from the first backbone curve of the connections' cyclic tests.

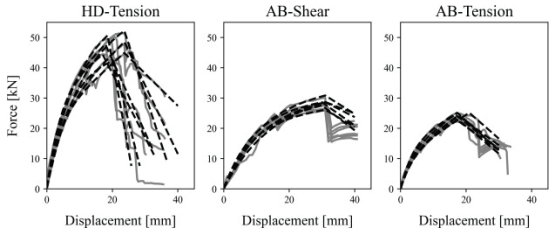

Figure 4: *Experimental data (solid lines) and numerical calibration (dashed lines): HD tension tests (left); AB shear tests (centre); AB tension tests (right)*

https://doi.org/10.52202/069179-0292

Since ABs are considered with a bi-directional behaviour, thirty-six types of different ABs are defined by combining the six experimental tests in the two main directions.
The experimental data highlights the general scatter between the capacity curves. HDs show a higher variation of the backbone curves compared to ABs, as shown in Figure 4. HDs have a higher scatter in terms of strength compared to the ABs. The main reason is the nature of the failure mechanisms: a sudden significant force drop can be recognised in HD tension tests due to several nails failing simultaneously in shear, including cap tear-off. On the other hands, ABs failure mechanism was a combination of progressive nails yielding, deformation of the brackets and embedment of CLT [9].

2.2 NUMERICAL MODEL OF THE CLT SHEAR WALL AND VALIDATION

A simplified two-dimensional FE model is implemented for the non-linear analyses of the shear wall, as reported in [6]. The model consists of an assembly of rigid and flexible frames to reproduce the CLT wall, whereas zero-length springs schematise the connections (Figure 5). The use of a frame-model instead of area-model for the CLT panels allowed the user to reduce the computational effort. As a shear-type model, the frame model includes the CLT panel deformability through analytical equations due to shear and bending deformation. The horizontal frames placed at the top and the bottom of the wall are assumed as rigid, whereas the two vertical frames on the left and the right edge of the wall are modelled as flexible frames. The flexibility of the vertical frames is calibrated by modifying the second moment of area of the element to account for the overall stiffness of the CLT panel.
All CLT panels are 120 mm thick, made of 5-layers (v30-20-v20-20-v30) with timber strength class C24, where "v" represents vertical orientation of laminations.
Axially rigid friction-contact elements with a Coulomb friction coefficient equal to 0.1 were adopted to simulate the steel-to-timber contact. HDs are modelled with a uni-directional behaviour, while ABs are modelled with bi-directional behaviour. A numerical uncoupled behaviour is assumed for the two orthogonal non-linear laws of the ABs.

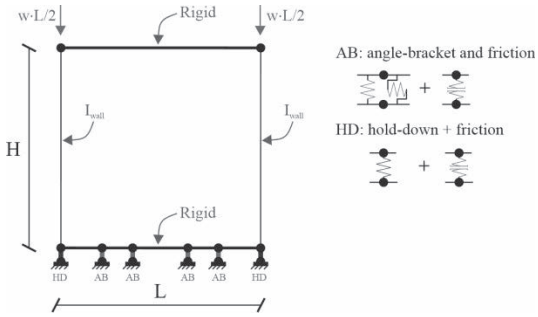

Figure 5: *Finite element model of a CLT shear wall*

The FE model is validated by comparing the experimental response of a CLT shear wall, shown in Figure 6 [7]. The validation was conducted through a NLSA numerical model, where the same connections (HDs and ABs), presented in Section 2.1, were used, in both numerical model and the experimental tests.

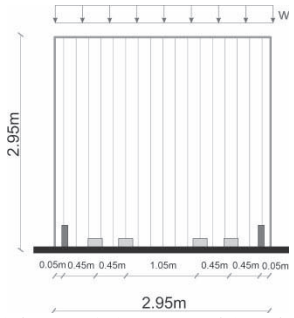

Figure 6: *Validation of the FE model and the parametric procedure of test I.1 [7] with w=18.5kN/m*

The experimental-numerical comparison is made in terms of a mean numerical curve obtained from one thousand different FE shear walls developed with a parametric procedure.
The mean numerical behaviour is reproduced by averaging the parameters of the numerical model respectively for HD in tension and AB in shear and tension. The parametric procedure generated thousand FE shear wall configurations by randomly combining and modifying the properties of every single connection. The parametric shear walls were defined using a random selection among seven different HD responses and thirty-six ABs responses.
As visible in Figure 7, the mean and the parametric curves fit well with the backbone curves of the cyclic experimental test. In addition, for the specific shear wall test, the parametric analysis shows in detail that the maximum strength and the degradation branch have high variability compared to the wall elastic stiffness.

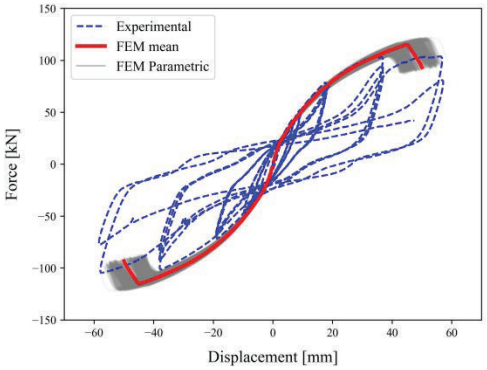

Figure 7: *Numerical validation of test I.1 [7]. Mean numerical curve (red) and a thousand of FE shear walls (gray)*

2.3 CLT SHEAR WALL CONFIGURATIONS

A parametric matrix of CLT shear wall configurations was defined to investigate: *i)* the CLT shear walls response under different conditions and *ii)* the variability of the main engineering parameters (Table 1).

The study considers three different shear wall aspect ratios L:H equal to 1:3 (1 m x 3 m), 1:1 (3 m x 3 m) and 3:1 (9 m x 3 m). The number of ABs is set with 60 cm spacing between the ABs, whereas one HD is placed at each corner of the CLT wall. Three different vertical loads (0 kN/m, 10 kN/m, 20 kN/m) are defined to compare the influence of the gravity loads. A total of nine CLT shear wall configurations are thus defined.

Table 1: *Matrix of the shear walls' configurations for the parametric study*

Vertical load [kN/m]	ID	Aspect ratio L:H		
		1:3 (1m x 3m) 1AB+2HD	1:1 (3m x 3m) 4AB+2HD	3:1 (9m x 3m) 12AB+2HD
0.0	#1	1:3	1:1	3:1
10.0	#2	1:3	1:1	3:1
20.0	#3	1:3	1:1	3:1

2.4 RANDOM SAMPLING AND ANALYSES

Each configuration in Table 1 was analysed with one thousand different shear wall models where each connection has different properties for HDs and ABs randomly generated by combining seven HDs backbone curves and thirty-six types of ABs.

The generation of all shear walls is performed with a Python script using the same random seed to keep the properties and location of each connection constant for the same aspect ratio in all vertical load cases. After applying the vertical loads, each shear wall is analysed through a NLSA with a displacement control approach.

In a post-processing phase, all curves are linearised with EN 12512, and engineering parameters are estimated.

3 RESULTS

Figure 8 shows the pushover curves of all configurations. The outcomes show how the vertical load increases the shear wall's total strength capacity and stiffness. This effect is most evident for 1:3 and 1:1 shear walls where, as expected, the rocking mechanism governed the deformation capacity of the shear wall. The 3:1 aspect ratio is hardly affected by the vertical load variations since the predominant deformation mechanism is sliding. The variability of connection capacity reported in Section 2.1 is evident for 1:3 shear walls, less so for 1:1 shear walls and negligible for 3:1 shear walls. Seven "groups" of pushover curves can be recognised for the 1:3 case. These groups are strictly related to the experimental response of the seven HDs tested since they mostly affect the overall behaviour of the shear wall due to the rocking mechanism. Tables 2-4 list the outcomes in terms of mean value and Coefficient of Variation (CoV) for all configurations, whereas Figures 9-12 represent the CoV of F_y, F_{max}, k_{el} and μ.

As a general trend, the CoV decreases with the length of the shear wall, while they show a limited variation with the vertical loads. The stiffness $k_{el,}$ and $k_{el,p}$ have the same CoV since they depend on each other according to EN 12512.

k_{el}	9.5-9.9	4.9-5.2	2.3-2.8
$k_{el,p}$	9.5-9.9	4.9-5.2	2.3-2.8
μ	12.7-15.9	8.5-10	3.0-3.3

To compare the overall variability, Table 5 summarises the minimum and maximum CoV of all parameters of the three configurations. The following remarks can be done:

- The CoV tends to decrease with the length of the shear wall;
- The strength F_0 shows the most significant variation among all configurations, with the lowest minimum and highest maximum coefficient of variation observed in configuration 1:3 due to the significant role played by the vertical loads;
- The strength F_y is relatively stable across all configurations, with a low coefficient of variation observed in all cases;
- The displacement u_y exhibits significant variations in all configurations, with a higher CoV than the other parameters;
- The parameters F_{max}, u_{max}, F_{ult}, and u_{ult} show variability across the different configurations, but the differences in the CoV among configurations are relatively small;
- The stiffnesses k_{el} and $k_{el,p}$ have the same CoV across all configurations (due to the EN 12512 linearisation);
- The ductility μ significantly varies among the configurations, with the lowest minimum and highest maximum coefficient of variation observed in configuration 1:3.

4 CONCLUSIONS

This paper investigates the variability of Cross-Laminated Timber (CLT) single-panel shear walls' response under in-plane lateral loads. The variability is considered by performing a parametric analysis on three different CLT shear wall configurations consisting of one thousand different finite element shear walls. The mechanical properties of all connections, based on experimental results, are randomly sampled to investigate several possible scenarios of the shear wall.

The results show that all mechanical properties, such as strength (yield, maximum, ultimate), stiffness (elastic, post-elastic), deformations (yield, maximum, ultimate) and ductility are influenced by the geometry of the shear wall and the vertical loads. As a general trend, the Coefficient of Variation (CoV) decreases with the length of the shear wall, whereas it shows limited variation with the vertical loads. All parameters have a different range of minimum and maximum CoV, varying from 1% to 17%.

Future studies are planned to investigate additional shear wall parameters and configurations and extend the analysis to multi-panel CLT shear walls.

SHEAR PERFORMANCE ESTIMATION OF WOODEN LATHS AND PLASTER WALLS THROUGH EXPERIMENTS AND NUMERICAL ANALYSIS

Naoyuki Matsumoto[1], Katsuhiko Yamawaki[2], Kaori Fujita[3]

ABSTRACT: Structural tests and analytical modelling were conducted to clarify the seismic performance of wooden laths and plaster walls, which are one of the representative types of modern Japanese wooden buildings. Wooden laths and plaster is a construction method where plaster is applied to substrates made with 50 mm wide and 10 mm thick boards. In this study, the plaster wall was fabricated with the four sides of the wall restrained by the frame (columns, a lintel, and a baseboard), and static lateral loading tests were conducted. The results indicated that the wall has two types of resistance mechanisms, one at the point of initial stiffness and the other at the point of reaching the maximum bearing capacity, due to the large influence of the wall restraint by the frame. Secondly, shear element tests of small walls and shear tests of plaster materials were conducted to simulate the two types of resistance mechanisms. Finally, two numerical analysis models were presented to estimate the initial stiffness and maximum bearing capacity in a full-scale test. The numerical analyses showed an initial stiffness of 80% and a maximum bearing capacity of 130%.

1 INTRODUCTION

1.1 BACKGROUND

Modern Japanese wooden buildings, from the Meiji Restoration to World War II, are built based on the mixed techniques of traditional and Western buildings, and many do not have reliable standards or data for structural evaluation. With the increase in the preservation and rehabilitation of modern wooden buildings, proper evaluations of their structural mechanisms are imminent. Few studies have focused on the structural systems of modern structural walls, and a variety of walls was found to have surplus capacity [1-3]. This study focuses on a wall with wooden laths as substrates and plaster as the finish. Although this type of wall is one of the most prevalent and existing experiments have reported the reinforcement effect of the plaster finish and its tough behavior, even after plaster failure, its structural mechanism has not yet been clarified. Therefore, establishing a numerical estimation method for evaluating the structural performance of wooden laths and plaster walls will lead to more flexible and appropriate seismic diagnoses and evaluations of modern wooden buildings.

1.2 PURPOSE AND METHODOLOGY

This study aims to experimentally elucidate the horizontal force resistance mechanisms of wooden laths and plaster walls and proposes a mechanical model to estimate the initial stiffness and maximum load as the basic structural performance of the wall. Here, the composition pattern of laths was based on the Japanese style; that is, laths were nailed only between the columns on the small studs next to them **(Figure 1)**.

First, we conducted full-scale lateral loading tests to understand the typical load deformation relationships and failure patterns and then proposed two phases of resistant systems. Subsequently, element tests on the shear performance of the plaster, lath-and-nails, and small laths-and-plaster walls were performed. Finally, in combination with the resulting data, an analytical model is proposed to assume the initial stiffness and maximum load.

2 WOODEN LATHS AND PLASTER

Wooden laths and plaster finishes quickly prevailed in Japan after the Meiji Restoration (1868), referring to the Western techniques and combining them with traditional plastering techniques. Thin wooden lath boards (approximately 50 mm wide and 10 mm thick) were used as substrates, and they were nailed to the columns. Hemp ropes were also nailed for fastening plaster and the laths, and plaster mixed with seaweed glue was applied in layers of approximately 20 mm. This method is commonly used for the walls of Western-style buildings as a substitute for mud walls and is sometimes applied to ceilings. **Figure 1** shows a schematic of wooden laths and plaster walls.

3 FULL-SCALE LATERAL LOADING TESTS

3.1 SUMMARY OF LATERAL LOADING TESTS

Full-scale static loading tests were conducted to clarify the horizontal force resistance mechanisms of the wooden laths and plaster walls. The dimensions of the specimens were based on those of a cultural heritage house built in Tokyo in 1928. To understand clearly the differences in the structural performances and mechanisms, the same tests were conducted on a frame wall (only with penetrating beams) with the same dimensions.

3.2 SPECIMENS

The specifications of the specimens are shown in **Figure 2**. The specimen was made with traditional unit wall dimensions of 910 mm × 2783 mm, referring to the walls of an important cultural property building located in Tokyo (constructed in 1928, modern Japanese-style architecture). The wall has four penetrating beams, two ledger strips at the bottom, and a void below the floor level. The wall was divided into upper and lower sections by a nailed lintel, and at the bottom of the plaster wall, a baseboard was inserted and nailed to the column.

The substrate of the wall was made of 50 mm wide and 8 mm thick wooden lath nailed to the pillar frames, and plaster was applied over the laths. The formulation of the plaster is listed in **Table 2**. Three types of plaster were used: undercoat, middle coat, and finish coat. The formulations conformed to the specifications of the buildings used as the reference. The materials used were slaked lime, sand, hemp fiber, seaweed glue, and water. The plaster material for each layer was prepared by first making a mixture of glue, slaked lime, and hemp fiber, called "*Tsuta-awase*," and then mixing sand into the mixture as needed. The total plaster thickness was approximately 20 mm.

Table 1: *Specifications of specimens [lath and plaster + frame]*

Item	Unit	Dimension/Specification
Column	mm	120×120
Beam	mm	120×180
Foundation	mm	135×135
Stud	mm	30×60, 20×25
Species	—	Sugi (Japanese Cedar)
Wooden Lath	mm	50×8×530 @58
Species	—	Sugi (Japanese Cedar)
Nail	mm	N32 * 2 [30 mm apart] @255; shell diameter: 1.9

Table 2: *Formulation of plaster*

Number of layer	Types of layer	unit	Thickness of each layer	Note on formulation
1st and 2nd layer	Under coat	mm	t = 2+1	*Tsuta-awase* (Plaster with hemp) Slaked lime Water
3rd layer	Flatten layer	mm	t = 1	Same as above
4th, 5th, and 6th layer	Middle layer	mm	t = 4+3+3	Plaster : Sand = 1:2 (or more)
7th layer	Finish coat	mm	t = 2	Plaster (shell ash) and algae glue

A static cyclic load ranging from 1/600 rad to 1/10 rad was applied, one cycle at each step. The test was terminated when the maximum load decreased to 80% or reached 1/10 rad.

https://doi.org/10.52202/069179-0293

3.3 RESULTS OF LATERAL LOADING TESTS

The maximum bearing capacity was 8.7 kN (at 1/60 rad). For the wooden lath and plaster wall, approximately 1.9 times higher than the 4.6 kN (at 1/15 rad) of the frame specimen. Elastic stiffness was 7.5 times greater for the wooden lath and plaster wall than for the frame specimen. The deformation angle at the maximum load capacity was +1/60 rad to −1/75 rad for the wooden lath and plaster wall, whereas the load did not decrease for the frame specimen.

Although the frame wall exhibited some damage to the penetrating beams and ledger strips by embedding, the load increased toward the end of the experiment, at 1/10 rad. In contrast, the wooden lath and plaster wall initially showed a stable high stiffness value; however, after exceeding the maximum load capacity, the load decreased to approximately 60% of the maximum load capacity, indicating a brittle behavior. Subsequently, the load gradually increased and was 1.5 times greater than that of the frame specimen, suggesting that the nails and residual plaster were functional up to large deformations.

Based on the observation of the failure conditions, the resistance mechanism of the wooden plaster and lath wall to horizontal forces can be divided into two phases.

The restraint condition of the plaster layer changes as the deformation progresses and the two lateral members (lintel and baseboard) that support the layers gradually break at their connections with the columns. When the two lateral members and joints are sound, as the initial stiffness is maintained, the shear and compression performances of the plaster are dominant, because the four-round members restrain the plaster layer. However, at approximately the maximum load after the loss of the baseboard restraint, the plaster layer was mainly restrained to only two columns, and the plaster layer began rotating. Then, the lateral resistance is dominated by the rotation-shear force between the plaster layer and the plaster filling the gap between the laths. Based on these two phases of resistance mechanisms, we propose an "initial stiffness estimation model" and a "maximum strength estimation model."

4 ELEMENT TESTS ON WOODEN LATHS AND PLASTER

Two types of element tests were conducted to determine the properties required to fulfil the analytical model: (1) shear tests on 580 mm square small laths and plaster walls, and (2) shear tests on the plaster material

4.1 SHEAR TESTS ON 580 MM SQUARE SMALL LATH AND PLASTER WALL

From the observations of the full-scale tests, it was estimated that the shear resistance of the wooden lath and plaster wall, when fully restrained on all four sides, is mainly due to the shear resistance of the nails, compressive effect of the wooden lath and plaster wall, and shear resistance of the plaster key. To verify these effects, elemental specimens of 580 mm square lath and plaster walls were prepared, and shear element experiments were conducted with and without plaster as parameters. The specimens are shown in **Figure 8**. The specifications of the wooden lath and plaster element wall were identical to those of the full-scale specimen.

WL series: Specimens without plaster finish

As the specimen deformed in shear, shear deformation occurred at the joints of each wooden lath to the supporting wood at the edge by the nails and studs. The distance between the edge of the wooden lath and the wood frame was approximately 1 to 1.5 mm, and the contact between the wood frame and the edge of the wooden lath was observed to be approximately 1/15 rad. Subsequently, the nails of the wood-frame support were pulled out and embedded in the wood frame. Although the load did not decrease, cracks and fractures were observed at the edges of the wooden lath. The maximum loads of three specimens were 1.4 kN (0.11 rad.), 1.4 kN (0.12 rad.), and 0.6 kN (0.1 rad.).

WL+P series: Specimens with plaster finish

In the test of WL+P1, the plaster layer gradually began to swell and went up on the wooden frame before it reached the maximum load. Eventually, the shear failure of the plaster at the gap between the wooden laths and the crushing of the plaster layer at the top and bottom edges occurred. However, shear cracks were not observed. However, in the case of WL+P2, although slip was observed at the beginning, the plaster layer did not protrude, but resisted within the wooden frame surface, and the load decreased after the deformation angle of 0.03 rad. Cracks were observed between the top and bottom at a deformation angle of approximately 1/22 rad.

In both specimens, the behavior was similar; compression between the top and bottom edges became remarkable, as the plaster layer did not follow the shear state in the large deformation. The maximum load was 10.7 kN (0.03 rad) for WL+P1 and 9.7 kN (0.036 rad) for WL+P 2.

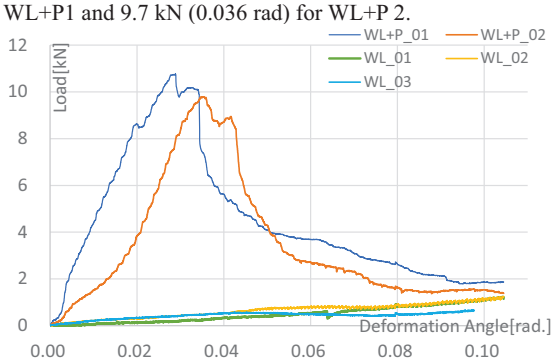

Figure 7: *Results of the Test: WL+P (wooden laths and plaster) and WL (wooden laths)*

Table 4: *Characteristic value of small wall shear tests*

4.2 SHEAR TESTS ON PLASTER MATERIAL

Based on the observation of the full-scale test, it was assumed that the plaster key between the wooden laths would reach the maximum load by shear resistance as a resistance mechanism after the failure of the baseboard. Therefore, material shear tests were conducted on the undercoat plaster to determine its shear stiffness and strength.

Maximum Shear Stress and Failure Process

The experimental results are listed in **Table 5**, and the load-deformation relationships are shown in **Figure 11**. The shear stress, τ, was calculated by dividing the load by the shear area (B * H'), and was generally 0.7–0.8 N/mm^2 for the other specimens, although it was about 1.5 times higher for PS6 and PS7. The overall average is approximately 0.89 N/mm^2. The displacement at the maximum load varied slightly from 0.64 to 1.6 mm, but the failure process was similar. Even after the shear face failed, the load gradually decreased as the plaster fragments became entangled with the fibers of the shear plane **(Figure 10)**. However, edge collapse was observed under the applied force.

Assumption of shear strain angle and elastic stiffness: Comparison with wood plaster

Because it was difficult to measure the shear strain directly, the following assumptions were made: The steel base that holds the specimen down has a 2 mm clearance from the shear plane of the plaster to remove the effect of compression at the corner. Considering the failure situation and assuming that the shear deformation in this area is significant and that the stress distribution is uniform, the shear strain γ is expressed as d/2, where d is the vertical displacement **(Figure 12)**. The shear elastic stiffness calculated with shear strain γ was approximately 3 N/mm^2.

In contrast, shear deformation was estimated to occur close to the surface of the actual plaster wall **(Figure 12)**. In addition, because the undercoat plaster and plaster key are integrated, it is assumed that this area (thickness L) is subjected to shear deformation if the plaster is sufficiently fixed in the gaps of the wooden laths. In this case, it was estimated that the size of the gap between laths affects the maximum shear force and has little effect on the failure displacement.

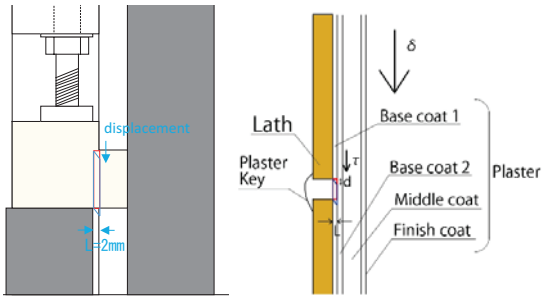

Figure 12: *Settings of shear tests(left) and Hypothesis of Shear Strain in the wall (right)*

5 ANALYSIS OF THE INITIAL STIFFNESS AND MAXIMUM LOAD

Two mechanical models were constructed based on previous tests to analyze the initial stiffness and maximum load. In the initial stiffness estimation model, in which the shear resistance of the wooden lath and plaster (both above and below the lintel) were considered, the shear stiffness was estimated to be approximately 80% accurate. In the model for estimating the maximum load, in which the shear resistance between the finish layer and the gaps of laths was dominant, particularly below the lintel, the maximum load was estimated to be approximately 1.3 times that of the tests. **(Figure 15)**

The horizontal shear stiffness and capacity of the wooden lath and plaster wall were calculated based on the results of the element tests described in Section 4. The calculation was performed on the portion of the wall that did not include the shear resistance of the frame wall (only the effects of the wooden lath and plaster were calculated).

https://doi.org/10.52202/069179-0293

In Section 3, the resistance mechanism of the Japanese-style (rounded by frames) plaster wall is divided into two phases, before and after the baseboard is damaged. The initial stiffness is assumed to be exerted mainly by the shear mechanism of the wall before the baseboard is damaged. The maximum bearing capacity was assumed to be reached through the process of shear failure of the plaster in the gap of the lath after the baseboard was damaged.

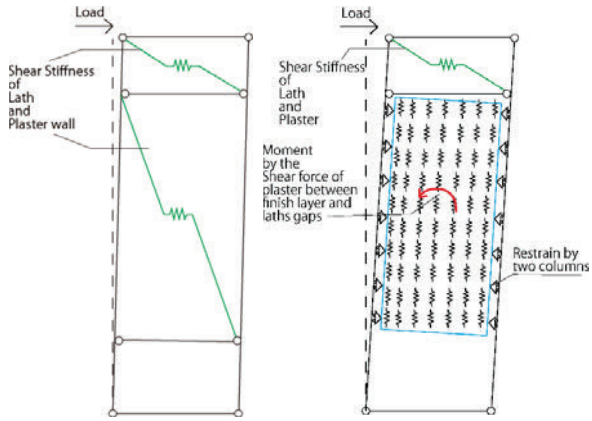

Figure 13: *Analytical model of lath and plaster wall: Initial stiffness phase (left), Maximum strength phase (right)*

1) Sound baseboard condition (initial stiffness model)

In the initial state of resistance, the lath and plaster walls were considered to act as shear-resisting elements. As shown in **Figure 13**, the stiffness and strength of the small-wall experiments were used to evaluate the initial stiffness.

The wall parameters applied to the initial stiffness model are as follows

$\tau_{max} = P_{max}/\sqrt{2}\ /L\ /t = 0.067\ [kN/cm^2]$

The initial stiffness of the hanging wall section is 88 [kN/cm^2] and that of the section from the lintel to the baseboard is 422 [kN/cm^2], totaling about 509 kN/cm^2, which is about 80% of the experimental elastic stiffness **(figure 15)**.

2) After baseboard failure (maximum bearing capacity)

From the observations of the full-scale test, it was estimated that when the base boards were damaged, the vertical restraining effect of the plaster layer was lost. In such a case, as explained in the previous section, it was assumed that the small area between the plaster and wooden lath substrates would resist shear deformation.

In the maximum bearing capacity model, the maximum bearing capacity is calculated based on the shear stiffness of the plaster. It is assumed that the upper and lower restraints are burned out and that only the left and right columns are restrained. The wooden frame was assumed to deform horizontally, whereas the plaster plate on the laths was assumed to deform rotationally while being restrained on the left and right sides. The load-deformation relationship for each angle of deformation was calculated from the balance between the total moment resistance owing to the shear force from the plaster key between the wooden laths and the horizontal force acting on the top.**(Figure 14)** The maximum bearing capacity was 9.1 kN, approximately 1.3 times of the experimental value, as shown in **Figure 15**.

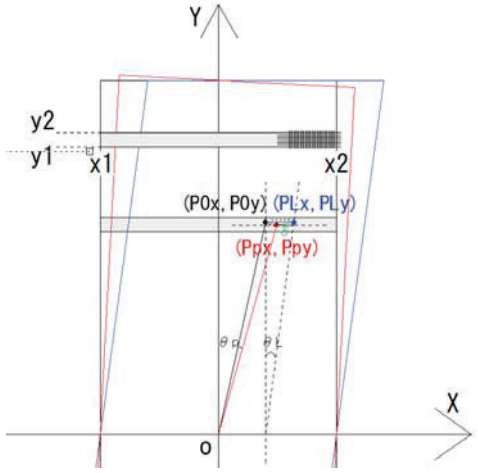

Figure 14: *Diagram of shear displacement of plaster key (plaster between the gaps of laths) from wooden lath*

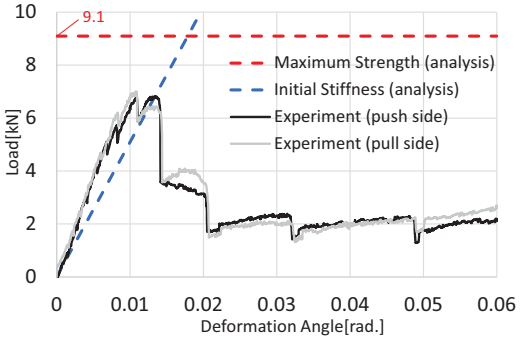

Figure 15: *Shear stress–displacement curves showing the shear test evaluations and shear strain hypothesis*

6 CONCLUSIONS

Lateral loading tests were conducted on laths and plaster walls to clarify their shear performances and failure mechanisms. The results indicate that the restraint conditions of the plaster layer (columns, lintel, and baseboard) significantly affected the resistance mechanism. Through element tests and analysis, we could accurately predict the initial stiffness (80% of the experiment) and maximum load (130% of the experiment). To clarify the proposed system further, the interactive behavior and stress distribution between the plaster and the laths must be investigated in detail.

ACKNOWLEDGEMENT

The authors would like to thank Japan Cultural Heritage Consultancy, Iwase Kenchiku and Osaki Sakan for technical assistance with the production of specimens and conducting the experiments. A SEISMIC RESPONSE ESTIMATION MODEL FOR CROSS-LAMINATED TIMBER WALLS USING MACHINE LEARNING

Eknara Junda[1], Christian Málaga-Chuquitaype[2]

ABSTRACT: This paper proposes a machine learning-based model for estimating the seismic damage of cross-laminated timber (CLT) walls. Random Forests are used to this end. A database is created using numerical results from nonlinear response history analyses under a large set of ground motions. 69 numerical models of CLT walls with various structural characteristics and design parameters are used. The maximum inter-storey drift ratio (MIDR), which plays an essential role in explaining the seismic damage of buildings, is adopted as the damage predictor target. Two feature selection techniques, sequential forward floating selection and LASSO are applied to evaluate the impact of various input features on the estimation performance. Results show that a high accuracy of the estimation is obtained if six features are employed as inputs. The proposed model performance is assessed and then compared with traditional methods. Finally, the Shapley Additive exPlanation method is employed to interpret the influence of the input features on the MIDR estimates in the machine-learning-based model.

KEYWORDS: Seismic demand estimation, Machine learning, CLT walls, Random Forests, Maximum inter-storey drift ratio

1 INTRODUCTION

Cross-laminated timber (CLT) is an environmentally friendly material that offers several advantages in construction, such as high prefabrication level, good thermal insulation, lightweight, and good fire performance when properly designed. CLT has enhanced mechanical properties springing from its manufacturing process resulting in high in-plane strength and stiffness. Thus, CLT has been widely used for walls as the load-bearing element of CLT buildings, including being considered as the lateral force-resisting system in seismic applications [1].

The advantageous mechanical and environmental characteristics of CLT have made it an attractive option for mid to high-rise buildings in earthquake-prone regions. Typical CLT buildings generally comprise panels linked by metal connectors such as hold-downs, angle brackets, and screws. These connectors play a vital role in dissipating the seismic energy through the nonlinear deformation under seismic actions. On the other hand, the CLT panel is assumed to behave as a rigid body [2]. This causes the lateral deformation of CLT buildings to be fundamentally based on a combination of rocking and sliding responses which are completely different from other structural systems, such as moment frames or braced frames governed by flexural behaviour. Such rocking and sliding deformation of CLT walls are complex and challenging to predict due to the overlying effects of pinching, friction, stiffness and strength degradation phenomena. These complex phenomena could also result in high inelastic deformations under strong earthquakes. All this in the context of the continuous push towards taller CLT buildings driven by current developments in construction technology. Therefore, more complex structural behaviours and high seismic demands are expected. Hence, an accurate tool for estimating and assessing the seismic demands of CLT walls is needed.

Seismic demand estimation using machine learning (ML) have increasingly been applied to various structural systems. As ML algorithms do not need functional forms to predict a target, they can successfully map the complex relations between inputs and the target by learning directly from a given dataset. Such abilities to learn and recognise data patterns make ML beneficial for dealing with high-dimensional spaces [3]. ML models for the estimation of seismically-induced responses have been developed for a variety of systems, from geotechnical structures [4] to extra-terrestrial constructions [5]. Likewise, several ML techniques were used to establish regression-based and classification-based models for reinforced concrete [6] and steel frames [7]. ML techniques were also used for other structural systems in the past few years [8-10]. Even though ML techniques have been used for the seismic response estimation of various structural systems, no previous study has applied such techniques to CLT walls. This despite the fact that, as mentioned earlier regarding the complexity of the seismic response of CLT walls, ML techniques have inherent advantages in handling the highly nonlinear

https://doi.org/10.52202/069179-0294

responses and explore the complex relations among parameters of multi-storey CLT walls.

This paper proposes a ML model for estimating the seismic response of multi-storey CLT walls. The maximum inter-storey drift ratio (MIDR) is chosen as the output target. Thirty input features are used as predictors. These features are composed of intensity measures (IMs) and structural parameters of CLT walls (SPs). Sixty-nine numerical models of CLT wall cases with different structural configurations are created and analysed using nonlinear response history analyses to obtain MIDR. Random Forests, a ML algorithm, is used to develop a regression model for MIDR estimates. Finally, the prediction performance of the ML-based models are evaluated and compared with traditional methods. In addition, the influence of each input features on the MIDR prediction is interpreted using SHAP.

2 CLT STRUCTURAL MODELS AND GROUND MOTIONS

2.1 CLT WALL MODELS

69 CLT structures representing residential multi-storey CLT buildings of different heights and panel fragmentation levels are considered. All buildings share the same plan layout and have a typical storey height of 3.5 m, except for the ground level which height is 4.3 m. Figure 1 shows the configuration of a typical 12-storey CLT building as an example. Dead loads were calculated considering all finishing and insulation, whereas a superimposed load of 2.0 kN/m^2 was assumed. Loads considered for seismic mass are a combination of 100% dead and 30% superimposed load. The response spectrum of Eurocode 8 Type 1 [11,12] at a Peak Ground Acceleration (PGA) of 3.0 m/s^2 with an importance factor of 1.0 was adopted to estimate the seismic load.

In this study, CLT Wall 2-BC was selected as the representative part of the structure. The wall is 8.5 m long (marked with dashed lines in Figure 1). All walls were designed using capacity design principles and current codified guidance. We followed ductile design and failure mode control principles informed by Eurocode 8, Part 1. More details of the design processes of the CLT structure can be found in [12].

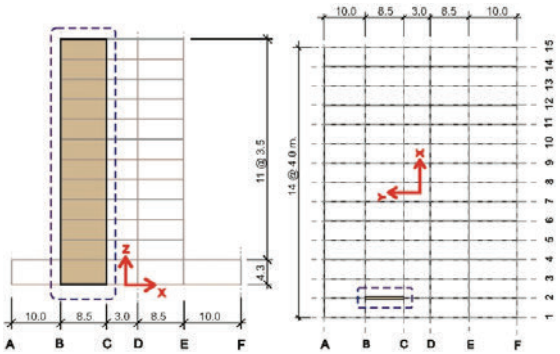

Figure 1: *Typical 12-storey building.*

Several parameters were varied during the design to cover a wide range of CLT buildings and evaluate their effects on the corresponding seismic demands. These parameters comprised the number of storeys, the sub-panel numbers, and the behaviour factors. Table 1 summarises parameters regarding CLT walls adopted in this study.

Table 1: *parameters regarding CLT walls*

Parameters	Variables
Number of stories (N)	6, 8, 12, 16, 20
Number of subpanels per wall (m)	1, 2, 3, 4
Behaviour factor (q)	1.5, 2, 2.5, 3, 4

We developed a series of 2D numerical models of the wall structures in OpenSees [13]. Figure 2 shows a schematic drawing of the model for a wall with m = 2. All CLT panels were discretised into a number of shell elements. In contrast, two-node link elements with zero length represented the three main steel connectors (hold-downs, shear brackets, and vertical screws). The link elements for hold-downs were located at the corners of the panels, represented by blue springs. Angle brackets were distributed along the length of the panels in the X direction (red springs), and self-threaded screws at the vertical joints were lumped into an equivalent single link element, placed at the mid-height of the panels (shown in green).

Since most of the nonlinear deformations in CLT walls under lateral actions occur at their joints and since the CLT panels themselves are expected to remain largely elastic [12,14], an equivalent isotropic material model with linear elastic properties was assumed for the CLT panels. In steel connectors, we used a hysteretic uniaxial material model to capture the global nonlinear responses. Both shear and axial direction capacities were modelled in all types of connectors, considering the uncoupled reaction between the two directions. The strength, deformation values, pinching, strength and stiffness degradation were calibrated against available data from previous experimental studies [15-17]. Moreover, a leaning column, modelled using beam-column elements, was connected to the wall through equal degree-of-freedom constraints to account for P-Delta effects caused by gravity loads. This was done to consider geometric nonlinear effects since the shell element type used in OpenSees only allows for a linear geometric transformation. A Rayleigh damping model with a damping ratio of 0.05 in the first and fifth mode was assumed in all cases.

https://doi.org/10.52202/069179-0294

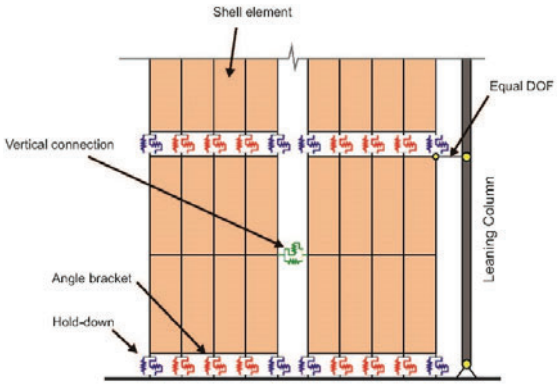

Figure 2: *Numerical model of CLT walls.*

The CLT-walled models mentioned above were validated against experimental results. Two cases of structures, single wall and couple walls are compared and shown In Figures 3 and 4. It is seen from the comparisons that our modelling approach can efficiently reproduce the experimental hysteretic response of CLT assemblages.

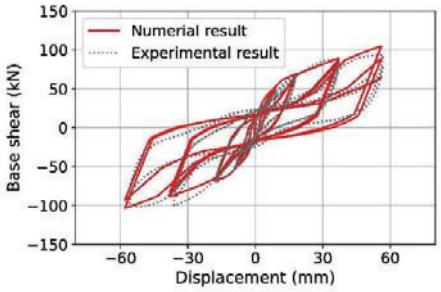

Figure 3: *Validation of the numerical model for a single wall.*

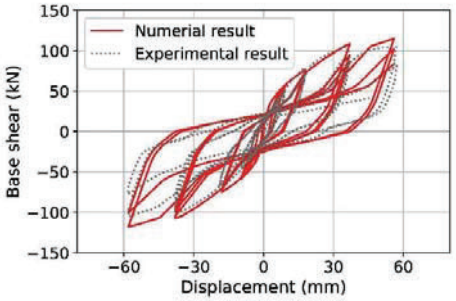

Figure 4: *Validation of the numerical model for coupled walls.*

2.2 GROUND MOTIONS

In this study, we used the 1,656 records selected by Hancock et al. [18] from the NGA-West database [19]. These records come from shallow crust seismic events with moment magnitudes between 5.1 and 7.9 and an average PGA of 1 g. More information regarding the ground motion set can be found in [18]. Moreover, scaling factors of 2 and 1 were used to scale up the original un-scaled records in order to increase the intensity of the ground motions, resulting in more cases of nonlinear responses. Therefore, the total number of ground motion records was 3,312 leading to 228,528 nonlinear response history analyses (NRHA). The massive analysis was performed on the high-performance computing facility (HPC) at Imperial College London.

3 FEATURE SELECTION

To develop an ML model for MIDR estimation, a training dataset was prepared. The dataset consists of the input features (predictors) and the output target (MIDR). Two main parameters were considered for the model development: ground-motion intensity measures (IMs) that describe earthquake characteristics and structural parameters (SPs) that describe structural properties in CLT walls. Nine common IMs were selected based on hazard computability, including Peak Ground Acceleration (PGA), Peak Ground Velocity (PGV), Peak Ground Displacement (PGD), total Arias intensity at the end of the time series (I_a), significant duration ($D_{5–75}$ and $D_{5–95}$), and spectral acceleration values at the building's fundamental period ($S_a(T_1)$) and at n times T_1 ($S_a(nT_1)$) where n was varied from 1.1 to 3.0, the mean period of the ground motion (T_m) and the ratio between the fundamental structural period and the ground-motion mean period (the tuning ratio, T_1/T_m). In addition, six structural parameters (SPs) were also considered as candidate input features. These include the behaviour factor (q), building height (H), slenderness (λ_w), length of fastening lines (FL), joint density (β_w), and wall subdivision ratio (m). These SPs have been reported in the literature to significantly impact the seismic response of CLT wall structures [14, 20, 21]. The total number of input features was 30.

We randomly divided the whole database into training and test sets to avoid overfitting during the model development. The training set contained 70 % of the database and was used for all the activities of the modelling processes, whereas the remaining 30 % of the data was kept as unseen data and was used for performance testing purposes at the final step. We transformed all IMs and MIDR to the log-normal space following the common assumption of lognormality adopted in earthquake engineering [22].

All 30 input features used for the model development were selected using different feature selection techniques, namely sequential forward floating selection (SFFS) and Least Absolute Shrinkage and Selection Operator (LASSO). The feature selection was carried out using the training dataset. Note that the objective of this process is to evaluate the predictive potential of the features and obtain a set of features influencing the prediction. The mean square error (MSE) was used to assess the fit, and a 10-fold cross-validation (CV) was applied to generalise the results, mitigate overfitting, and improve the model's robustness [23]. The features which finally selected were PGV, $S_a(T_s)$, T_1/T_m, q, H, and m. This set was considered

as an optimised combination of predictors, which was used to develop the ML model in this paper.

4 MACHINE LEARNING MODEL DEVELOPMENT

4.1 MODEL TRAINING

As mentioned previously, this paper compares the performance of MIDR estimates between a traditional regression model and an ML-based model. The algorithm used for a traditional method is Multiple Linear Regression, whereas an ML method is Random Forest. We have implemented the algorithms using the Scikit-learn package in the Python-based computational platform. Note that hyper-parameters of Random Forest were tuned to minimise a cost function using GridSearchCV, also available from the Scikit-learn package.

4.2 PERFORMANCE MEASURES

This study employs two performance metrics, the coefficient of determination (R^2) and the root mean square error (RMSE), to assess the applied models' prediction performance. These two indicators, widely adopted in ML performance studies, are provided for training and test sets. The expressions for R^2 and RMSE are given in Equations 1 and 2.

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y}_i)} \quad (1)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (2)$$

where $\hat{y}_i$ is the estimated target out, y_i is the real target value, and n is the number of data points.

5 RESULTS

5.1 MODEL PERFORMANCES

The prediction performances of the training and test datasets for the regression models are presented in Table 2. The MIDR estimates versus actual values are depicted in Figures 5 and 6 for the linear regression and random forest models, respectively. The result shows a comparable prediction performance between the training and the test set. This indicates that the models developed do not overfit the training data and should perform well on unseen data.

Table 2: *Comparison of the prediction performances*

Algorithm	MIDR			
	Training set		Test set	
	R^2	RMSE	R^2	RMSE
Linear regression	0.778	0.368	0.777	0.369
Random Forest	0.950	0.102	0.946	0.198

The traditional linear regression, which has been broadly applied for estimating seismic demands of structures, shows relatively low prediction power, evidenced by the lower R^2 and higher values of RMSE, compared to the Random Forest. The linear regression model clearly has notable dispersion levels between its predictions and numerical results, especially underestimating MIDRs at higher levels of demand. Lower performances are observed from the linear regression with R^2 of 0.777 and RMSE of 0.369 on the test set for MIDR estimates. This indicates that traditional approaches like Linear Regression might not be able to predict MIDR over the full range of deformation in CLT structures. The low prediction performances can be partially attributed to its inability to describe highly nonlinear processes and complex relationships between the input features and MIDRs. On the other hand, the model developed from Random Forest shows substantial improvements in prediction power over the traditional method, reflected by 21.75% higher values of R^2 and 46.34% lower values of RMSE. The results clearly show that Random Forest can capture better the non-linearity in the drift response of CLT walls.

5.2 MODEL INTERPRETATION

Machine learning models can be difficult to understand and are sometimes seen as black boxes due to their complex algorithms. It is essential to know how a model makes predictions and which factors affect the model. To this end, SHAP methodology [24] was used to explain our ML model, Random Forest. Figure 7 shows the SHAP summary plot for MIDR. Each point in this graph shows the relation between the six features and the SHAP value obtained from the Random Forest model. The features are ordered from top to bottom based on their overall importance to the model prediction. It is observed that $\ln(S_a(T_1))$ is the most important feature, followed by H, ln(PGV), m, q, and $\ln(T_1/T_m)$. The variation in colours, from blue to red, represents the variation of the features from low to high, respectively. Moreover, data points that result in the same SHAP value are scattered, leading to different distribution shapes for the features.

The SHAP summary indicates that MIDR positively corresponds to almost input features except for $\ln(T_1/T_m)$. An increase in SHAP value goes along with an increase in $\ln(S_a(T_1))$, H, ln(PGV), m, and q. In the case of $\ln(T_1/T_m)$, lower values have more impact on MIDR than higher values, as the red dots are concentrated approximately in the SHAP value of 0. It is also observed that small SHAP values (SHAP values < 0) are sensitive to the variation of all features, reflected in the long blue tails to the left. This indicates that all features significantly impact the low range of MIDR, especially in the case of $\ln(S_a(T_1))$. The SHAP explanation is consistent with the fact that this range of MIDR is strongly dependent on the elastic stiffness of the structures, as well as their yield strength and structural configuration. On the other hand, ln(PGV) influences the model for large MIDR values significantly. Other features become progressively less influential on the prediction, especially m, q, and $\ln(T_1/T_m)$.

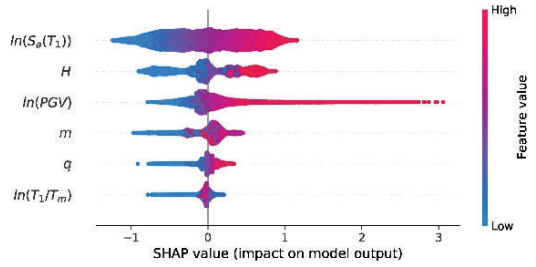

Figure 7: *SHAP summary plots for MIDR.*

Figures 8, 9 and 10 show scatter diagrams displaying local feature importance for the input features and SHAP values. The plots also indicate the interaction between a pair of features considered represented by the transition from blue (low values) to red (high values), as shown on the right of the plots. Overall, it is observed that a highly nonlinear influence of all the IMs examined over the MIDR. $\ln(S_a(T_1))$ and ln(PGV) have a positive relation with MIDR, although they have different trends. This can be explained by the fact that higher values of $\ln(S_a(T_1))$ and ln(PGV) lead to higher SHAP values, which are associated with larger MIDRs. The impact of $\ln(S_a(T_1))$ on the estimation of MIDR decreases moderately, while ln(PGV) tends to increase exponentially.

In the case of $\ln(T_1/T_m)$, a positive impact on the drift estimation is observed until $\ln(T_1/T_m)$ reaches a value of 1. After that, $\ln(T_1/T_m)$ has no impact on the prediction denoted by the almost unchanged SHAP values. This marks an explicit limitation to the predictive power of T_1/T_m that peaks at "resonance" and decays afterwards. This reduction in the predictive ability of T_1/T_m can be partially due to the rise in the importance of structural yielding.

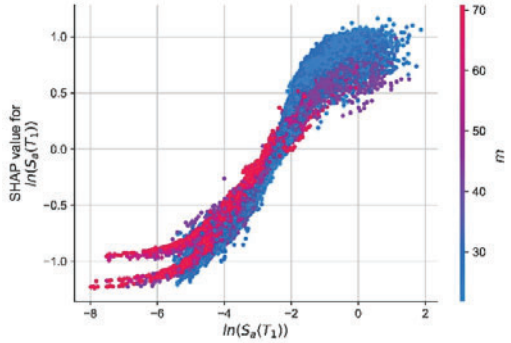

Figure 8: *SHAP dependent plots for MIDR and $\ln(S_a(T_1))$.*

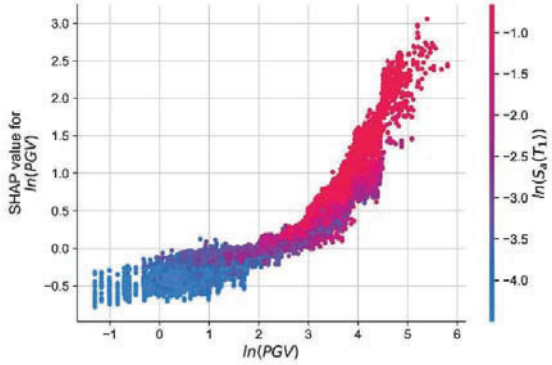

Figure 9: *SHAP-dependent plots for MIDR and ln(PGV).*

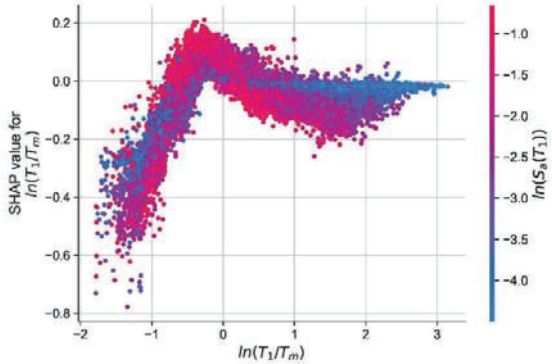

Figure 10: *SHAP-dependent plots for MIDR and $\ln(T_1/T_m)$.*

Figures 11, 12, and 13 depict the SHAP dependency plots for the three structural parameters used to formulate our model. They show that H and q positively impact the MIDR prediction. However, for q values of 3 or larger, MIDR becomes less sensitive to q. On the other hand, the trend of m changes from positive to slightly negative after a value of 3. This suggests that subdividing a CLT wall into more than three sub-panels is unnecessary.

6 CONCLUSION

This paper has investigated the use of machine learning (ML) to estimate the maximum inter-storey drift (MIDR) in multi-story CLT structures and compared it with traditional regression approaches. To do this, we have built numerical models of 69 CLT-walled structures with various structural configurations and design attributes, which reflect a wide variety of CLT building configurations. After calibrating the accuracy of the numerical models against available experimental data, we use them to generate MIDRs of the wall structures using extensive nonlinear response history analyses under a database of 3,312 real ground-motion records scaled with factors of 1.0 and 2.0. The large dataset of seismic drift demands is used as output targets. A total of 30 characteristics, including ground-motion intensity measurements and structural factors, were examined for their influence on the MIDR estimates. Two data-science-based feature selection methods, SFFS and LASSO, are used to inform the suitable set of features to estimate MIDR. A set of six most significant features is obtained, namely the spectral acceleration at T_1 ($S_a(T_1)$), peak ground velocity (PGV), the period ratio (T_1/T_m), behaviour factor (q), structure height (H), and wall ratios (m).

Two regression models are developed and compared with their prediction performances using R^2 and RMSE. The results demonstrate that the traditional linear regression, widely applied for estimating seismic demands of structures, has low prediction power. This indicates that the traditional method oversimplifies the complex nature of the seismic response and cannot provide reliable MIDR estimates over the full range of deformations in CLT structures, but this is especially true at higher deformation levels where the linear model underestimates the drift response. In contrast, the Random Forest model significantly outperforms the traditional method, which is 21.75% higher in R^2 and 46.34% lower in RMSE. The findings show that Random Forest captures better the nonlinearity of MIDR in multi-storey CLT walls.

The SHAP important plots reveal that $S_a(T_1)$ and T_1/T_m strongly influence the drift prediction for tiny drifts where the structure remains elastic while PGV dominates the model at large displacements. The results also imply that a q and an m value of 3 can be optimal for multi-story CLT buildings since an increase in their value beyond those levels will not significantly improve the overall ductility of CLT structures.

ADAPTIVE COMPOSITE RUBBER BEARINGS FOR TIMBER STRUCTURE: A CASE STUDY FOR EARTHQUAKE-PRONE REGIONS

W.C. Liao[1], Kin Sang Michael Wong[2]

ABSTRACT: Mass timber buildings are becoming more popular in Europe and America for its low carbon footprint compared with traditional construction materials. However, its earthquake resistance should be carefully considered if it is to be used in earthquake-prone areas such as the Asia-Pacific region. The use of traditional base isolators such as lead rubber bearing was already prohibited in Europe due to its toxic gas emission during melting of lead core when large displacement occurs. Therefore, alternative bearing such as adaptive composite rubber bearing (ACRB) made with more environmental-friendly material is being developed. This study applies carbon fabric, layered rubber sheet and novel core materials to fabricate an ACRB base isolator with adjustable damping ratio and lateral shear stiffness. A quasi-isotropic layup of carbon fabric, high temperature resin prepreg system and hot press is adopted in the fabrication of composite laminates. The selection of primer coat between composites and raw rubber is determined by the double lap shear test of a single composite/rubber unit. Through the biaxial test of this novel ACRB base isolator, the equivalent damping ratio, equivalent lateral stiffness and friction coefficient of the isolator can be characterized. Under low shear strain, the damping ratio of the isolator can be as high as 0.58, and the envelopes of their hysteretic loop shows prominent seismic energy absorption capacity. In order to verify the earthquake mitigation performance of these adaptive composite rubber bearings, shaking table tests of several down-scaled multi-story mass timber buildings were carried out.

KEYWORDS: Mass timber building, adaptive rubber bearing, carbon fabric, biaxial test, shaking table seismic test

1 INTRODUCTION

Mass timber buildings includes cross laminated timber (CLT), glued laminated timber (GLT) and dowel laminated timber (DLT) are popular construction materials used for medium to tall buildings in Europe and America. The reason for the trend to use more timber over conventional construction materials is due to its low carbon footprint and urban heat island effect. With the improvement of timber material against fire, corrosion and pest, it is foreseen that timber would become more popular in other urban areas. In order to improve the earthquake resistance of timber buildings, the most cost-effective way would be by the implementation of passive control measures at the base of the timber structure.

During an earthquake, energy was transferred into buildings through forced vibration. As the major frequency of earthquake shown in typical response spectrum coincides with the natural frequency (1-10Hz) of conventional building structures, resonance effect would be resulted during an earthquake. The structural members would exhibit large internal force during resonance vibration and be damaged. Passive isolation makes use of the low stiffness of the isolator to change the natural frequency of the above building to lower than 0.5Hz. Passive control measures include three major principles: base isolation, energy dissipation and vibration mitigation. Energy dissipation method relies on the hysteretic damping through yielding of metal core, friction damping or viscous damping to provide supplementary damping to dissipate the vibration response of the structure.

This study aimed at fabricating an adaptive composite elastomeric base isolator and verify its performance in mass timber structure. In the past, high damping rubber bearing (HDRB) and lead rubber bearing (LRB) were efficient elastomeric base isolators to make use of the low strength of rubber to change the frequency of the structure and dissipate the earthquake energy transferred up to the structure. The addition of lead core could even provide larger energy dissipation through the plastic deformation of the core during extremely large displacement [2][3]. However, in 2009, Kalpakidis and Constantinou [4][5] carried out studies on the effects of heating on the behaviour of lead-core rubber bearings and concluded that the lead core would have zero yield strength when it reached its melting point at 327°C and thus the earthquake energy would be absorbed by the adjacent rubber and resulted in its damage and failure. During the Tohoku earthquake in Japan in 2011, some of the lead core in LRB were found to be having irreversible deformation due to the sudden rise in temperature resulted from extremely large displacement[6][7]. The European Union had banned the use of lead core in LRB in 2011. Therefore, it is urgent to find alternative laminate material that could replace the function of lead core in rubber bearing.

In contrary to LRBs, HDRB uses laminated specialized high damping rubber (HDR) and had slightly lower energy dissipation capacity [8].

In this study, carbon fabric, layered rubber sheet and novel core materials were used to fabricate an ACRB base isolator with adjustable damping ratio and lateral shear stiffness. A quasi-isotropic layup of carbon fabric, high temperature prepreg resin system and hot press is adopted in the fabrication of composite laminates. The selection of primer coat between composites and raw rubber is determined by the double lap shear test of a single composite/rubber unit. Through the biaxial test of this novel ACRB base isolator, the equivalent damping ratio, equivalent lateral stiffness and friction coefficient of the isolator can be characterized. Under low shear strain, the damping ratio of the isolator can be as high as 0.58, and the envelopes of their hysteretic loop shows prominent seismic energy absorption capacity. In order to verify the earthquake mitigation performance of these adaptive composite rubber bearings, shaking table tests of several down-scaled multi-story mass timber buildings were carried out.

2 CHARACTERISTICS TEST OF ACRB

2.1 DESIGN AND MANUFACTURING OF AN ADAPTIVE FIBER-REINFORCED RUBBER BEARING BASE ISOLATOR

Carbon roving TC360 from Formosa Plastic Group has a tensile modulus of 250 GPa, and tensile strength of 4890 MPa, respectively, were adopted in this research. The UD carbon laminate has E_1=117.29 GPa, E_2=E_3=7.44 GPa, G_{12}=3.77GPa, and v_{12} = 0.1946. In order to avoid the misalignment in the curing of composite laminate and rubber layers, a quasi-isotropic stacking sequence of [0/90/+45/-45]s is adopted. All carbon plates were made through hot press to about 3mm thick. High temperature resin prepreg of EPO-HTG™ G351N from Epotech Taiwan was applied during the layup. The carbon plates were then cut to Φ130mm discs and stacked with Φ 60mm shim core steel plates and sliding plates to form the core of the ACRB. The outer side of the core layer were filled up by high damping rubber. From 3-D effective moduli theory, we can estimate E_x=E_y = 44.66 GPa, which are close to experimental data. The layup of an adaptive composite rubber bearing is shown in Figure 1.

2.2 BIAXIAL TEST ON ACRB

Biaxial test was used to test the ACRB under different frequency, loading directions and shear strain. The typical experimental setup for ACRB is shown in Figure 2. After setting a vertical force, horizontal displacement would applied through the MTS dynamic system with sine wave movement at different frequencies and amplitudes. Vertical force, horizontal force and displacement were recorded by imc μ-sys to yield hysteresis loops.

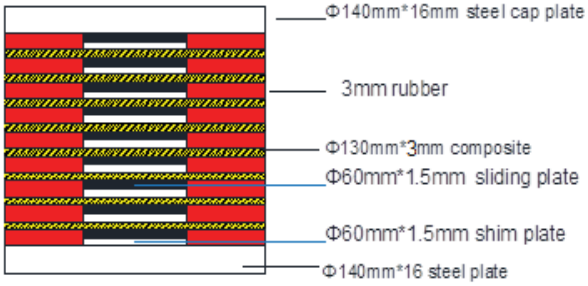

Figure 1: *Scaled down ACRB*

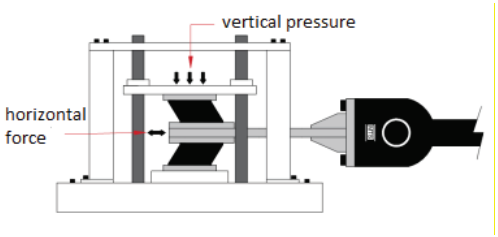

Figure 2: *Setup for biaxial test*

2.3 SHAKING TABLE TEST FOR SCALED TIMBER STRUCTURE WITH ACRB

Four scaled ACRB were then installed under a scaled 3-storey steel structure which was designed to have the weight and natural frequency similar to timber structure to carry out the shaking table test. The earthquake loading used were scaled-down El Centro earthquake (1940) and Chi-Chi earthquake (1999) under x and y directions separately. Control tests with no ACRB were also recorded for comparison with the use of scaled-down earthquakes at 0.05g to prevent extensive damage to the structure. Accelerometers and displacement gauges were installed at every storey to record the acceleration and displacement in x and y directions as shown in Figure 3 and 4. The reason for the use of steel structure instead of real timber structure was due to the consideration on transportation and size limit of the shaking table.

3 RESULTS AND DISCUSSION

3.1 BIAXIAL TEST ON ACRB

Biaxial tests were carried out under 5t(3.7MPa) & 7t(5.2MPa) vertical force with sine wave signals at different frequencies (0.1Hz, 0.2Hz, 0.5Hz, 1.0Hz & 1.5Hz) and different horizontal shear strain (25%, 50%, 100% & 150%) of the total thickness of rubber. Typical hysteresis loops for two repeated cycles under different shear strains are shown in Figure 5 and Figure 6.

The data obtained from the hysteresis loops was used to calculate the effective stiffness (K_{eff}) as demonstrated by Liao, Tsai and Hsieh [9] by the following Equation (1):

https://doi.org/10.52202/069179-0295

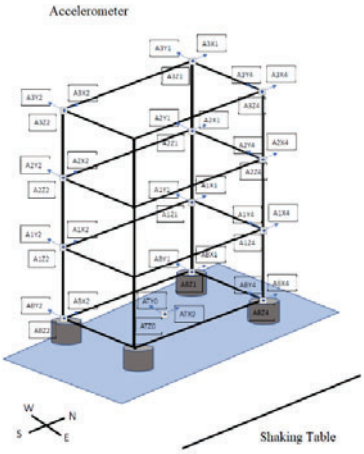

Figure 3: *Setup for accelerometers for shaking table test*

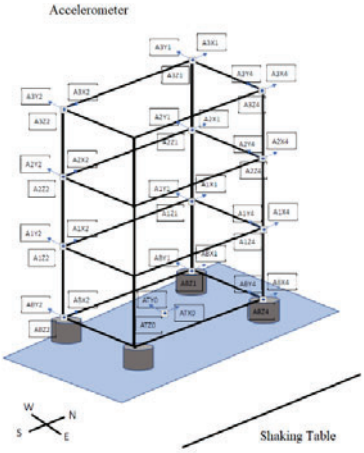

Figure 4: *Setup for displacement gauges for shaking table test*

$$K_{eff} = \frac{F_i^+ - F_i^-}{2\Delta_i} \quad (1)$$

where F_i^+ = maximum horizontal force of ith cycle,
F_i^- = minimum horizontal force of ith cycle,
Δ_i = average horizontal displacement of ith cycle.

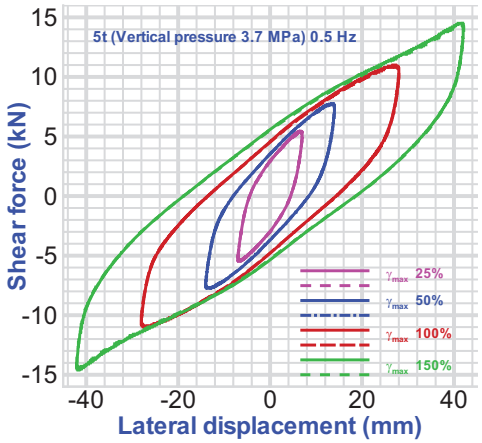

Figure 5: *Hysteresis loop of ACRB at different shear strains under pressure of 3.7MPa at 0.5Hz frequency*

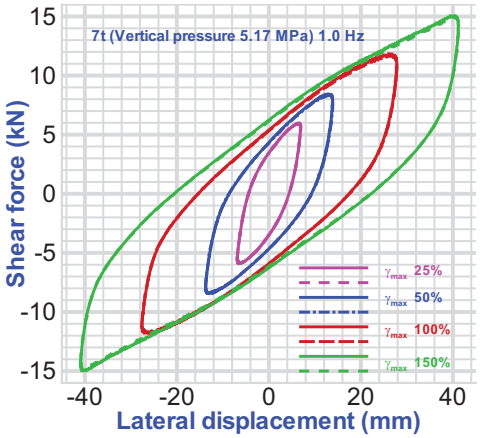

Figure 6: *Hysteresis loop of ACRB at different shear strains under pressure of 5.2MPa at 1.0Hz frequency*

The effective stiffness (K_{eff}) was plotted against the shear strain under different frequencies of loading. As shown in Figure 7 and 8 below, K_{eff} decreased significantly when the shear strain increased. The effect on frequencies was relatively insignificant.

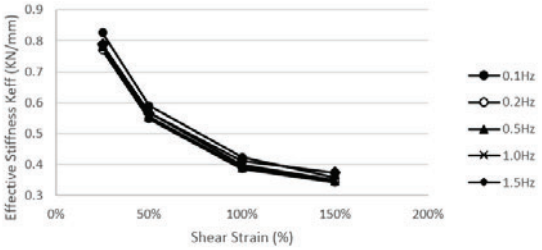

Figure 7: *Effective stiffness against shear strain under pressure of 3.7MPa*

https://doi.org/10.52202/069179-0295

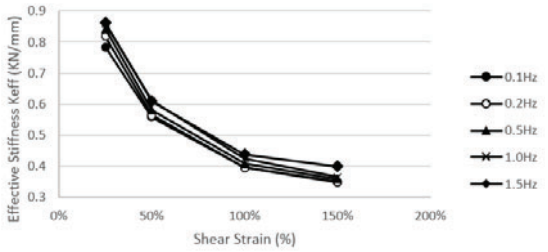

Figure 8: *Effective stiffness against shear strain under pressure of 5.2MPa*

The equivalent damping ratio (ξ_e^i) as demonstrated by Liao, Tsai and Hsieh [9] by the following Equation (2):

$$\xi_e^i = \frac{E_d^i}{2\pi k_{eff}^i \Delta_i^2} \tag{2}$$

where E_d^i= area enclosed by ith cycle in loop.

The test results of equivalent damping ratio under 5t (3.7MPa) and 7t (5.2MPa) are summarized in Table 1 and Table 2 below:

Table 1: *Equivalent damping ratio ξ_e^i of ACRB under 5t(3.7MPa) vertical pressure.*

Shear strain	Frequency				
	0.1Hz	0.2Hz	0.5Hz	1.0Hz	1.5Hz
25%	24.7%	27.5%	27.6%	28.0%	28.3%
50%	22.5%	24.9%	25.2%	25.6%	26.0%
100%	19.8%	22.7%	23.1%	23.4%	23.4%
150%	18.0%	19.1%	19.5%	20.2%	22.2%

Table 2: *Equivalent damping ratio ξ_e^i of ACRB under 7t(5.2MPa) vertical pressure.*

Shear strain	Frequency				
	0.1Hz	0.2Hz	0.5Hz	1.0Hz	1.5Hz
25%	27.9%	28.5%	28.4%	29.4%	29.7%
50%	27.0%	27.6%	27.8%	28.2%	28.7%
100%	24.3%	24.7%	25.5%	26.1%	26.1%
150%	21.4%	21.4%	22.3%	22.4%	25.5%

As shown in the tables above, the equivalent damping ratio is relatively insensitive to frequency of loading. However, it increased when the vertical pressure increased and dropped when the shear strain increased.

3.2 SHAKING TABLE TEST FOR SCALED TIMBER STRUCTURE WITH ACRB

From the shaking table results, the inter-storey displacement and relative acceleration were both significantly reduced after ACRB were installed. The displacement of each storey in x-direction under 0.5g El Centro (NS) earthquake was plotted against time in Figure 9 below:

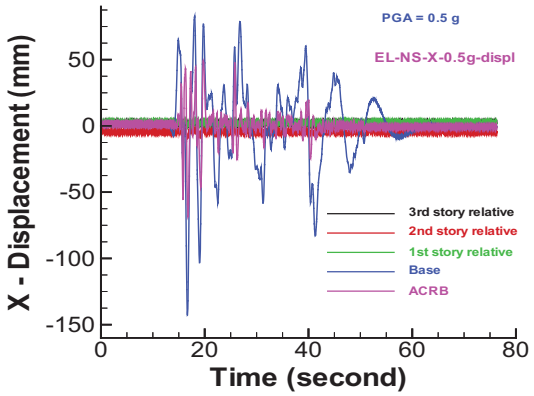

Figure 9: *Displacement of base and relative displacement of different storeys under PGA of 0.5g El Centro (NS) Earthquake.*

The above figure showed that the relative displacement of the structure itself was small and not more than 5mm. When compared with the base displacement (with maximum at about 140mm), the inter-storey movement was almost negligible and the structure was shaking with rigid body motion.

A typical plot about the acceleration at different storeys against time is shown in Figure 10 below.

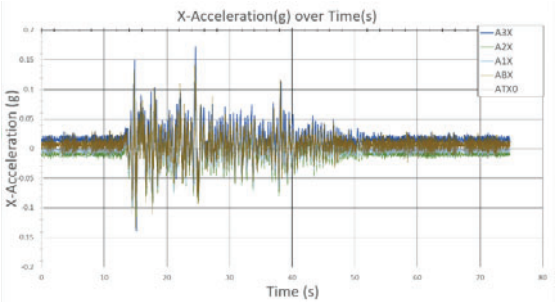

Figure 10: *Acceleration of base, ACRB and each storey under PGA of 0.2g El Centro Earthquake.*

The peak acceleration of each storey within the earthquake was extracted for comparison to calculate the acceleration reduction efficiency of the ACRB. The ratio for comparison would be by comparing the peak ground acceleration (PGA) actually measured by 0.05g loading of the same earthquake. The summary on acceleration reduction efficiency of El Centro-NS loading were compared in Table 3 below.

Table 3: *Acceleration reduction efficiency of ACRB under different levels of El Centro (NS) loading*

	w/o ACRB	w/ ACRB		
Test name	0.05g	0.2g	0.3g	0.4g
PGA (g)	0.060	0.181	0.320	0.424

https://doi.org/10.52202/069179-0295

3F	0.099	0.170	43%	0.371	29%	0.397	43%
2F	0.082	0.154	37%	0.222	49%	0.311	46%
1F	0.068	0.157	23%	0.317	12%	0.358	25%

In order to further check the damping efficiency of the ACRB under earthquake loadings, the base shear was plotted against the average x-displacement of the ACRB to show the relationship between ACRB displacement and base shear under various earthquake acceleration. The base shear was calculated based on the sum of the products of storey mass times average acceleration in x direction for each storey. The result of the hysteresis loops were shown in Figure 11-16 below.

As shown in Figure 11, 14 & 15 where the shear strain was up to 138%, the equivalent damping ratio was up to 23.7%. As shown in Figure 13, 14 & 16 where the shear strain was up to 256%, the equivalent damping ratio would gradually decrease to 15.8%.

4 CONCLUSIONS

Mass timber buildings are becoming more popular in view of the improved characteristics of laminated timber. Existing bearings such as LRB were already banned due to toxic emission. The performance of its alternative (HDRB) relies on the vertical pressure on the bearing. With the decrease in weight of timber structure compared with conventional concrete or steel structure, it is essential to investigate the possibility of improved bearing which could perform. We manufactured ACRB with carbon fabric. The damping efficiency of ACRB on timber structure was demonstrated under the experiments in this paper. The use of this alternative damper could lower the cost and number of dampers and become more environmental-friendly.

SEISMIC DESIGN OF A CLT MULTI-STOREY BUILDING IN DIFFERENT DUCTILITY CLASSES

Giuseppe Cenci[1], Maurizio Follesa[2], Vincenzo Rinaldi[3], Daniele Casagrande[4], Massimo Fragiacomo[5]

ABSTRACT: This study aims to clarify fundamental concepts related to the design of Cross-Laminated Timber (CLT) multi-storey buildings in seismic-prone areas. An in-depth worked example of a CLT multi-storey building design is presented following four different cases of analysis: low and medium ductility according to the current Italian regulations (NTC 2018), and medium and high ductility (DC2 and DC3) according to the new draft of Eurocode 8. Finite Element (FE) models of the building have been implemented to analyse the linear dynamic behaviour of the structure. In high ductility class, a couple-panel behaviour of shear walls is achieved by following the analytical provisions reported in the new draft of the Eurocode 8. As a result, a clear design process is defined for each case analysed. Through the analysis of the individual steps, possible issues in the interpretation and application of the rules are highlighted and resolved. Finally, this study allows an easy and direct comparison between the various cases.

KEYWORDS: CLT buildings, Seismic analysis, Capacity-based design, Practice-oriented.

1 INTRODUCTION

The use of Cross-Laminated Timber (CLT) panels has become widespread for the construction of low-to-mid-rise multi-storey buildings, representing a valuable alternative to other traditional structural types also in seismic-prone areas [1,2]. However, the development of Standard provisions framing the design and calculation of this type of structure is still lacking in Europe, especially for seismic load situations.

1.1 DPC-ReLUIS 2019-2021

Through the DPC-ReLUIS 2019-2021 research project, the Italian Civil Protection Department and the ReLUIS research consortium have promoted the development of pre-normative documents related to structural types not yet considered in the current standards. They have also assisted in the actual drafting of the technical standards. Concerning CLT structures, the aim is to produce effective documentation to support normative review [3]. Therefore, an in-depth worked example of a CLT multi-storey building has been prepared by applying both the Italian Technical Regulations for Construction (NTC 2018) [4] and the new draft of the Eurocode 8 still under revision (prEN 1998-1-2: 2020) [5,6].

2 SCOPE

The primary purpose of the aforementioned document is to clarify fundamental concepts related to the design of CLT buildings in seismic areas, such as: (i) dissipative mechanisms, allowing the use of a specific value of the behaviour factor q; (ii) the minimum ductility values that the dissipative connections should exhibit; (iii) the design conditions for attaining those minimum ductility values; (iv) the over-strength factors used in the design of the non-dissipative components; (v) the partial safety factors to be used in the design while taking into account the strength reduction due to cyclic loading. Therefore, the objective of the present study is to clarify the practical application of the capacity-based design by defining unambiguous procedures.

3 ANALYSIS CASES

A 5-storey CLT residential building (Figures 1, 2 and 3) is designed following four different cases of analysis: low and medium ductility class in accordance with the current Italian regulations (NTC 2018), and medium and high ductility (DC2 and DC3) according to the new draft of Eurocode 8.

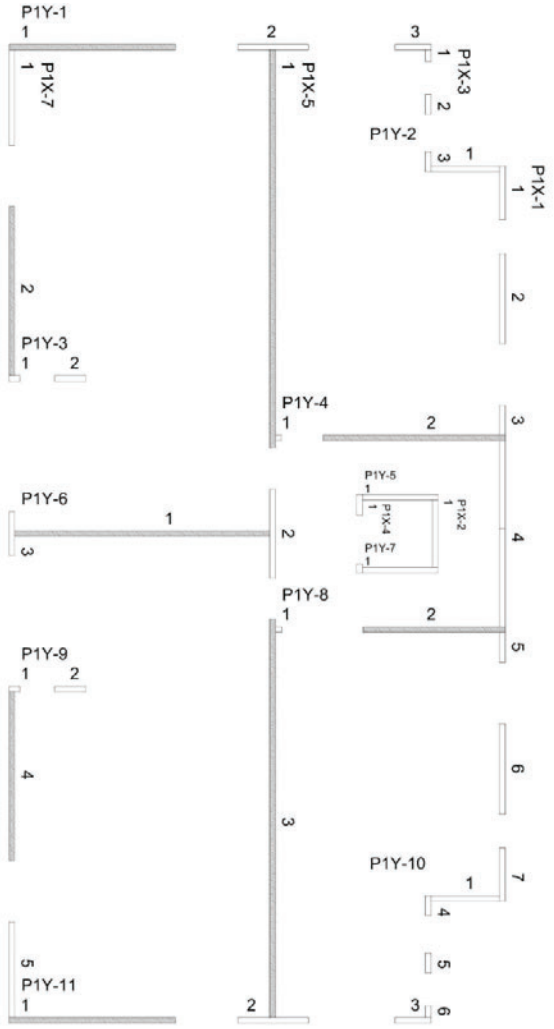

Figure 3: *CLT walls*

4 DESIGN DATA

4.1 THE BUILDING

The building is composed of five storeys, with an inter-storey height of 3.12 m; the total height of the buildings is 17.5 m. The structure is built using CLT panels (walls and slabs); the shear walls are designed to support both gravitational and lateral loads (wind and seismic action). The presence of many openings (windows and balconies) results in a segmentation of the shear walls that was addressed to define the Seismic Force Resisting System. The stairwell and the elevator shaft are also made of CLT panels; the connections with the diaphragm have been designed to ensure an adequate in-plane behaviour of floors. Neither the foundation system nor the soil-structure interaction are taken into account in the analysis. Three different types of panels are used, as shown in the table below.

Table 2: *CLT layup and thickness*

Element	Layup	Thickness
Slab	7 layers	220 mm
Walls level 1 to 3	5 layers	140 mm
Walls level 4 to 5	5 layers	120 mm

4.2 GRAVITY LOADS AND SEISMIC ACTION

Table 3 lists the values of the gravity loads acting on the building while Table 4 reports the parameters of the pseudo-elastic spectrum for the two limit states considered: Significant Damage SD (SLV according to NTC18) and Damage Limitation DL (SLD according to NTC18). Values of the seismic actions are selected with reference to common real cases in Italy. The peak ground accelerations for SD and DL have a probability of exceedance of 10% and 63% in 50 years, respectively. The site is mainly flat (topographic amplification factor S_t = 1) with a soil class C (180 m/s < $v_{s,30}$ < 360 m/s).

Table 3: *Gravitational loads*

Element	G_2	Q_{LIVE}
Slab	2.5 / 3.0 kN/m^2	2.0 / 4.0 kN/m^2
Roof	0.5 kN/m^2	-
Walls	0.5 kN/m^2	-

Table 4: *Seismic action parameters*

Limit state	a_g/g	F_0	T_C*
SD (SLV)	0.266 g	2.312	0.351
DL (SLD)	0.101 g	2.336	0.284

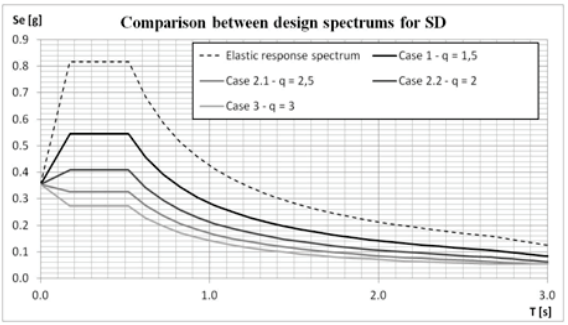

Figure 4: *Comparison between design spectrums for SD*

Given the interest on the seismic behaviour, only the seismic combination is considered, including all the possible variable loads.

$$E + G_1 + G_2 + P + \psi_{21} \cdot Q_{k1} + \psi_{22} \cdot Q_{k2} + \psi_{33} \cdot Q_{k3} \ldots$$

5 DESIGN PRINCIPLES AND FEM MODEL

The seismic design principles used in this example are based on the results of several research projects and of some full-scale tests on earthquake shaking tables (e.g. SOFIE project, IVALSA-CNR institute) [7]. These tests also enabled some modelling methods to be validated, like the one mentioned in the next paragraph.

5.1 FINITE ELEMENT MODEL

A 3D Finite Element (FE) model of the building is defined for each analysis case following the method proposed in [8]. Each model simulates the behaviour of the real structure in the context of linear dynamics.

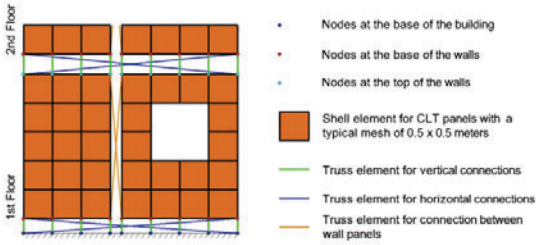

Figure 5: *Typical wall schematisation*

https://doi.org/10.52202/069179-0296

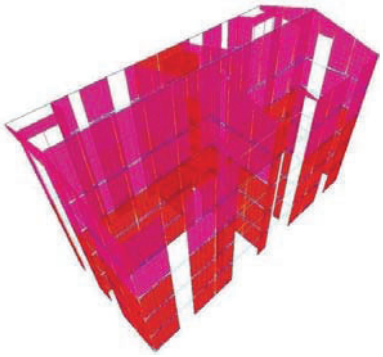

Figure 6: *Finite Element model*

Through an iterative process, it is possible to check the force level of the connections and update the corresponding deformability values which strongly affect the structure's vibration modes.

6 CAPACITY-BASED DESIGN

The design of dissipative seismic-resistant structures requires that a portion of the energy transferred by the earthquake to the structure is dissipated through the plasticisation of some connections. In this case, the seismic actions can be reduced provided that the Lateral Load Resisting System (LLRS) is able to provide an extra post-elastic resistance through well-localised plastic deformations. This means that the plasticisation phenomena must not make the structure unstable and must not compromise its overall behaviour. To achieve this goal, all the elements that must not exceed the elastic phase are designed with an over-strength factor compared to those with ductile behaviour, so that the dissipative phenomena will concentrate on the latter one [9,10].

6.1 OVER-STRENGTH LEVELS

As described below, the over-strength condition affects a structure at different levels:

- Single connector: in connection with Johansen's formulas, the brittle failure modes must have adequate over-strength with respect to ductile failure mode, represented by the plasticisation of the fasteners through one or more plastic hinges.
- Connections: the brittle failure mode of an entire connection must have adequate over-strength with respect to ductile failure mode. Typical brittle failure modes are shear failure in the carpentry nodes, shear or tension failure in wood sections, tensile or shear failure of metal plates and shear or punching shear failure of bolts and screws. Ductile failure modes are typically shear failures of dowel-type fasteners characterised by at least a plastic hinge formation;
- Structural elements and global behaviour: collapse of structural elements with non-dissipative behaviour and the formation of soft storey mechanisms are avoided, enhancing the overall behaviour of the entire structure.

6.1 HIGH DUCTILITY CASES (DC3)

In the new draft of Eurocode 8, a high ductility class (DC3) is proposed for CLT buildings consisting of LLRS made with multi-panel shear walls. In these walls, the panels are connected together with vertical joints that can dissipate energy primarily through the yielding of fasteners, leading to a coupled-panel (CP) behaviour where all the panels remain in contact with the ground or the floor below and a significant slip of vertical joints is attained. In order to ensure that CP behaviour is also attained in the plastic region, vertical joints have to be designed to yield before the hold-downs whereas angle brackets have to be slightly over-designed so that the sliding failure mechanism of the wall is prevented. Non-dissipative elements, typically characterised by a brittle failure mode, are designed to remain elastic when the vertical joints attain the desired level of inelastic displacement according to the capacity-based design approach.
The analytical expressions proposed by Casagrande et al. [9] are used in the draft of the new Eurocode 8 to ensure that CLT shear walls of buildings designed in DC3 attain the desired kinematic mode.

7 DISSIPATIVE CONNECTIONS

Dissipative connections must ensure proper energy dissipation; it is therefore important to analyse the different failure mechanisms in order to provide sufficient over-strength to those that exhibit brittle behaviour.

7.1 ANGLE BRACKETS FOR SHEAR LOAD

Angle brackets for shear load connect the wall panels to the floor panels or to the concrete foundation. To ensure the desired behaviour, the following failure mechanisms have been analysed:

- Shear failure of the steel plates;
- Failure of the plate-to-wall dowel-type connection;
- Failure of the plate-to-slab dowel-type connection.

Four types of angle brackets manufactured by Rothoblaas have been analysed in combination with two different types of fasteners (LBA 4 x 60 mm high bond nails and LBS 5 x 70 mm screws):

- TCN240 for timber-to-concrete connections;
- TTN240 for timber-to-timber connections;
- TTV240 for timber-to-timber connections with reinforcing screws that absorbs the eccentricity in the vertical plate of the bracket;
- TTF200 for timber-to-timber connections for lower loads.

In this case, the energy dissipation is exclusively located in the plate-to-wall screwed connection. The NTC2018 and the draft of the Eurocode 8 used for this work provide different over-strength factors, 1.3 and 1.6, respectively.

https://doi.org/10.52202/069179-0296

These values considerably affect the design resistance of the connection, as shown in the table below.

Table 5: *Angle brackets resistance in each case*

Angle bracket	Non-dissipative joints (from ETA)		Dissipative joints	
	Case 1	Cases 2.1, 2.2, 3	Case 2.1	Cases 2.2, 3
TCN240 + LBA	23.8 kN	33.3 kN	26.8 kN	26.8 kN
TCN240 + LBS	28.5 kN	39.9 kN	33.0 kN	33.0 kN
TTV240 + LBA	46.9 kN	65.7 kN	39.0 kN	31.7 kN
TTV240 + LBS	46.9 kN	65.7 kN	39.1 kN	31.8 kN
TTN240 + LBA	29.8 kN	41.7 kN	26.8 kN	21.8 kN
TTN240 + LBS	36.7 kN	51.4 kN	33.0 kN	26.9 kN
TTF200 + LBA	27.9 kN	39.1 kN	23.4 kN	19.0 kN
TTF200 + LBS	33.4 kN	46.8 kN	29.0 kN	23.6 kN

7.2 HOLD-DOWNS AND TIE-DOWNS

The anchoring connections against uplift (hold-downs, tie-downs) have been similarly analysed. Tie-down anchors through the floor panels have been used in combination with screwed connections between the steel plate and the CLT wall panel. The following failure mechanisms have been analysed:

- Tensile failure of the steel plate;
- Failure in shear of screwed connections between metal plate and CLT panel.

7.3 VERTICAL JOINTS BETWEEN WALL PANELS

In case 3 (high ductility case DC3), the increased demand for energy dissipation is ensured by the panel-to-panel connections; such joints are activated by the coupled-panel (CP) behaviour previously mentioned. The capacity-based design for a segmented wall requires that the vertical joints must yield before the anchoring connections against uplift [11,12]; this condition strongly affects the design of vertical joint between the wall panels. The half-lap joint replaces the step joints made with a cross-layer stripe inserted in grooves on one side of the CLT panels. The step joints are used only for low and medium ductility cases.

The shear force acting on the vertical joints has been calculated by isolating each individual wall (continuous wall from the foundation to the roof) and analysing it as disconnected from the rest of the structure. The actions (lateral load and gravitational loads for seismic combination) are taken from the global model. Once the loads are defined, it is possible to design the joints between adjacent wall panels by using the analytical expressions proposed by Casagrande et al. [9]

8 LINEAR DYNAMIC ANALYSIS

The stiffness of timber structures, particularly the CLT platform-frame type, is markedly affected by the deformability of the connections. However, this deformability can only be determined after the design of the connection itself.

The first step involves the use of a linear static analysis; this analysis allows for the "calibration" of the connections' resistance through a preliminary design.

Both the NTC2018 and the new draft of the Eurocode 8 propose Equation (1) as a method to identify the building's fundamental period of vibration.

$$T_1 = 0.05 \cdot h^{\frac{3}{4}} \quad (1)$$

where h is the height of the building, in [m], measured from the foundation or from the top of a rigid basement.

Once the connections are preliminarily designed, it is possible to calculate the related deformations that will be used to complete the numerical model. The dynamic analysis that, through an iterative process, leads to the convergence of the solution can then be run.

9 ANALYSIS OF RESULTS

The results obtained make it possible to compare the cases analysed, evaluating the differences in relation to various aspects.

9.1 MODAL ANALYSIS

A comparison of the results of the modal analysis demonstrates that the differences between the vibration periods of cases 1, 2.1 and 2.2 are negligible (in the order of a hundredth of a second). On the contrary, for case 3 there is an increase of about one-tenth of a second in the first vibration period; this result reflects the larger deformability of the structure due to the wall segmentation. The following table summarises the values for the first three modes of vibration.

Table 6: *Vibration periods*

Mode	Vibration periods	
	Cases 1, 2.1, 2.2	Case 3
1	0.384 s	0.486 s
2	0.363 s	0.479 s
3	0.294 s	0.398 s

The mode shapes do not present significant variations; the first three mode shapes are translational along the two horizontal directions and rotational along the vertical axis.

https://doi.org/10.52202/069179-0296

9.2 CONNECTIONS

The following subparagraphs compare the loads obtained for the different types of connections. Two shear walls have been chosen for the sake of synthesis: the first P1X-5-1 is a long wall on the first level, with significant gravitational loads; the second P4Y-11-1 is a short external wall on the fourth level, only slightly loaded in terms of vertical loads.

9.2.1 Angle brackets

The following table shows the number of angle brackets for the two walls analysed. It is interesting to compare the values relating to cases 2.1 and 2.2: the number of angle brackets in case 2.2, already increased due to the lower behaviour factor, is further amplified by the lower performance of the angle brackets themselves, caused by the greater over-strength factor.

Table 7: *Number of angle brackets per wall*

Wall (angle bracket)	Number of angle brackets (load) Case 1	Cases 2.1	Case 2.2	Cases 3
P1X-5-1 (TCN240)	14 (535 kN)	9 (324 kN)	13 (380 kN)	4 (118 kN)
P4Y-11-1 (TTN240)	5 (182 kN)	3 (110 kN)	5 (139 kN)	5 (110 kN)

9.2.2 Hold-down/Tie-down

In the case of anchoring connections against uplift, the design loads are shown instead of the connection setup. This is because in case 3, the connection setup was changed to accommodate the needs of the capacity-based design in high ductility.

Table 8: *Uplift forces in hold-down / tie-down*

Wall	Uplift forces Case 1	Cases 2.1	Case 2.2	Cases 3
P1X-5-1	26 kN	0 kN	0 kN	4 kN
P4Y-11-1	69 kN	32 kN	46 kN	42 kN

9.2.3 Non-dissipative connections

For medium and high ductility, the non-dissipative connections must ensure sufficient over-strength in order to remain elastic when the dissipative connections attain the desired level of inelastic displacement. With Equation (2) it is possible to take into account the effective resistance of the dissipative connections before applying the desired over-resistance factor to it.

$$F_{Rd,b} \geq \frac{\gamma_{Rd}}{k_{deg}} \cdot \Omega_d \cdot F_{Ed,E} + F_{Ed,G} \qquad (2)$$

where F_{Rd} = design resistance of the non-dissipative joints, γ_{Rd} = over-resistance factor, k_{deg} = strength reduction factor, $F_{Ed,E}$ = action effect in the non-dissipative joint, or member due to the design seismic action, $F_{Ed,G}$ = action effect in the non-dissipative joint or member due to the non-seismic actions in the design seismic situation, and Ω_d = minimum value of all the over-strength ratios $\Omega_{d,i}$, where i is the storey (see CEN/TC250/SC8 prEN 1998-1-2:2020 for further information).

Table 9 shows the results obtained for the joints between orthogonal walls; due to the heavy loads, these connections are made with angle brackets for shear forces; two connections were chosen in locations where the greatest loads occur.

It is important to point out that these connections are schematised with rigid links in the numerical model.

Table 9: *Number of angle brackets for joints between orthogonal walls*

Wall (angle bracket)	Number of angle brackets (load) Case 1	Cases 2.1	Case 2.2	Cases 3
P1X-5-1 (TTF200)	6 (169 kN)	4 (173 kN)	5 (231 kN)	4 (177 kN)
P4Y-11-1 (TTF200)	2 (66 kN)	2 (68 kN)	3 (96 kN)	2 (85 kN)

9.3 DESIGN COMPLEXITY

Finally, the design complexity of the different cases is analysed. After having calibrated the model through the linear static analysis, few iterations in the dynamic analysis are enough to make the solution converge for low and medium ductility. The angle brackets for shear loads represent the only deformable connections in the numerical model. With the results extracted from the model, it is possible to design all the joints.

In the case of high ductility, one more step must be added: once the global numerical model of the structure is completed, the loads acting on the different connections of the segmented walls are calculated through free body diagrams on each single wall. Horizontal and vertical loads acting on the wall can be extracted from the numerical model. These conditions must be validated through the equations proposed by Casagrande et al. [9] in order to attain the desired kinematic mode.

10 CONCLUSIONS

This study presents the design process of a multi-storey CLT building according to the methods and design provisions included in the new draft of the Eurocode 8. A detailed worked example of design is presented for four different cases of analysis, including also a comparison with the current Italian regulations (NTC 2018). The design process starts from the calibration of the global models through an equivalent static analysis up to the characterization of the main connections that this construction system requires.

Through the detailed analysis of each individual step, possible issues in the interpretation and application of the

rules are highlighted. Some solutions complying with the requirements related to the various cases and ensuring ease of use in the application are then proposed. Such simplified solutions are indispensable for a practical design.

Finally, the results of the various cases analysed are compared. When it comes to capacity-based design, the effects of the over-strength factors strongly characterise the design of each connection as well as the choice of connection types. This over-strength requirement makes the implementation of the connections more difficult in some cases. Furthermore, these coefficients cancel out almost completely the advantage of using higher behaviour factors for all the non-dissipative joints and elements.

Therefore, some serious considerations should be made about the values of the over-strength factors to be used in the seismic design of highly redundant structures like multi-storey CLT buildings. The fairly high values currently proposed in the new Eurocode 8 draft, in fact, may lead to a limited use of these structures in seismic prone areas. On the other hand the full-scale tests conducted so far demonstrated that such structures are capable to withstand severe seismic actions with limited damage and high dissipative behaviour.

Several issues related to the modelling process are also analysed in order to verify the underlying hypotheses and their correspondence with the experimental results.

ACKNOWLEDGEMENT

SEISMIC RESPONSE OF BALLOON TYPE CLT SHEAR WALLS

Zhiyong Chen[1], Marjan Popovski[2]

ABSTRACT: Balloon-type mass timber shear walls are one of the most efficient structural systems to resist lateral loads induced by earthquakes or high winds. This system, however, is not included in the 2020 National Building Code of Canada and has no design guidelines in the 2019 Canadian Standard for Engineering Design in Wood, so it is out of reach of most designers. A multi-year research project has been initiated at FPInnovations to quantify the system performance and develop the necessary technical information to codify balloon-type mass timber shear walls. This paper presents the initial results of a study on the seismic response of balloon-type CLT shear walls. A mechanics-based analytical model was updated to predict the CLT panel resistance, in addition to predicting the deflection and resistance of balloon type CLT shear walls. The influence of specific key parameters such as wall length and thickness, aspect ratio, vertical loads, and vertical joints, on the structural performance of this wall system under lateral loads was investigated using the updated model. The results of this study will give a valuable insight into the seismic performance of balloon type CLT shear walls.

KEYWORDS: Mass timber, CLT, balloon walls, tall wood construction, seismic response, numerical model

1 INTRODUCTION

Balloon-type mass timber shear walls (Figure 1) are one of the most efficient structural systems to resist lateral loads induced by earthquakes or high winds. They allow use of longer mass timber panels, reduction of number of connections, and prevention of the accumulated compression perpendicular to grain in floor panels [1]. This system, however, is not included in the 2020 National Building Code of Canada and has no design guidelines in the 2019 Canadian Standard for Engineering Design in Wood, so it is out of reach of most designers.

***Figure 1: E**xample of a balloon wall in CLT construction*

Most of the research on CLT as a lateral load resisting system so far has been conducted on platform-type construction [2]. A multi-year research project has been initiated at FPInnovations to quantify the system performance and develop the design information to codify balloon-type mass timber shear walls [3]. This paper presents the initial results of the study related to the seismic response of balloon-type CLT shear walls. A mechanics-based analytical model [1] was updated to predict the CLT panel resistance, in addition to predicting the deflection and resistance of these types of CLT shear walls. The influence of wall length and thickness, wall aspect ratio, vertical loads, and vertical joint properties on the structural performance of this wall system under seismic loads was investigated using the developed model.

2 ANALYTICAL MODELS

2.1 DEVELOPED MODELS

Two analytical models (rigid- and elastic-base models) were developed and verified at FPInnovations to predict the resistance and deflection of balloon-type CLT shear walls [4]. Single- and coupled panel balloon-type CLT walls (Figure 2) were considered by the developed models [1]. The seismic actions on these walls create a base shear force and overturning moment(s). As illustrated in Figure 2, the vertical uplift forces are taken by hold-downs at both ends of the wall, while the shear forces are taken by shear connectors, shear keys, or both. The vertical joints between the panels are not only used to connect the panels in the coupled walls, but also add to the energy dissipation properties of the system. Using the capacity design methodology for seismic lateral loads, the capacity of the wall system is governed solely by the capacity of the connections. The CLT panels are designed to exhibit elastic in-plane deformations, while the connections provide all the ductility and energy dissipation [5, 6].

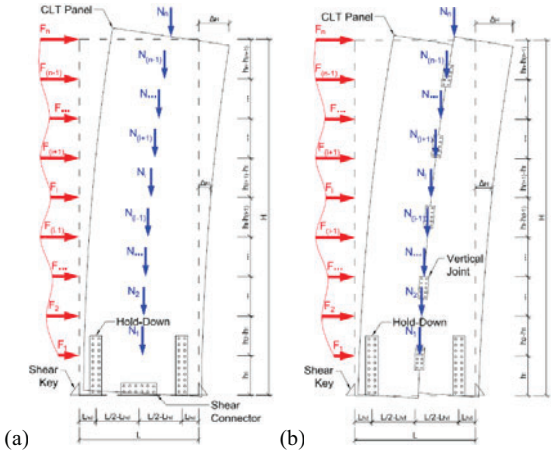

Figure 2: *(a) Single and (b) coupled wall model. Note: F_i and N_i represent the lateral load and the vertical load on the wall at a height level i, respectively [kN]; h_i represents the height level of the lateral and vertical load [m]; the deflection of the wall at the top (level $h_n = H$) and at any level i is designated as Δ_H and Δ_{hi}, respectively [mm]; n indicates the number of load levels.*

The total lateral deflection of a single-panel balloon-type CLT shear wall at any height level *i*, Δ_{hi}, is comprised of four deflection components: wall bending $\Delta_{hi,b}$, wall shear $\Delta_{hi,s}$, rotation (anchorage deformation) $\Delta_{hi,rot}$, and sliding $\Delta_{hi,sld}$, (Figure 3a to 3d). In case of walls with multiple panels an additional component $\Delta_{hi,slp}$ (Figure 3e) that represents the slip between the panels, needs to be added. Thus, the total deflection can be calculated using Eq. (1).

$$\Delta_{hi} = \Delta_{hi,b} + \Delta_{hi,s} + \Delta_{hi,rot} + \Delta_{hi,sld} + \Delta_{hi,slp} \quad (1)$$

The lateral resistance of the system is governed by the strength of the hold-downs, shear connector(s), wood in contact with shear keys, and vertical joints, if present, using three failure scenarios: (a) when shear failure occurs in the bottom connections where the hold-downs and shear connector yield horizontally, and the wood in contact with the shear key at one end crushes successively under base shear; (b) when overturning occurs in single-panel walls where the hold-down at one end yields vertically; and (c) when overturning occurs in coupled walls where the vertical joints yield first followed by yielding of hold-down at one end. The actual resistance can be taken as the minimum resistance derived from the three scenarios.

The balloon-type shear wall is a statically indeterminate system where the connections resist the loads following deformation coordination principle. The deflection and resistance of the wall system can be derived by solving the nonlinear equations of the developed analytical models using the trial-and-error method. Detailed derivation of the deformation components and resistances in different scenarios is provided in Chen and Popovski [1].

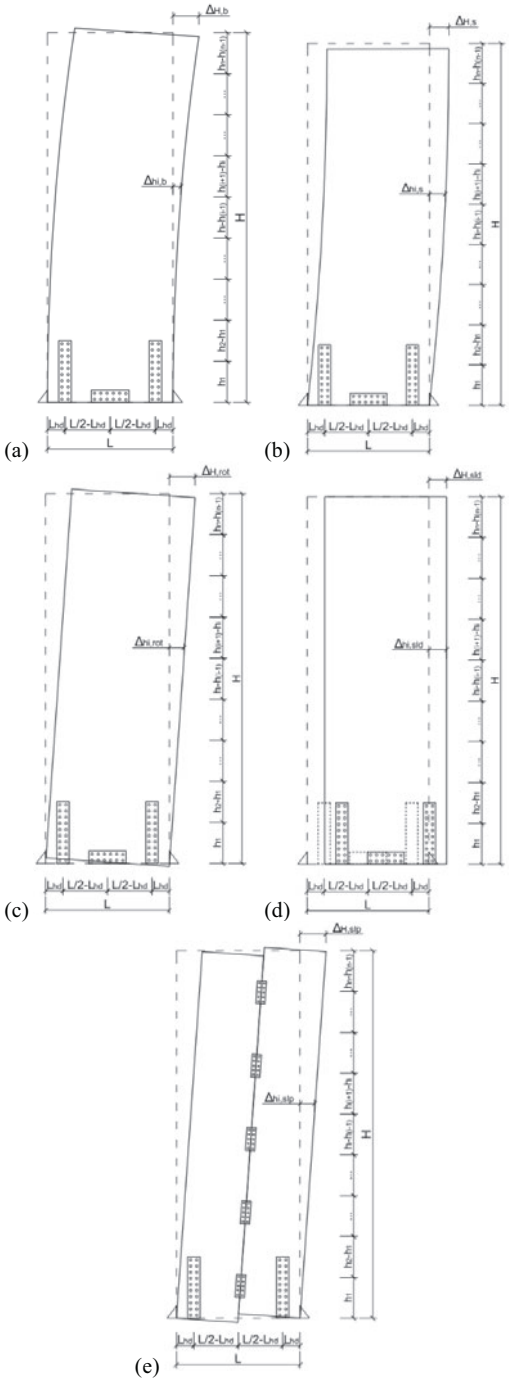

Figure 3: *Lateral deflection components of balloon-type walls: (a) bending; (b) shear; (c) rotation; (d) sliding; and (e) slip*

Generally, the CLT panels in balloon wall system when subjected to in-plane lateral loads present a complex stress state and many failure modes need to be considered in the design [7]. Therefore, the developed elastic-base model was updated in this study to predict the CLT panel resistance to support the capacity design of the balloon-type CLT shear walls.

https://doi.org/10.52202/069179-0297

2.2 PANEL RESISTANCE

CLT panels considered in this study have all longitudinal layer with equal thickness and equal width of the boards in the layers. It is assumed that the resistance of CLT panels is governed by bending and shear failure (gross shear, net shear, rolling shear and torsion). It is also assumed that reinforcing solutions are present in areas where some stress concentration is to be expected, e.g., around openings, bottom of the panels, and others, so that the failure does not occur in the panel.

A balloon-type CLT shear wall acts like a vertical cantilever beam in which the wall panels generally behave elastically. The normal stress distribution due to bending in the cross section of the CLT panel is illustrated in Figure 4. Accordingly, the maximum bending stress, σ_{max}, at the bottom for a balloon-type shear wall under a number of lateral loads at different height levels can be calculated using Eq.(2) that is derived using structural mechanics based on a beam theory.

$$\sigma_{max} = \frac{LE_{mean}}{2(EI)_{eff}} \sum_{j=1}^{n} F_j h_j \qquad (2)$$

where E_{mean} is the mean modulus of elasticity [N/mm^2] of the longitudinal layers (the horizontal layers in Figure 4) of the CLT panel; $(EI)_{eff}$ is the effective bending stiffness [N·mm^2] of the CLT panel which can be calculated using the simplified design method [8], or using the k method (composite theory) provided by Blass and Fellmoser [9].

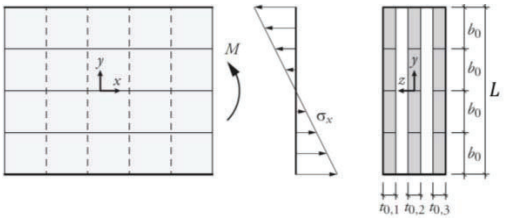

Figure 4. *Illustration of normal stress distribution due to bending [7]*

The calculated maximum stress should not be larger than the bending strength f_b of the CLT panel specified in the material design standards or product manuals. Therefore, the maximum base shear V_b can be calculated using Equation (3).

$$V_b = \frac{2f_b(EI)_{eff}}{LE_{mean}} \Big/ \sum_{j=1}^{n} F_{pattern,j} h_j \qquad (3)$$

where $F_{pattern,j}$ is the normalized lateral load factor for the j_{th} storey according to the lateral load pattern along the height of the wall. Lateral load F_j is the product of V_b and $F_{pattern,j}$.

In CLT cantilever beams where adjacent lamellas (boards) within individual layer are not edge-glued, the thickness is not constant throughout the height of the CLT beam. In cross-sections at unglued joints between neighbouring lamellas, the shear forces can only be transferred by lamellas in the perpendicular direction. Consequently, the shear stresses in these so-called net cross sections are higher than in the gross cross-sections (between unglued joints). The transfer of shear forces between longitudinal and transversal lamellas also causes shear stresses in the crossing areas of orthogonally bonded lamellas. By considering the shear stresses in the lamellas and in the crossing areas, three different failure modes (Figure 5) exist in CLT beams subjected to shear stresses [10].

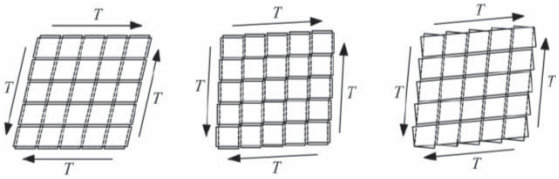

Figure 5. *Failure modes I, II and III in CLT-panel subjected to transversal forces in plane direction (from left to right) [10]*

Failure mode I is characterised by shear failure parallel to the grain in the gross cross-section of the CLT panels. This failure occurs in sections between unglued joints with τ_I equaling to the gross shear strength $f_{v,gross}$ in longitudinal layers and transversal layers. Therefore, the maximum base shear, V_{sI}, can be calculated using Equation (4).

$$V_{sI} = \frac{2Lt_{gross}f_{v,gross}}{3} \qquad (4)$$

where t_{gross} is the gross thickness of the CLT panels.

Failure mode II is characterised by shear failure perpendicular to the grain in the net cross-section of the CLT panels. This failure occurs in sections coinciding with unglued joints with shear stresses only in lamellas perpendicular to the joints. The maximum base shears ($V_{sII,90}$ and $V_{sII,0}$) can be calculated using Eqs. (5) and (6).

$$V_{sII,90} = \frac{2Lt_{net,90}f_v}{3} \qquad (5)$$

$$V_{sII,0} = \frac{2Lt_{net,0}f_v}{3} \qquad (6)$$

where $t_{net,90}$ is the total thickness of all perpendicular layers in the CLT panels; $t_{net,0}$ is the CLT panel net cross-section thickness when considering longitudinal layers only.

Failure mode III is characterised by shear failure within the crossing areas between the orthogonally glued boards (lamellas). This failure mode is caused by torsional and unidirectional shear stresses form the transfer of the shear forces between adjacent layers. The maximum base shear (V_{sIII}) can be calculated using Equation (7).

$$V_{sIII} = \frac{b_0^2 n_{ca}}{\frac{6\left(\frac{1}{m}+\frac{1}{m^3}\right)}{f_{tor}} \frac{b_0 b_{max}}{b_0^2+b_{90}^2} + \frac{6\left(\frac{1}{m^2}+\frac{1}{m^3}\right)1.33}{f_s}} \quad (7)$$

where n_{ca} is the number of crossing areas that longitudinal lamination shares with adjacent transversal laminations; m is the number of horizontal boards in the CLT beam or $m = L/b_0$; q is the local compression [kN/m]; b_{max} is the maximum value for the width of either the longitudinal boards (b_0) or the transversal boards (b_{90}), i.e., $b_{max} = max\{b_0, b_{90}\}$.

3 KEY PARAMETERS AFFECTING STRUCTURAL PERFORMANCE

Using the updated analytical elastic-base model, parametric analyses were conducted to investigate the influence of various key parameters on the structural performance of balloon-type CLT walls. The key parameters that were investigated include (a) CLT panel thickness (number of layers); (b) wall length (panel width); (c) wall aspect ratio; (d) level of vertical loads; and (e) vertical joint properties (coupled walls). The influence of the first four parameters was studied with single-panel shear walls (Figure 2a) under multiple point loads in reversed triangular pattern (Figure 6), while that of the fifth parameter was studied with coupled shear walls (Figure 2b).

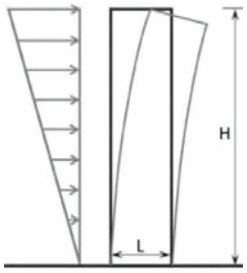

Figure 6: *Reversed triangular lateral load pattern applied to the wall*

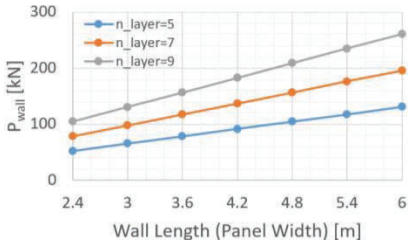
The CLT panels and shear connectors were capacity designed; while the hold-downs were designed to yield under lateral loads once the maximum stresses in the panels reach 30% design bending or shear strength, whichever is less, i.e., lateral load level (LLL) = 30%. The distance of hold-downs to the close edge, L_{hd} (Figure 2), was taken as $L/20$.

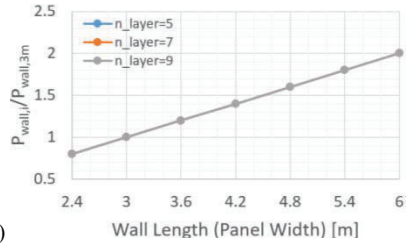
3.1 WALL LENGTH

The influence of wall length (CLT panel width) was studied on single-panel shear walls with a wall height of 18 m, which is typical for a 6-storey building with a storey height of 3 m. The considered wall lengths, L, were 2.4 m, 3.0 m, 3.6 m, 4.2 m, 4.8 m, 5.4 m, and 6.0 m. The commonly used 5-, 7-, and 9-ply CLT panels were investigated.

Figures 7 and 8 show the relationship of the wall length to the resistance (P_{wall}) and stiffness (K_{wall}) of the analysed balloon-type CLT shear walls. The ratios in Figures 7b and 8b were based on the structural performance properties of the shear walls with 3.0 m wall length and a given wall thickness. With an increase in the wall length, the resistance increased linearly, while the stiffness increased nonlinearly. This is because the resistance of all walls was governed by the shear failure, while the deflection was a combination of bending and shear deformation, rotation, and sliding.

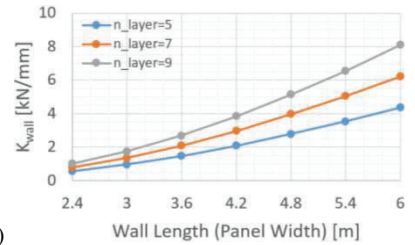


(a)

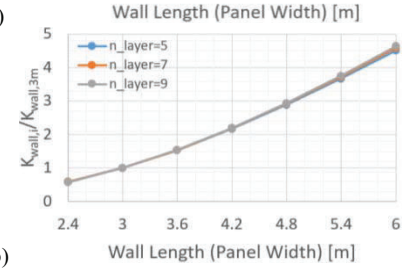


(b)

Figure 7: *Relationship between the wall length and the wall resistance: (a) Absolute values; and (b) Relative values with respect to a 3m long wall*



(a)



(b)

Figure 8: *Relationship between the wall length and the wall stiffness: (a) Absolute values; and (b) Relative values with respect to 3 m long wall*

The relationship between the wall length and the ratio of the compression zone length to the wall length (L_c/L) for the analysed balloon-type CLT shear walls is shown in Figure 9. The L_c/L ratio was constant for all wall lengths

https://doi.org/10.52202/069179-0297

of the same wall thickness. This is because the lateral loads applied on the walls is governed by shear resistance of the panels, which by itself is in linear relationship with the wall length. Thus, the L_c/L ratio remained constant.

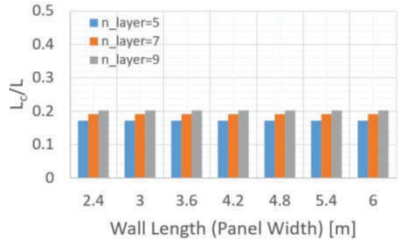


Figure 9: *Relationship between the wall length and the compression zone length*

3.2 WALL THICKNESS

The influence of wall thickness can be analysed by comparing the structural performance of the analysed shear walls with different thickness. The thickness depends on the number of layers in the CLT panel (0.175 m for 5-ply, 0.245 m for 7-ply, and 0.315m for 9-ply panels). The relationship of the wall thickness to the wall resistance and stiffness is shown in Figures 10 and 11. The ratios in Figures. 10b and 11b were based on the structural performance properties of walls with 0.175 m thickness (5-ply) for a given wall length. With an increase in wall thickness, the resistance and the stiffness of the shear walls increased linearly. In both, Figure 10b and 11b, the relationships for all wall lengths are identical. All shear walls were governed by shear (type II in transversal laminations) failure of which the resistance and stiffness increase linearly with the number of transversal laminations (i.e., 2, 3, and 4).

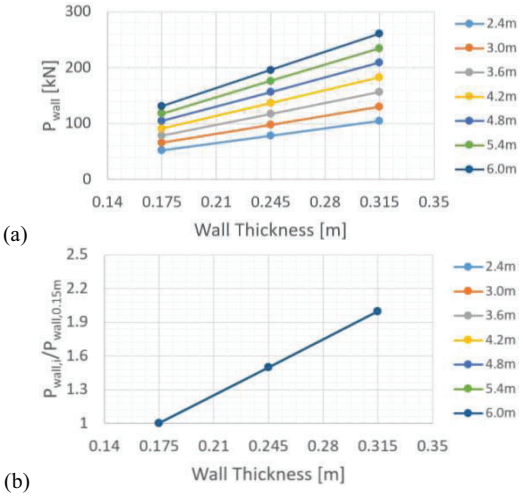

Figure 10: *Relationship between the wall thickness and the wall resistance: (a) Absolute values; and (b) Relative values with respect to 175 mm thick wall*

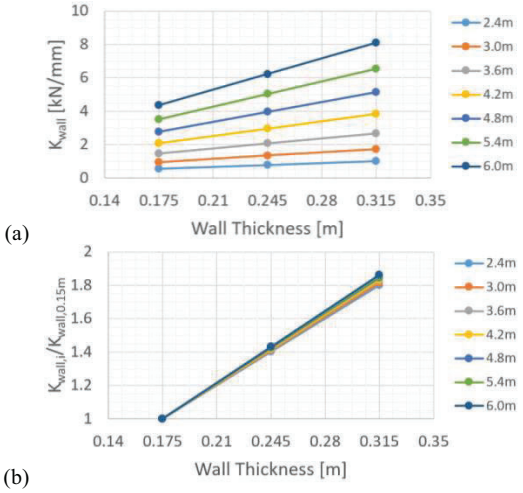

Figure 11: *Relationship between the wall thickness and the wall stiffness: (a) Absolute values; and (b) Relative values with respect to 175 mm thick wall*

The relationship between the wall thickness and the ratio of the compression zone length to the entire wall length (L_c/L) for the analysed balloon walls is shown in Figure 12. The ratio L_c/L increased with an increase in wall thickness.

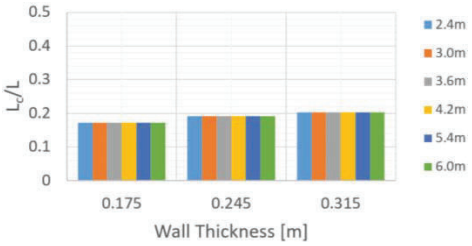

Figure 12: *Relationship between wall thickness and compression length*

3.3 WALL ASPECT RATIO

The influence of the wall aspect ratio was studied on 7-ply single-panel shear walls with a wall length of 1.5 m, 3.0 m, and 6.0 m. The considered aspect ratios were 4, 6, 8, 10, and 12. Correspondingly, the wall heights were 6m, 9 m, 12 m, 15 m, and 18 m for 1.5m long shear walls; 12 m, 18 m, 24 m, 30 m, and 36 m for 3.0 m long walls; and 24 m, 36 m, 48 m, 60 m, and 72 m for 6.0 m long walls.

Figures 13 and 14 show the relationship of the wall aspect ratio to wall resistance and stiffness of the analysed balloon walls. The ratios (Figures 13b and 14b) were based on the structural performance properties of the shear walls with the aspect ratio of 4.0 and a given wall length. The resistance kept constant until the aspect ratio of 8.0. Beyond that it decreased in a nonlinear fashion with an increase in the aspect ratio. This is because the shear failure governed the wider walls while bending failure governed the slender walls. The critical aspect

ratio for the change of governing failure mode was around 8.0. The stiffness decreased in a nonlinear fashion with an increase in the aspect ratio. Slender walls showed to have less resistance and be more flexible, compared to wider walls.

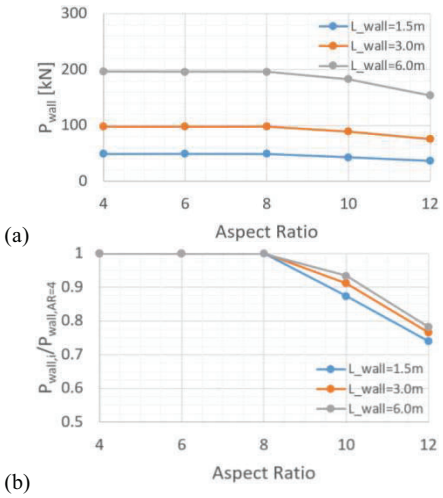

Figure 13: *Relationship between the aspect ratio and the wall resistance: (a) Absolute values; and (b) Relative values with respect to walls with aspect ratio of 4.0*

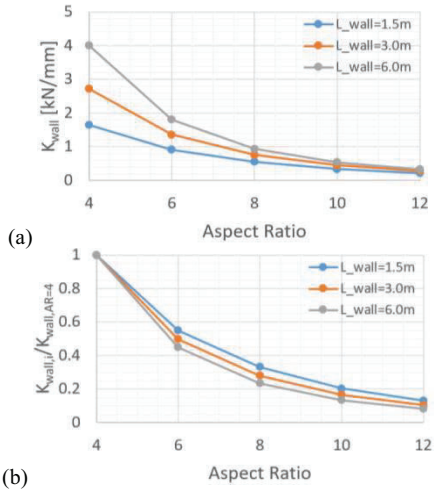

Figure 14: *Relationship between the aspect ratio and wall stiffness: (a) Absolute values; and (b) Relative values with respect to wall with an aspect ratio of 4.0*

The relationship between the wall aspect ratio and the ratio of the compression zone length to the entire wall length (L_c/L) for analysed balloon-type CLT shear walls is shown in Figure 15. As can be seen, an increase in wall aspect ratio resulted in a non-linear increase in the L_c/L ratio until a wall aspect ratio of 8.0, beyond which L_c/L was constant. For the walls governed by shear failure, where the wall aspect ratio is not larger than 8.0, slender walls needed longer L_c to resist larger compression under the same later loads. In walls governed by bending failure, where the wall aspect ratio is over 8.0, a balance was achieved between L_c and the aspect ratio. A larger wall aspect ratio resulted in an increase in the compression stress at the wall base and thus L_c; however, it also reduced the amount lateral load that the wall can carry and thus the compression portion and L_c.

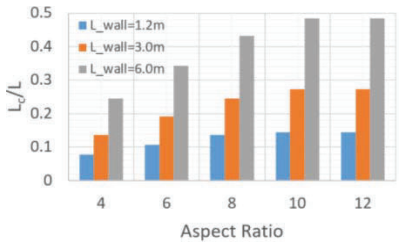

Figure 15: *Relationship between the wall aspect ratio and the compression zone length for walls designed for the same lateral load*

The deflection components of the balloon-type CLT shear walls with different aspect ratios were decoupled and the percentage of each component is shown in Figures 16 to 18. The rotation and bending deflection were the major contributors to the deflection of the walls, while the shear deflection had less contribution. The contribution of sliding was small enough to be ignored. As the wall aspect ratio increased, the walls became slenderer and the contribution of the bending deflection increased and became predominant, while the contribution of rotation and shear deflection decreased. The intersection between the rotation and the bending deformation curves occurred at a lower aspect ratio for longer walls (e.g., 6.0 m) compared to a short wall (e.g., 1.5m). This is due to the fact that the bending deflection is a function of aspect ratio but also of the applied loads. For the same aspect ratio, the higher the loads, the larger the deflection.

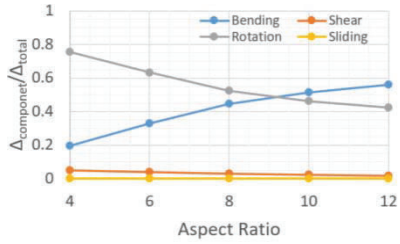

Figure 16: *Influence of wall aspect ratio on the deflection components in 1.5 m long single-panel walls*

https://doi.org/10.52202/069179-0297

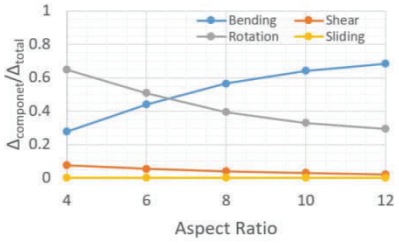

Figure 17: *Influence of wall aspect ratio on the deflection components in 3.0 m long single-panel walls*

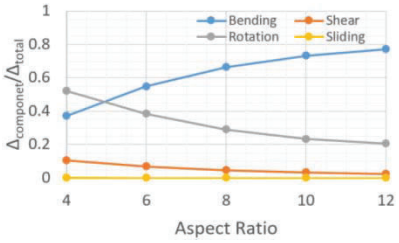

Figure 18: *Influence of wall aspect ratio on the deflection components in 6.0 m long single-panel walls*

3.4 VERTICAL LOADS

Vertical loads applied to the shear walls provide additional overturning resistance to the walls, and as a result, they affect wall's lateral stiffness and resistance. The influence of the vertical loads was studied on 7-ply single-panel shear walls with a wall length of 1.5 m (H = 9 m), 3.0 m (H = 18 m), and 6.0 m (H = 36 m). Six vertical load levels (VLLs), 0%, 20%, 40%, 60%, 80% and 100% of the reference vertical loads, were analysed for each wall length. The reference vertical loads were defined as loads that can counteract the overturning resistance of a wall without vertical loads. Thus, the reference vertical loads were taken as 1200 kN, 2300 kN, and 4300 kN for 1.5 m, 3.0 m, and 6.0 m walls, respectively.

Figures 19 and 20 show the relationship of vertical loads to wall resistance and stiffness of the analysed balloon-type CLT shear walls. The ratios (Figures 19b and 20b) were based on the structural performance properties of the shear walls with the vertical load level of 0% (no vertical loads) and a given wall length. As shown in Figure 19, the resistance of 1.5 m walls increased with an increase in the VLL up to 60% and then started to decrease. The resistance of 3.0 m long walls increased with an increase in the VLL at the beginning, but then very soon after 40% VLL the resistance started to decrease. The resistance of 6.0 m walls decreased with an increase in VLL until VLL reached 60% beyond which the resistance increased with the increases in the VLL. As shown in Figure 20, the stiffness of 1.5 m and 3.0 m long walls increased with an increase in VLL, while the stiffness of 6.0 m walls decreased with an increase in VLL. All these findings indicate that the wall resistance and stiffness were affected by not only the VLL, but also the ratio between compression length and the wall length ($\boldsymbol{L_c/L}$, Figure 21).

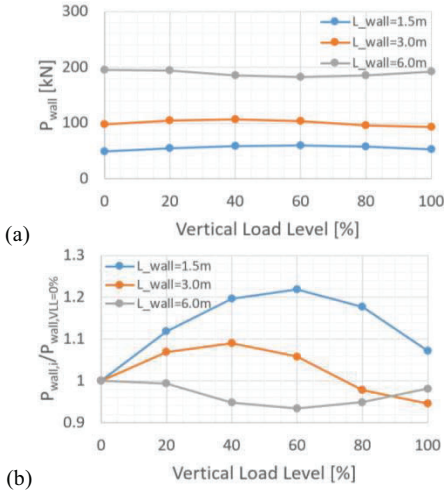

Figure 19: *Relationship between VLL and wall resistance: (a) Absolute values; and (b) Relative values with respect to walls without vertical load*

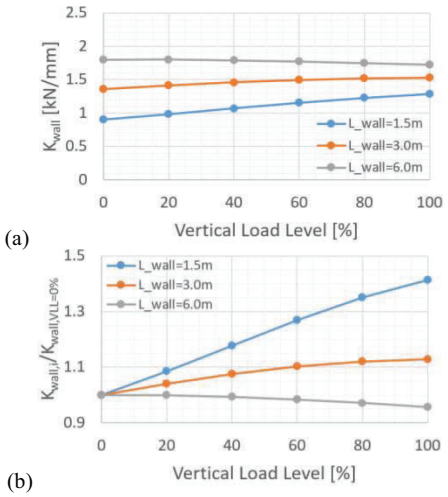

Figure 20: *Relationship between vertical loads level and compression zone length*

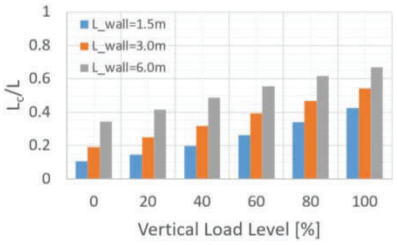

Figure 21: *Relationship between vertical loads level and compression zone length*

The stiffness of the walls increased with an increase in VLL when L_c/L was less than 0.4 and decreased when L_c/L was larger than 0.4. The resistance of walls increased with an increase in VLL when L_c/L was either

less than 0.4 or larger than 0.6, while it decreased with an increase in VLL when L_c/L was between 0.4 and 0.6. This is because the effect of vertical loads changes from been helpful (increasing the resistance) to detrimental (decreasing the resistance) under lateral loads, when L_c/L changes from less than 0.4 to larger than 0.6, with the range of 0.4 to 0.6 L_c/L been the transition zone. For cases with large L_c/L (e.g., over 0.6), the vertical loads provide some kind of prestressing at the wall bottom and thus increase the wall resistance.

3.5 VERTICAL JOINTS

The influence of the vertical joints was studied on a 7-ply coupled balloon-type CLT walls with two configurations. Configuration A was a 9 m high coupled wall with 1.5 m panel width (3.0 m total wall length), while Configuration B was 18 m high coupled wall with 3.0 m panel width and a total wall length of 6.0 m. A shear stiffness ratio (SSR) was defined as the ratio of the stiffness of the vertical joints to the shear stiffness of the wall along the height. Seven (7) shear stiffness ratios (SSR) were considered in the investigation: 0.01, 0.1, 0.2, 0.4, 0.6, 0.8, and 1.0. The ratio between the resistance and the stiffness of the vertical joints was taken as that of the self-tapping screw connections tested at FPInnovations [4], i.e., 5.0.

Figures 22 and 23 show the relationship of the shear stiffness ratio to wall resistance and stiffness of the analysed balloon-type CLT shear walls. The ratios (Figures 22b and 23b) were based on the structural performance properties of the shear walls with the SSR of 0.01 and a given wall length. As shown in Figure 22, the resistance of 3 m and 6 m coupled walls increased with an increase in the SSR until 0.4 and 0.6, respectively, beyond which the resistance of the walls was governed by the hold-downs rather than the vertical joints. The stiffness of both wall configurations (Figure 23), increased dramatically when the SSR was less than 0.4, beyond that the increases became smaller. The relationship between the SSR and the $\boldsymbol{L_c/L}$ for analysed balloon-type walls is shown in Figure 24. The ratio $\boldsymbol{L_c/L}$ stayed constant for different SSRs, indicating that $\boldsymbol{L_c/L}$ of coupled shear walls is not affected by the SSR.

The deflection components of the coupled CLT shear walls with different SSRs were decoupled and the percentage of each component is shown in Figures 25 and 26. Bending, rotation, shear, and sliding deformation increased with an increase in the SSR, while the slip defection decreased. Slip deformation was the major component for coupled walls with a small SSR, while bending deformation became the major component for coupled walls when the SSR was larger than 0.1.

4 CONCLUSIONS

A multi-year research project has been initiated at FPInnovations to quantify the system performance and develop the design information to codify balloon-type mass timber shear walls. A mechanics-based analytical model was updated to predict the CLT panel resistance, in addition to the deflection and resistance of balloon type CLT shear walls. Using this updated model, the influence of wall length and thickness, aspect ratio, vertical loads, and vertical joints on the seismic performance of this wall system was investigated. The findings are listed as follows:

- The lateral resistance and stiffness of balloon-type CLT shear walls increased with an increase in the wall length and thickness and decreased with an increase in the wall aspect ratio.
- The rotation and bending deflection were the two major contributors (e.g., 90% in total) to the total deflection of single panel balloon walls, while the shear deflection was the third one (e.g., 10%). The contribution of sliding was small enough to be ignored. As the wall aspect ratio increased, the walls became slender, and as a result the contribution of bending deflection increased (e.g., from 20% to 80%) and became the largest contributor to the total deflection, while the contribution of the rotation and the shear deflection decreased (e.g., rotational deflection changed from 80% to 20% and shear deflection changed from 10% to 1%).
- The lateral resistance and stiffness were affected by the vertical load level and the ratio of compression zone length to the wall length (L_c/L). The resistance of walls increased with an increase in the vertical load level when L_c/L was either less than 0.4 or larger than 0.6, while it decreased with an increase in vertical load level when L_c/L was between 0.4 and 0.6. The stiffness of walls increased with vertical load level when L_c/L was less than 0.4 and decreased when L_c/L was larger than 0.4.
- The lateral resistance of 3 m and 6 m coupled walls increased with an increase in the shear stiffness ratio until 0.4 and 0.6, respectively, beyond which the resistance of the walls was governed by the hold-downs rather than the vertical joints. The stiffness of both wall configurations increased dramatically when the shear stiffness ratio was less than 0.4, beyond that the increase became smaller.
- In coupled balloon-type CLT shear walls, the bending, rotation, shear, and sliding deflection increased with an increase of the shear stiffness ratio, while the slip deflection decreased with increases in the shear stiffness ratio.

The updated analytical model will assist researchers and structural designers in developing and designing appropriate balloon-type CLT shear walls for timber structures. The analytical model can also be used to quantify the performance of balloon-type CLT structures subjected to seismic loads and thus providing the research background for drafting of the seismic design guidelines for balloon-type CLT construction for CSA O86 and National Building Code of Canada.

EFFECTS OF VARIABLE CLIMATE CONDITIONS ON THE BEHAVIOR OF POST-TENSIONED MASS TIMBER WALL PANELS

Jacob Gesh[1], Esther Baas[2], Ryan Longman[3], Mariapaola Riggio[4], Andre R. Barbosa[5], Lech Muszynski[6], and Gabriele Granello[7]

ABSTRACT: Post-tensioned (PT) mass timber rocking walls are innovative lateral force-resisting systems used in resilient seismic design. The system relies on an initial tensioning of wall panels using high-strength steel rods. However, tension losses are known to occur in PT systems over time, especially when these systems are exposed to variable climate conditions. In mass timber rocking wall designs, existing creep models do not allow for reliable prediction of long-term PT losses. Thus, the purpose of this research is to characterize the long-term behaviour of PT mass-timber wall panels exposed to variable climate conditions and to develop a model for reliable prediction of the effects of such exposures. The mass timber panels consist of ANSI PRG 320 approved cross-laminated timber (CLT) and mass ply panels (MPP). The components of the complex effect of long-term variable climate exposure are isolated by comparing data collected on similar panel specimens exposed to controlled humidity cycles in post-tensioned and unloaded conditions with those collected on loaded specimens exposed to a constant environment. Panel in-plane deformations, loads, and moisture content in the tested systems are continuously monitored. These tests provide data for the development of an in-plane creep model for mass timber panels that will be validated on two monitored full-scale 9.1 m tall post-tensioned rocking walls, exposed to naturally varying indoor conditions in a large-scale structural testing laboratory for 12 months. This paper summarizes the experimental data collected from specimens in the environment with controlled humidity cycles and the constant environment and some lessons learned. The data shows the following trends: (1) it appears that, during the test time frame and under the imposed changing environmental conditions, the PT system's response is dominated by the in-plane shrinkage and swelling of the specimens, (2) the MC profiles of the PT panels have a significant effect on the panel's strain behaviour, and (3) under constant environmental conditions, the CLT panels experienced more viscoelastic creep compared to the MPP panels.

KEY WORDS: Creep, Mass timber panels, Post-tensioning

1 INTRODUCTION

Utilizing timber in large structures is a sustainable option for construction and is made possible with mass timber panels, such as cross-laminated timber (CLT) and mass ply panels (MPP) [1]. Post-tensioned (PT) mass timber rocking walls have been developed as an innovative lateral force-resisting system to allow for resilient, low-damage seismic designs [2-4]. However, substantial tension losses have been recorded in monitored mass timber panel PT systems [4]. Existing models do not allow for reliable prediction of long-term PT losses, due to sparse data and limited understanding of the complex mechanisms of in-plane deformations in loaded mass timber panels experiencing non-uniform moisture variations induced by variable climate conditions. There is a general understanding that such models must be able to account for dynamic moisture transfer through thick composite panels and contributions of resulting hygro-expansion as well as viscoelastic and mechano-sorptive creep and relaxation [4-8]. This paper presents the experimental study conducted to measure the components of strain resulting from these entangled phenomena. However, in the interest of brevity of this conference paper, the isolation of these components is not included

herein. The presented study is part of a project carried out at Oregon State University, whose overall objective is to provide data and a functional model to allow engineers to confidently incorporate PT mass timber rocking walls in resilient seismic design.

2 METHODOLOGY

The experimental methodology provides for a comprehensive separation of the contribution of the effects of free hygro-expansion, viscoelastic creep, and mechano-sorption [9].

2.1 MEDIUM-SCALE SPECIMENS IN A CONTROLLED VARYING ENVIRONMENT

A total of twelve medium-scale panels have been tested in a climate chamber that has dimensions of 2.48 m x 2.44 m and can maintain temperatures ranging from -30 ℃ to +40 ℃ and relative humidities (RH) from 10% to 90% (Figure 1).

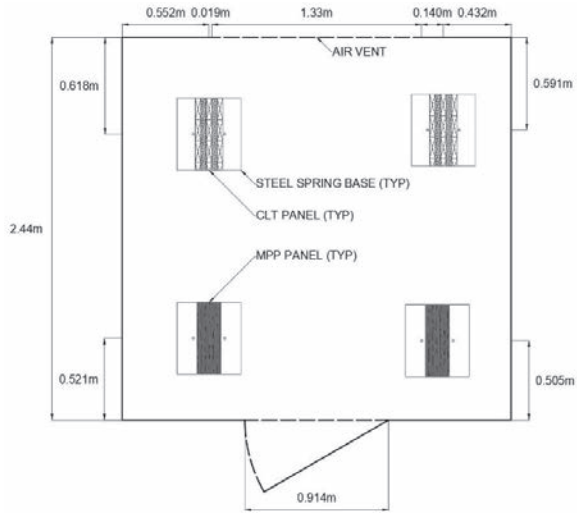

Figure 1: *Plan view of panel layout in climate chamber (approximate actual panel locations).*

Ten specimens are loaded with the tensioning of the PT rods and two are not loaded, designated here as unloaded specimens. One of the unloaded and five of the loaded panels were 5-ply Douglas fir-Larch CLT (1.52 m x 0.457 m x 0.174 m) while the remaining panels were 152.4 mm-thick Douglas fir MPP (1.52 m x 0.457 m x 0.152 m). Since full-scale applications of the mass timber PT wall systems generally have the edges of the walls concealed by other structural components, moisture flow is typically 1-dimensional through the face of the wall [8]. Therefore, in this test, each panel was edge-sealed such that moisture flow was perpendicular to the panel face. Due to the sizes of the panels and the geometry of the chamber, only four panels could be tested at a time thus, there was a total of three batches of specimens. Each test cycle consisted of an initial exposing of the panels to two weeks of uncontrolled environmental conditions to provide more time for the panels to creep under the applied load. Following the two-week period in uncontrolled conditions, three cycles of humidity ranging from 30% RH (two weeks) to 90% RH (two weeks) at constant temperature (20 ℃) were then applied to the panels to determine the complex deformation resulting from the superposition of viscoelastic and mechano-sorptive creep, shrinkage, and swelling [1,5].

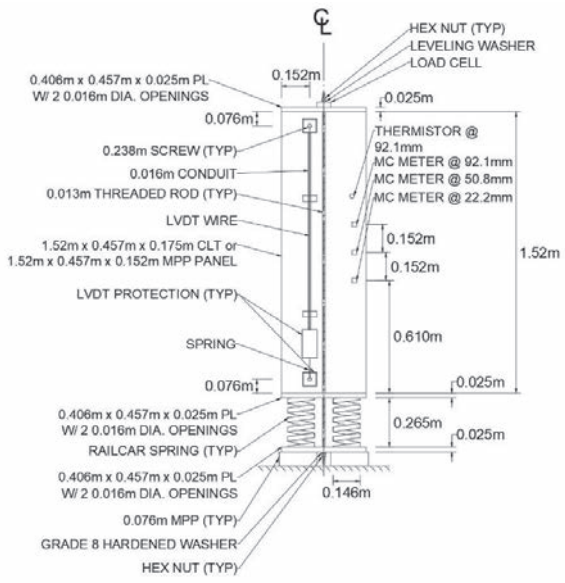

Figure 2: *Test setup for loaded specimens exposed to a controlled varying environment (frontal view).*

Each loaded panel is placed on steel spring bases to minimize the tension losses to less than 2% of the applied force (Figures 2-4). The load is transferred through two post-tensioned threaded steel rods running through holes in the top plate and the bottom of the spring base and monitored by two load cells placed at the end of each rod. The level of applied PT load was chosen to be approximately 7% of the compressive strength of each panel. The loading process was comprised of two phases: during phase 1, the panels were loaded to the chosen level of stress, and during phase 2, the spring bases maintained the applied load within 2% of the initially applied load for the remainder of the test.

The instrumentation setup includes a linear variable differential transformer (LVDT) which measures the vertical deformation of each timber panel. Electric resistance moisture sensors equipped with screws with insulated shafts monitor the moisture content (MC) over an approximate length of 13 mm within the first three plies of the CLT panels and the first, second, and forth plies of the MPP panels as indicated in Figure 5.

Two unloaded reference panels with a similar setup as the loaded panels were tested in the same climate conditions to determine the effect of free shrinkage and swelling [5]. When compared to the loaded panels shown in Figure 2, the unloaded panels did not have a top plate or PT rods installed (Figure 6). The instrumentation on the unloaded panels was similar to the instrumentation installed on the loaded panels except the unloaded panels did not include load cells.

https://doi.org/10.52202/069179-0298

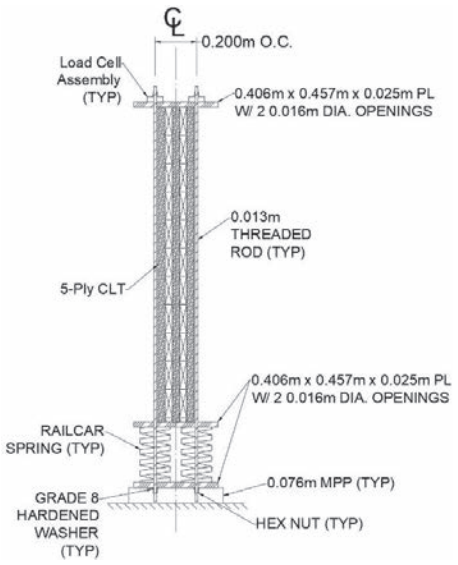

Figure 3: *Test setup for loaded CLT specimens exposed to controlled varying environment (profile cross-section).*

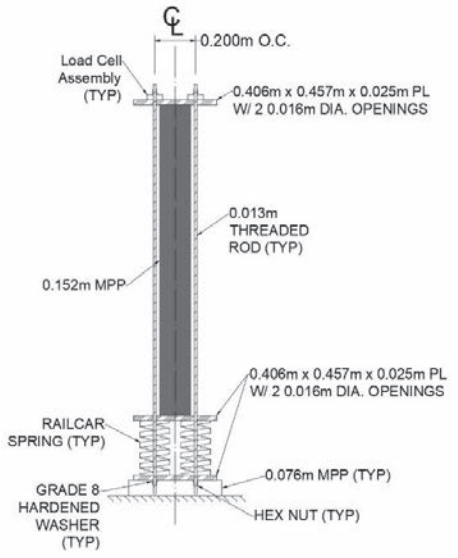

Figure 4: *Test setup for loaded MPP specimens exposed to controlled varying environment (profile cross-section).*

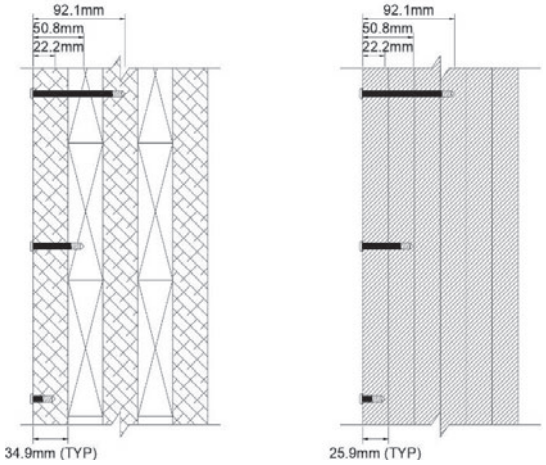

Figure 5: *Electric resistance moisture sensor depths (Left: CLT cross-section along panel height. Right: MPP cross-section along panel height).*

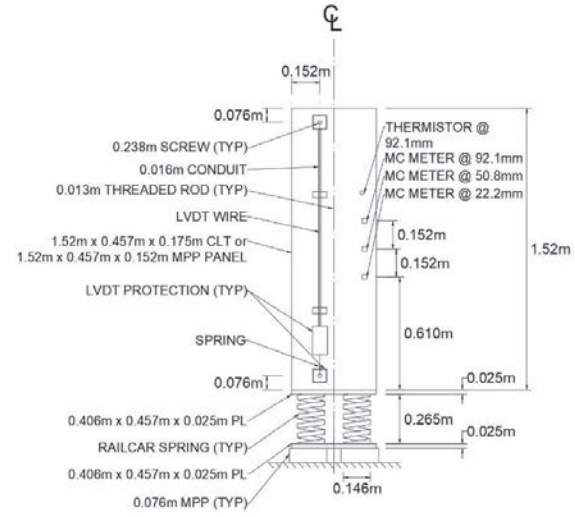

Figure 6: *Test setup for unloaded specimens exposed to controlled varying environment (frontal view).*

For safety reasons, panels were laterally braced with pins at the top of each panel to prevent any tipping motions. The pin connection between the lateral support system and the panels is used to not restrict any vertical deformation of the panels.

Figure 7: *Test setup inside the climate chamber.*

2.2 MEDIUM-SCALE SPECIMENS IN CONSTANT ENVIRONMENT

Three CLT and three MPP panels of the same dimensions as the specimens described in 2.1 are tested in an environment with constant RH and temperature, to isolate the viscoelastic creep component within the panels [5]. The setup is as described in 2.1 except that the specimens are not instrumented with moisture sensors and are not edge sealed. The specimens are PT-loaded at the same level as specimens tested in variable climate conditions.

Figure 8: *Test setup inside constant climate conditions (sensors unattached).*

3 DATA ANALYSIS AND PRELIMINARY RESULTS

The preliminary results presented in this paper include the two unloaded specimens, and six of the ten PT specimens tested in the controlled and varying environment. Additionally, approximately 10.5 months of data from the six specimens in the constant environment are presented. Data processing consisted in three phases: (1) Offsetting, (2) Signal Processing, and (3) Calculations.

3.1 DATA OFFSETS

Prior to loading each specimen, the LVDTs were physically adjusted such that the output reading was approximately zero. However, the readings were not exactly zero, therefore, during post-processing, offsets were applied to the displacement readings of each sample. For consistency, the average of the first three data points prior to the beginning of the loading process was taken as zero displacements and then used as the offset for the respective specimen.

Additionally, the average percent MC (calculated as described in section 3.3.4) of the loaded MPP panel in the first batch of samples had a portion of data with unnatural changes in MC during the third dry cycle. Therefore, for this section of data only, the data line was smoothed to eliminate the obvious signal offsets.

Offsets to zero the load cells were not applied during post processing since at the beginning of the tests, offsets were initially programmed into the data acquisition system. However, for the panels in the constant environment, there were portions of data that had rapid changes in loads throughout the tests. Therefore, the data line was smoothed to eliminate the large erratic changes in measured load.

3.2 SIGNAL PROCESSING

Signal irregularities such as unexplained spikes were removed by means of a median filter with an overall window of 13 data points determined iteratively until all artifacts were removed. It should be noted that the median filter was applied once to the offset LVDT readings, the load cell readings, and the average moisture contents (calculated as described in section 3.3.4).

3.3 CALCULATIONS

The measured data were used to determine the following derived quantities: 1) panel displacement, 2) average strains in the panel, 3) average panel stress, and 4) average moisture content in the panel.

3.3.1 Panel-spring displacement

For the panels in the constant climate only, the LVDT signals were erratic and inconsistent with what would be physically expected. Therefore, the displacements of these panels during loading phase 2 were calculated using the corresponding phase 2 load cell data in combination with the stiffnesses of the spring bases following the general relationship:

https://doi.org/10.52202/069179-0298

$$\delta = \frac{F}{k} \quad (1)$$

in which δ is the displacement of the spring base, F is the force applied to the system, and k is the stiffness of the spring base. At the start of loading phase 2, after the spring bases were compressed under the initially applied load, the displacements of the spring bases would be equal to the displacements of the panels. Therefore, the point at which each panel was fully loaded (beginning of phase 2) was assumed to be zero displacement within the panel.

3.3.2 Panel strain

Following typical convention, positive strains measured indicated panel growth while negative strains indicated panel contraction. Since the LVDTs on the panels in the climate chamber did not have erratic readings, the average longitudinal strains (ε) in the panels were calculated based on the readings from the LVDTs as:

$$\varepsilon = \frac{\delta_{LVDT}}{l_0} \quad (2)$$

where l_0 is the initial length of the specimen between the wood screws used to secure the LVDT wire to the sample (or 1371.6 mm), and δ_{LVDT} is the displacement reading from the LVDT.

For the panels in the constant climate, δ_{LVDT} in Equation 2 was substituted with δ calculated by Equation 1 and l_0 was assumed to be the panel's undeformed height (1524 mm). It should be noted that assuming l_0 to be equal to the panels' undeformed height is not entirely accurate since after loading, the panels would deform elastically and would therefore be shorter overall. However, this assumption gives a reasonable approximation.

3.3.3 Panel stress

The engineering stress (σ) in each panel was calculated using the readings from two load cells as:

$$\sigma = \frac{P_1 + P_2}{A_{panel}} \quad (3)$$

where P_1 and P_2 are the loads measured by the load cells applied at the two post-tensioned rods and A_{panel} is the cross-sectional area of the panels (CLT: 0.080 m^2, MPP: 0.070 m^2).

3.3.4 Average panel moisture content

The average MC in each panel was calculated using data from the resistance sensors embedded into each panel at the various depths shown in Figure 5. More specifically, the first three plies of the CLT panels were monitored while the first, second, and fourth plies of the MPP panels were monitored. Since the panels are symmetric, it was assumed that the moisture profile in the panels would also be symmetric around the centre thickness. Therefore, since the MPP panels have an even number of plies (i.e., six, 25.9 mm-thick plies), the average of the three percent MC readings of each panel can be taken to represent the overall average panel percent MC ($MC_{MPP\ avg}$):

$$MC_{MPP\ avg} = \frac{MC_{ply1} + MC_{ply2} + MC_{ply4}}{3} \quad (4)$$

where MC_{ply1}, MC_{ply2}, and MC_{ply4} are the percent MC readings of the 22 mm, 51 mm, and 92 mm long sensor pins in the MPP panel, respectively.

However, since the CLT has five plies, a weighted average percent MC ($MC_{CLT\ wavg}$) was calculated assuming the sensors capture the percent MC in ply one, ply two, and half of ply three. The equation is as follows:

$$MC_{CLT\ wavg} = \frac{MC_{ply1} + MC_{ply2} + 0.5MC_{ply3}}{2.5} \quad (5)$$

where MC_{ply1}, MC_{ply2}, and MC_{ply3} are the percent MC readings of the 22 mm, 51 mm, and 92 mm long sensor pins in the CLT panel, respectively.

3.3.5 Interpolation of data

Due to differing time steps for the data within both batches of samples tested, it was necessary to interpolate between data points so that displacements and MCs could be compared at specific points in time. Therefore, each data set was linearly interpolated between measured data points to get the displacement and MC readings every 30 seconds throughout the entirety of the tests.

3.3.6 Cumulative moisture content

Although the same humidity cycle program was applied to both batches of samples, the differences in initial MC in the panels, the first two-week period after loading in uncontrolled environments, and mechanical issues with the climate chamber resulted in variability of specimen initial conditions. Because of this, it is difficult to directly compare the deformations recorded on separate batches of panels tested with different humidity programs in the time domain. To facilitate a more meaningful comparison, the cumulative moisture content (CMC) in each panel was calculated (Equation 6) to present strains as a function of CMC rather than time [9], where the CMC is given by:

$$CMC = \sum_{0}^{i} |MC_{i+1} - MC_i| \quad (6)$$

where MC_i and MC_{i+1} is the ith and ith+1 average percent MC sensor readings of an individual panel, respectively. Each CMC value aligns with a corresponding measured strain value thus allowing for convenient comparison.

3.3.7 Summary of data

Figures 9 and 10 summarize the environmental and moisture content data from the first and second batches of CLT and MPP samples tested in the climate chamber in the time domain. Additionally, Figures 11 and 12 summarize the strain and CMC data from the first and second batches of CLT and MPP samples tested in the climate chamber presented in the time domain. The first batch of samples included one loaded CLT and one loaded MPP panel and the two unloaded panels used to capture the free shrinkage and swelling. The second batch of

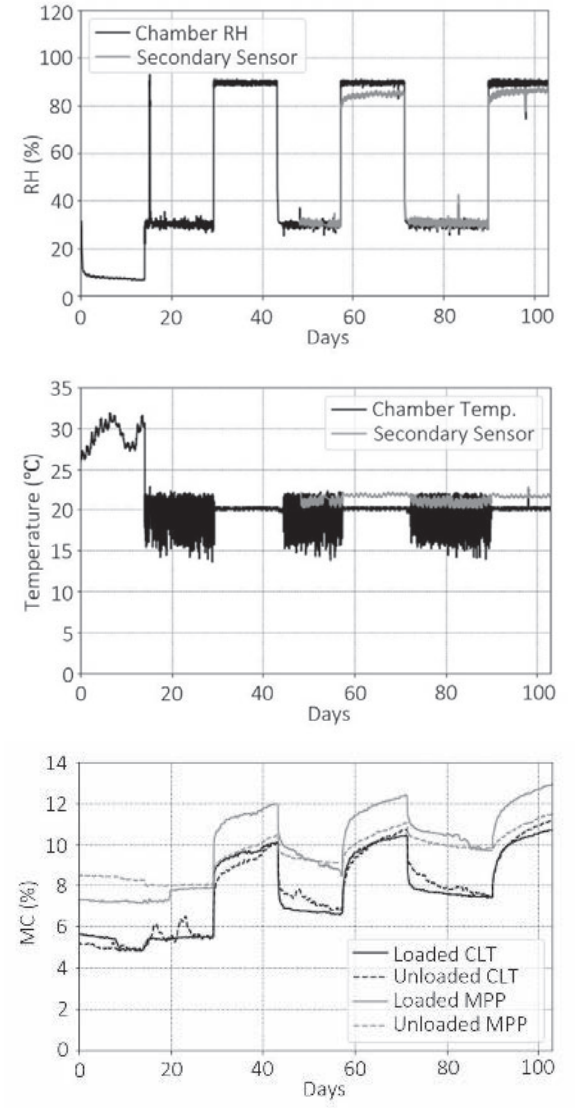

Figure 9: *Batch one environmental and MC data (top: RH over time, middle: temperature over time, bottom: weighted average percent MC over time).*

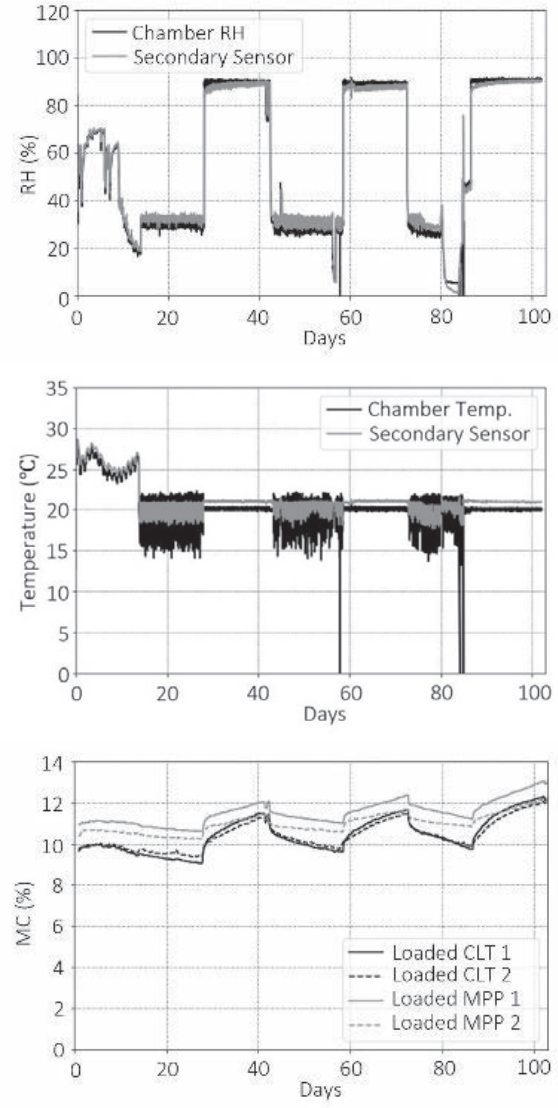

Figure 10: *Batch two environmental and MC data (top: RH over time, middle: temperature over time, bottom: weighted average percent MC over time).*

samples included two loaded CLT panels and two loaded MPP panels. It should be noted that during the second batch of tests, one of the MPP panels was unloaded and re-loaded approximately seven days into the test period in the uncontrolled environment. Therefore, the plots show data for this particular panel starting at the point in time just before the reloading. Throughout the tests, the spring bases were able to maintain the applied stresses within 2% of the initially applied stress. As seen in the strain vs. time plots in Figures 11 and 12, during the first 14 days after initial tensioning, the deformation in the panels was dominated by shrinkage and swelling due to the uncontrolled conditions in the chamber environment (approximately 6-10% RH and 26-32 ℃ for the first batch and 16-70% RH and 23-29 ℃ for the second batch). Following the commencement of the first dry cycle on day 14, a rapid increase in strain indicates a sudden expansion in the panels equilibrating to the 30% RH. As each dry and wet cycle commence, the rate of strain changes. During the dry cycles, the strain rates are negative indicating the effect of shrinkage due to a loss of moisture to the surrounding environment. During the wet cycles, the strain rates are positive indicating the effect of swelling induced by the gain of moisture from the ambient environment.

Unexpectedly, however, the overall trends in the strain of the first batch of samples indicated that the loaded CLT panel (and portions of the loaded MPP panel) experienced more elongation than the unloaded panels.

Based on the strain vs CMC plots, each of these described trends are reiterated; the panels from the second batch experienced less strain and less CMC compared to the first. After plotting the response of both batches of panels together in Figure 13, it can be seen that the free shrinkage

https://doi.org/10.52202/069179-0298

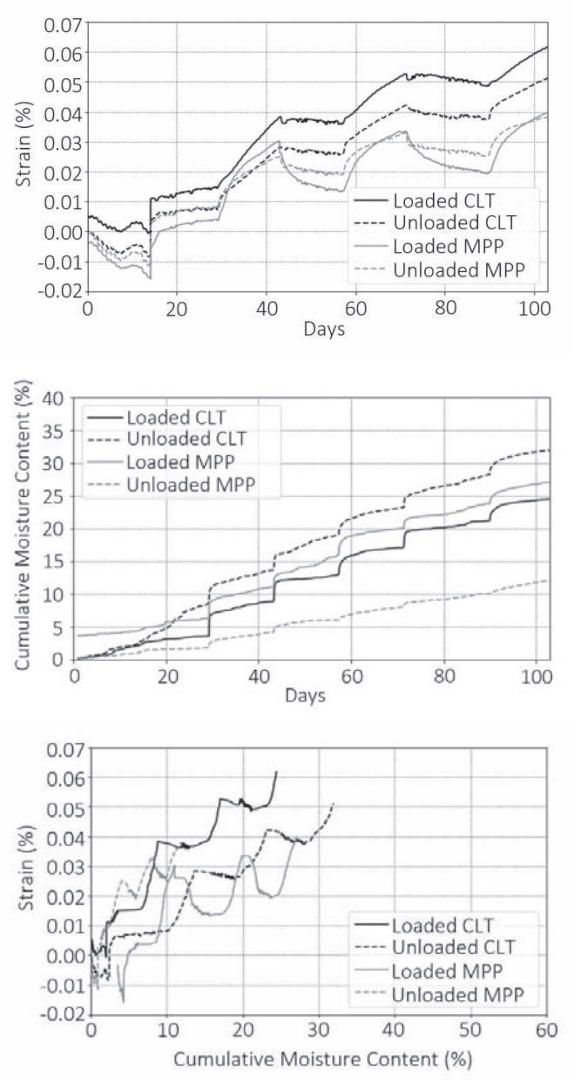

Figure 11: *Batch one specimen data (top: strain over time, middle: CMC over time, bottom: strain versus CMC).*

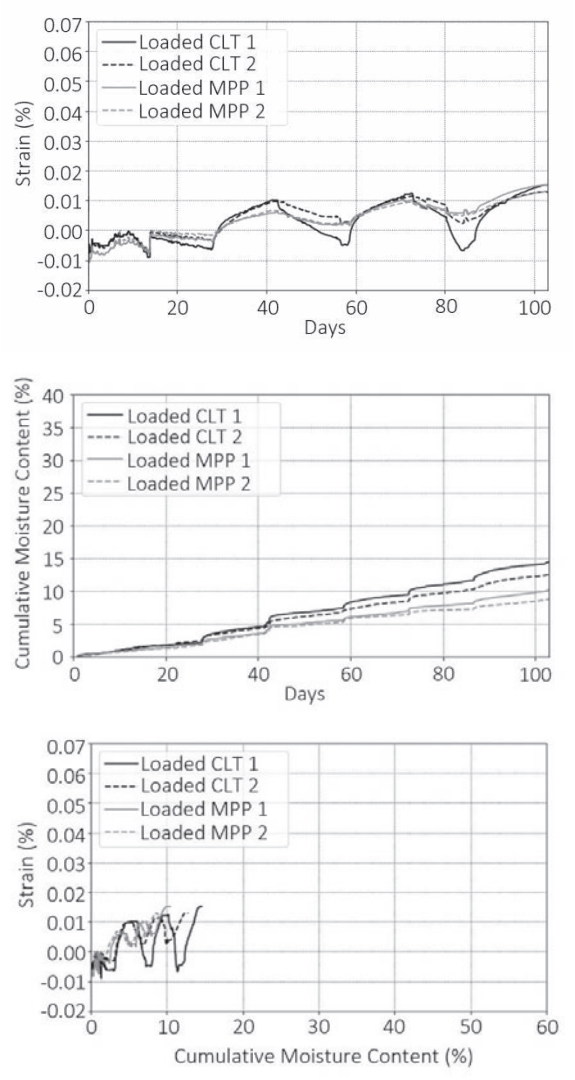

Figure 12: *Batch two specimen data (top: strain over time, middle: CMC over time, bottom: strain versus CMC).*

and swelling strains are in fact generally greater than the total strains of the loaded panels from the second batch (except for the CLT specimens from approximately 4% to 6.4% and from 7.8% to 10.4% CMC).

Figure 14 summarizes the test data from the panels in the constant environment over a period of approximately 10.5 months. It should be noted that the loading of the CLT panels occurred approximately one week after the loading of the MPP panels. Since the panels were close to each other, the loading of the CLT panels disrupted the MPP data around day 7. Additionally, it can be noticed that shortly after the loading of the CLT panels, a portion of data is missing. This data was removed due to an error with the data acquisition system.

As expected, based on the calculated displacements, the panels exhibit an overall shortening over time. In particular, the CLT panels displace more than the MPP panels even though both were loaded to the same percentage of their respective compressive strengths. When compared to the test data from the varying environment (Figure 15) over the same time domain, it can be seen that the panel behaviour between the tests in the different environments nearly mirror each other (excluding the cyclic behaviours from the changing RH). Strains of the panels in the changing environment increase with time to a maximum strain between approximately 0.0004 mm/mm to 0.0006 mm/mm while strains in the constant environment decrease with time to a minimum strain between approximately -0.0003 mm/mm to -0.0007 mm/mm.

4 DISCUSSION

The unusual trend observed in both batches of specimens tested in the climate chamber could be attributed to differences in moisture profiles between the panels as each panel had different initial MCs. It could also be attributed to layup differences between panels which in turn could affect the diffusion coefficients. Another possibility could be caused by inaccurate sensor readings.

https://doi.org/10.52202/069179-0298

For example, as seen at day 0 of the test for the first batch of panels (Figure 11), the loaded CLT panel increases in strain as it is loaded whereas the loaded MPP panel decreases in strain. This would mean that the CLT panel elongates as it is loaded which is not reasonable.

Overall, the second batch of specimens (Figure 12) experienced significantly less amounts of strains which may in part be due to the overall differences in CMC between the panels. It is also important to point out the initial MCs between both batches. The first batch of samples had more dispersed MC levels between approximately 5% and 10% while the second batch of samples had more consistent MC levels of approximately 10% or more. The causes leading to the differences in initial MCs between batches of specimens stems from the storage conditions of the panels. For example, the first batch of panels were left in the chamber powered off for several months prior to testing while the second batch of panels were left outside of the chamber in an uncontrolled indoor environment. Additionally, the first batch of panels began testing in May of 2022 while the second batch of panels began testing at the end of the summer in September of 2022. As might be expected, the higher temperatures and likely higher humidities in the unconditioned indoor environment at the end of the summer likely led to the second batch of samples equilibrating to the larger initial MC levels measured at the beginning of the tests. Since changes in MC inherently affects strains due to shrinkage, swelling and mechano-sorptive creep in timber, it would be expected that more drastic CMC curves would result in more drastic strains. This is evident between the two tests as the first batch of specimens have more CMC and more strain contrary to the second batch of specimens which have less CMC and therefore less strain (Figures 11 and 12). Additionally, beginning at a higher moisture content may mean that the panels have more dimensional stability when exposed to changing MC as they are further along in the moisture sorption isotherm curves.

Another important detail is the relative position of each specimen in the chamber. As seen in Figure 1, for both rounds, the CLT panels were arranged such that they were closest to the chamber vents from which the dry and wet air and temperature were controlled. Therefore, these panels would be the first to experience MC changes which can generally be seen in the data from Figures 11 and 12; most of the MPP panels had less CMC. This observation concerning lower CMC levels in the MPP panels could also be attributed to the larger number of layers of adhesives within the MPP panels which may affect the moisture diffusion properties.

The larger amounts of strain observed in the CLT panels compared to the MPP panels in the constant environment is likely due to differences in the mechanical properties of the panels. Although the wood in both panel types are similar species, the difference in the general layup will affect the overall panel properties.

Another possible contributor to the differences in overall strain between both panel types could stem from differences in the moisture profiles of the panels. While all panels were placed in the constant environment and allowed to react with the environmental conditions, it is possible that the panels did not all reach equilibrium by the start of the test. Based on the observations from the specimens tested in the changing environment, it would be reasonable to suspect that if the initial MC profiles of the specimens are different, then there would likely be large variations in the measured strains.

5 PRELIMINARY CONCLUSIONS

This paper presents a preliminary analysis of data of medium-scale PT CLT and MPP systems with the objective of providing data and a functional model to allow engineers to confidently incorporate PT mass

https://doi.org/10.52202/069179-0298

timber rocking walls in resilient seismic design. The data shows the following trends: (1) it appears that, during the test time frame and under the imposed changing environmental conditions, the PT system's response is dominated by the in-plane shrinkage and swelling of the specimens, (2) the MC profiles of the PT panels have a significant effect on the panel's strain behaviour, and (3) under constant environmental conditions, the CLT panels experienced more viscoelastic creep compared to the MPP panels, which is likely due to differences in the material properties of the panels and or differences in panel moisture profiles. The data also allows for the isolation of the viscoelastic and mechano-sorptive creep which will facilitate model development in future works.

The difference in responses of the panels between the two test batches exposed to cyclic climates may be explained by different initial MCs. A practical conclusion for future testing is that prior to testing all panels should be equilibrated to the same MC and that the environment during the two-week period prior to the launching of humidity cycles should be replicated for each batch so that all panels will start the humidity cycles with the same MCs. The MC of panels in the constant environment should be checked prior to testing as well.

In the current study, the CLT panels were located closest to the climate chamber vents in each batch of tests involving cyclic climate conditions and were observed to absorb more moisture. Therefore, in the future work, the effect of panel location in the chamber on the moisture absorbed into the CLT and MPP specimens should be determined.

OPTIMIZED CLT-RC FRAME CONNECTION FOR SEISMIC RETROFITTING

Zabih Mehdipour[1], Jorge M. Branco[2], Elisa Poletti[3], Paulo B. Lourenço[4]

ABSTRACT: Cross-laminated timber (CLT) panels have been used as a renovation solution to be adopted in existing masonry-infilled RC buildings, especially those which were designed based on old seismic codes. The connections through which the panels are attached to the RC frames have shown to provide the most contribution to the seismic behaviour of buildings, highly depending on the type of connections used. In this study, to investigate the effect of design procedures of bilinear RC-CLT connections on the dissipated energy and peak displacement of the retrofitted building, their optimum number, location, and mechanical properties, including elastic/inelastic stiffness and yielding displacement, are aimed to be found using genetic a algorithm in a one-bay one-story RC frame. Two structures, (1) a masonry-infilled frame strengthened by CLT panel and (2) a CLT-infilled frame, are used to take the effect of masonry infill into account for two optimization purposes, maximum energy dissipation and minimum structural drift. Results show that under different predefined levels of structural performance, different optimum bilinear curves are achieved. In a parallel study, concerning connectors' arrangement, it was found that their horizontal distribution in beams, starting from the middle and moving to the corners, result in a much better response than a vertical distribution in columns.

KEYWORDS: Cross-laminated timber panel, Infilled RC frame, CLT-RC connection, Optimization, Genetic algorithm

1 INTRODUCTION

Cross-laminated timber (CLT) shear walls have developed recently as an infill added to existing buildings [1][2]. These buildings, mainly made of reinforced concrete frames infilled with masonry walls, have shown to be vulnerable to seismic actions due to in-plane and out-of-plane failures of the infills and shear failure of RC columns [3][4]. CLT panels added to those frames are able to improve elastic response with increasing stiffness and load-carrying capacity and inelastic response with ductile deformations and limited impairment of strength at the same time. Elastic contribution of the walls are made by the panels which are rigid due to their layers arranged crosswise to each other at an angle of 90° [5][6]. On the other hand, inelastic behaviour is improved only by the connections where CLT is attached to the frame [5][7][8]. Many traditional and innovative RC-CLT connections have been suggested to demonstrate their abilities to improve the main frame responses emphasizing on nonlinear analyses [9][10][11][12][13].
A comparison made between those connectors which have various Force/Deformation curves shows how much elastic/inelastic response of the frame strengthened by CLT is associated to the connector curve [2][8]. Stiffer connectors provide more stiffness and strength for the main frame, while energy dissipated by the connectors depends on the yielding displacement. Materials with low-yield displacement produce plastic loops with low load-carrying capacity under cyclic/seismic loadings. Also, the ones with high-yield displacement almost lack plastic loops. In both case, energy dissipated that is represented by the area inside the plastic loops is the lowest. It can be proved that there is a specific yielding point between these two extremities where the energy is the greatest. Moreover, the locations of connectors along the frame are effective in changing the Dissipated Energy (DE), strength or drift of the frame [14]. The problem would have an economically advantage where, among different connectors with the same cyclic performance, the cheapest one can be adopted arranged optimally along the frame.
To find the values resulting in the most favourable response of the frame, an optimization process is carried out using Genetic Algorithm (GA) in binary form, which is a stochastic optimization technique based on the process of natural selection that belongs to the evolutionary algorithm [15]. It is considered as a powerful tool for discrete problems like here where optimum arrangement is sought, and the problems with high degree of nonlinearity where plastic deformations of different materials under dynamic loadings are evaluated.
In this study, a RC-CLT connector is represented by two perpendicular split and uplift springs where Force-Deformation curves are assumed to be bilinear for simplicity. The arrangement and yielding displacement of the connectors are obtained so that the strengthened frame has the highest dissipated energy and strength, and least drift in cyclic and seismic analysis, respectively, for both bare and masonry-infilled RC frames. In the final section, an economical survey is performed between two connectors with different stiffness and prices.

2 Modelling of the infilled RC frame coupled with CLT panel

The first step to proceed with the study's plan is to define and characterize the structure's elements and the renovation solution, and describe how to simulate them. Then, the optimization problem, including the

optimization algorithm, goal function, variables, constraints, will be defined clearly. The last step is to connect the frame strengthened with the optimization process. All aforementioned will be discussed as follows.

2.1 THE INFILLED RC FRAME COUPLED WITH CLT SHEAR WALL

Due to the nature of the problem, where the hybrid frame is analysed many times to achieve the optimal solution and nonlinear behaviour of materials (RC frame, masonry infill, and RC-CLT connector), the finite element analyses of the frame are carried out in OpenSees [16]. Figure 1 shows the geometry and reinforcement of the RC frame where the beams and columns cross-sections are, respectively, 160×270 mm^2 and 160×160 mm^2 with the rebars made of A400NR and concrete of class C55/67 [17].

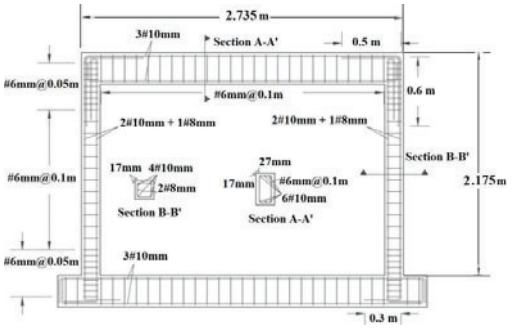

Figure 1: *Reinforcement and geometry of the RC frame*

In simulations, the beams were considered elastic, while the columns were constructed by FiberSection object, available in the software, governed by Concrete02 material assigned to concrete and Steel02 assigned to rebars as shown schematically in Figure 2.

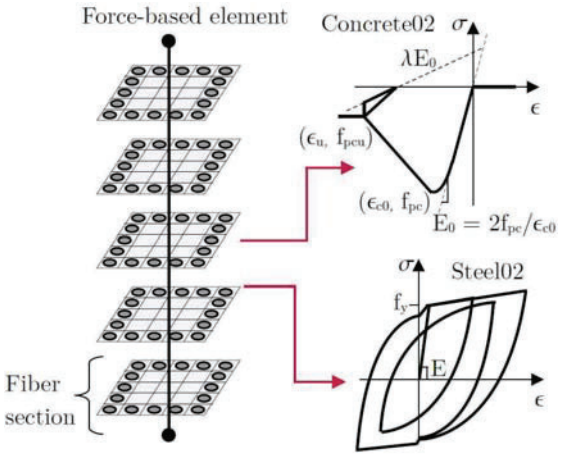

Figure 2: *The materials assigned to the RC elements*

In Table 1 and 2, calibrated parameters of Concrete02 and Steel02 material are presented, respectively. Figure 3 displays the cyclic response of the frame taken from the experimental [17] and numerical analysis, confirming the accuracy of materials used in modelling.

Table 1: *The parameters for Concrete02 material*

f_{pc} (MPa)	ε_{co} (-)	f_{pcu} (MPa)	ε_u (-)	λ (-)	f_t (MPa)	E_{ts} (MPa)

400	205000	0.015	10	0.94	0.20

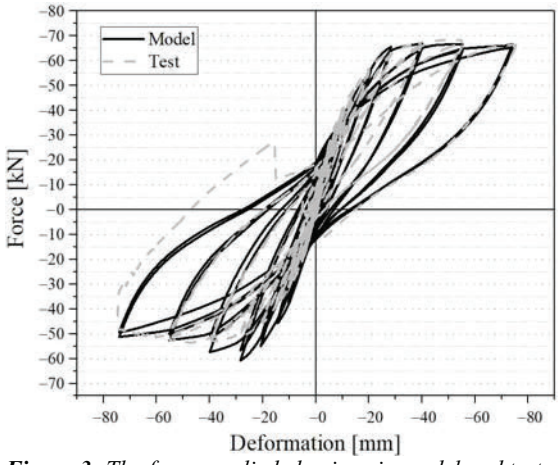

Figure 3: *The frame cyclic behaviour in model and test*

Also, masonry infill is made of vertically perforated masonry units reinforced in bed joints and connected to the RC columns in the interface by metallic connectors [17]. The panels are replaced with the solid parts, made of triangle solid beam elements, that are connected together by Zero-Length element assigned by Pinching4 element, as seen in Figure 4, [18] suitable to consider strength degradation and pinching effect typical of masonry walls due to crack openings. The equivalent scheme for the wall is shown in Figure 5 with the element governing horizontal spring in which the parameters reproduced by Genetic algorithm are listed in Table 3.

With the above-shown elements representing masonry infill, variation of base shear against peak displacement in the infilled frame resulted from test and simulation are similar (Figure 6).

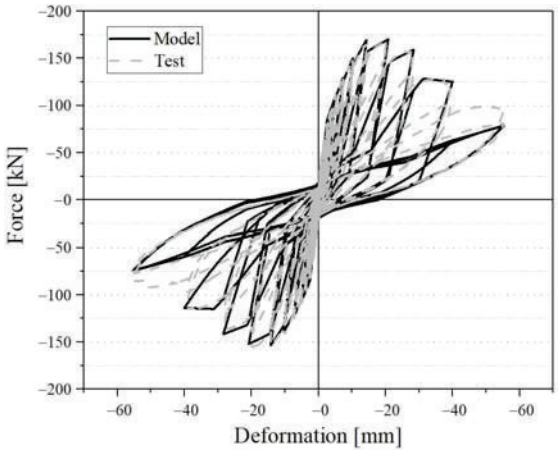

Figure 6*: The infilled frame response in cyclic analyses*

The CLT panel, used here, has 97 mm thickness in three layers, which are 35, 27, and 35 mm, respectively. Because of the panel staying elastic in elastic analyses, only elastic moduli of elasticity, shear modulus, and Poisson's ratio need to be defined (Table 4), and are taken into account in simulations [19][20][21].

Table 4: *The panel characteristics*

Property	Value
E_L	11,000 N/mm²
E_R	370 N/mm²
E_T	370 N/mm²
G_{LR}	688 N/mm²
G_{LT}	688 N/mm²
G_{RT}	68.8 N/mm²
υ_{LR}	0.02
υ_{LT}	0.02
υ_{RT}	0.3

CLT shear wall generally are simulated in the same way as masonry infill did, meaning that, as shown in Figure 7, the wall is replaced by two frames made of solid beam elements at the top and bottom of the frame that attach CLT-frame connectors and a horizontal elastic shear spring at the middle of the wall, representing the CLT lateral stiffness.

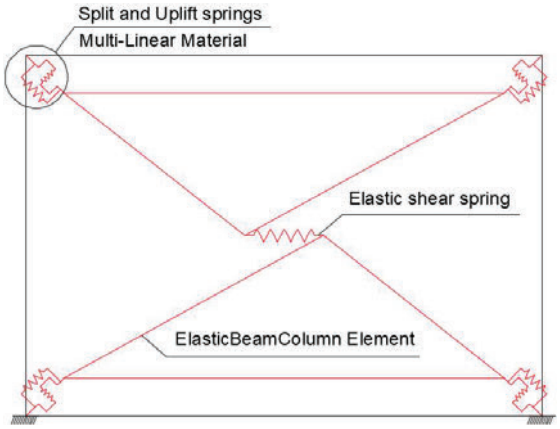

Figure 7: *The panel with the connectors in the model*

The stiffness of the mid-spring in Figure 7 is determined by the following equation [13]:

$$k_{CLT} = \frac{1}{\frac{h^3}{12EI} + \frac{1.2h}{GA}} \quad (1)$$

where h is the panel height, A is the cross-section area, I is the cross-section inertia, and E and G are the moduli of elasticity and shear modulus of the panel, respectively.
Both uplift and split springs that represent the connectors are usually attributed by Pinching4 or SAWS elements [22], but here to satisfy this study's purposes investigating bilinear spring, Multi-Linear material, available in the software library, is assigned to each of them comprising only two lines for simplicity. Stiffness of the second line is assumed as 10% of the first one. It can not be considered

https://doi.org/10.52202/069179-0299

as a separate optimization variable since it has a straight effect on increasing energy dissipated and strength.

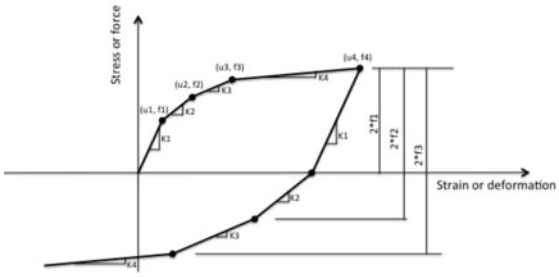

Figure 8: *Multi-Linear material assigned to both split and uplift springs*

2.2 THE OPTIMIZATION PROBLEM

It is supposed that only one kind of CLT-RC connection represented with split and uplift springs being characterized by bilinear Force-Deformation curves is used in the frame. Yielding displacement and elastic stiffness of the split and uplift springs are of four variables of the connector with the inelastic stiffness considered as 10% of the elastic one. Each of RC elements has 6, 8, and 10 potential locations where the connector can connect RC frame to the CLT panel. 6, 8, 10 spots per element (or 24, 32, 40, respectively, spots in total along the frame) are for the problem with 4, 8 and 12, and 16 and 20 connectors, respectively.

Number of possible locations of connectors along the frame, which are 24, 32, and 40, depending on the number of connectors, are of the variables assigned for the possible location of connectors, each of which can be 1, meaning there is the connector, or zero. Optimum locations and connector's properties are sought for specific number of connectors, that is, 4, 8, 12, 16 and 20. Number of population was assumed to be number of variables multiplied by 40. The lower and upper bound for elastic stiffness of springs are respectively 0.1 and 100 *kN/mm* and those of yielding displacement are 0.5 mm and 50 mm, respectively. For the problem where only spring's location is sought, elastic and inelastic stiffness of split springs are taken 3 and 0.5 and those of uplift springs are 2 and 0.6 *kN/mm*, respectively. Also, in the problem where only spring properties are demanded, optimum locations resulted from former analysis are considered for specific number of connectors. In the GA algorithm, for crossover, roulette wheel selection is used, and mutation coefficient is taken 0.2. The algorithm stops when the best answer stays unvaried for 15 iterations. For the sake of simplicity in expressing the variables, especially location of springs, binary genetic algorithm is adopted here meaning that all the variables in the population are expressed as binary numbers in the base-2 numeral system. Two loadings are applied to the bare/infilled frames: cyclic and seismic. The goal function is defined depending on the loading. Table 5 presents in summary all analyse with loading, goal function (GF), frame, and variables.

Table 5: *Optimization problems studied here*

No.	Frame	Loading	GF	Variables
1	Bare	Cyclic	DE	Location/Properties
2	Bare	Cyclic	Strength	Location
3	Infilled	Cyclic	DE	Location/Properties
4	Infilled	Cyclic	Strength	Location
5	Bare	Seismic	DE	Location/Properties
6	Bare	Seismic	Drift	Location
7	Infilled	Seismic	DE	Location/Properties
8	Infilled	Seismic	Drift	Location

2.3 THE LOADINGS PROTOCOL

Two kinds of loadings, cyclic and seismic, are applied to the frame to figure out the dependency of them to the optimum arrangement and properties of the connectors. The loading pattern is obtained according to FEMA 461 [23] and has 16 steps, starting from 0.5 mm, regarding 0.026% drift, and ending in 75, regarding 3.94% drift. Each step is repeated two times with the exception of the first one repeating six times. Also, a set of six earthquake records as the seismic loading, mentioned in Table 6, is exerted on the structure.

Table 6: *The seismic records* [24]

3 RESULTS AND DISCUSSIONS

3.1 OPTIMUM ARRANGMENT

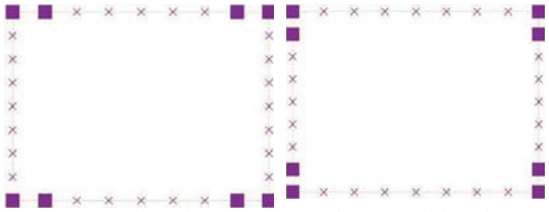
The specific number of connectors (4, 8, 12, 16, and 20) was selected to be a multiple of 4 for regularity as there are four RC joints or four RC elements. In the first section optimum location to attach the panel along the RC frame is shown for those numbers of connectors with the specific properties, as mentioned before.

In the figures schematically shown as follows, the infilled squares show where the connector attach CLT and RC frame resulting in a better response, but cross signs are the potential locations of connectors which are not preferred. In case of using 4 connectors, in all cases, the best arrangement is displayed in Figure 9. As it is usually considered, four connectors in the corners, RC joints, give the most favorable response.

https://doi.org/10.52202/069179-0299

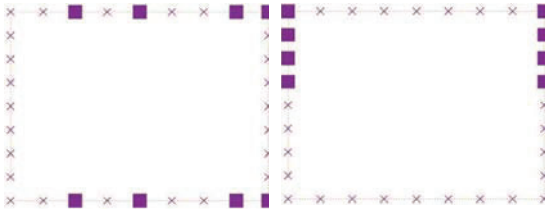
Figure 9: *Optimal locations of 4 connectors*

For 8 connectors, Figure 10 and 11 show the frame with the highest DE, and strength, respectively, under cyclic loading. In the seismic action, the optimal distribution is different from cyclic loading, but in both cases, connectors are located along the beams and columns in terms of DE and strength criteria.



(a) DE-based (b) Strength-based

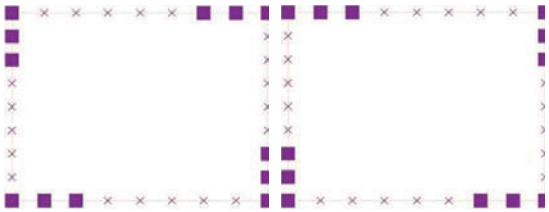
Figure 10: *Optimal locations of 8 connectors under cyclic loading*



(a) DE-based (b) Drift-based

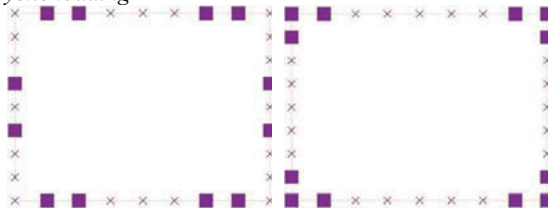
Figure 11: *Optimal locations of 8 connectors under seismic loading*

With the same order, Figures 12 and 13 demonstrate the connectors optimally arranged under cyclic and seismic loadings, respectively.



(a) DE-based (b) Strength-based

Figure 12: *Optimal locations of 12 connectors under cyclic loading*

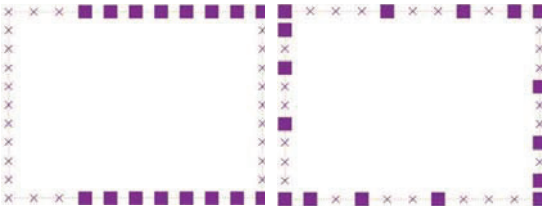


(a) DE-based (b) Drift-based

Figure 13: *Optimal locations of 12 connectors under seismic loading*

The following figures show the distribution of 16 connectors:

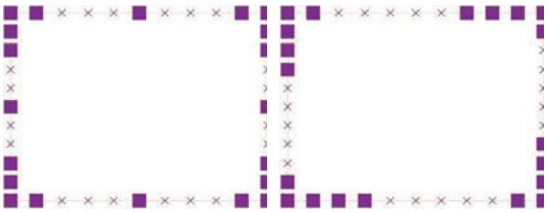
Figure 14: *Optimal locations of 16 connectors under cyclic loading*



(a) DE-based (b) Drift-based

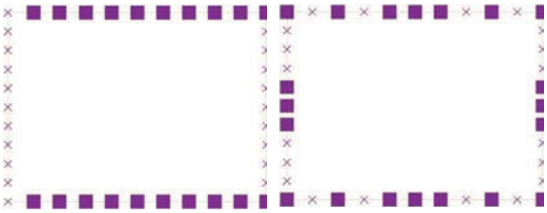
Figure 15: *Optimal locations of 16 connectors under seismic loading*

And finally, in the presence of 20 connectors, optimal positions of connectors are shown in the following figures:



(a) DE-based (b) Strength-based

Figure 16: *Optimal locations of 20 connectors under seismic loading*



(a) DE-based (b) Drift-based

Figure 17: *Optimal locations of 20 connectors under seismic loading*

The first outcome shown in Figures 9 to 17 is that the optimum arrangement depends on the loading and the criteria used to determine it. That is, the DE of the structure under cyclic loading is completely different from the one under seismic action, or what is obtained as a result of having the highest DE is not the same as the highest strength or lowest drift. By classifying the

https://doi.org/10.52202/069179-0299

problem based on loadings and objective function, some general outlines are extracted: optimal connectors' positions in the frame under seismic loading are equal along the upper and lower beam, leading to the highest DE, while under cyclic loading, the connectors in the corners offer the best response. The connectors, however, often occupy the frame corners while there are few of them in order to achieve the lowest drift, but as their number increases, this ideal location shifts to along the beams. Finally, although usually more strength is associated with less drift, the optimal solution of the frame with the highest strength is not exactly the same as that for the frame with the lowest drift since the locations of the former are concentrated in the frame corners, regardless of their number.

3.2 OPTIMUM BI-LINEAR CURVE

As mentioned before, yielding displacement of connectors is the only feature of the springs on which the dissipated energy of the frame depends. There is a specific point of split and uplift yielding where the dissipated energy is the highest, as demonstrated in Figure 18 for the bare frame attached to the panel by four-in-corners connectors under cyclic loading. Searching all possible variables is time-consuming and adopting an optimization methodology is unavoidable. As mentioned section 3.1, this solution is sought here by GA. Table 7 and 8 present the optimal values of yielding displacements in the bare and infilled frames, respectively, for both horizontal and vertical springs in the presence of different specific even number of connectors, ranging from 4 to 20 optimally arranged along the frame as a result of previous subsection. Here only cyclic analysis was conducted since the seismic loading cannot necessarily push the frame until the yielding point, especially when the frame is equipped with higher number of connectors.

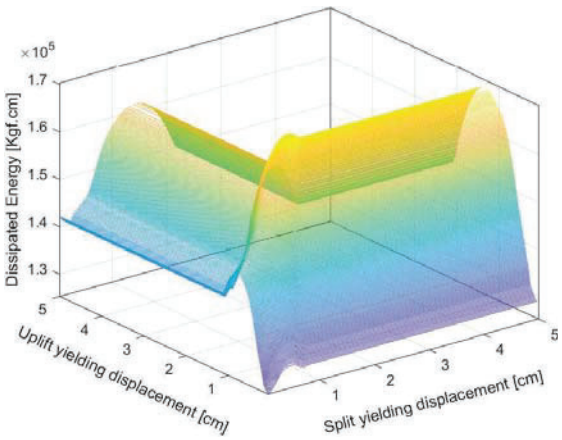


Figure 18: *Energy dissipated versus yielding points of split and uplift springs*

Table 7: *Optimal yielding points of bare RC-CLT connectors*

Connectors number	Split yielding point (cm)	Uplift yielding point (cm)
4	1.32	1.38
6	1.31	1.36
8	1.04	1.19
10	0.92	1.02
12	0.95	0.86
14	1.02	0.92
16	0.86	1.00
18	0.87	1.00
20	0.99	1.17

Table 8: *Optimal yielding points of infilled RC-CLT connectors*

Connectors number	Split yielding point (cm)	Uplift yielding point (cm)
4	1.31	1.47
6	0.95	1.73
8	1.24	1.40
10	1.29	1.58
12	1.42	1.53
14	1.21	1.80
16	1.58	1.49
18	1.13	1.94
20	1.39	1.65

Table 7 and 8 confirm that uplift yielding points are greater than split ones for both bare and infilled frames coupled to the panel by various numbers of connectors. Also, the corresponding split and uplift yielding displacements of the infilled frame strengthened is more than the bare frame for nearly all number of connectors. The average of split and uplift displacements of the reinforced bare frame are 1.03 and 1.10 cm, and those of the reinforced infilled frame are 1.28 and 1.62 cm, respectively.

3.3 ECONOMICAL CONNECTOR

After analysing the optimal yielding displacement and distribution of a specific connector with predefined elastic and inelastic stiffness, the next issue is to find out the connector with optimal stiffness. To achieve it, there needs to be a relationship between the stiffness and price of connectors. The research aims at analysing if a lesser number of stronger connectors (or more expensive ones) is more economical than a greater number of weaker connectors (or cheaper ones), considering an equal structural response with an optimal distributed. Due to lack of the stiffness-price relationship of connectors or a table including different connectors in terms of price and stiffness, the investigation here is summarized as follows comparing two connectors: a traditional angle bracket (AE116) and an innovative connection proposed by Rothoblaas, so-called X-RAD. Tables 9 and 10 compare the price of each connector and their stiffness.

Table 9: *The prices of two connections*

Connector	Unit type	No.	Unit cost (€)	Total (€)
AE116	WBR90110	1	8.5	8.5
	LBA450	21	0.087	1.83
	Total cost (€)			10.33
XRAD	XONE	1	194	194
	XVGS11350	4	8.56	34.24
	MI120	1	105	105
	XBOLT1665	8	2.91	23.28

Total cost (€)		356.52

***Table 10**: The stiffness of two connections*

Connector	Stiffness	Split	Uplift
AE116	Elastic	2857.31	6448.89
	Inelastic	980.85	1008.86
X-RAD	Elastic	8675.80	20751.64
	Inelastic	1392.20	4374.79

A comparison is made between two cases; (1) four strong connectors (X-RAD) in the corners of the frame are installed; and (2) the number and distribution of the weaker one (AE116) is optimally found so that both cases result in an equal energy dissipation. The result shows that 16 AE116 connectors optimally distributed around the frame have approximately the same response, in terms of strength and dissipated energy (Figure 19), to the frame as 4 X-RAD connectors do. However, according to Table 9, the total material price of AE116 used is 165.28 (€), while X-RADs cost 1426.08 (€), confirming the importance of using connectors optimally designed both in number and mechanical properties in reducing expenses. Nonetheless, the former takes more time to be installed and this translates into increasing labour costs, thus resulting in a higher the total cost compared to X-RADs.

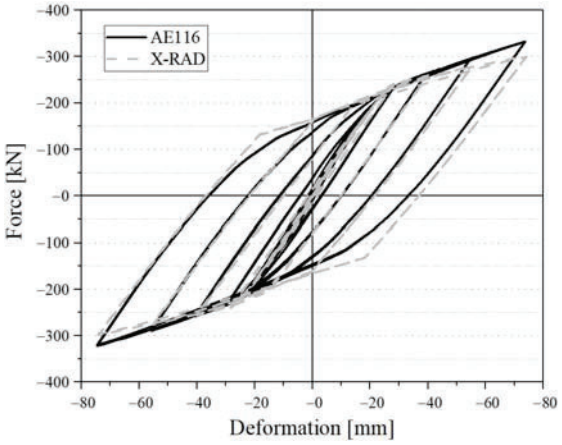

***Figure 19:** Force-Deformation of the reinforced frame for two cases*

4 CONCLUSIONS

In this work, the optimum bilinear CLT-RC connectors on the one hand, and optimum configuration with certain numbers of those connectors on the other hand, were found. The outcome would be beneficial to design a real-case CLT-RC connector with the same properties as the one that was optimally attained here. This connector turned out to have a split and uplift yielding displacement of 1.03 and 1.10 cm for the CLT-infilled RC frame, and 1.28 and 1.62 cm for the masonry-infilled frame coupled with externally added CLT panel, respectively. It was observed that their placements are affected by both loadings and objective functions, though generally, no matter how many of them are utilized, the highest DE and strength are produced by corner-distributed connectors under cyclic loading, whereas the highest DE is produced by along-beam-distributed connectors under seismic loading. In the case of the lowest drift in the frame, both distributions were observed.

World Conference on Timber Engineering Oslo 2023

LESSONS LEARNED FROM A DECADE OF RESEARCH ON WOOD ASSEMBLIES UNDER BLAST LOADING

Ghasan Doudak[1], Christian Viau[2], Daniel Lacroix[3]

ABSTRACT: A comprehensive research program, combining experimental and analytical research, has resulted in significant advancements of knowledge pertaining to the behaviour of various structural timber assemblies subjected to blast loads. The full paper will report on key findings obtained from investigating light-frame walls, mass timber elements, and boundary connections. Significant results on the effect of strain rate on the material behaviour, typical failure modes observed, as well as influence on connections will be discussed. The main outcomes from this decade-long research program have paved the way to the development of design methodologies and retrofit options.

KEYWORDS: Design, Blast, Timber, Glulam, CLT, Stud walls, Connections, Retrofits, Mitigation

1 INTRODUCTION AND RESEARCH NEEDS

Targeted attacks or accidental explosions near civilian infrastructures have highlighted the need for developing reliable and robust design methodologies to address the behaviour of structural elements subjected to blast loading. With increasing number of timber structures built around the world, and evidence of their relatively poor performance when subjected to blast loads [1], there is a critical need to establish and enhance the behaviour of timber structural elements under high strain rates. Mid- and high-rise mass-timber structures comprised of engineered wood products (EWPs), such as glued laminated timber (glulam) and cross-laminated timber (CLT), are often accompanied by higher risk of being exposed to potential effects of blast loading.

American and Canadian blast standards (i.e., ASCE/SEI 59-11 and CSA S850) have been developed based on an experimental program on light-frame wood structures [1, 2], which focused on the overall qualitative behaviour of the structures. Since no in-situ properties of the structural members were measured during testing, published data was used to obtain the strength and stiffness of the specimens in order to conduct damage assessment, develop design provisions and propose response limits for wood structures [3]. Investigations into material behaviour under high strain-rate effects necessitates comprehensives experimental research programs, which can be accomplished through live explosion or simulated blast load testing (e.g., shock tube). While the former replicates the complete effects of a blast event (e.g., shock wave, fireball, fragmentation, debris throw, etc.) challenges arise with regard to the collection of reliable data. Conversely, the main benefit of laboratory experimentation simulating the shock wave over live arena testing is the richness of information generated.

A comprehensive research program has been established at the University of Ottawa to investigate the performance of light-frame stud walls, glued laminated timber (glulam) beams and columns, cross-laminated timber (CLT) slabs, and various connections (e.g., bolts, bearing angles, specialized energy-dissipative connections) when subjected to simulated blast loads. This paper presents key research results from the past decade including well over 200 tests conducted at the University of Ottawa Shock Tube Test Facility with the aim of establishing and improving the behaviour of several types of timber systems under blast loading.

2 EXPERIMENTAL PROGRAM

The Shock Tube (Figure 1), used in the experimental campaigns, is a test apparatus capable of simulating shock waves similar to those found in far-field explosions, on small-to-full-scale structural and non-structural components. A wide range of pressure and impulse combinations, representing different charge-weights and stand-off distances can be simulated.

***(b)** Driver section (back view)*

***Figure 1:** University of Ottawa Shock Tube*

The Shock Tube consists of three main components: driver, spool, and expansion sections. The shock wave is created by the release of compressed air stored in the driver section. This forms a shock front that travels along the 6096 mm expansion section and interacts with the specimen mounted at the end-frame (Figure 1b). The reflected pressure can be measured by two dynamic piezoelectric pressure sensors. Strain gauges are typically used to obtain strain data and determine the dynamic failure point for each test. Linear variable displacement transducers (LVDTs) are used to measure the specimen deflection. The data acquisition system is also connected to a full colour high-speed camera, capable of recording videos at a rate of 2000 frames per second.

3 KEY RESEARCH FINDINGS

3.1 MATERIAL PROPERTIES

Structural materials subjected to high strain rates during blast or impact loading tend to experience apparent increases in strength and sometimes stiffness [e.g. 4, 5-7], typically quantified as dynamic increase factors (DIFs). The current version of the Canadian blast design standard (CSA S850) assigns a DIF value of 1.4 to all wood element types [8]. Extensive static and dynamic experimental testing on full-scale studs, stud walls, glulam beams and columns, as well as CLT panels, has provided insight to values of DIFs for various wood products. As shown in Table 1, the current DIF value provided by the Canadian blast design standard [8] is clearly not sufficiently nuanced to capture the behaviour of different timber elements, and it may in several instances lead to a design that is not adequately conservative.

***Table 1:** Observed and code DIF values*

	Experimentally Observed	CSA S850 [8]
Solid Sawn	1.40	
CLT	1.28	1.40
Glulam	1.14	

The values reported in Table 1 were based on testing of fifty-three light frame wood stud walls [6, 9, 10], seventy-one glulam beams [11-14], twenty-five CLT panels [7, 15, 16].

3.2 LIGHT-FRAME WOOD STUD WALLS

Light-frame stud walls of various configurations have been studied experimentally, involving various types and thicknesses of sheathing, stud size, and fasteners. Full-scale flexural tests on lumber elements have shown that the characteristics of the failure often shift from that of splintering failure when loaded under static loading to a brash “cut-through” failure when loaded dynamically (Figure 2).

***(a)** Static* ***(b)** Dynamic*

***Figure 2:** Representative failure modes for studs*

Results also showed indications of premature failure in some sheathing panels prior to achieving full flexural failure in the stud elements (Figure 3a). When sheathing failure occurred, debris was also produced, with some pieces being as large as the gap between the studs. Detachment of failed stud fragments was caused by the weak withdrawal capacity of the nail connections between the sheathing and the stud. While nails behave efficiently in shear when in-plane loads are imparted on the wall (i.e., shearwall), nails involved in out-of-plane motion are eventually loaded in withdrawal, where they are known to be very weak. The use of screws was found to significantly limit debris throw (Figure 3b), which has been shown to be the principal cause of injuries and deaths during blast events [17].

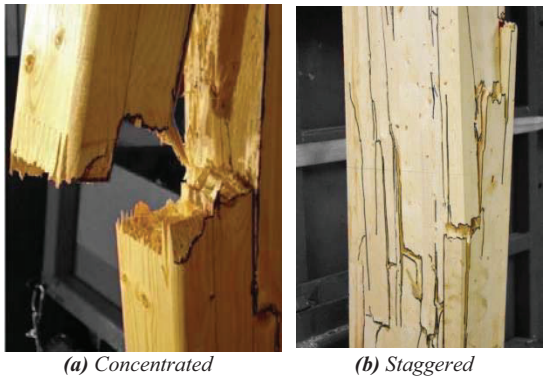
***(b)** Wall specimen with thicker sheathing and screws*

***Figure 3:** Light-frame wall specimens after testing*

3.3 GLUED-LAMINATED TIMBER

Failure of glulam members have been observed to consistently initiate at a tension-side finger joint or natural defect. In some instances, glulam specimens with localized concentration of finger joints on the tension-side laminate (Figure 4a) lacked the increase observed in specimens containing no finger joints in the middle one-third span (Figure 4b).



***(a)** Concentrated* ***(b)** Staggered*

***Figure 4:** Glulam finger joints*

The effect of axial load on the dynamic behaviour was also investigated. Three different axial load ratios were considered. The addition of axial load reduced the resistance of the column and contributed to concentrating the damage at midspan when compared to the case without axial load (Figure 5). It should be noted, however, that the contribution of axial loads in actual structures would highly depend on the connection detailing between the columns and the elements they support.

***(a)** Without axial load* ***(b)** With axial load*

***Figure 5:** Effect of axial load on glulam specimens*

3.4 CROSS-LAMINATED TIMBER

Two experimental programs investigating the out-of-plane behaviour of CLT under static and simulated blast loading of twenty-two panels, with different panel thicknesses was undertaken [7, 16]. The dynamic behaviour of CLT panels under bending consisted of a primarily flexural failure mode, accompanied by rolling shear damage in the transverse layers, particularly in specimens with low span-to-depth ratios. The overall behaviour of CLT panels can be generalized as a progression of failure of the longitudinal layers, initiating at the outermost longitudinal laminate, and crack propagation within the transverse laminates due to rolling shear (see Figure 6).

***(a)** 3-ply*

https://doi.org/10.52202/069179-0300

(b) *5-ply* ***(c)*** *7-ply*

Figure 6: *Representative failure modes for CLT panels*

The CLT panels were observed to have significant post-peak resistance [7]. The initial drop in resistance represents the loss of the tension longitudinal and transversal laminates. For example, for a 7-ply specimen, which consist of four longitudinal and three transverse layers, this failure mechanism implies that the specimen would now behave as a 5-ply member, consisting of three longitudinal and two transverse layers.

4 CONNECTIONS

4.1 LIGHT-FRAME CONNECTIONS

Premature failure of the wall connections to the roof and the foundation has been identified as the cause for most collapses [18]. A research study was undertaken to investigate the behaviour of typical nailed boundary connections, designed according to the National Building Code of Canada's prescriptive design guidelines [19]. The results showed that such detailing was not adequate to withstand the blast pressure and resulted in premature connection failure occurring at the top and bottom plates, as shown in Figure 7.

(a) *Arrival of blast wave* ***(b)*** *Top connection failure*

Figure 7: *Failure of nailed stud wall boundary connection*

Off-the-shelf joist hangers, typically used in light-frame wood floor systems, as well as simple angle brackets, were used to connect the studs to the boundary elements, as shown in Figure 8. The results showed that while overdesigned connections allowed the studs to achieve their flexural capacities, walls with connections designed to yield in a controlled manner could withstand greater blast pressures and impulses, and exhibit less damage.

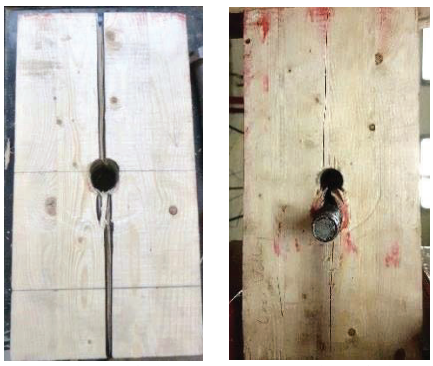
(a) *Failed wall specimen*

(b) *Relatively intact bottom plate connections*

Figure 8: *Wall specimen with joist hanger connections*

4.2 BOLTED GLULAM CONNECTIONS

A study was carried out on single-bolt joints of various slenderness ratios in both principal load direction (i.e., parallel- and perpendicular-to-grain), with the aim to investigated high strain-rate effects on the connections. An average dynamic increase ratio of 1.2 was observed on the yield load of connections designed to fail via wood crushing, while no significant dynamic increase on the yield load or stiffness was found for connections designed to fail in bolt bending and yielding. A loss in connection ductility was also noted when comparing static to dynamic loading, and the use of self-tapping screws (STS) as joint reinforcement was proved effective (see Figure 9).



(a) *Splitting failure (unreinforced)* ***(b)*** *Crushing failure (reinforced)*

Figure 9: *Dynamic stocky bolt specimens (parallel-to-grain)*

https://doi.org/10.52202/069179-0300

Glulam beams with bolted end connections with slenderness ratio of 10.8 were tested under shock tube simulated blast loads [12]. It was observed that bolted connections designed to yield and undergo significant inelastic deformations (Figure 10a) had enhanced overall energy dissipation when compared to specimens with overdesigned bolted connections, as required by the CSA S850.

***(a)** Yielding in connection*

***(b)** After blast test*

***Figure 10:** Full-scale bolted glulam specimen*

4.3 SELF-TAPPING SCREWS IN CLT

Self-tapping screws (STS) were used in end-grain with full-scale CLT specimens subjected to simulated blast loads. Significant damage was observed in the STS connections, where tension perpendicular-to-grain failure as well as combination of shear and withdrawal failure were prevalent. To take advantage of timber's relatively high capacity in bearing, the use of angle brackets with STS, which are traditionally used for in-plane loading for wind and seismic, were also investigated. Two angle brackets were tested, representing two distinct design philosophies; a thin and flexible angle bracket, designed to undergo significant yielding and wood crushing, and a robust and stiff angle bracket, designed to remain elastic and not cause significant wood crushing. The flexible angle bracket was found to fail in yielding and wood crushing. The overdesigned and stiff bracket exhibited a brittle failure mode when the capacity of the connection was exceeded, namely by rupturing the fasteners that connect the bracket to the base of the test assembly. As shown in Figure 11, full-scale test specimens with the flexible angle brackets were seen capable of absorbing more blast pressure and impulse prior to failure in the CLT panel.

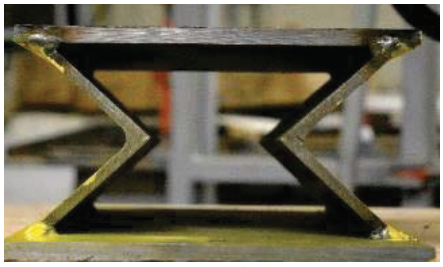
***(a)** Flexible angle*

***(b)** Overdesigned angle*

***Figure 11:** Full-scale CLT specimens with angled connections*

4.4 ENERGY ABSORBING CONNECTIONS

The use of energy absorbing connections (EAC), which are purposefully designed to dissipate energy through controlled deformations of a steel fuse, were observed to improve the capability of a timber assembly to withstand blast explosions. Various configurations of EACs were investigated, all of which comprised of mild-steel shapes with various thickness and dimensions. The connections that were identified to perform optimally were found to exhibit a bi-linear elastic-perfectly plastic behaviour. The connection deemed the most efficient (Figure 12a) was implemented into full-scale glulam and CLT specimens. In comparison to specimens with simply-supported idealized boundary conditions, or overdesigned connections, the EACs were found to provide around 75%-115% increase in total impulse absorbed by the assembly prior to flexural failure of the wood element. A time lapse of a test is shown in Figure 12b.



***(a)** Tested EAC*

***(b)** Time-lapse*

***Figure 12:** Full-scale CLT specimens with EACs*

5 WOOD ELEMENT RETROFITS

Identified deficiencies found during the research program were used as motivation for investigating possible retrofit options to increase the overall performance of various timber systems. This includes enhancing the performance of sheathing elements, load-bearing elements (i.e., stud, glulam column), boundary connections, as well as minimizing high-velocity flying debris. Stud walls designed according to typical prescriptive requirements often experienced premature failure of sheathing panels [9]. This not only caused flying debris but a loss in structure integrity, where the load-bearing elements cannot achieve their full flexural capacity. The use of thicker wood-based sheathing was found to shift the failures to the studs, while concurrently decrease the amount of sheathing debris. Corrugated steel panels were also tested (Figure 13) and the results showed that they provide significant increase in stiffness and strength.

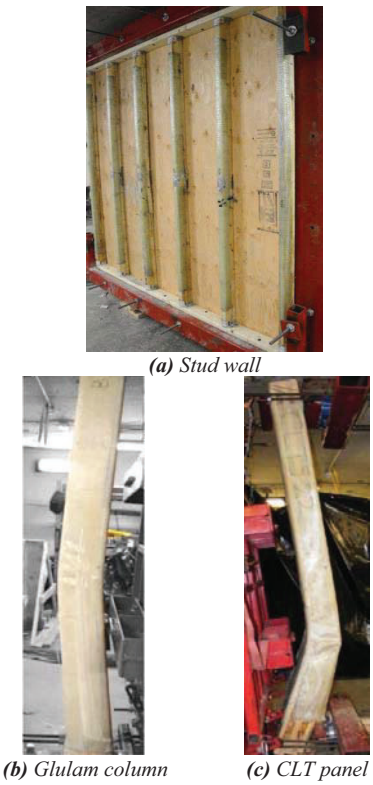
***Figure 13:** Corrugated steel panels as sheathing retrofit*

Welded-wire-mesh (WWM) was implemented as a sheathing retrofit, as well as a catcher system. In both applications, it was found to perform adequately well. As a sheathing reinforcement, the WWM acted similar to a skin reinforcement, thus reducing the demand on the panel in bending and minimizing overall damage and fragmentation (see Figure 14a), while as a catcher system, it adequately captured all debris of significant sizes (Figure 14b).

***(a)** Sheathing reinforcement* ***(b)** Catcher system*

***Figure 14:** Application of welded wire mesh (WWM) as retrofit*

Different retrofit configurations using fibre-reinforced-polymers (FRP) were investigated for light-frame stud walls, glulam columns, and CLT panels, as shown in Figure 15.



***(a)** Stud wall*

***(b)** Glulam column* ***(c)** CLT panel*

***Figure 15:** Retrofits using fibre-reinforced polymers*

https://doi.org/10.52202/069179-0300

When adequate confinement in tandem with longitudinal tension reinforcement was provided, the application of FRP tended to delay and contain brittle tension parallel-to-grain failure and allowed for the compression-side longitudinal fibres to crush in a ductile manner [20-22]. In general, this allowed for the reinforced specimens to have sustained post-peak capacities, which would otherwise be limited, due to the inherent brittle nature of wood in flexure.

6 CONCLUSIONS

The key findings of a decade-long experimental and analytical research program investigating the behaviour of structural timber systems subjected to blast loads are summarized. High strain rate effects for various structural components and connections have been documented, paving the way for more accurate and resilient structural designs of wood assemblies. Mitigation strategies to improve the blast resistance of wood assemblies have been investigated, including boundary connections, sheathing reinforcements, and the use of fibre-reinforced polymers.

World Conference on Timber Engineering Oslo 2023

A NONLINEAR DYNAMIC MODEL FOR COLLAPSE INVESTIGATIONS IN TALL TIMBER BUILDINGS – PRELIMINARY RESULTS

Alex Sixie Cao[1], Lukas Esser[2], Ben Glarner[3] Andrea Frangi[4]

ABSTRACT: Structural robustness of timber buildings is becoming increasingly relevant because of the increasing use of timber in the built environment. An important tool for assessing the robustness of any structure is an efficient numerical model capable of simulating progressive collapse. With such a model, physical tests can be limited to a few carefully selected validation tests and the robustness of a wide range of building typologies and geometries can be investigated efficiently. In this paper, a parametric nonlinear dynamic model for simulating progressive collapse of timber buildings is presented. Because of the parametric capabilities of the model, a vast range of buildings can be modelled. Moreover, the entirety of a collapse can be simulated with the recently developed mixed element method and the implementation of stress- and energy-based failure criteria for normal loading and impact loading. To demonstrate the capabilities of the model, a case study is presented on a symmetrical three-dimensional frame building with varying cross-sectional member dimensions. The model is an indispensable tool for investigating the robustness of timber buildings.

KEYWORDS: Structural robustness, Progressive collapse, Nonlinear dynamic modelling, Impact loading, OpenSees

1 INTRODUCTION

Buildings and other infrastructure are essential in our daily life. They provide us with shelter from the weather, working and leisure spaces, and they serve logistical purposes in our society. When a building is damaged, it may lose its main function of providing shelter and instead become a hazard to its users. To limit such hazards, buildings should be built such that the damage can be confined, and a disproportionate and progressive collapse can be prevented. This property of a structure is its structural robustness, which can be defined as the insensitivity to initial damage [1].

After the progressive collapses of Ronan Point in 1968 and the World Trade Center in 2001 [2,3], substantial efforts have been put into research on the robustness of steel and reinforced concrete structures [3]. At present, most of the building stock in Europe comprises reinforced concrete and masonry buildings [4]. As the use of timber in our built environment is being increasingly recognized as an important carbon sequestration tool [5], more and more timber buildings are also being built [6–8]. However, the knowledge on structural robustness of timber buildings is still scarce [3,9,10].

Dissimilar to steel and reinforced concrete, timber is an intrinsically lightweight material [11,12]. This leads to vastly different behaviour when subjected to lateral loading, such as wind and seismic loading [12–15]. Besides the weight difference, the material and its connections are also dissimilar to its conventional steel and reinforced concrete opponents [16–18]. Therefore, existing knowledge on the robustness of steel and reinforced concrete structures cannot be directly applied to timber buildings [10].

To assess the robustness of any structure, one of the primary tools is an efficient and accurate numerical model [3]. Because of the complexity of the behaviour of timber and its connections, and the highly dynamic nature of a collapse, a nonlinear dynamic model accounting for large deformations is necessary [3,9,19]. [3,9]With such a model, the structural robustness of a vast range of buildings and materials can be investigated, and physical experiments can be reduced to a few validation tests of the model.

In this paper, a fully parametric nonlinear dynamic model for simulating progressive collapse of timber buildings is presented. The model can simulate the entirety of a progressive collapse with large deformations and incremental damping. To facilitate the separation, detachment, and loss of members, the recently developed mixed element method was implemented [20]. Besides commonly used stress-based failure criteria [21], an energy-based failure criterion based on extensive impact tests on full-size timber beams was used [22–25]. The collapse model was written in Python with the open-source finite element framework OpenSees [26].

To demonstrate the model, a three-dimensional frame subjected to a corner, edge, and internal ground-floor column removal was analysed. The frame comprises glued laminated timber beams and columns, and laterally loaded dowel-type connections with slotted-in steel plates. The frames are designed for the vertical gravity loads in the ultimate and serviceability limit states, as well as serviceability-level wind-induced vibrations.

2 MODEL DESCRIPTION

2.1 CONCEPTUAL FRAMEWORK

The conceptual framework comprises the seven different modules shown in Figure 1. In the framework's development, a basic requirement was the ability to have a fully parametric model with a programmable input interface of the different model parameters. To accommodate this requirement, the building geometry was constrained to an irregular orthogonal grid. This enables an irregular positioning of the orthogonal grid axes, which makes different bay lengths and floor heights possible. Beam elements can be positioned on any of the grid axes, and shell elements can be positioned on any of the three surface planes following the grid. In the future, trusses will be implemented following the same system. For the programmable input interface, a matrix equivalent representation of the building was developed. These features are shown in Figure 1a.

Another requirement was the possibility of adapting the model to commonly used connections in timber buildings, such as laterally loaded dowel-type connections and axially loaded dowel-type connections. It is also possible to implement connection models with hysteresis. The parametric connection model is shown in Figure 1b.

It was decided that the framework would be required to simulate the entirety of a collapse. For this purpose, the mixed element method was developed and verified [20]. The method uses finite elements with physical lengths and properties, interspersed with rigid zero-length elements. For each time-step, a failure detection algorithm detects the exceedance of a failure criterion in the model and removes the rigid zero-length elements at the points of failure. With this, the simulation can continue after the failure of a building member. This is shown in Figure 1c.

To impose initial damage scenarios and to remove elements in the analysis upon failure, an element removal algorithm was developed [27]. The real removal of these elements is advantageous over a stiffness reduction approach, since the stiffness reduction approach may lead to convergence problems. The element removal algorithm is shown in Figure 1d.

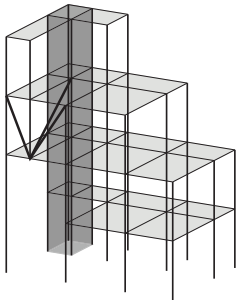
If a rigid zero-length element is removed such that a finite element with physical length is entirely disconnected from the rest of the model, a convergence problem would occur. To avoid such convergence problems, any disconnected parts of the model with rigid-body motions were removed. The removal was conducted with the element removal algorithm shown in Figure 1d. In reality, the rigid-body motion of the removed parts would be building debris, which would lead to impact loading at some point. Therefore, a debris tracking algorithm was implemented for any parts with rigid-body motion. The debris tracking algorithm calculates the trajectory of the debris as projectiles. This is shown in Figure 1e.

Besides the debris tracking algorithm, an impact detection and loading algorithm was developed. If the impact detection algorithm detects debris is impacting a member of the remaining structure, the impact loading algorithm is activated. This loads the impacted member over a pre-determined time-step and is shown in Figure 1f.

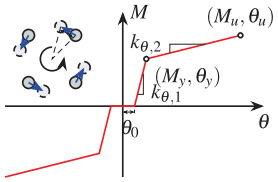
Based on impact tests of full-size glued laminated timber beams [22–25], an energy-based failure criterion was developed, and the impact time was found. If the kinetic energy of the debris exceeds the energy capacity given by the failure criterion, local failure of the member will occur. This is shown in Figure 1g.

2.2 ANALYSIS DESCRIPTION

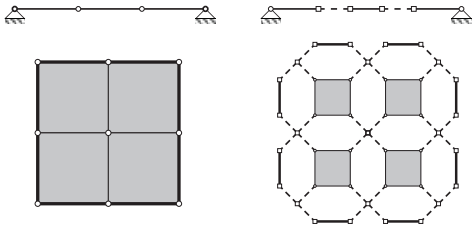
The conceptual framework of the collapse model in Section 2.1 was implemented in Python, with the open-source finite element framework OpenSeesPy [26] as the computational engine. To organise the input and output of



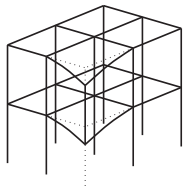
(a) Parametric global model.



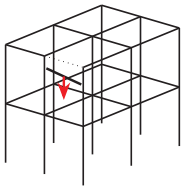
(b) Parametric multi-scale connection model.



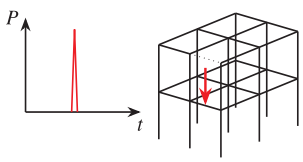
(c) Mixed element method and element separation algorithm.



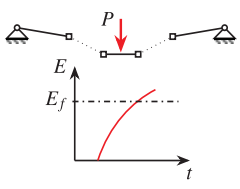
(d) Element removal algorithm



(e) Debris tracking algorithm.



(f) Impact loading.



(g) Energy-based failure criterion.

Figure 1: *Conceptual framework of the collapse model and figurative illustrations of the different modules.*

https://doi.org/10.52202/069179-0301

the model, an SQL database was developed with SQLite in Python. In the general framework, one-dimensional *forceBeamColumn* elements were implemented for the beams and the columns, and two-dimensional *ShellMITC4* elements were implemented for wall and slab members. The connections and the rigid links interspersed between the finite elements were modelled with the zero-length element *twoNodeLink*. The beam and column members were modelled with a linear-elastic perfectly brittle material behaviour, which is concurrent with high strain-rate models for glued laminated timber [28]. As a simplification, the connections were also modelled as a linear-elastic perfectly brittle material. A corotational transformation was used for the entire model.

2.2.1 Element-removal algorithm

The element-removal algorithm can be described in the following steps:

1. Solve the system of equations to get the internal forces of the element to be removed.
2. Remove the element from the model and re-apply the internal forces of the removed element.
3. Step down the internal forces of the removed element linearly over a time t_r.

The algorithm can be used for static or dynamic analysis and can also be used for the removal of entire members. In the collapse model, it is used for in situ removal of any failed elements, detached model parts with rigid-body motion, and to impose damage by removing single elements or members. A full description of the element removal algorithm can be found in Cao et al. [27].

For a column-removal scenario, the UFC 4-023-03 [29] states that the removal time t_r must be less than 1/10 of the natural period of the vibration mode associated with the damage, whereas ASCE 7-22 recommends an impact duration between 30 ms for modelling flood-borne debris. In EN 1991-1-7 [30], hard impact for vehicles results an impact time of 70 ms. The results from the impact tests conducted by Cao et al. [22–25] showed that the mean impact time was 12 ms, with an impact velocity of around 9.6 m/s, which corresponds to a free-fall of about 4.7 m. The natural period associated with the initial damage scenario was in the order of 400 ms. On this basis, a removal time t_r of 20 ms was chosen.

2.2.2 Incremental damping

One of the main drawbacks of previous models was the lack of an incremental damping formulation [31], which is also a general weakness for the most common damping implementations [32]. During a collapse, the connections and members may enter the nonlinear range and parts of the building may detach from the surviving structure. Because of the potential nonlinearities of the members, the stiffness of the system may change. Similarly, the detached parts do not contribute to the mass or stiffness of the remaining building. Therefore, a damping scheme which does not account for the changes in the stiffness and mass of the building during a collapse may lead to gross errors. Moreover, modal analysis in the undamaged state will not reflect the vibration modes throughout a collapse.

In the current state of the model, an incremental damping scheme based on Rayleigh damping is implemented. Rayleigh damping considers both stiffness- and mass-proportionate damping in the damping matrix **C**:

$$\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K}, \tag{1}$$

where **M** is the mass matrix, **K** is the stiffness matrix, and α and β are calibration parameters. The calibration parameters α and β are selected based on the natural angular frequency ω_i and ω_j, of two vibration modes or frequencies from an eigenvalue analysis, which determine the range of interest for the damping scheme. The two calibration parameters α and β can be computed from:

$$\alpha = \zeta\frac{2\omega_i\omega_j}{\omega_i + \omega_j}, \qquad \beta = \zeta\frac{2}{\omega_i + \omega_j}, \tag{2}$$

where ζ is the damping ratio. Because the vibration modes at the undamaged state of the model will not reflect the vibration modes throughout the collapse, the iterative damping scheme is based on updating the mass **M** and stiffness **K** matrices at each time-step. By doing so, nonlinearities and physical detachments of building parts will be reflected in the damping **C** of the analysis. The calibration parameters α and β are only computed at the start of the analysis because of difficulties with high-frequency modes ω_i and instabilities throughout the simulation. To avoid the calibration parameters α and β coefficients from being computed too close to each other, the frequency j was set as ω_j=5ω_i, and frequency i was set as the first natural frequency ω_i= ω_1.

2.2.3 Convergence check

The dynamic analysis was conducted with an implicit time integration scheme. For the implicit integration, the unconditionally stable average acceleration method in the Newmark family is used. To solve the nonlinear equations of motion, the Newton-Raphson method was used.

Because the failure criteria in the model are checked at each time-step, an optimum maximum time-step had to be determined. If the maximum time-step is too large, the utilization of the members will grossly exceed the capacity. If the maximum time-step is too small, the model will be computationally inefficient. Based on a sensitivity analysis of the maximum time-step, a time-step of 0.5 ms was used for the collapse simulations. Compared to a time-step of 0.1 ms, the difference in the time of the last element failure was about 1.6%. The difference in the vertical deflections of the node above the removed column was about 4.6%, and the maximum utilization in the model was 1.08, compared to 1.04 for a time-step of 0.1 ms.

Like the sensitivity analysis of the maximum time-step, a mesh sensitivity analysis was conducted to determine the best member discretization. A member discretization of five finite elements per member was found as the optimum between computational expenses and accuracy. Compared with a discretization of ten finite elements per member, the difference in the time of the last element failure was about 0.2%, and the difference in the vertical deflections of the node above the removed column was about 0.8%. The computation time of the simulation was approximately 56% shorter for the discretization with five

finite elements per member. The incremental Rayleigh damping scheme in Section 2.2.2 was calibrated for the first and fifth vibration modes.

2.3 FAILURE CRITERIA

For most of the failure checks in the model, stress-based failure criteria according to EN 1995-1-1:2004 [21] were used at each time-step. The design checks were conducted on the mean material strength level, without load factors on the action side. The connections were modelled as linear elastic and perfectly brittle in rotation, with a maximum allowable rotation θ_y of 25.8 mrad, or a moment M_y of 52.4 kNm. For the mean material strengths, parameters from Schilling et al. [33] were used for glued laminated timber of strength class GL24h. For the mean elastic and shear modulus, values from EN 14080:2013 [34] were used for GL24h.

2.3.1 Combined compression and bending action

In the model, a corotational transformation was used. The corotational transformation is suitable for problems with large deformations, which are expected during a collapse. Because of the corotational transformation, a second order failure criterion for combined compression and bending action can be used without buckling coefficients. This is possible because second order P-Δ-effects are automatically considered in the equilibrium computations. Therefore, the failure criterion for combined compression and bending action was:

$$\frac{\sigma_{c,0}}{f_{c,0}} + \frac{\sigma_{m,y} + \sigma_{m,z}}{f_m} \leq 1, \tag{3}$$

where $\sigma_{c,0}$ is the compressive stress parallel to the grain, $f_{t,0}$ is the compressive strength parallel to the grain, $\sigma_{m,y}$ and $\sigma_{m,z}$ are the maximum bending stresses about the strong and weak axis of the cross-section, and f_m is the bending strength.

2.3.2 Energy-based failure criterion

In this paper, the energy-based failure criterion was based on work done on impact loading of timber beams at ETH Zurich [22–25]. Because of the dynamic nature of impact loading, a limit state based on energy was used instead of one based on stresses. From the pendulum impact hammer tests on full-size timber beams, the failure energy E_r was determined directly. The failure energy E_r from the tests is analogous to the strength of a material in terms of stresses. If the strain energy in the member E_s from imposed loads exceeds the failure energy E_r, the member has failed. This can be expressed as:

$$E_s \leq E_r \Leftrightarrow \frac{E_s}{E_r} \leq 1. \tag{4}$$

If the kinetic energy of a projectile from impact loading E_k is considered as well, Equation (4) can be expanded to:

$$\frac{E_s + E_k}{E_r} \leq 1. \tag{5}$$

The kinetic energy of a projectile can be computed from E_k=0.5mv^2, where m is the mass of the projectile, and v is the velocity of the projectile. The velocity v of the projectile can be found directly from classical projectile motion, with the initial velocity vector $\boldsymbol{v}$ from the collapse model. From the impact tests, the failure energy E_r of the beams in this paper is 22.2 kJ.

3 FRAME DESIGN AND SIMULATIONS

3.1 DESIGN OF FRAMES

The design of the frames was conducted for gravity loads according to EN 1990:2002 [35] and EN 1991-1-1:2002 [36], and wind-induced vibrations according to EN 1991-1-4:2005 Annex B [37] and ISO 10137:2007 [38]. The beams and columns were assumed to be spruce glued laminated timber with a strength class of GL24h. For the design of the cross-sections, strength and stiffness parameters were assumed from EN 14080:2013 [34]. The members and connections were designed with EN 1995-1-1:2004 [21].

The load combination for the gravity loads was chosen for office buildings in category B. The beams were designed with the following load combination:

$$p_{Ed} = \xi\gamma_G g_k + \gamma_Q q_k, \tag{6}$$

where ξ is 0.85, γ_G is 1.35, γ_Q is 1.50, g_k is 3.5 kN/m^2, and q_k is 3.0 kN/m^2. For the design of the columns, the design gravity load p_{Ed} in Equation (6) was multiplied with the reduction factor α_n in EN 1991-1-1:2002 [36] for multi-storey buildings.

The connections were designed against the load combination in Equation (6) with laterally loaded steel dowels and a slotted-in steel plate. Based on the joint slip K_{ser}=$\rho_m^{1.5}d$/23 in EN 1995-1-1:2004 [36], the connection stiffness k_θ was computed with:

$$k_\theta = K_{ser} \sum_i^{n_d} r_i^2, \tag{7}$$

where index n_d is the number of dowels in the connection, and r_i is the distance of each dowel from the connection's centre of rotation. To find the connection stiffness per shear plane k_θ in Equation (7), the spacing of the dowels was chosen as the minimum spacing in EN 1995-1-1:2004 [36]. The resulting connection stiffness k_θ was 210 kNm/rad. The connections were assumed to be rigid on the column-side of the beam-column connection.

In the serviceability wind-design, terrain category III and a mean wind velocity of 26 m/s were chosen. Since the frames were symmetrical, only a planar frame was considered in the design against wind-induced vibrations. For the wind-design and the collapse simulations, a damping ratio ζ of 2% was chosen based on ambient vibration tests [39].

In the collapse simulations, the following accidental load combination from EN 1990:2002 [35] was used:

$$p_{Ed} = g_k + \psi_{2,1} q_k, \tag{8}$$

where g_k is 3.5 kN/m^2, q_k is 3.0 kN/m^2, and $\psi_{2,1}$ is 0.3. For all the frames, the initial damage scenario was the rapid loss of a ground-floor corner column.

https://doi.org/10.52202/069179-0301

3.2 FRAME CONFIGURATIONS

The frames were symmetrical in the horizontal plane with four bays and storeys. The beams and columns were placed on an orthogonal grid with a uniform spacing of 3600 mm in each axis direction. Two variations of the beam cross-sections were designed: (1) optimised for maximum utilisation; and (2) 50% utilisation. Both variations were designed for ultimate and serviceability limit states with EN 1995-1-1:2004 [21] with standard glued laminated timber dimensions. Bending stresses in the ultimate limit state was the governing design criterion for the design of the beams.

In the connection design, a dowel diameter of 8 mm and a steel plate thickness of 10 mm were chosen with an S235 steel quality. The dowels were arranged in a 3×2 rectangular pattern. With this layout, the shear capacity of the connection was 30 kN. The rotational stiffness of the connection k_θ was 210 kNm/rad, which resulted in a peak acceleration of the softest frame of 0.053 m/s^2. This satisfies the serviceability criterion of office buildings for wind-induced vibrations in ISO 10137:2013 [38]. For the collapse simulations, a linear-elastic behaviour of the connections and the members was assumed. The incremental damping scheme in Section 2.2.2 was adopted for the collapse simulations, with a damping ratio ζ of 2%. An overview of the different frames is shown in Table 1.

Table 1: *Beam and column cross-sections of the frames.*

No.	Damage	Cross-section $b \times h$ (mm)	
		Beam	Column
120×240C	Corner		
120×240E	Edge	120×240	360×360
120×240I	Inner		
120×320C	Corner		
120×320E	Edge	120×320	360×360
120×320I	Inner		

4 RESULTS AND DISCUSSION

Both the models with the smaller and larger beam cross-sections suffered from near identical collapses when comparing the same column removal scenarios, as shown in Figure 2. This was because of the same failure modes being activated after column removal. In each simulation, after the column removal, the loads were diverted to the beams above the removed column, resulting in increased moments in the connections. The connections of the beams adjacent to and above the removed column were the first to exceed their capacity. For each damage-scenario, the damage propagated progressively from the removed column. The damage-scenario with the least collapsed floor area was the removal of the corner-column with a collapsed floor area of 6.3%, or 51 m^2, including the roof. For the edge-column removal, the collapsed floor area was 12.5% or 104 m^2, and 25% or 207 m^2 for the internal column removal.

The initial maximum static deformations of the frames before the column removals were 10.5 mm for the 120×240 scenarios and 5.6 mm for the 120×320 scenarios. After the progressive collapses, the remaining members almost returned to their initial static deflections because of the complete vertical collapses of the bays adjacent to the removed columns. This is also because of the absence of inelastic material behaviour in the model.

Although the failure criterion of the connections was the maximum rotation θ_y, the maximum deformations of the models at the first failure w_f were different. This can be attributed to the dynamic response of the frames and is shown in Table 2 and is reflected in the maximum moments at the first failure M_f. The progressive collapses of all the damage-scenarios stopped between a failure time t_f between 116 and 136 ms. The first failure in the corner column damage-scenario occurred up to 20 ms later than that of the internal damage-scenario. However, these differences are almost negligible and do not improve the robustness properties of the structure.

Table 2: *Comparison of failure times t_f, durations of the collapse scenarios t_c, maximum deformations at the first failure w_f, and the corresponding moment M_f at the first failure.*

No.	t_f (ms)	t_c (ms)	w_f (mm)	M_f (kNm)
120×240C	136	3	88.3	50.3
120×240E	126	2	85.5	50.4
120×240I	116	4	78.2	48.9
120×320C	136	4	89.4	49.7
120×320E	129	3	88.2	51.4
120×320I	124	4	88.6	49.9

4.1 COLLAPSE MITIGATION

Here, suggestions are made for how the structure could be modified to increase its robustness and also how the model could capture other effects. Because the connections are the primary cause of the progressive collapses in the damage-scenarios, adjustments to their design could improve the robustness. However, changing one property of the connections could directly influence other properties. This can be exemplified in the following scenario. An increase of the moment capacity M_y may be conducted by increasing the distances of the fasteners in a laterally loaded timber connection with dowel-type fasteners. The moment capacity increases proportionally to the distance of the dowels to the centre of rotation of the connection, and the stiffness k_θ increases quadratically, according to Equation (7). Consequently, the elastic rotational capacity $\theta_y = M_y/k_\theta$ will decrease with increased distances. An increased moment capacity M_y of the connection could activate an alternative load path via bending. However, a reduced rotational capacity θ_y would constrain the development of other alternative load paths, which require larger member rotations to be activated. An example is catenary action [40,41]. Moreover, overly strong connections may cause failures of the beams, which in practice is undesirable since timber has a predominantly brittle failure mode in bending [42,43]. Therefore, the modification of connection design without consideration of the impact of this on the larger structure may not necessarily increase the robustness of the structure.

https://doi.org/10.52202/069179-0301

The activation of alternative load paths may cause a progressive collapse [44], similar to the collapse of the Bad Reichenhall ice-arena [45]. Here, transferring loads from a damaged member to the adjacent structure may overload the structure. Considering this, a partial but more confined collapse may be preferable, similar to the collapse of the Siemens Arena [45]. For the considered damage-scenarios, the collapse propagated vertically and is shown in Figure 2. Fuse elements may prevent the horizontal propagation of a collapse, but not a vertical propagation [10]. To prevent the vertical propagation of a collapse, strong floors can be used for compartmentalization [10]. Future work could include scenarios where failure is not concentrated in the connections, and the effect of using members with a surplus capacity reserve could be evaluated. It is uncertain if this will be beneficial for the robustness of such structures, and if the increased material volume will justify such an approach.

https://doi.org/10.52202/069179-0301

4.2 PLAUSIBILITY OF DEFORMATIONS

To evaluate the plausibility of the model, the two-dimensional static model depicted in Figure 3 was assessed for a corner-column damage-scenario. The structural system in Figure 3 is similar to the loading conditions in each storey above the removed column. To account for the stiffness of the laterally loaded timber connections with dowel-type fasteners, the beam ends were constrained by rotational springs with a rotational stiffness k_θ, as defined in Section 3.2. The accuracy of the simplified beam model is more dependent on the rotational constraint than the axial constraint. For 120×240C, the maximum static deformation was 224 mm, and 213 mm for 120×320C.

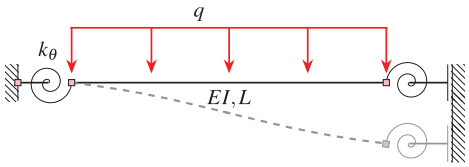

Figure 3: *Simplified beam model of a corner-column damage-scenario.*

To obtain comparable deformations to those of the simplified model, the nonlinear parametric collapse model was modified to neglect the failure of the connection elements. The maximum dynamic deformations from the column removal for 120×240C was 446 mm, and 425 mm for 120×320C. To compare the dynamic deformations from the nonlinear parametric collapse model and the static deformations from the simplified beam model, a dynamic amplification factor was necessary. Here, the dynamic amplification factor was defined as the ratio between the maximum dynamic and the maximum static deformations for the considered damage-scenario. For linear elastic structures without damping, the dynamic amplification factor attains a value of 2.0 [46]. Because of the limited damping for the considered structure, a dynamic amplification factor of 2.0 is reasonable [27]. With this dynamic amplification factor, the deviations between the parametric nonlinear collapse model and the simplified beam model are less than 0.25%. Therefore, the model results are reasonable.

4.3 LIMITATIONS

4.3.1 Connection behaviour

In the presented case study, the connection behaviour is linear elastic and perfectly brittle. This is a large simplification of the real behaviour of laterally loaded dowel-type connections with slotted-in steel plates, which could have hysteresis. The current iteration of the model neglects inelastic material behaviour, shear or tensile failure, as well as any energy dissipation from hysteretic behaviour. For connections which remain in the elastic domain, the modelled behaviour is realistic. For a column-removal scenario with no propagation of the failure, the linear-elastic connection assumption is conservative. This may not hold true if the collapse propagates further. Accounting for inelastic behaviour in the model would have increased the rotational capacity $\underline{\theta}_v$ and may increase the deformations of the members before failure. However, including ductility in the inelastic behaviour of the connections may not increase the robustness of the structure [31]. For edge or internal column damage-scenarios, ductility in the connections could be beneficial. Here, the static system in Figure 3 remains a good approximation of the members above the removed column because of the symmetry. Ductility in the connections or member could cause larger deformations in the system and the activation of catenary action [40,41]. Further research should be conducted on the static and dynamic characterisation of the hysteretic behaviour of laterally loaded dowel-type connections with slotted in steel plates subjected to large deformations, combined loading, and full or partial load reversals.

4.3.2 Slabs and walls

Currently, the model offers a realistic depiction for frame-type buildings with non-load-bearing walls and disconnected floors. However, most buildings include floors and walls, which act as rigid diaphragms to transfer lateral loads. This behaviour is not reflected in the current model and may significantly influence the progressive collapse. Other researchers have shown that walls and slabs are beneficial for the structural robustness [41,47]. Hence, including walls and slabs in future models is important to expand the scope of the model.

4.3.3 Damping formulation

There are notable uncertainties related to the level of damping in the model, which are also difficult to quantify. The implemented amount of damping corresponds to a service-level situation in timber buildings. However, the level of damping in a progressive collapse of a timber building is not known. A collapse situation is also an extreme loading scenario with large deformations and nonlinearities [9], which is dissimilar to the situations in which previous measurements were conducted [39]. The amount of modelled damping may therefore be severely under- or overestimated. Moreover, there is not a clear consensus in the scientific community on how damping should be modelled in such situations [32].

Because glued laminated timber can be considered as a linear-elastic perfectly brittle material, it is safe to assume that any plasticity and energy dissipation will mainly be in the connections. Therefore, implementing hysteretic connection behaviour can reduce the uncertainties related to damping. By introducing damping directly into the connections, the incremental damping can be reduced to a minimum, which will also reduce the modelling uncertainties. Like the connection behaviour, the neglection of damping in a column-removal scenario with no propagation of the failure is conservative.

4.3.4 Model validation

The presented model is not validated with physical column-removal experiments. Because of the intrinsic nature of a collapse, it is difficult to conduct building-scale validation experiments. However, the individual modules of the model which require the input of physical parameters can be validated by component-scale experiments. The validation of the full model can be conducted with full-size dynamic member-removal

experiments on building sub-assemblies. Previously, the implemented mixed element method was verified against the finite element method for both static and dynamic analysis. Moreover, an extensive experimental campaign on impact loading of full-size timber beams was conducted to improve the modelling of the impact loading and the energy-based failure criterion.

5 CONCLUSIONS

In this paper, a nonlinear dynamic model was presented for investigating the progressive collapse of timber buildings. The model is fully parametric and can model the entirety of a progressive collapse, including features such as member failure, element removal, debris tracking, impact loading, and incremental damping. The model was demonstrated on symmetrical three-dimensional frames with four floors and bays. One frame was designed for a maximum utilisation in the ultimate limit state, and another for a 50% utilisation. The frames were subjected to a corner, edge, and internal column-removal scenario.

All simulations resulted in vertically propagating collapses in the bays above the removed column. This was because of the failure of connections in bending. These connections acted as fuse elements and inhibited the horizontal propagation of damage. The capacity reserve in the beams was not activated because of the prior failure of the connections and did not lead to an increased robustness. Increasing the strength of the connections could activate alternative load paths via bending and an increase of the rotational capacity could do so through catenary action. However, a strength increase may not lead to an increase in the rotational capacity and further research is needed to assess the consequences on the failure mode of structures undergoing a column removal scenario.

The presented results are valid for frame-type structures with non-load-bearing walls and disconnected slabs. However, many structures have load slabs and walls acting as diaphragms. The current iteration of the collapse model cannot assess the contribution of these members. Similarly, trusses are also not implemented at the time of writing. These features are planned for the next iteration of the model. Besides the aforementioned limitations, the current incremental damping scheme is based on Rayleigh damping with fixed calibration factors with a damping ratio based on serviceability measurements of the damping ratio. There are several uncertainties related to the damping in this paper. To increase modelling accuracy and to reduce the uncertainties related to damping, more numerical and experimental research is needed.

The results in this paper were for linear elastic and perfectly brittle connections. However, the best practice in timber engineering is to design the connections with ductile behaviour. Future investigations should include inelastic connection behaviour to include connection hysteresis and the possible activation of alternative load paths.

The presented collapse model is an important step in the quantification and prevention of progressive and disproportionate collapse of timber buildings. The plausibility of the deformations in the model was verified with a simplified beam model. However, there are still some hurdles left before the model can be used on a large scale. One of the main challenges is the validation of the model, which is only possible through full-size experiments of an entire building or a representative sub-assembly. Despite the aforementioned limitations, the presented model is an important step for assessing the robustness of timber structures.

RESEARCH AND DEVELOPMENT OF SMALL-SCALE TIMBER CONSTRUCTION SYSTEM "BI-TREE STRUCTURE" WITH SMALL-DIAMETER TIMBER

Toko Kamata[1], Satoru Ito[2], Yuya Takaiwa[3]

ABSTRACT: We propose a rational small-scale building structure system "Bi-tree structure" that incorporates the idea of biomimetics using red cedar (38 mm square, 900 mm), which is a short piece of wood. A bending loading test was carried out to determine the Young's modulus and the allowable stress, and a finite element analysis was performed using the obtained results to evaluate the allowable stress calculation and structural safety. The validity of the model was confirmed by comparing the analysis results with the tensile loading test results of the shed.

KEYWORDS: Small-Diameter Timber, Biomimetics, Tree structure, Allowable stress degree, Finite element analysis

1 INTRODUCTION

Considering the environment, many methods have been adopted for processing short and small lumber, which is leftover wood when sawing, into woody biomass fuel, wood chips, laminated lumber, and paper raw materials. However, it has been clarified that the above-mentioned method is generally expensive, and it is regarded as a problem. [1] If it can be applied directly to the building structural system without processing the offcuts, it will be an economical and rational way to utilize wood, but there are few such cases. The main reasons for this are that joining details using ready-made hardware cannot be used for short and small materials, and that using fitting details causes large cross-sectional defects and almost no yield strength can be obtained. In addition, although it is possible to propose a building structure with a lattice structure by applying pin joints to short and small materials, the number of members will inevitably increase, so it is rather uneconomical to build a building structure other than a large scale. It becomes a structure. Therefore, in this research, we propose a rational and small-scale building structural system using small-diameter timber.

Here, the dominant load of the structure changes depending on the scale. When constructing a large-scale wooden building, the vertical load (self-weight) becomes dominant compared to the horizontal load, and the vertical load is designed as the dominant load. There are many cases of adopting dendritic pillars and dendritic lattices. For example, "Yamaga City Yamaga Elementary School (Kumamoto Prefecture, Japan)" which designed by Kazumi Kudo + Hiroshi Horiba / Shirakansu K & H [2] shown in Figure 1 and "Roadside Station Aizu Yugawa / Aizu Bange (Fukushima Prefecture, Japan)" which designed by Arsed Building Research Institute shown in Figure 2 [3]. These are considered to be a structural system that regards the leaves of a tree as a load distributed to the entire canopy, supports it with twigs, and transmits it to the trunk by an optimal route. Regarding this tree structure (Figre 3), Gaudi and Frei Otto conducted an upside-down suspension test (Figure 4) to clarify the load propagation path [4] and to set the optimum member arrangement for low-stress members. Research [5] has been conducted to propose a method for removing the stress. However, these are verifications for vertical loads, and in the case of small buildings such as the shed in this study, horizontal loads are the dominant load rather than vertical loads, and the required

Figure 1: *Yamaga City Yamaga Elementary School, Kumamoto Prefecture, Japan [2]*

performance to the dominant load is different from the case of large-scale buildings.

Figure 3: *A model of tree structure [4]*

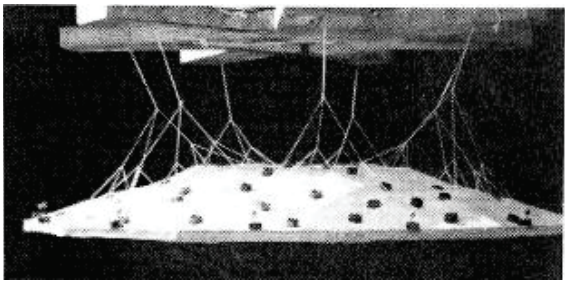

Figure 4: *Upside-down model [4]*

Therefore, in this research, we think that the structural system is different from that when constructing a large-scale building. And in order to construct a small-scale wooden building, we propose a structural system which has a rational dendritic shape not only for vertical load but also for horizontal load. Specifically, a tree system that transmits the load in the shortest path when a vertical load is applied, and a brace structure where the branch part is tensioned and compressed while bending resistance is generated in the trunk part and deformation is released when a horizontal load is applied. In this study, this structure is called "Bi-tree structure". In addition, there are only a few cases in the world where biomimetics are used in architecture, and we believe that this research will contribute to the development of biomimetics by becoming one of these cases.

Based on the above background, the allowable stress of the red cedar used in the proposed structural system was calculated by testing and calculation, and the stress transfer mechanism was clarified by finite element analysis. And a loading test was conducted after the shed construction to make a comparison with analysis model. By doing so, the validity of the analysis is verified.

2 THE OUTLINE OF ARCHITECTURE

2.1 THE OUTLINE OF THE SHED

2.1.1 Materials and dimensions

Figure 5 shows the appearance of the shed. A 38 mm square, 900 mm long red cedar was used as the structural material. Polycarbonate is used for the roofing material and exterior material. The dimensions are 4320 mm in width, 975 mm in depth, and 2000 mm in maximum height. The location is somewhere in Karuizawa Town, Kita-Saku District, Nagano Prefecture, Japan.

Figure 5: *Appearance of the shed*

2.1.2 MATERIALS

Figure 6: *Parts of the shed*

Figure 6 shows a reference to the members of the shed. The shed is made up of three types of members. Here, in this research, a 38 mm square lumber with a material length of 900 mm is a "Single Timber", two Single Timber laminated with an adhesive is a "Piled Beam", and a column which sandwiches three square lumbers between

the two single materials is defined as " Intermitted column ". In the lower photograph of Figure 2, the Piled Beam is shown on the left side, the Intermitted Column is shown on the right side, and the other parts are all made of a Single Timber.

2.2 THE OUTLINE OF RED CEDAR

Figure 7: *Enlargement of a red cedar [6]*

An enlarged photograph of Red Cedar is shown in Figure 7 [6]. Red cedar is a softwood of the Cupressaceae family, and its absolute dry specific density is 0.37, which is close to that of Sugi. In addition to being used as solid wood for

https://doi.org/10.52202/069179-0302

greenhouses and barns, it can also be used for building columns and fences by shaving it into a cylindrical shape.

2.3 ALLOWABLE STRESS OF RED CEDAR

In order to use building materials in buildings, the allowable stress must be defined. However, among the woods designated as building materials in Japan, the allowable stress level of red cedar is not defined as a structural member by the Building Standard Law. Therefore, a test was conducted (see Chapter 4), and the allowable stress level was set by itself based on the obtained results, making it possible to apply it to building structures.

3 STRUCTURAL PLAN

3.1 PROPOSAL OF STRUCTURAL SYSTEM

This time, we propose the following two structural systems. The first is the "Bi-tree structure," in which the axial force fluctuates when vertical or horizontal loads are applied, and also the type of structure changes.

Figure 8 shows the force flow when a vertical load is applied. When a vertical load is applied, a compressive force is transmitted from the upper surface to the tree part, which is decomposed to generate two thrusts, which are offset by acting in opposite directions. This is a structure that imitates the continuous arch in Figure 9.

Figure 8: *The shed when vertical load applies*

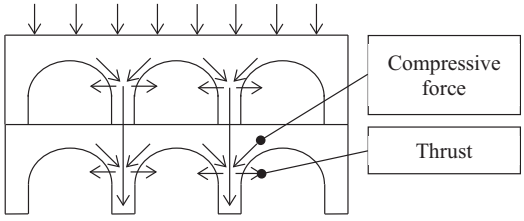

Figure 9: *The continuous arch when vertical load applies*

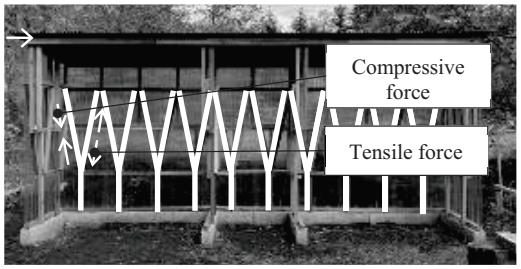

Figure 10: *The shed when a horizontal load applies*

Figure 10 shows the force flow when a horizontal load is applied. When a horizontal load is applied, one diagonal member bears the compressive force and the other diagonal member bears the tensile force in the tree part. This mimics the brace structure shown in Figure 11.

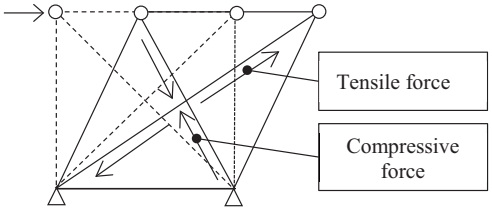

Figure 11: *A brace structure when a horizontal load applies*

The second is a structural system that applies the mechanism of independent columns with hanging walls, which is a traditional Japanese construction method. Independent columns with hanging walls are a construction method that is often used in traditional Japanese wooden houses, and are like the circled parts in Figures 12 and 13.

Figure 12: *An independent column with hanging walls*

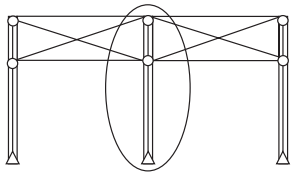

Figure 13: *A diagram of an independent column with hanging walls*

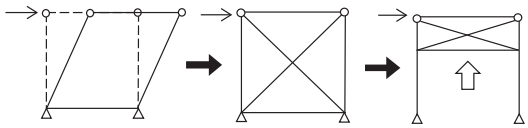

Figure14: *The origin of independent column with hanging walls*

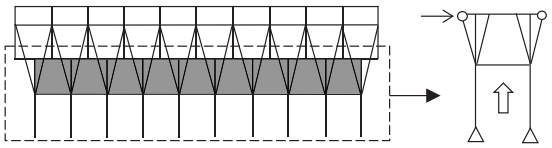

Figure 15: *The relation between trass part of the shed and an independent column with hanging walls*

Figure 14 shows the formation of an independent column with a hanging wall. With only a normal framework, the deformation becomes large when a horizontal load is applied, so a brace is incorporated to suppress the deformation of the entire wall. Furthermore, in order to secure a living space, the wall part is reduced. In this study, we applied this structure to the shed. As shown in Figure 15, the lower part of the truss part "Bi-tree structure" of the shed corresponds to the brace of the independent column with hanging walls. The position of

https://doi.org/10.52202/069179-0302

the truss is raised to keep the truss away from the ground and protect it from moisture and water splashes. In this way, we make proposals to rationally incorporate traditional construction methods.

4 TEST

4.1 BENDING LOAD TEST 1

4.1.1 Purpose

The purpose of this test is to clarify the strength of red cedar and to obtain the value used for the allowable stress calculation.

4.1.2 The outline of specimens

The target materials in this test are the three bodies defined in Chapter 2, Section 2. The Single Timber is the specimen 1, the Piled Beam is the specimen 2, and the Intermitted Column is the specimen 3, as shown in Figures 15 to 17.

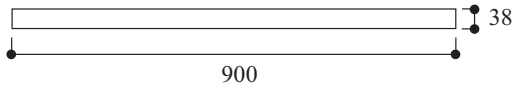

Figure 15: *Single timber; Specimen 1*

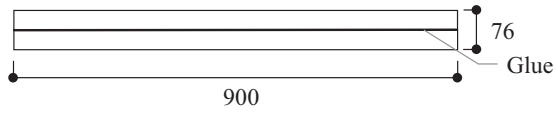

Figure 16: *Piled beam; Specimen 2*

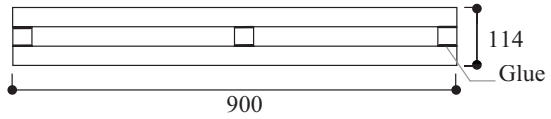

Figure 17: *Intermitted column; Specimen 3*

4.1.3 Test method

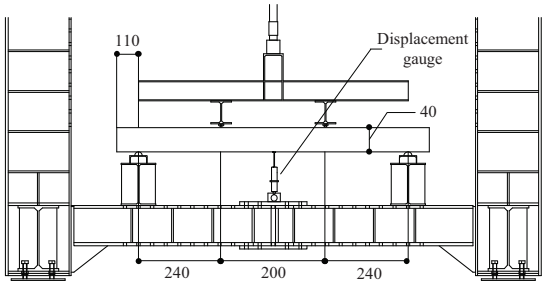

Figure 18: *Distance between fulcrums of a vertical hydraulic jack*

Figure 18 shows the distance between fulcrums and the equipment used. Using a vertical hydraulic jack, a load test was carried out by bending and loading at three equal parts of the push-off point at a load speed of 0.5 mm / sec. For the distance between fulcrums, we referred to the strength test manual [7] for structural timber established by the Japan Housing and Wood Technology Center.

4.1.4 Test result

Table 2: *Test result of Specimen 1*

Specimen	1-1	1-2	1-3	1-4	1-5
F_{max}	10.32	9.92	9.59	7.51	9.00
f_b	68.44	59.25	69.73	47.01	74.20
D	Simple Tension	Cross-grain Tension	Splintering Tension	Simple Tension	Cross-grain Tension

F_{max}: Max load(N)
f_b: Bending Strength(N/mm^2)
D: Destruction Mode [8]

Table 2 shows the test results of Specimen 1. For the strength, the 95% lower allowable limit value at the 75% confidence level was obtained in consideration of the variation of each specimen, and this was treated as the lower limit value of 5%, and the allowable bending stress was evaluated as 39.9N/mm2 from that value. The Young's modulus was 9.268 kN/mm² from the average value of the five bodies.

Table 3: *Test result of Specimen2 and 3*

Specimen	2	3
F_{max}	9250	8500
f_b	25.76	10.23
D	 Simple Tension	Cross-grain Tension

F_{max}: Max load(N)
f_b: Bending Strength(N/mm^2)
D: Destruction Mod [8]

Table 3 shows the test results of Specimen 2 and 3, and Specimen 2 showed the highest strength. In addition, the Specimen 3 had cracks not on the adhesive surface but on the base metal part.

4.1.5 CONSIDERATION

Regarding the Specimen 1, the reason why the Specimen 2 had the highest strength is considered to be that the adhesive surface was the widest compared to the other two bodies and it was able to resist bending. In addition, it was confirmed that the adhesive strength was higher than the base metal strength at the location where cracks occurred in the Specimen 3, and there was no problem with the strength of the members.

4.2 BENDING LOAD TEST 2

4.2.1 Purpose

The purpose of this test is to verify that there is no problem in the strength even if the joint part of the Piled Beam (Specimen 2 in Chapter 4.1) is shortened to 450 mm, which is half of 900 mm, and used as a long member. This is because it was necessary to construct a long member in order to provide an opening in a part of the shed.

https://doi.org/10.52202/069179-0302

4.2.2 The outline of specimens

The target materials in this test is shown in Figere 19. This is a specimen whose the adhesive part of the Piled beam (Specimen 2 in Chapter 4.1) is shortened from 900 mm to half of 450 mm. And this is referred to as the Specimen 4.

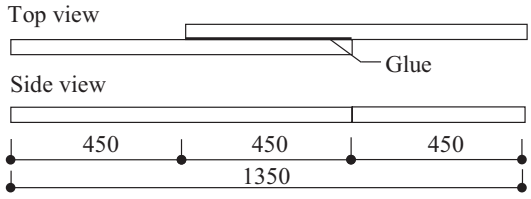

Figure 19: *Piled beams which were shortened their bonded zone in half; Specimen 4*

4.2.3 Test method

The test method is the same as that described in Chapter 4, Section 1, Section 3.

4.2.4 Test result

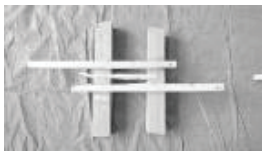

Figure 20: *The condition of specimen No.4 after broken*

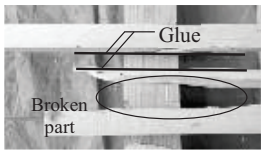

Figure 21: *Enlargement of Figure16*

Figure 20 shows the state after the destruction of the Specimen 4. In addition, as shown in Figure 21, in the loading test, the destruction of the material occurred not in the adhesive part but in the base material part.

4.2.5 CONSIDERATION

Since the destruction of the Specimen 4 occurred not in the adhesive part but in the base material part as in the Specimen 3, it can be confirmed that the adhesive strength is higher than the base material strength and there is no problem in the strength of the member.

5 STRUCTURAL ANALYSIS

5.1 THE OUTLINE OF ALALYSIS

The two types of analysis models created in this analysis are Model 1 and Model 2, respectively. The purpose of this analysis is to calculate the allowable stress using the results obtained from the analysis of Model 1 and to confirm whether the structure is as proposed. In addition, the results obtained from the analysis of Model 2 and the results of the tensile test of the shed in Chapter 6 are used to compare and consider the amount of deformation during load action.

5.2 ANALYSIS METHOD

We created and analyzed models using the finite element analysis software "midas iGen".

5.3 ANALYSIS MODEL SPECIFICATIONS

5.3.1 Model 1

Table 4: *List of elements in analysis Model 1*

	Widen (mm)	Height (mm)	Bending Strength (N/mm^2)	Young's Modulus (kN/mm^2)
Single timber	38	38	39.90	9.268
Piled beams	38	76	25.76	
Intermittent column	38	38	10.23	

Model 1 is model 2 (leftmost column of Figure 18) with the exterior material removed. The specifications are shown in Table 4. For the Young's modulus, the average value of 9.268 kN/mm^2 of the five bodies obtained in Chapter 4, Section 1 is used.

5.3.2 Model 2

Table 5: *List of elements in analysis Model 2*

	W	D	T	E	S
Roof	4300	862	5	2.15	58.8×10^{-9}
Wall	38	76			

References
W: Widen (mm) D: Depth (mm) T: Thickness (mm)
E: Young's Modulus (kN/mm^2) S: Specific Weight (kN/mm^3)

The specifications of Model 2 are shown in Table 5. It is used to compare the amount of displacement with the loading test of the shed.

5.3.3 Joining/supporting

As shown in Figure 19, all the joints are pin joints, and the 15Φ screw is used. The support is also pin-joined.

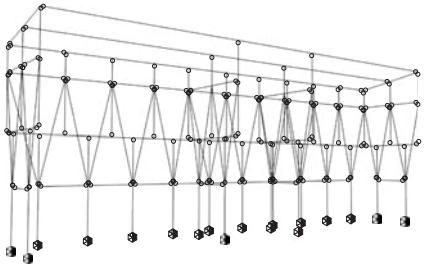

Figure 22*: Structure of joint and support*

5.4 SAFETY EVALUATION USING ANALYSIS RESULTS

To evaluate the structural safety, we carried out the allowable stress calculation. Also, we made sure that the structure of the building was not hindered by deformation or vibration.

https://doi.org/10.52202/069179-0302

5.4.1 The outline of allowable stress calculation

Calculate and confirm whether the design stress is less than the allowable stress.

Table 6: *Testal Result of Specimen from No.1 to No.3*

Specimen	1-1	1-2	1-3	1-4	1-5	2	3
F_{max}	6200	5350	6300	4250	6700	9250	8500
f_b	68.44	59.25	69.73	47.01	74.20	25.76	10.23
f_m			39.90			25.76	10.23

References
F_{max}: Max load(N) f_b: Bending Strength(N/mm^2)
f_m: Adopted Bending Strength(N/mm^2)

Table 7: *Long and short allowable stress degree of Specimen from No.1 to No.3*

Specimen	1	2	3
Long Allowable stress degree(N/mm^2)	14.63	9.45	3.75
Short Allowable stress degree(N/mm^2)	26.60	17.17	6.82

Table 6 shows the outline of the test results in Chapter 4. From this, the long-term and short-term allowable stress of each member is obtained. It is necessary to evaluate long-term allowable stress such as fixed load and snow load using long-term allowable stress, and rarely generated force such as seismic load and wind load using short-term allowable stress. The long-term allowable stress and the short-term allowable stress are calculated by multiplying the reference strength by 1.1 / 3 and 2/3, respectively. Table 7 is the value obtained by the above calculation. We evaluate safety by comparing these with the design stress degree of each member.
The following equation (1) is the equation to obtain the design stress degree of each member.

$$\sigma = \frac{M}{bh^2/6} \quad (1)$$

Here, σ = design stress degree (N / mm²), M = bending moment (N ・ mm), b = wood width (mm), h = wood fault (mm).

5.4.2 Allowable stress degree calculation for Single Timber

We calculate the allowable stress of a single timber. The parts shown in a and b in Figure 23 are composed of a single material, and the maximum bending moments in the vertical and horizontal directions show the same value of 10550 N ・ mm. Therefore, the calculation is as follows from Eq. (1).

$$\sigma = \frac{10550(N \cdot mm)}{38(mm) \times 38(mm) \times 38(mm)/6}$$

From this, the following results can be obtained.

$$\sigma = 1.153594\, N/mm2$$

Comparing this result with the long-term allowable stress of 14.63N / mm2 and the short-term allowable stress of 26.60N / mm2 for a single material in Table 7, the following results are obtained.

$$\sigma = 1.153594\, N/mm2 < 14.63\, N/mm2$$
$$\sigma = 1.153594\, N/mm2 < 26.60\, N/mm2$$

From this, it was confirmed that the values were smaller than the long-term and short-term allowable stress degrees. Here, the long-term allowable stress and the short-term allowable stress divided by the obtained allowable stress are defined as the safety factors in the vertical and horizontal directions, respectively. The calculation is as follows.

【Vertical direction】

$14.63\, N/mm^2 / 1.153594\, N/mm^2 = 8.196 \ldots \fallingdotseq 8.2$

【Horizonal direction】

$26.60\, N/mm^2 / 1.153594\, N/mm^2 = 23.05 \ldots \fallingdotseq 23.1$

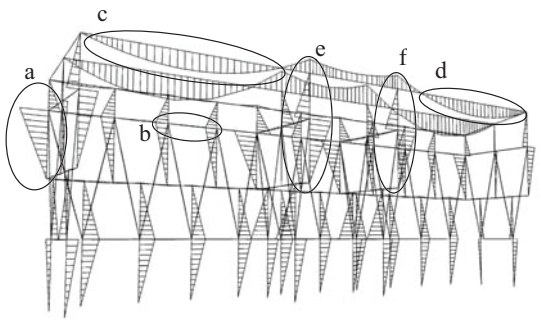

Figure 23: *Bending moment diagram of the shed when dead load and seismic load work*

From this, it can be said that the single timber can withstand up to about 8 times the vertical force and about 23 times the horizontal force.

5.4.3 Allowable stress degree calculation for Piled Beam

Similarly, we calculate the allowable stress of the Piled Beam. C and d in Figure 23 are composed of Piled Beams, which receive bending moments only in the vertical direction. Therefore, the calculation is as follows from Eq. (1).

$$\sigma = \frac{10550(N \cdot mm)}{38(mm) \times 76(mm) \times 76(mm)/6}$$

$$\sigma = 0.288398\, N/mm^2$$

Comparing this with the long-term allowable stress of 9.45 N / mm² for the lap beam in Table 7, the following results are obtained.

https://doi.org/10.52202/069179-0302

$$\sigma = 0.288398\,N/mm2 < 9.45\,N/mm2$$

From this, it was confirmed that the obtained allowable stress is smaller than the long-term allowable stress. If the safety factor is calculated in the same way as for a Single Timber, it will be as follows.

$$9.45\,N/mm2/0.288398N/mm2 = 32.76 \ldots \fallingdotseq 32.8$$

From this, it can be said that the Piled Beam can withstand up to about 33 times the force in the vertical direction.

5.4.4 Allowable stress degree calculation for Intermitted Column

Similarly, we calculate the allowable stress of the Intermitted Column. e and f in Figure 23 composed of Intermitted Column, which receives the bending moment only in the horizontal direction. Therefore, the calculation is as follows from Eq. (1).

$$\sigma = \frac{10550(N \cdot mm)}{38(mm) \times 38(mm) \times 38(mm)/6}$$

$$\sigma = 1.153594\,N/mm2$$

Comparing this with the short-term allowable stress of 6.82 N / mm² for the lap beam in Table 7, the following results are obtained.

$$\sigma = 1.153594\,N/mm2 < 6.82\,N/mm2$$

From this, it was confirmed that the obtained allowable stress is smaller than the short-term allowable stress. When the safety factor is calculated in the same way as for single materials and lap beams, it is as follows.

$$6.82N/mm2/1.153594N/mm2 = 5.91 \ldots \fallingdotseq 5.9$$

From this, it can be said that the Intermitted Column can withstand up to about 6 times the horizontal force.

From the all above calculations, it can be evaluated that the safety of this shed is maintained in small and medium-sized earthquakes and does not collapse in large earthquakes.

5.4.5 Impact on buildings due to deformation and vibration

We check if the building is hindered by vertical and horizontal deformation and vibration.

First, we evaluate the vertical weight and snow load. According to the "Deflection Limit" of the Building Standard Law in Japan, it is necessary to satisfy the condition of the following formula (2) when a fixed load and a live load are applied.

$$\frac{\delta}{\ell} \leq \frac{1}{250} \qquad (2)$$

Here, let δ = deflection amount (mm) and ℓ = member length (mm). From Figure 24, the amount of deflection in the vertical direction σ = 0.21 (mm) and the member length ℓ = 1700 (mm), so the ratio of the amount of deflection to the member length in this shed is as follows.

$$\frac{\delta}{\ell} = \frac{0.21}{1700}$$

Therefore, it can be compared with Eq. (2) as follows.

$$\frac{\delta}{\ell} = \frac{1}{3695.65} \fallingdotseq \frac{1}{3696} < \frac{1}{250}$$

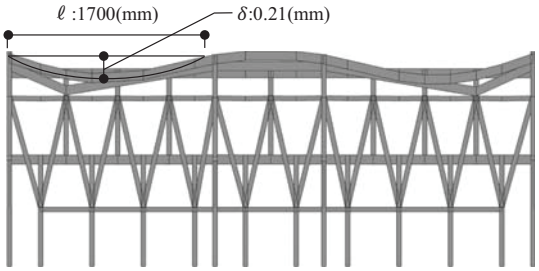

Figure 24: *Displacement diagram of the shed when vertical load works*

From the above, it can be evaluated that the building is not hindered by deformation and vibration caused by its own weight and snow load because it satisfies the deflection limit of the Building Standard Law.

Next, we evaluate the horizontal seismic load and wind load with reference to the guideline of deformation angle and damage rank in wooden buildings. There are four damage ranks: "Minor damage", "Small damage", "Medium damage", and "Great damage". When a horizontal load is applied to the shed, it is desirable that it be suppressed with minor damage, in which case the deformation angle must be less than 1/120, as in Eq. (3).

$$\frac{\delta}{\ell} \leq \frac{1}{120} \qquad (3)$$

Here, δ = deformation amount (mm) and ℓ = member length (mm). From Figure 25, the horizontal deformation amount σ = 15.08 (mm) and the member length ℓ = 1900 (mm), so the ratio of the deformation amount to the member length in this shed is as follows.

$$\frac{\delta}{\ell} = \frac{15.08}{1900}$$

Therefore, it can be compared with Eq. (3) as follows.

$$\frac{\delta}{\ell} = \frac{1}{125.99} \fallingdotseq \frac{1}{126} < \frac{1}{120}$$

https://doi.org/10.52202/069179-0302

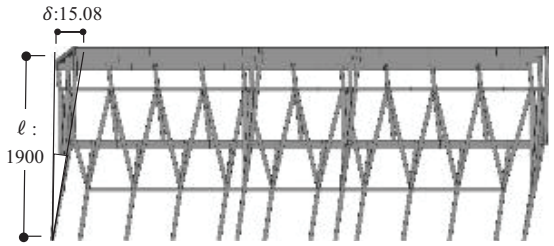

Figure 25: *Displacement diagram of the shed when horizontal load works*

From the above, it can be evaluated that the deformation and vibration caused by the seismic load and the wind load do not cause any trouble to the building because the deformation angle and the damage rank of the wooden building are satisfied.

Here, there was a difference between the comparison result with the deflection limit in the vertical direction and the comparison result with the deformation angle in the horizontal direction and the guideline of the damage rank. We give a reason for this.

Table 8: *Total amount of snowfall (as of May 11,2021)*

Municipalities	Site	Total amount of snowfall (cm)	The ratio this year: Common year(%)	Common value (cm)
Nagano City	Nagano	107	43	250
Karuizawa town, Kita-Saku District	**Karuizawa**	**35**	**30**	**117**

First, we paid attention to the snow load in the vertical direction. When snow accumulates on the upper surface of the shed, the snow load is a load that acts for a long period of time, so the vertical direction was set safely to prevent creep. In addition, as shown in lower column of Table 8, it is hard to say that Karuizawa Town, where the shed is located, is a heavy snowfall area when considering only the amount of snowfall. However, considering the frequency of natural disasters caused by abnormal weather in recent years and the damage situation, it was designed so that it can withstand sufficient strength even in the unlikely event of heavy snowfall.

Next, in the horizontal direction, we focus on earthquakes for evaluation. J-SHIS data show that the probability of earthquake occurrence within 30 and 50 years in the major active fault zone near Karuizawa Town is 0%, and that the ground amplification factor at the same site is low[9]. Therefore, it was judged that the probability of damage to the building due to the earthquake is not high.

The above are reasons for differences between the comparison result with the deflection limit in the vertical direction and the comparison result with the deformation angle in the horizontal direction and the guideline of the damage rank.

5.5 COLLATION OF SUGGESTIONS AND ANALYSIS

Using the axial force diagram obtained from the analysis, we confirm whether the structure of this shed proposed in Chapter 3 is realized. First, we proposed a "Bi-tree structure" in which a force like a continuous arch structure acts on the tree part when a vertical load is applied.

Figure 26 is an axial force diagram when a vertical load is applied to the shed. It can be seen that in the tree structure, the two thrusts generated by the decomposition of the compressive force work in opposite directions and cancel each other out.

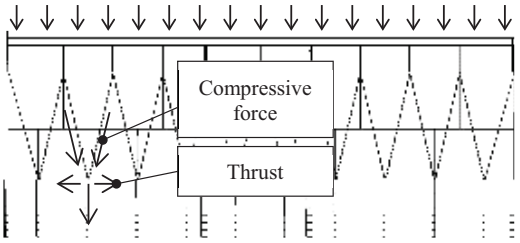

Figure 26: *Axial force diagram of the shed when vertical load works*

We also proposed a frame in which the dendritic part becomes a force flow like a brace structure when a horizontal load is applied.

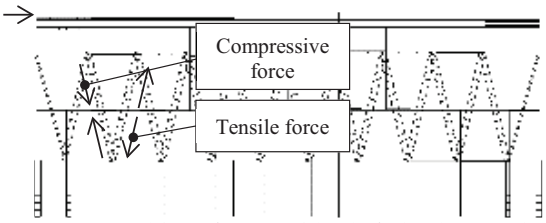

Figure 27: *Axial force diagram of the shed when horizontal load works*

Figure 27 is an axial force diagram when a horizontal load is applied to the shed. The tree part of the shed, which has a brace structure and is a diagonal lumber, bears the compressive and tensile forces, respectively.

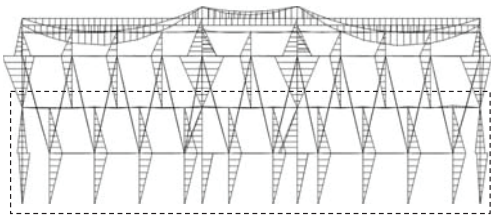

Figure 28: *Bending moment diagram of the shed when dead load and horizontal load work*

Furthermore, we proposed a frame with reference to the structure of an independent column with hanging walls, which is a traditional construction method. Figure 28 is a bending moment diagram of this shed. It can be seen that the bending moment diagram of the lower part (broken line part) of the shed that adopted the structure of the

https://doi.org/10.52202/069179-0302

independent column with hanging walls matches the bending moment diagram of the independent column with hanging walls.
Based on the collations with the above three analysis results, the structural system of this shed is as proposed in Chapter 3.

5.6 COMPARISON OF THE AMOUNT OF DEFORMATION BETWEEN ACTUAL MEASUREMENT AND ANALYSIS

We performed a manual tensile test to show the reproducibility of the analytical model and the validity of the proposal.

Table 9: *Tensile testing and deformation of analysis model*

Z, X, Y	Photo of tensile testing	Deformation (Analysis model No.2)
X-direction		
Y-direction		Z-direction		

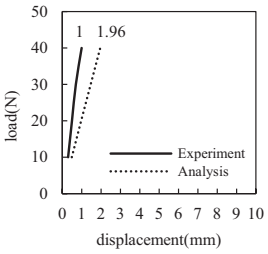

Figure 28: *Load-displacement graph of X-direction*

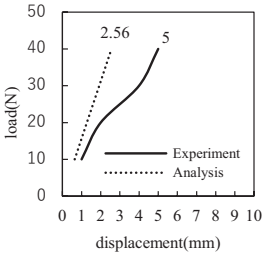

Figure 29: *Load-displacement graph of Y-direction*

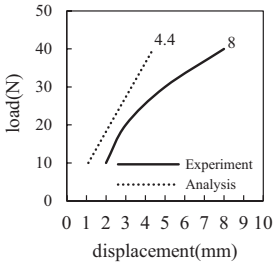

Figure 30: *Load-displacement graph of Z-direction*

As shown in Table 9, we defined three directions in the shed, and compared the amount of deformation when an arbitrary point was manually pulled in each direction with the amount of deformation when a load was applied in the analysis. The model used for the analysis is Model 2 with the exterior material. The displacement charts when a load is applied in each direction are shown in the rightmost column of Table 9, and the graphs comparing the amount of deformation in each direction are shown in Figures 28, 29, and 30.
The maximum value of the displacement error in each direction was 3.6 mm in the Z direction.
From this, it can be said that the analysis model can almost reproduce the real thing, and the proposal is valid.

6 CONCLUSIONS

In this research, we proposed a rational small-scale building structure system "Bio-tree structure" using small-diameter timber. This is a tree system that transmits the load in the shortest path when a vertical load is applied, and a structure in which the branch part becomes a tension / compression brace structure while causing bending resistance in the trunk part and allowing deformation to escape when a horizontal load is applied. In addition, we conducted a bending load test of red cedar, determined the allowable stress level indispensable for building design, calculated the allowable stress degree, evaluated the safety, and it became possible to design a small-scale building. Furthermore, we shown the validity of the proposal by performing numerical analysis and actual loading test on the proposed structural system. These are the results that suggest the possibility that small-diameter timber will be used for building structural systems in the future, and it can be expected to contribute to the development goals of SDGs "11. Creating a town where people can continue to live" and "15. Protecting the abundance of greenery", and the development of biomimetics in architecture.

ACKNOWLEDGEMENT

This work was supported by Toyo University Top Priority Research Program (2021.4～2024.3). Also, Ms. Yagi, Mr. Akimoto, Mr. Ozawa, Mr. Tobari of the Department of Architecture, Faculty of Science and Technology, Toyo University, and Mr. Hosokawa, Ms. Nakata, and Mr. Yoshinuma of the Takaiwa Laboratory of the same department were helped us. We would like to express my gratitude here. Thank you very much.

MODELLING OF TIMBER STRUCTURES

Zhiyong Chen[1], Dorian Tung[2], Erol Karacabeyli[3]

ABSTRACT: Computer modelling is an essential part in the analysis and design of residential and commercial buildings as well as long-span structures. It is also a valuable tool in the development and optimisation of wood-based products, connections, and systems. A survey shows that practicing engineers are typically unfamiliar with timber structure modelling, and researchers generally lack resources for advanced modelling of timber systems. A global collaboration, including research institutes, consulting firms, manufactures, software companies, and government and associations, was initiated by FPInnovations in 2020 to develop a guide for supporting the application of numerical modelling on analysis and design of timber structures, and development and optimisation of wood-based products and systems. The guide – Modelling Guide for Timber Structures – covers a wide range of practical and advanced modelling topics, including a comparison (in terms of modelling) among timber, steel, and concrete structures; key modelling principles, methods, and techniques that are specific to timber structures; modelling approaches and considerations for wood-based components, connections, and assemblies; and analysing approaches and considerations for timber structures during progressive collapse, wind, and earthquake events. This paper provides a high-level overview of this guide, with the goal of assisting practicing engineers in application of computer modelling to timber structures, enriching researchers' resources for advanced computer modelling of timber systems; and assisting software companies to identify the gaps and upgrade programs accordingly to accommodate advanced computer modelling of timber structures.

KEYWORDS: Timber structures, digital twins, performance-based design, modelling, analyses, optimisation

1 INTRODUCTION

Computer modelling is an essential part in the analysis and design of residential and commercial buildings as well as long-span structures. It is also a valuable tool in the development and optimisation of wood-based products, connections, and systems. A survey by FPInnovations [1] shows that practicing engineers are typically unfamiliar with timber structure modelling, and researchers generally lack resources for advanced modelling of timber systems. Furthermore, wood analysis and design modules currently implemented in a few structural analysis software packages are usually not suitable for complex or hybrid timber structures. This will hinder the application and development of timber construction given that timber structures increasingly require demonstration of performance or equivalency through computer modelling, regardless of whether prescriptive or performance-based design procedures are used.

A global collaboration (Figure 1), including research institutes, consulting firms, manufactures, software companies, and government and associations, was initiated by FPInnovations in 2020 to develop a guide for supporting the application of numerical modelling on analysis and design of timber structures, and development and optimisation of wood-based products and systems. The guide – Modelling Guide for Timber Structures [2] (web.fpinnovations.ca/modelling) – has been developed by selecting efficient modelling methodologies and analysis methods, and robust evaluation criteria for timber structures: seismic response, wind-induced response, and progressive collapse robustness; and developing basic principles for the application of computer modelling in timber building design, including modelling assumptions, validation of assumptions and modelling results, and demonstrating compliance with the building code. The guide consists of three parts: Part A – Introduction (in green), Part B – Modelling (in red), and Part C – Analyses (in blue), see Figure 2.

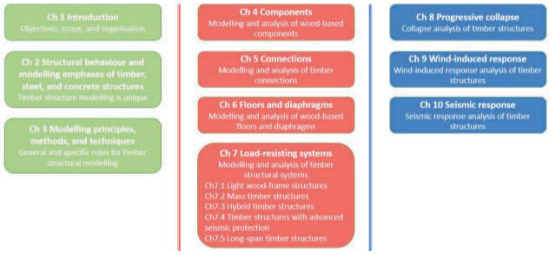

Figure 2: *Organisation of modelling guide*

This paper provides a high-level overview of this guide, including a comparison among timber, steel, and concrete structures, in terms of modelling emphases; key modelling principles, methods, and techniques specific for timber structures; modelling approaches and considerations for timber components, connections, floor diaphragms, and load resisting systems; and analysis approaches and considerations for timber structures during progressive collapse, wind, and earthquake events.

2 DIFFERENCE AMONG TIMBER, STEEL, AND CONCRETE STRUCTURES

Every structural material has unique mechanical characteristics. Consequently, different design strategies have been adopted for structural systems using different materials to optimise the material use. The structural behaviour and modelling emphases of structural systems with different materials vary accordingly.

Steel is a ductile material and is generally considered to be a homogeneous, isotropic, elastoplastic material with equal strength in tension and compression. Reinforced concrete (RC) is a composite material that is concrete into which steel reinforcement bars, plates, or fibres have been incorporated, where the two materials work together, with concrete providing the compressive strength, and steel providing the tensile strength primarily. While wood has characteristic anisotropy due to its fibrous structure, which can be considered as producing three-dimensional orthotropy. Its stiffness and strength properties vary as a function of grain orientation among the longitudinal, radial, and tangential directions. The failure modes and the stress-strain relationships of wood depend on the direction of the load relative to the grain and on the type of load (tension, compression, or shear). For wood in tension and shear, the stress-strain relationship is typically linear, and the failure is brittle, while for wood in compression, the stress-strain relationship is typically nonlinear, and the failure is ductile.

Due to their high strength-to-weight ratio, steel elements are, in general, relatively slender. The design should account for the buckling resistance of slender steel compression and bending elements. Care is needed to ensure that connections do not unduly influence the overall response of a steel structure, especially for seismic design. As a composite material, maintaining composite action requires the transfer of load between the concrete and steel that is achieved by means of bond (anchorage). Thus, detailing of reinforcement, particularly for seismic conditions, is a key design aspect for RC structures. Because of their anisotropic mechanical properties, timber elements possess much higher stiffness and strength in the parallel-to-grain direction than in the perpendicular directions. Due to the presence of growth characteristics (e.g., knots), which significantly impair the tension and shear strength of wood, timber elements are most suitable for use in resisting compression parallel to the grain, followed by bending. Tension strength parallel-to-grain is as good or better than compression strength parallel-to-grain; however, the tension connections are prone to brittle failure. Tension perpendicular to the grain should be avoided or minimised in timber elements whenever possible because the capacity of wood in this direction is limited, and any splits effectively remove this capacity altogether. The main area that requires attention in the design of timber structures is connections. Timber connections typically govern the strength of timber structures, either light wood-frame structures or mass timber structures and can contribute significantly to the stiffness of the structures.

To model steel elements and connections, material models must simulate the homogeneous, isotropic, and elastoplastic behaviour of steel. For simple or equivalent models, RC elements can be simulated using elastic material models with effective stiffness, while an inelastic mechanism can be simulated using plastic hinges. With respect to complex or detailed models, typically, the constitutive response of the concrete and reinforcement comprising the RC are modelled separately. Timber elements generally can be simulated using orthotropic elastic material models. In some cases, such as balloon-type mass timber walls, elastoplastic behaviour of timber elements must be included in the material models at the wall bottom that connects to the foundation. Compared to other connections, timber connections are much more complex due to the highly variable anisotropic mechanical properties of wood, existing growth characteristics such as splits and knots, and other effects, such as moisture content and temperature. Various types of failure modes can occur in timber connections, and they should have ductile failure modes, such as yielding, rather than brittle modes, such as splitting. When properly designed, timber connections can be simulated using models that represent the connection stiffness and strength. For analysing timber systems under cyclic loading, suitable hysteretic models are required to accurately reflect the structural response of timber connections and assemblies, as these may possess highly pinched hysteresis and degradation of strength and stiffness.

General comparisons, in terms of material and structural behaviour, and modelling emphases, among timber, steel, and RC are presented in Chapter 2 of the modelling guide. Selected timber structural systems with analogous ones from steel and concrete are also compared.

3 MODELLING PRINCIPLES, METHODS, AND TECHNIQUES

3.1 PRINCIPLES

To obtain the best possible analysis results, it is important that engineers follow a formal modelling process that is based on sound engineering and finite element (FE) analysis principles. A typical modelling process includes the following key elements: (a) understanding the structure and planning the modelling process; (b) selecting the software; (c) developing the analysis model; (d) verifying the results; (e) performing a sensitivity analysis; and (f) deciding on the accepted model and results. General and specific principles, in terms of the modelling process, model development, model validation, result verification, model interpretation, and competence are introduced in Chapter 3 of the modelling guide.

3.2 METHODS

Various numerical modelling methods are available for simulating the behaviour of structures under different loading conditions. Mechanics-based modelling, FE modelling, hybrid simulation, and material-based modelling are introduced in the modelling guide. Only the former two are briefly summarised in this paper.

3.2.1 Mechanics-based Modelling

Mechanics-based modelling, also called analytical modelling, is used to calculate the forces and deformation in a structure induced by various actions through applying engineering principles and fundamental mechanics. It usually involves establishing and solving equilibrium, compatibility, and constitutive equations. Hand calculation or any engineering calculation program can be adopted depending on the complexity of the equations. Mechanics-based models provide simple methods that help understand and predict the performance of structures. Such models are suitable for conceptual designs and for verifying the results obtained from complex FE models. Once such models are developed, the analysis of corresponding structures with various key parameters (e.g., sensitivity analysis) is straightforward. These types of models are more suitable for analysing relatively simple problems (e.g., static performance) of uncomplicated structures (e.g., elastic material behaviour and/or boundary conditions). With respect to structures for which mechanics-based models do not exist or their development outweighs the benefit, FE modelling is a more efficient approach.

3.2.2 FE Modelling

In this modelling approach, the major structural components and connections are developed using any FE-type software. The software develops and solves equilibrium equations, compatibility equations, and constitutive equations. Problems ranging from simple to complex (e.g., time-history analysis) and models with different levels of complexity (e.g., nonlinear material behaviour and boundary conditions) can be analysed by FE modelling, which is usually limited by software capacity (e.g., material models).

In terms of model scale, two types of models are available: microscale and macroscale. Microscale models form a broad class of computational models that simulate fine-scale details. In contrast, macroscale models amalgamate the details into selected coarse-scale categories. The goals and complexities of the models determine which modelling scale is used for a specific work. In the area of structural engineering, microscale models are commonly used in analyses of structural components and connections, with testing results of materials as model input. These models focus on how the behaviour of the modelled object is influenced by its geometric and material properties. In contrast, macroscale models are widely used in the analyses of structural assemblies and entire buildings. For structures where the storey shear deformation is the major component induced by lateral loads, such as low-rise light wood-frame buildings, mass-spring-damper (Macroscale) models can be used to simulate the entire building or the main lateral load-resisting assemblies at each storey. When bending deformation cannot be ignored under lateral loads (e.g., balloon-type mass timber shear wall structures), mass-spring-damper models are no longer suitable, and the lateral load-resisting assemblies must be modelled in a relatively more detailed approach. The connections in these assemblies, however, can be simulated using suitable nonlinear hysteretic springs.

In the FE modelling approach, the major structural components and connections should be developed using any type of software. Because of the anisotropic material characteristics of wood, orthotropic material properties are required for the 2D or 3D model input for wood-based products. When the capacity design is used, the timber structural components that are capacity-protected can be modelled as orthotropic elastic members.

Connections play a critical role in any timber structural model in terms of stiffness, ductility, and energy dissipation of the entire system. Connections that experience semirigid behaviour can be modelled using spring or connection elements. In cases of conducting nonlinear analyses (pushover or nonlinear dynamic analysis), suitable backbone curve models that can represent the yielding and post-yield behaviour of the connections, as well as hysteretic models that can represent the energy dissipation and the pinching effect of timber connections, must be used. As timber connections have high variability in stiffness and strength, the ranges of these parameters must be established during modelling, and the lower and upper bounds of the connection mechanical properties should be considered. Specific key connections should be considered as semirigid joints when calculating the deformation or stiffness and the natural period of vibration of the building. Upper bound limits should also be used when analysing the natural period of vibration of the buildings because simplified numerical models can easily produce unrealistically high and therefore nonconservative natural vibration periods.

https://doi.org/10.52202/069179-0303

Floor and roof diaphragms as horizontal assemblies distribute the gravity and lateral loads to load-resisting assemblies underneath. Diaphragm flexibility is a key factor affecting the lateral load distribution to the walls and other elements below. It is suggested that diaphragms be modelled in the structural models according to their stiffness and deformability characteristics. Nonstructural components, such as gypsum wallboard, provide considerable additional stiffness to lateral load-resisting systems. Engineers must exercise judgment about whether the contribution of nonstructural components should be considered in the model.

3.3 TECHNIQUES

Due to the highly variable anisotropic mechanical properties of wood, this variability has to be accounted for in the design and analysis of timber structures. The stochastic FE method (SFEM) accounts for the uncertainty of a structure that occurs as a result of variations in geometry, materials, or loading condition, thus being one of the best modelling approaches to quantify or predict the influence and sources of randomness in timber structures. Monte Carlo simulation, perturbation method, and the spectral SFEM are the most commonly used and accepted SFEM. Each method adopts a different approach to represent, solve, and study the randomness of a structure. Computational structural design, including parametric analysis, structural optimisation, and form-finding, can influence or enable the exploration of design space. Its application will dramatically improve the efficiency of identifying the best solutions for the structural design of geometrically complex or free-form timber structures.

BIM is a technology-driven integrated digital process that uses intelligent geometric and data models to provide coordinated, reliable information about a project throughout its entire life cycle. With the BIM revolution, the focus has been on the M—modelling: creating accurate and highly detailed models and drawings which represent the design, effectively creating digital twins (Figure 3). However, the building industry does not merely need increasingly more detailed 3D models; it needs a design for manufacture and assembly (DfMA) process to increase design and on-site efficiency while systematically reducing construction change orders.

Figure 3: *Digital twin model of UBC Brock Common*

4 MODELLING OF WOOD-BASED COMPONENTS

4.1 CONSTITUTIVE MODELS AND KEY INFLUENCING FACTORS

Wood is an anisotropic material. Because of its inherent characteristics, the mechanical behaviour of wood depends on the direction of the grain and the load type, as illustrated in Figure 4. Appropriate material models are the fundamental basis of reliable simulations.

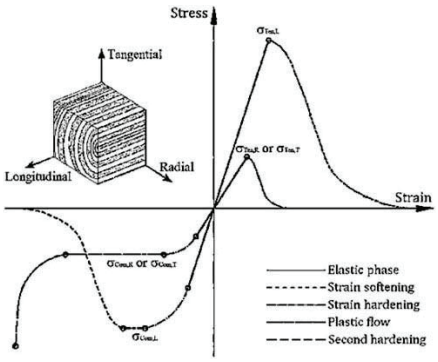

Figure 4: *Typical stress-strain behaviour of wood*

The constitutive models incorporated in existing general design software packages are often limited, making the software unsuitable for accurately predicting the mechanical behaviour and failure modes of wood-based materials. Some researchers have developed specific constitutive models for wood-based members, e.g., Wood^{S} and WoodST. Typically, a material model is composed of sub-models for describing the elastic properties, strength criterion, post-peak softening for quasi-brittle failure modes, plastic flow, and hardening rule for yielding failure modes, and densification perpendicular to grain. Depending on the modelling complexities, scenarios, and demands, however, different constitutive models with various combinations of the sub-models can be adopted.

As tall or large timber structures are becoming a viable option in the construction industry, the structural elements and connections are becoming more complex, and the corresponding design is beyond the compatibility of general design software packages. Designers can still carry out the design using any tools by making more assumptions. The design as well as the assumptions must be verified by testing, numerical simulation, or both. In such a scenario, general purpose FE software with a comprehensive constitutive model of wood-based material is the first choice for the simulation. A comprehensive constitutive model can predict potential failure modes, including those that may be overlooked in design, providing more reliable analysis results to support the design. With the appropriate constitutive model, the strength, stability, and deflection problems of wood-based members can be investigated and evaluated. The outputs still need to be interpreted carefully using engineering judgment.

https://doi.org/10.52202/069179-0303

The mechanical properties of wood change as temperature, moisture, and loading time change. Moreover, growth characteristics such as slope of grain and knots significantly affect the mechanical behaviour of wood-based products. These key influencing factors are discussed in Chapter 4.1 of the guide along with corresponding modelling recommendations.

4.2 STRUCTURAL COMPONENT ANALYSIS

Analyses of timber components under various loads are essential for structural design and product optimisation. Numerous studies have been conducted on traditional wood-based products such as lumber. However, there is limited information on newer wood products such as cross-laminated timber (CLT), nail-laminated timber (NLT), dowel-laminated timber (DLT), and other types of composite components.

Of the two approaches used in the analysis and design of timber components, analytical models are very efficient for the specific cases for which the models have been developed. FE methods are capable of handling complex cases and can provide results that are more comprehensive than those provided by analytical methods. Eigenvalue buckling, linear load-displacement, and nonlinear load-displacement analyses are usually adopted to analyse timber components in FE modelling. Linear analysis is the most common method to determine the deformation, reaction, and stresses when an element is in its elastic stage. With engineering adjustment, the lower bound of resistance and the corresponding failure mode of the components can be predicted manually based on the results of linear elastic analysis, for example, stress distribution and the highest stress, for simple cases. Eigenvalue buckling analysis is commonly used to derive buckling resistances and mode shapes for beams and columns. This analysis is best suited for walls, slender beams, and columns where the members are likely to buckle in the elastic range. Nonlinear analysis is capable of predicting the resistance, failure modes, and post-failure behaviour of analysed components, with or without imperfection (e.g., post-buckling analysis). This analysis requires more refined models, or comprehensive material models and specific input. Key considerations, such as imperfection for the post buckling analysis of columns (Figure 5) and beams, for modelling wood-based components under various loading conditions can be found in Chapter 4.2 of the modelling guide.

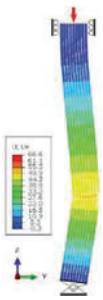

Figure 5: *Deformation (deformation scale factor = 3) of a glulam column under a vertical point load*

4.3 MODELLING PROCESSES AND PROPERTIES OF STRUCTURAL WOOD PRODUCTS

The development of new wood-based products, plus the optimisation of existing products, plays a key role in the expansion of timber construction, especially for taller and larger structures. Manufacture of wood-based products, however, is complex, involving a variety of influencing factors—the properties of the constituents, the structure, and the many parameters of the manufacturing process. Traditional product development and optimisation usually uses trial-and-error laboratory experiments and mill trials, or empirical approaches. While they can offer direct and short-term solutions, experimental studies are generally time consuming and expensive to run; more importantly, they have limitations in providing fundamental understanding. Modelling offers an efficient and cost-effective approach to advancing wood science and industrial composites manufacture. It applies mathematics, physics, and mechanics principles and computer numerical simulation techniques to the field of wood composites. Modelling also helps understand the complex manufacturing process and optimises the product performance by reducing the number and scope of experimental variables.

The production and quality control process are straightforward compared with hot-pressed veneer and strand composites, very few process models are available for lumber-based productions. Many structural models, including empirical models, probabilistic models, and FE models, have been developed for glulam and CLT, to investigate the influence of lumber grades, layup arrangement of graded lumber, species, density, and defects. Several phases of veneer and veneer-based products require careful attention to material and process control as these feed into and affect subsequent steps as well as final product quality and performance. Such processes include log conditioning/heating, peeling, defect and moisture detection, veneer-ribbon clipping, veneer drying, glue application, panel layup, prepressing, and hot-pressing. A series of computer simulation and optimisation models for almost all stages of the process of veneer and veneer-based product manufacture have been developed. FE models are usually used for the mechanical modelling of veneer-based product. Integrative models can be developed on three essential parameter sets for the entire manufacturing process of strand-base products. The first parameter set defines the constituents from which wood composites are made: mainly wood, resin, and wax. The second parameter set defines the structure (the spatial organisation) of the constituents: density, strand orientation, porosity, and contact. The final parameter set concerns major processing steps: strand preparation, drying, blending, forming, and pressing. Various physical models have been developed to simulate strand cutting (from bamboo culms); particulate or strand drying; resin; mat forming and consolidation; and hot-pressing. FE modelling, multiscale modelling, and integrated modelling are used to predict the mechanical properties of strand-based products. Figure 6 illustrates an integrated

https://doi.org/10.52202/069179-0303

model for LSL. More detail information can be found in Chapter 4.3 of the modelling guide.

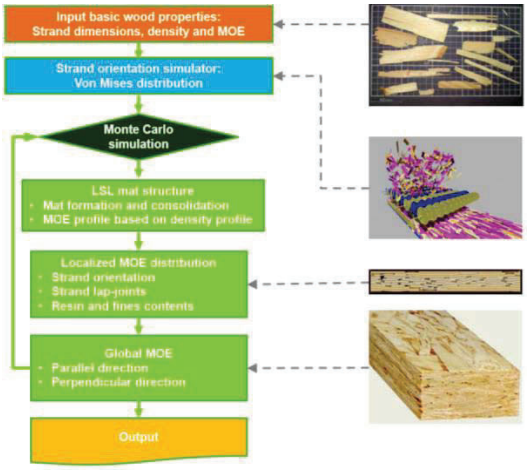

Figure 6: *Schedule diagram of an integrated model for predicting the MOE of LSL*

5 MODELLING OF WOOD-BASED CONNECTIONS

Connections play a crucial role in the integrity and load-resisting mechanism of structures. Well-designed timber connections with mechanical fasteners are usually characterised by highly nonlinear behaviour, strength and stiffness degradation, and pinching effect on their hysteresis loops. All these aspects may pose significant challenges for modelling of timber connections (Figure 7) and how they interact with other elements in the structure.

When modelling timber connections in structures, depending on the purpose of the model, it may be necessary to model the response of the connections, providing upper and lower bounds, particularly for the yielding resistance. These are often built-in to typical backbone curve forms provided in analysis software. When considering modelling stability, it is often useful to implement a post-failure tail to ensure model stability. Where a nonlinear time-history analysis is required, it is also important to properly implement the correct hysteresis form. The main features shown in typical hysteresis loops of timber connections include (a) nonlinear connection behaviour, (b) slightly asymmetric loops, (c) indistinct yield point, (d) stiffness degradation with increasing load cycles, (e) relatively fat initial hysteresis loops that imply large amounts of energy dissipation, (f) narrowed loop areas (pinching effect) in the middle of the hysteretic loops after the first load cycle, (g) strength degradation at the same deformation level for repeating loading cycles, (h) strength degradation for larger deformations, and (i) relatively high values of ductility. Therefore, a hysteretic model capable of predicting stiffness and strength degradation, along with the pinching effect, is desirable for timber connections. During the past several decades, various types of hysteretic models have been developed for dynamic analysis of timber connections and structures. Generally, they can be categorised as three major types: mechanics-based models, piecewise linear functions models, and mathematical models. Chapter 7.1 of the modelling guide discusses the backbone curve and hysteretic models in detail.

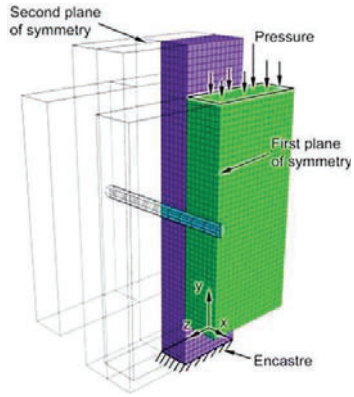

Figure 7: *FE model for bolted connection [3]*

The steel dowel type and glued-in-rod type connections, which involve timber and steel materials, are more complex than the other types of connections composed primarily of steel. Efficient models, e.g., European yield model, have been developed for predicting mechanical properties of ductile failure modes of dowel type connections. However, the brittle failure modes typically can be precited by FE modelling. In such cases, the timber, steel, and contact between them, e.g., gap or glue, must be simulated using proper elements and constitutive models. Figure 8 illustrates modelling examples for dowel type connections.

More information, e.g., the structural behaviour, failure mechanism, design considerations, modelling methods, and key considerations of timber connections can be found in Chapter 5 of the modelling guide.

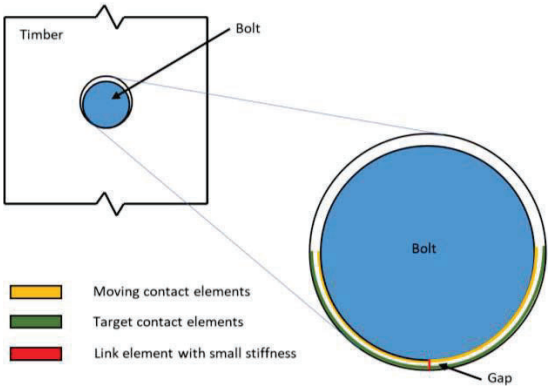

Figure 8: *Example where contact elements are used between fastener and timber*

6 MODELLING OF WOOD-BASED FLOOR DIAPHRAGMS

6.1 FLOOR AND ROOFS

Timber-based roofs and floors, whether light wood-frame, mass timber, or timber-concrete composite (TCC) systems, are complex structures to analyse despite their relatively simple construction. This is because they are constructed with multiple components and multiple materials that are often connected by mechanical fasteners, leading to semi-rigid connections between components, which is called composite action.

In analysing the structural performance of floor systems, composite beam and ribbed-plate models are available. The ribbed-plate models are typically only used for light wood frame floors to account for its two-way action. There are two main categories of beam models in composite systems: continuous bond models and discrete bond models. The continuous bond models, where the connections are modelled as evenly distributed, include the Gamma method and the Shear Analogy method, among others. The discrete bond models, where the connections are modelled as individual members, include beam models with rigid-perfectly plastic connections or elastic-perfectly plastic connections (also called progressive yielding model, release-and-restore method). Continuous bond models are more suited for composite systems with continuous connections or uniformly distributed connections that are closely spaced, while the discrete bond models are more suited for discontinuous connections. Because of their complexity and efficiency, discrete bond models are usually applied to composite systems with nonuniformly and widely spaced distributed connections, for example, TCC floors.

While most floors and roofs can be designed using the analytical approaches, advanced modelling methods such as FE models can be used for cases beyond the scope of the analytical methods and the system development and optimisation. Framework/truss model (Figure 9) and space-exact element model are two typical FE models for floor systems. More details regarding the analytical and FE models, general rules, and specific consideration for developing FE models for different types of floors are provided in Chapter 6.1 of the modelling guide.

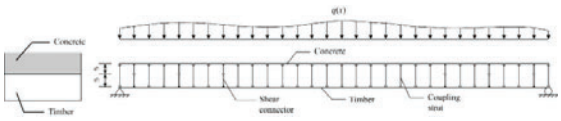

Figure 9: *Framework model*

6.2 DIAPHRAMGS

Diaphragms not only transfer any horizontal load to the vertical lateral load-resisting system (LLRS) but also tie all structural and nonstructural elements together, providing integrity to a building. Several different analysis methods and approaches that can serve to analyse diaphragms include deep beam/girder analogy, shear field analogy, truss analogy, and FE methods. Beam analogy methods provide satisfactory results, as long as the floor is rectangular and does not contain substantial irregularities, such as floor openings, re-entrant corners, and concentrated forces. These influence the load path, leading to stress concentrations, and therefore require more specific designs. The shear field analogy provides a reasonably easy method to analyse wood frame diaphragms with irregularities like openings or re-entrant corners. As the number of irregularities increases, however, this method, based on hand calculations, soon becomes too complex. The assumptions of the shear field analogy are very often violated in real structures. Loads not applied via the framing elements in their axial direction, as well as displacement incompatibilities, cause inconsistencies in the method. The truss analogy can be seen as a compromise between a simple approach like the girder analogy and a sophisticated FE analysis. It allows for irregular geometries and provides a clear force path through all involved members. Complex geometries might need a refined mesh, resulting in a number of different diagonals. Because the forces are introduced as concentrated loads in the nodes, some calculated results (like the axial force in framing members) require post-processing to account for the real force distribution along the member length.

FE analysis of diaphragms provides the most realistic load path and information on the general performance of the diaphragms, but it also requires a high degree of knowledge about the specific software package and a larger number of input parameters. A designer must determine the level of analysis required for the specific diaphragm. For timber diaphragms, this can range from elastic models with homogenous material parameters that have reduced shear stiffness to account for fastener stiffness to orthotropic panels connected with discrete nonlinear links to model the individual fasteners (Figure 10b). Designers need to decide which approach best suits the given problem and what level of accuracy is required. More details on the modelling and design of wood-based diaphragms are presented in Chapter 6.2 of the modelling guide, along with connection options linking diaphragms to lateral load-resisting systems.

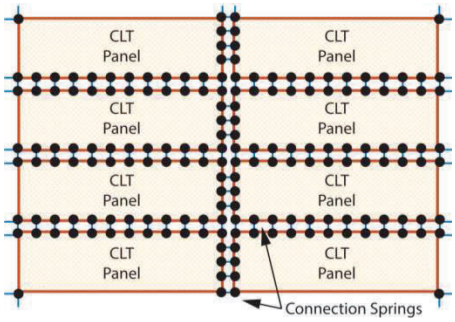

Figure 10: *Discrete panel model with spaced connections [4]*

7 MODELLING OF LOAD-RESISTING SYSTEMS

7.1 LIGHT WOOD-FRAME STRUCTURES

Light wood-frame buildings are constructed using dimensional lumber framing and wood-based sheathing connected to each other with metal fasteners. This type of system has been dominated in timber engineering for a long while and been investigated intensively. Elastic model, plastic models with upper bound method (Kinematic theorem) and lower bound method (static theorem) are the three main analytical models for light wood-frame buildings, the last one has been adopted by many countries' standards to design this system. Regarding advanced FE modelling methods, this system can be simulated using either very detailed models that includes lumber, panels, and nails, or macro-element models where each wall or diaphragm assembly is simulated using an equivalent spring. For both types of models, backbone curve and hysteretic model play a crucial rule in the performance of this system. Generally, mechanics-based models, empirical models, and mathematical models are the three main types of hysteretic models for timber structures. For practical analyses, the shear walls can also be simulated using stick and rotational spring model or equivalent beam model. More information regarding the structural behaviour and modelling considerations can be found in Chapter 7.1 of the modelling guide.

7.2 MASS TIMBER STRUCTURES

Mass timber structures are a viable solution for taller and larger construction. The existing pure mass timber lateral load-resisting systems include platform-type shear walls, balloon-type shear walls, braced frames, and moment frames.

CLT shear walls are the latest lateral load-resisting system of timber structures accepted by codes and standards around the world, while RC shear walls are a system made of other materials that is most similar to CLT shear walls. Unlike RC shear walls, CLT panels are typically capacity-designed, and the connections govern the capacity of the CLT shear walls. CLT panels can be modelled as orthotropic plates, and the connections must be simulated using specific models to represent their stiffness, strength, plastic deformation, and even the hysteretic behaviour, see Figure 11. Braced frames are essentially planar vertically cantilevered trusses. Unlike braced steel frames, braced timber frames yield and dissipate energy primarily through energy-dissipative connections. The diagonal brace assembly or the two end connections must be modelled with equivalent spring elements that can represent their stiffness, strength, plastic deformation, and hysteretic behaviour, while other timber elements can be modelled as elastic truss or beam elements. Moment-resisting frames are rectilinear assemblages of beams and columns, with the beams rigidly connected to the columns. Unlike in moment-resisting frames using steel or concrete, the inelasticity of timber moment-resisting frames is typically concentrated in the beam-to-column connection area due to the nonlinear response of the connections. The beams and columns can be simulated using elastic beam elements, while the connections are modelled using linear or nonlinear spring elements. More information regarding the analytical models and FE modelling considerations for each type of mass timber systems can be found in Chapter 7.2 of the modelling guide.

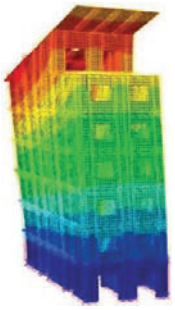

Figure 11: *FE model of a 7-storey CLT building [5]*

7.3 HYBRID TIMBER STRUCTURES

One solution with significant potential for the increased use of wood beyond previous limitations, e.g., building height, involves 'hybrid structures' that integrate wood with different materials. Hybridisation is the process of combining two or more materials to form a system that makes use of the strength of each material and simultaneously overcomes their individual weaknesses.

The gravity load resisting system (GLRS) and LLRS of a hybrid timber structure are typically analysed separately. A main reason for this is to simplify the design by limiting the model contribution of the GLRS to the LLRS, and vice-versa. To conduct a seismic analysis of hybrid timber structures using FE models, it is possible to consider i) the LLRS only; ii) LLRS with connecting GLRS only using appropriate boundary conditions; and iii) both the LLRS and GLRS. For the first approach, one should apply the seismic forces calculated by the ESFP, distributed to the individual LLRS components based on diaphragm flexibility, as a lateral point load at each level. For buildings with core or irregularly shaped LLRSs, the second approach is generally better for determining complex lateral force distribution. The third approach for seismic analysis considers the full building with a complete LLRS, with or without a GLRS, respectively. Special considerations for the design, modelling, and analysis of such structures are provided in Chapter 7.3 of the modelling guide in detail.

7.4 TIMBER STRUCTURES WITH ADVANCED SEISMIC PROTECTION

Timber structures traditionally provided satisfactory seismic performance due to such features as a light weight, high strength-to-weight ratio, structural redundancy, elastic deformation capacity, and the ductility of connections. Nowadays, however, they aim for greater heights and longer spans, resulting in

https://doi.org/10.52202/069179-0303

challenging seismic designs. Rather than increasing the seismic resistance of a structure, more recent work applies advanced seismic protection technologies to reduce the seismic demand from other structures on those made of timber. Such seismic protection technologies can be grouped into supplemental damping, rocking systems, and seismic isolation.

Modelling Press-Lam systems (Post-tensioned shear walls and moment frames) can involve two main categories of model. The first are spring type models, including the rotational spring models and multi-spring models, with either the rocking connections or the gap opening mechanics simulated using spring elements. The second are material- or component-based models, with geometric and material properties as input. The modelling methods for mass timber structures discussed in Section 7.2 are applicable to timber structures with resilient slip friction joints (RSFJs), but RSFJs are different from common timber connections. The models should properly simulate the RSFJ's flag-shaped hysteresis loops. It is advisable to connect the seismic fuse to another link that accounts for the actual stiffness of the connection between the damper and the remaining timber structural element. The modelling of the seismic isolation plays a key role in the analysis of timber structures with seismic isolation. Typical numerical models include plasticity model for coupled shear behaviour, Bouc-Wen model for coupled shear behaviour, advanced model for elastomeric and lead-rubber bearings, extension of bidirectionally coupled models to friction pendulum behaviour, model for tension-capable double pendulum bearing, and model for triple pendulum bearing. More information regarding mechanics-based modelling and advanced modelling methods is provided in Chapter 7.4 of the modelling guide, along with corresponding recommendations.

7.5 LONG-SPAN TIMBER STRUCTURES

Long-span timber structures are usually adopted by stadiums and bridges. Typical structural forms include trusses, portal frames, arches, suspended structures, and domes. Such long-span structures, like roof applications, are typically designed based on static (strength and stability) analyses, however, dynamics often govern the design of some types of long-span structures, e.g., pedestrian bridges and floors. Free-form systems are also an aesthetically attractive and structurally viable options for long-span timber structures. Dynamic relaxation, among others, is an efficient method in form-finding of free-form structures. The modelling approaches discussed in the above sections, i.e., Sections 7.1 to 7.4, can apply to long-span structures, however, some specific modelling methods or tricks have been developed specifically for long-span timber structures, e.g., how to consider the connections at the end of web members in a truss analysis, how to consider the risk of both in-plane and out-of-plane buckling in an arch analysis, whether the first-, second-, or third-order analysis is more suitable for timber-based suspend structures, and the importance of consideration of geometric imperfections in the analysis of domes. The analysis and modelling of the typical structural types of long-span timber structures are described in detail in Chapter 7.5 of the modelling guide, with corresponding recommendations.

8 PROGRESSIVE COLLASPE

Progressive collapse is a phenomenon initiated by local damage to a structure that propagates throughout the structural system in a chain reaction, leading to the partial or entire collapse of the structure, see Figure 12. Typical design and analysis approaches of progressive collapse include tie forces, redundancy, alternative load paths (ALPs) for static analysis and dynamic analysis, compartmentalisation, and the key element method. In the modelling of both platform-type shear wall systems and post-and-beam systems, the model of connections plays a crucial role and needs load-deformation curves as input. The difference between the platform-type buildings and post-and-beam buildings is in the modelling of the beam-to-column connections where it is needed to quantify their residual shear capacity after they undergo large deformation. Model development and analysis of shear wall systems and post-and-beam systems are described in detail in Chapter 8 of the modelling guide. Key modelling considerations for the progressive collapse analysis of hybrid systems, long-span structures, and prefabricated module structures are also provided.

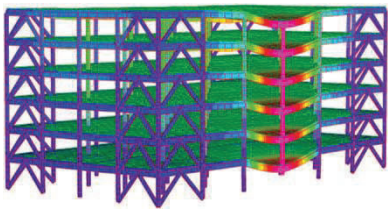

Figure 12: *Progressive collapse analysis of a timber structure*

9 WIND-INDUCED RESPONSE ANALYSIS

Within wind engineering literature and practice, it is generally recognised that wind forces govern the structural design of lightweight and flexible buildings for both safety and serviceability limit states. In general, the action of wind (Figure 13) on tall timber buildings depends on wind hazard, nearby buildings, terrain conditions, building shape, and dynamic structural properties, which is described in the wind loading chain.

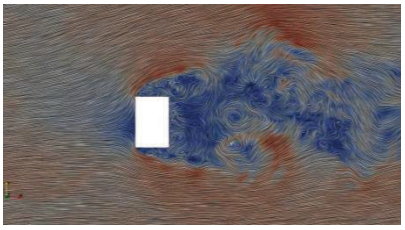

Figure 13: *Wind field around a building*

Wind tunnel techniques are typically used to assess the design wind loads and dynamic wind response of

buildings, while computational fluid dynamics (CFD) simulation is adopted for preliminary design and aerodynamic optimisation applications. As with wind tunnel studies, when modelling wind effects using CFD, care must be taken at each step of the wind loading chain. The structural wind-induced response analysis methods mainly include frequency domain analysis method and time domain analysis method. Among them, the frequency domain method uses Fourier transform to transform the wind load into a series of simple harmonic loads, and finally superimposes the response of the structure under each simple harmonic load to obtain the total response of the structure. The disadvantage of this method is that the non-linearity of the structure cannot be considered, and the calculation results are not accurate enough. The time-domain analysis method is to directly use the wind pressure time history of the wind tunnel test or the wind pressure history of the numerical simulation to be used in the calculation model. The response of the structure can be obtained by directly solving the motion equation in the time domain, and the nonlinear response of the structure can be considered. In addition to the above analyses and modelling with key considerations, a framework for the wind design of timber buildings and performance-based wind engineering approaches are also introduced in Chapter 9 of the modelling guide.

10 SEISMIC RESPONSE ANALYSIS

Seismic response analysis is a crucial evaluation of timber structures in earthquake-prone areas. There are two main types of static analysis: linear and nonlinear. Nonlinear static analysis is used where a structural system is expected to experience changes in its strength and stiffness properties with varying loads over time. There are different approaches for performing nonlinear static pushover analyses and calculating the target displacement. The two most prevalent in North America are the so-called coefficient method and the capacity spectrum method, while in Europe the N2 method is widely used. Response spectrum analysis is a linear dynamic analysis method which determines the contribution from each natural mode of vibration (Figure 14) on structural performance. It provides insight into dynamic behaviour by measuring pseudospectral acceleration, velocity, or displacement as a function of structural period for a given level of damping, thus being accepted as a standard analysis method in many standards. The time-history analysis provides an evaluation of the time evolution of the building response. Generally, two types of time-history analyses can be performed: linear and nonlinear. Both approaches require a numerical model with its characteristics tuned well to represent the lateral resistance mechanism of a real structure, and properly selected and scaled ground motions. Detailed information related to different types and methods of static and dynamic analyses used to quantify the seismic response of timber structures is provided in Chapter 10 of the modelling guide, along with their advantages and drawbacks. It also highlights the specific modelling requirements and considerations for different types of seismic response analyses, along with their suitability for timber structures.

PREDICTIVE CAPABILITIES OF FINITE ELEMENT MODELLING FOR TIMBER MEMBERS SUBJECTED TO BLAST LOADS

Damian Oliveira[1], Christian Viau[2], Ghasan Doudak[3]

ABSTRACT: High-fidelity modelling used to predict the dynamic behaviour in terms of displacement-time history and failure mechanism of heavy timber elements are presented and validated. A material predictive model was implemented in ABAQUS through a dynamic user subroutine using continuum damage mechanics. Full-scale experimental test results were analysed and used to validate the modelling predictions. Compared with the experimental test results, the finite element models simulated the displacement-time histories and overall failure behaviour reasonably well. The accurate prediction of failure modes and overall responses of timber elements, including those with complex properties such as cross-laminated timber, is important to ensure safer designs, and lead to a better overall understanding of the material behaviour when subjected to very short duration loading.

KEYWORDS: Blast, Glulam, CLT, Dynamic, Finite element, Modelling, Failure, Criteria, Resistance, Damage

1 INTRODUCTION

Investigations into wood behaviour under extreme loadings have historically focussed on small-scale clear wood specimens subjected to impact loading. Recent effort in this field has dealt with full-scale structural elements, such as stud walls, glued-laminated (glulam) members, and cross-laminated timber (CLT) panels under simulated blast loading. The validity of using single-degree-of-freedom (SDOF) analysis to predict and investigate the behaviour of full-scale heavy-timber structural elements subjected to blast loading has been extensively investigated [1-3], while the use and application of FEA has been very limited, in part due the need for material properties that are difficult to isolate and establish experimentally [4].

The continuum damage approach, whereby stress-based criteria are used to initiate the damage process, allows for the detection of both brittle and ductile failure modes, whereas simplified modelling methods, such as SDOF analysis, are typically limited to a single failure mode. The applicability of the SDOF modelling approach has been investigated for wood elements [2, 3, 5-10]. The current study presents and validates a FE modelling approach capable of capturing the behaviour of glulam and CLT elements when subjected to blast loading. Validation of the model is undertaken using published full-scale experimental test results from [11].

2 LITERATURE REVIEW

Analytical and numerical models are often used for the purpose of analysis and design of structural systems due to their low cost and their ability to expand the scope of experimental studies. The most common analysis method for blast is the equivalent single-degree-of-freedom (SDOF) analysis, which consists of lumping continuous structural elements into a system with given resistance function, equivalent mass, and based on assumed deflected shapes [12]. SDOF analysis has been shown to provide adequate numerical predictions with little required computational efforts [2, 3, 5-10]. However, such simplified modelling techniques are limited to their assumed deflected shape and associated failure mode, and may therefore lead to inconsistencies between modelling predictions and actual sequence of damage or failure events in complex structural systems.

Modelling wood components within a finite element analysis (FEA) environment carries challenges related to properly reproducing the anisotropic nature of the wood material and the interactions between various failure mechanisms. Wood may exhibit brittle and ductile failure mechanisms depending on the failure plane and direction, and such failures may need to be considered simultaneously. While brittle failure modes are typically modelled using fracture mechanics or discrete lattice models, which are capable of capturing detailed property variation [13], ductile failure modes are usually captured using plasticity-based models, such as the Hill criterion [14] and the Tsai-Wu criterion [15].

Continuum damage mechanics-based models [16], whereby elements are modelled as being composed of subdivided areas for the purpose of developing formulations that provide average stress and strains, have been widely implemented in a variety of commercial software packages. Sandhaas, et al. [17] developed a static material model for timber in ABAQUS using solid three-dimensional elements within a continuum damage approach, which allowed for the detection of both brittle and ductile failure modes. The model used stress-based

https://doi.org/10.52202/069179-0304

criteria, each associated with a specific failure mode, to initiate the damage process.

The current study focuses on developing and validating a FEA model based on the continuum damage approach that can predict the behaviour of full-scale wood elements subjected to far-field blast explosions, and their associated strain rate effects. The numerical investigation will focus on glulam and CLT as these are the dominant engineered wood products (EWPs) currently being used for mid- and high-rise wood and hybrid construction.

3 FINITE ELEMENT MODEL

3.1 MODEL DEFINITION

ABAQUS was chosen for the purpose of this study due to its ability to perform both static and dynamic analyses with a variety of element types and applications. An advancing time-step solution, suitable for high-speed dynamic analyses with nonlinear behaviour, was utilized to determine the kinematic state of the model at every time-step. The non-iterative nature of this specific formulation tends to result in less memory usage and runtime.

The models utilized three-dimensional solid geometries without planes of symmetry. Eight-node continuum linear hexahedral elements (C3D8) were used in all analyses and the overall solution algorithm uses a continuum damage approach [4], based on the approach proposed by Sandhaas, et al. [17]. The model was developed following five assumptions, as follows:

1. the adhesive used for bonding the lamination of the timber elements is at least as strong as the surrounding wood fibres and the modelling of the bonds between individual laminations can be omitted;
2. the ultimate compressive behaviour of wood does not result in complete material failure, leading to element deletion from the model environment;
3. damage accumulation in the tension parallel-to-grain direction does not influence damage in other stress components until complete failure;
4. deletion of elements subjected to only shear stresses require not only the exceedance of the failure criterion associated with shear stress, but also additional stresses which would widen the existing cracks in situ, and;
5. the inclusion of the rolling shear component alongside the longitudinal shear component was found to lead to unrealistic and rapid degradation in tension perpendicular-to-grain, and was therefore omitted from any interaction with the tension perpendicular-to-grain stress component.

A total of eight failure criteria are used to represent the state of damage in a given element. The predicted stresses are evaluated using failure criteria which represent the stress-capacity ratios for the element. The respective damage components are identified using specific subscripts: longitudinal tension (t0), longitudinal compression (c0), radial tension (t90R), radial compression (c90R), tangential tension (t90T), tangential compression (c90T), longitudinal shear with respect to the radial plane (vR), and longitudinal shear with respect to the tangential plane (vT). These are presented as follows:

$$F_{t0}(\sigma) = \frac{\sigma_L}{f_{t0}} \tag{1}$$

$$F_{c0}(\sigma) = \frac{-\sigma_L}{f_{c0}} \tag{2}$$

$$F_{c90R|T}(\sigma) = \frac{-\sigma_{R|T}}{f_{c90}} \tag{3}$$

$$F_{t90T|R}(\sigma) = \frac{\sigma_{R|T}^2}{f_{t90}^2} + \frac{\sigma_{LT|LR}^2}{f_v^2} \tag{4}$$

$$F_{vR|T}(\sigma) = \frac{\sigma_{LT|LR}^2}{f_v^2} + \frac{\sigma_{RT}^2}{f_{roll}^2} \tag{5}$$

Each criterion presented above can be considered as a ratio of applied stress (σ) to the material capacity (f). The damage process is initiated if a failure criterion is evaluated to be greater than unity, at which point it is established that an element stress exceeded the elastic limit.

The criterion result of each stress component is then verified against the respective maximum ratio from the previous time steps to determine if damage within the element has progressed. This is performed through the peak stress-history variable, κ, which is used to calculate damage. Depending on the detected failure mode, the damage progression either weakens the element (i.e., brittle tension failure) or allows for sustained stress to take place while the element deforms (i.e., ductile compression failure). In addition, as shear damage can be initialized by other failure criteria, the method of superposition, or coupling, is utilized to capture the complex interactions occurring within the three shear planes (i.e. RT, LR, and LT), as proposed in [18]. For CLT, it is also proposed in the current study that the rolling shear damage variable (d_{roll}) is comprised of the longitudinal shear (d_{vR} and d_{vT}) and perpendicular-to-grain tension (d_{t90R} and d_{t90T}) damage components. The damage equations are presented below:

$$d_t = 1 - \frac{1}{f_{max}^2 - 2G_f E}\left(f_{max}^2 - \frac{2G_f E}{\kappa}\right) \tag{6}$$

$$d_v = 1 - \frac{1}{f_{max}^2 - 2G_f G}\left(f_{max}^2 - \frac{2G_f G}{\kappa}\right) \tag{7}$$

$$d_c = 1 - \frac{1}{\kappa} \tag{8}$$

$$d_{roll} = 1 - (1 - d_{t90R})(1 - d_{t90T})(1 - d_{vR})(1 - d_{vT}) \tag{9}$$

$$d^{eff}{}_{vR|T} = 1 - \left(1 - d_{t90R|T}\right)\left(1 - d_{vR|T}\right) \tag{10}$$

where d_t is the brittle damage in tension, d_v is the brittle damage in shear, d_c is the ductile damage in compression, and $d^{eff}{}_{vR|T}$ is the effective shear damage variable.

As seen in Equations (9) and (10), the method of superposition was utilized to capture the complex interactions occurring within the three shear planes (i.e. RT, LR, and LT), as proposed in [18], to calculate shear damages.

https://doi.org/10.52202/069179-0304

Viscous stabilization was incorporated into the damage algorithm through a modification of the damage variables using a bulk viscosity parameter to limit the damage development within the element and prevent large sections of the model from being deleted instantaneously, which is an unrealistic behaviour [4].

The cylindrical axes of wood, namely longitudinal, radial, and tangential, were replaced with the default local cartesian system of reference used within ABAQUS (i.e., X, Y, Z). The behaviour assigned to the perpendicular-to-grain axes within the material was smeared into a homogenized plane, whereby the local longitudinal X-axis was assigned parallel-to-grain properties while identical perpendicular-to-grain properties were assigned to the radial and tangential axes. The stress and strains present within a wood element are therefore defined by a total of six components, as shown in Equation (11) and Equation (12), respectively. These are written using unique properties for the three cartesian axes, but the terms are simplified as the implemented version assigns identical perpendicular-to-grain properties to the Y (denoted *R*) and Z (denoted *T*) axes and parallel-to-grain properties to the X (or *L*) axis. The general constitutive relationship equation includes the elastic modulus parallel-to-grain, E_0, and perpendicular-to-grain, E_{90}, for the axial components rather than a unique value for each axis, while a longitudinal shear modulus, G, is implemented for both the LR and LT orientations in combination with a rolling shear modulus, G_{roll}, for the RT orientation. The constitutive relationship is presented in Equation (13), while the stiffness matrix of an element, $[k]$, is provided in the literature [4, 19].

$$\{\sigma\} = \{\sigma_L \quad \sigma_R \quad \sigma_T \quad \sigma_{vR} \quad \sigma_{roll} \quad \sigma_{vT}\}^T \tag{11}$$

$$\{\epsilon\} = \{\epsilon_L \quad \epsilon_R \quad \epsilon_T \quad \epsilon_{vR} \quad \epsilon_{roll} \quad \epsilon_{vT}\}^T \tag{12}$$

$$\{\sigma\} = [k]\{\epsilon\} \tag{13}$$

After receiving new incremental strains from the previous step of the ABAQUS analysis, the material model estimates the new stress based on the assumption of linear elastic behaviour. If a damage parameter is evaluated at a value near to unity, the element is identified for deletion.

3.2 TESTING PROGRAM AND MODELLING INPUT

The test configuration and specimens from an experimental study investigating the behaviour of glulam and CLT structural elements subjected to simulated blast loads were utilized for the purpose of validating the finite element model and modelling approach [11]. The experimental testing was conducted using the Shock Tube Test Facility at the University of Ottawa (see Figure 1).

Figure 1: *University of Ottawa Shock Tube Test Facility*

The specimens, boundary conditions, and loading of ten experimental tests were replicated within the FEA environment and the predicted results (i.e., displacements, reactions, and failure modes) were compared with the experimental test data. The 2,500 mm long specimens consisted of 24f-ES grade glulam beams (86 mm x 178 mm) and E1 grade 5-ply CLT panels (445 mm x 175 mm), subjected to dynamic four-point bending. Strain-rates in the testing varied between 0.10 to 0.32 s^{-1}.

Inputs for the material model pertaining to wood properties were obtained from published manufacturer data and research studies, modified to consider high-strain rate effects. The parallel-to-grain elastic modulus (E_0) was obtained from published design information by the manufacturer. The perpendicular-to-grain modulus of elasticity (E_{90}) and the shear and rolling shear moduli (G and G_{roll}, respectively) were calculated using relationships from the CSA O86 wood design standard [20]. Average strength material properties rather than the design-level properties were obtained from the literature in order to model the in-situ test specimens. The 5th percentile compression and tension parallel-to-grain, as well as perpendicular-to-grain strengths were modified using a load-duration factor (K_D) of 1.25, as well as strength and dynamic increase factors (*SIF* and *DIF*). The *SIF* is used to transform design-level strengths to average static strength values, while the *DIF*, which is the ratio of the dynamic strength over the static strength, takes into consideration high strain-rate effects [21]. The values for the material properties utilized in the FEA models, including elastic moduli (E), shear moduli (G), strengths (f), fracture energies (G_f), and Poisson's ratios (υ), are summarized in Table 1.

Table 1: *Material properties*

Property	Glulam	CLT (Long./Trans.)	Ref.
E_0	13,100 MPa	11,700 / 9,000 MPa	[20]
E_{90}	437 MPa	390 / 300 MPa	[20]
G	819 MPa	731 / 563 MPa	[20]
G_{roll}	81.9 MPa	73.1 / 56.3 MPa	[20]
f_{t0}	33.7 MPa	27.7 / 5.8 MPa	[22, 23]
f_{c0}	54.5 MPa	34.7 / 16.2 MPa	[22, 23]
f_{c90}	11.3 MPa	8.0 / 8.0 MPa	[22, 23]
f_{t90}	1.4 MPa		[24]
f_v	10.9 MPa		[25]
f_{roll}	1.5 MPa		[26]
G_{f0}	6.0 N/mm		[4]
G_{f90}	0.5 N/mm		[4]
G_{fv}	1.2 N/mm		[4]
G_{froll}	0.6 N/mm		[4]
υ_{LR}	0.47		[27]
υ_{LT}	0.37		[27]
υ_{RT}	0.44		[27]

The glulam specimens were modelled as homogenous members, while the plies of the modelled CLT panel were created by portioning sections of the panel geometry. This significantly reduced computational efforts by reducing contact relationships in the analysis. An example of a modelled CLT panel is presented in Figure 2. The boundary supports for the models consisted of four cylindrical rigid bodies, acting as pinned supports, in order to replicate the boundary conditions used during the full-scale experimental tests.

As the validation of the FE model was to be conducted through comparisons with published full-scale test results which utilized a load-transfer device (LTD) to convert the blast pressure into two concentrated point loads, the inertial contribution of the LTD was accounted for by distributing the effective mass of the LTD over the middle third of the member. This was implemented by increasing the material density in the region between the loading areas.

In order to select an appropriate mesh for the finite element material model, an h-refinement based sensitivity analysis was conducted for the glulam and CLT models using a blast load that would induce an elastic response in both specimens. For the purpose of this study, a mesh size of 20 mm was used for the glulam specimens as it provided the highest resolution of results. For the CLT model, considerations were made to include at least two elements for each ply. Overall, the CLT model was found to be more sensitive to mesh size, and a 17.5 mm element size was chosen, since it provided a reasonable balance of result fidelity and runtime.

4 RESULTS AND DISCUSSION

The finite element modelling results were evaluated through the displacement-time history and resistance-displacement relationship, as well as the observed overall damage behaviour. The displacement-time history was obtained from a mid-span node, located at mid-depth of the modelled specimen. The numerical results and the corresponding experimental test results are presented in Table 2, which includes the peak resistance and the mid-span displacement occurring at peak resistance.

https://doi.org/10.52202/069179-0304

Table 2: *Summary of numerical and experimental results*

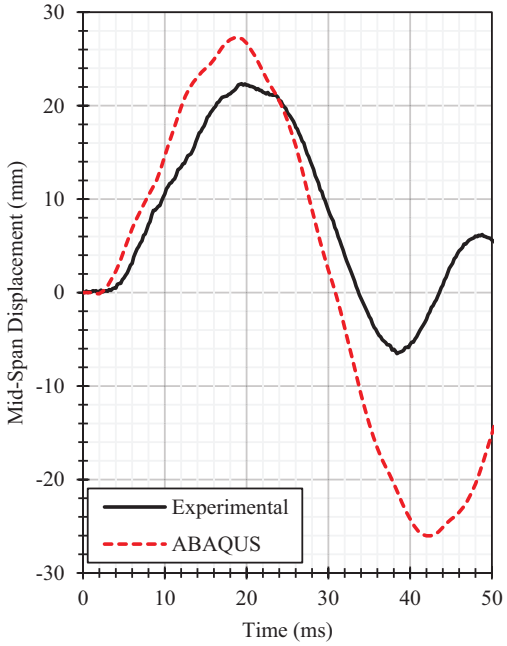
Test Name	Peak Resistance (kN)			Displacement at Peak (mm)		
	Exp.	Num.	Err. (%)	Exp.	Num.	Err. (%)
GL1.1	54	53	-2	26	25	-4
GL2.1	77	61	-21	33	38	+15
GL2.2	79	65	-18	34	42	+24
GL3.1	29	30	+3	13	13	0
GL3.2	66	56	-15	28	28	0
GL3.3	70	63	-10	31	38	+23
CLT1.1	187	188	+1	33	31	-6
CLT2.1	126	150	+19	22	26	+18
CLT2.2	181	170	-6	34	36	+6
CLT3.1	167	176	+5	26	34	+31

The resistance curves and peak resistances were obtained by establishing equilibrium of the dynamic systems, taking into account the dynamic reactions, $V(t)$, imparted blast load, $F(t)$, and mass properties. The closed-form formulation for the resistance at a certain point in time, $R(t)$, is given in Equation (14):

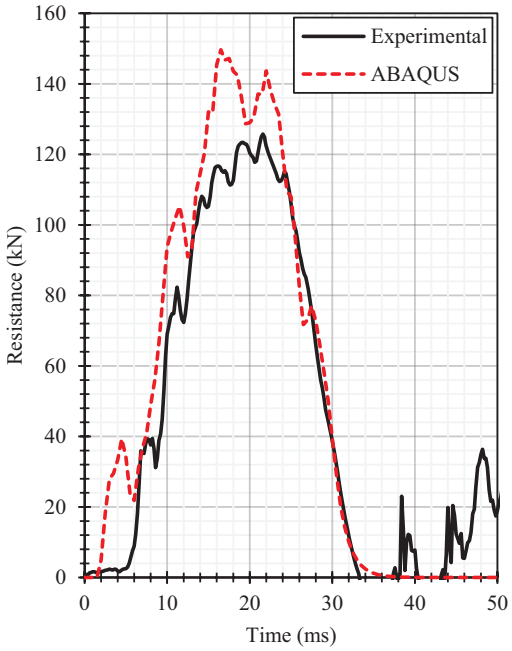
$$R(t) = \frac{6}{L}\left(V(t)x_{eq} + \left(\frac{L}{3} - x_{eq}\right)\frac{F(t)}{2}\right) \qquad (14)$$

where L is the clear span of the specimen, and x_{eq} is the location of the equivalent effective inertial force, which can be determined based on previously derived solutions [28]. The reaction-time histories were obtained from the rigid pins in contact with the tension face of the structural elements at the supports.

On average, the model underpredicted the peak resistance by 4.3 % (COV = 12 %) and overpredicted the displacement-at-peak on average by 10.6 % (COV = 11 %). These ratios are well within the expected margins of variability, considering that the inputs were obtained from the timber design standard (CSA O86) [40], manufacturer's data, and studies on similar specimens. Representative experimental and numerical time histories are shown in Figure 3 for specimen CLT2.1. While the model permitted both the inbound and rebound phases of the response to be investigated, the comparison with the experimental test results only extended to the maximum inbound behaviour and response, due to the underlying assumptions involving the LTD mass. While the model considers that the LTD is constantly in contact with the specimen, experimentally this was often not the case, particularly when specimens experienced failure.



(a) *Displacement-time*



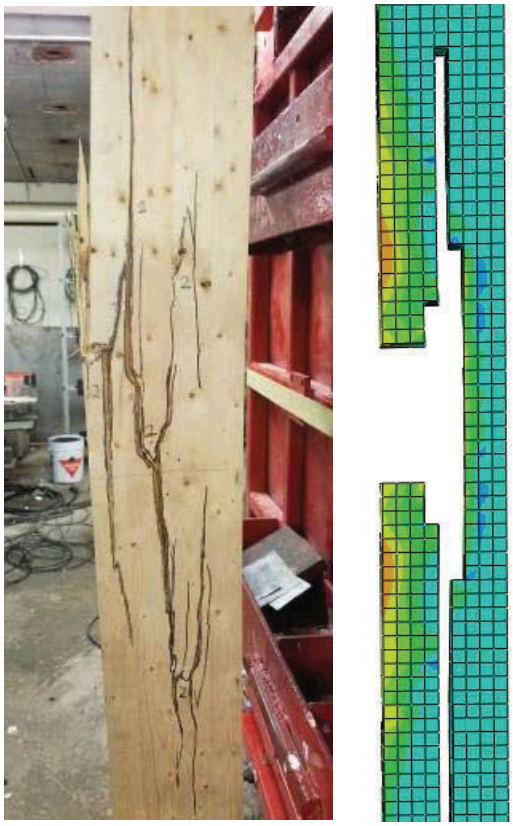
(b) *Resistance-time*

Figure 3*: Representative results (CLT2.1)*

The reaction-time histories included numerical scatter due to the solution method used by ABAQUS, which does not calculate the global stiffness or equilibrium. Another potential cause could be attributed to the mismatch between the frequency at which the results from the model outputs are stored and the stable time increment used within the analysis. The stable time increment is related to stress wave propagation velocity within an element, and

thus the output at a certain integration point can vary depending on whether the stress wave has propagated through that specific point of the model at the given time increment.

The FEM results for the glulam specimens matched well in terms of overall deflected shapes and load-displacement behaviour, and propagation of damage through cracks. Failure in the glulam specimens was always initiated on the tension-side outer laminate near the mid-span, corresponding to initial element deletion, followed by damage propagation towards the rest of the cross-section. As shown in Figure 4, the shape and extent of the damage were consistent among simulations and corresponded generally well to the experimental test results.



(a) *Experimental* ***(b)*** *FE Model*

Figure 4*: Representative results for glulam*

Similar to glulam, the simulated sequence of failure and overall damage characteristics of CLT elements correlated well with those observed in the experimental test specimens, as shown in Figure 5. Two specific failure mechanisms, namely flexural failure of the longitudinal laminates and rolling shear failure of the transverse laminates, were observed experimentally and within the numerical models. This combination of failure modes caused greater variability in terms of the accuracy of the numerical results. However, the FEM consistently predicted rolling shear damage occurring near or at the instance of flexural failure; an observation that was also documented in the experimental tests.

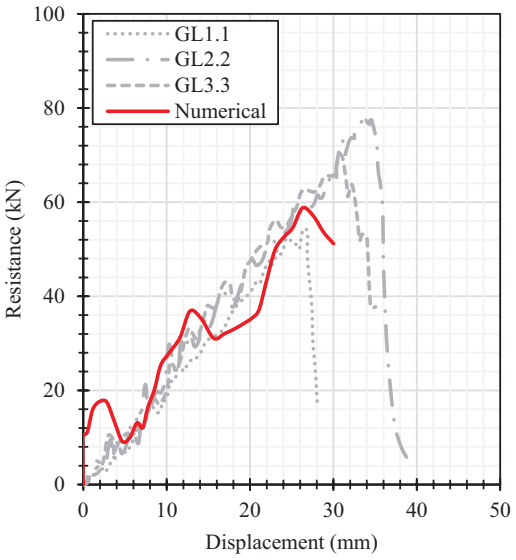
(a) *Experimental* ***(b)*** *FE Model*

Figure 5*: Representative results for CLT*

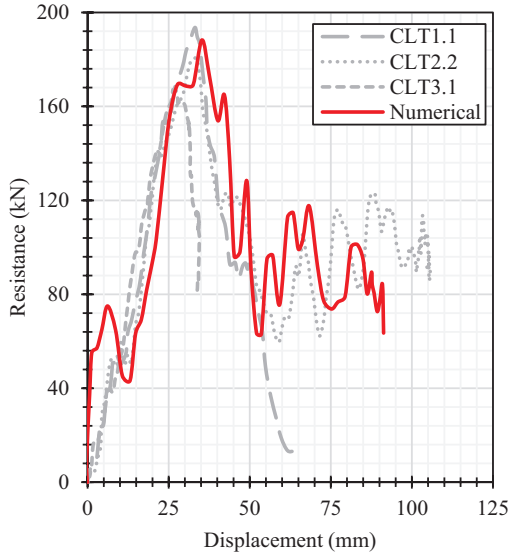
Previous studies on CLT panels under blast have underlined the limitations in the use of simplified SDOF modelling due to the inability of the model to consider two concurrent failure modes [3, 29]. Herein lies the significant advantage of the described ABAQUS model, whereby a multitude of damage types and failure mechanisms can be studied simultaneously, and the output of the model can provide the resistance curve; and input that usually required when performing SDOF analysis.

The resistance curves generated by the finite element method generally correlated well with experimental results despite the presence of artificial numerical fluctuation, as shown in (Figure 6).

https://doi.org/10.52202/069179-0304



***(a)** Glulam*



***(b)** CLT*

***Figure 6**: Comparison between experimental and numerical resistance curves*

The overall numerical results in terms of resistance curve within the elastic regime were very consistent with the experimental test results, with the exception that a very high initial stiffness was observed in all models within the first two milliseconds. This phenomenon does not, however, affect the overall accuracy and results from the FEA model. In both the experimental and numerical results, no post-peak behaviour was observed for the glulam specimens, as shown in Figure 6a, while the CLT specimens exhibited significant post-peak capacity, as shown in Figure 6b. The loss of the outermost longitudinal laminates corresponded with the peak resistance of the panel.

5 CONCLUSIONS

A material predictive model for glued-laminated and cross-laminated timber structural elements was implemented into ABAQUS/Explicit through a dynamic user subroutine following a continuum damage approach. The experimental test results of 10 full-scale shock tube tests were used to validate the accuracy of the model, which was determined to be effective in capturing the dynamic response of timber elements. Reasonably accurate numerical predictions were obtained for peak resistance, as well as mid-span displacements at peak resistance. The finite element models were also capable of predicting damage and failure in the specimen, similar to those observed experimentally. The FE model was found to produce resistance-displacement relationships which correlated well to the corresponding experimental results. This finding identifies a key advantage to using sophisticated FEA over simplified modelling methodologies, such as single-degree-of-freedom modelling. While the latter requires that the resistance curve as input, the former produces the resistance curve, given appropriate material properties are implemented by the analyst. The modelling results also show that the lack of actual in-situ material properties does not pose a challenge in obtaining realistic predictions of overall behaviour and resistance curves, as published data from available manufacturer spec sheets, design provisions, and published studies can be used to obtain generally good results.

EXPERIMENTAL INVESTIGATIONS ON CLT PANELS WITH OPENINGS

Xiaoyue Zhang [1], Lu Xuan [2], Weitian Li [3], Thomas Tannert [4]

ABSTRACT: The design of cross-laminated timber (CLT) shear walls demands careful consideration. In order to reduce cost and speed up construction time, large panel sizes are often preferred, yet sometimes openings are required for architectural purposes. However, the Canadian Standard for Engineering Design in Wood (CSA O86-19) prohibits openings in CLT shear walls due to a lack of research quantifying the reduction of stiffness as a function of opening size. To address this research gap, the impact of opening size on the stiffness of CLT panels was investigated. A total of 43 tests were conducted on panels with two different aspect ratios, two different thicknesses, and various opening sizes. The results indicate that the panel stiffness decreases non-linearly with an increase in opening size. However, even opening sizes large in relation to the panel width have only a minimal impact on the panel stiffness. These findings provide valuable insights for future design provisions for openings in CLT shear walls.

KEYWORDS: Cross-laminated timber, Push-over test, In-plane stiffness, Opening size

1 INTRODUCTION

1.1 CLT SHEAR WALLS WITH OPENING

The use of cross-laminated timber (CLT) in construction has significantly increased in the 21st century, with numerous structures built worldwide demonstrating the benefits of this material [1]. One emerging application of CLT is as shear walls, which commonly feature openings for doors and windows. However, such openings create stress concentrations that can reduce the panel's in-plane stiffness and load-carrying capacity.

While previous research has largely focused on the mechanical properties of CLT panels, limited work has been conducted on openings to determine a reduction coefficient. Dujic et al. [2] utilized a combination of experiments and numerical analysis to investigate how the size and shape of openings affect the strength and stiffness of shear walls. Through a parametric study, the authors proposed Equations (1) and (2) to estimate the stiffness and strength of panels with openings:

$$K_{opening} = K_{full} \cdot \frac{r}{2-r} \tag{1}$$

$$F_{opening} = F_{full} \cdot r(2-r) \tag{2}$$

Where $K_{opening}$ and K_{full} denote the stiffness of a CLT wall with and without and openings, respectively. The panel area ratio, r, is calculated using Equation (3):

$$r = \frac{1}{1+\frac{\alpha}{\beta}} \cdot \frac{H\Sigma L_i}{H\Sigma L_i + \Sigma A_i} \tag{3}$$

In this equation, H is the height of wall, ΣL_i is the sum of length of full height wall segments (excluding length of openings from the total length), and ΣA_i is the sum of the openings area. The parameters used in these equations are illustrated in Figure 1.

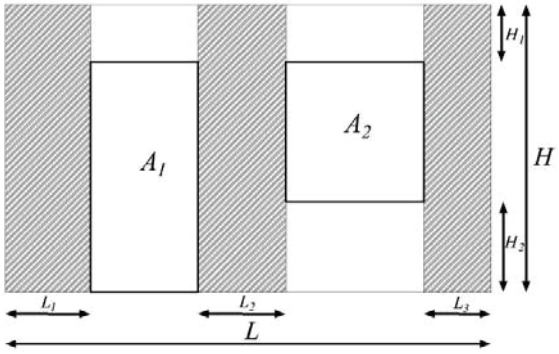

Figure 1: *Opening parameters for Equations (1) and (2)*

Ashtari [3] investigated the in-plane stiffness of four configurations of CLT floor diaphragms, with and without openings, utilizing a numerical model. The study determined that several key factors significantly influenced the in-plane stiffness, including the panel-to-panel connections of the CLT, the in-plane shear modulus of the CLT panels, the stiffness of the shear walls, and the configuration of the floor diaphragm. The numerical model was considered to be appropriate for CLT shear walls with openings, but it was noted that the findings require further experimental validation.

Pai et al. [4] studied the force transfer mechanism around openings in CLT shear walls and identified reinforcement requirements for the opening corners. The study revealed high concentrations of shear stress, indicating a likelihood of shear failure. To mitigate this issue, the authors recommended adding reinforcement to the opening.

Yasamura et al. [5] created 3D models and examined the mechanical properties of full-size CLT structures subjected to reverse cyclic horizontal loads. The results highlighted the importance of considering panel failure when designing CLT plates with openings.

Shahnewaz et al. [6] utilized numerical methods to calculate the in-plane stiffness of fenestrated three-ply single CLT walls. Through a parametric study, the authors evaluated the impact of changing the size and shape of openings and proposed Equation (4) to calculate the stiffness reduction as function of opening size and shape.

$$K_{opening} = K_{full} \cdot \left(1 - \frac{r_{o/w}\left({}^{A_0}/_{A_w}\right)}{\sqrt{r_{o/w} + r_o\left({}^{A_0}/_{A_w}\right) - 2\left({}^{r_{off}}/_{r_w}\right)}}\right) \quad (4)$$

Where $K_{opening}$ and K_{full} represent the stiffness of walls with and without opening, respectively. A_0 and A_w represent the areas of walls with and without opening, respectively. The aspect ratio of the opening, r_o, is defined as the ratio of the smaller to larger dimension of the opening. The maximum aspect ratio of opening to wall dimension, $r_{o/w}$ is calculated as the maximum of l_0/L or h_0/H, where L and H are the wall length and height, respectively, and l_0 and h_0 are the opening length and height, respectively. The wall aspect ratio, r_w, is defined as L/H, and the ratio of wall offset to wall dimension, r_{off}, is defined as x_{off}/L or y_{off}/H, respectively). These parameters are illustrated in Figure 2.

Mestar et al. [7] and Casagrande et al. [8] studied CLT shear walls with openings and found that for large lintel slenderness, bending failure occurred. Additionally, a numerical calculation method was proposed for simulating laminated plates using homogeneous shell elements with effective moduli of elasticity and shear.

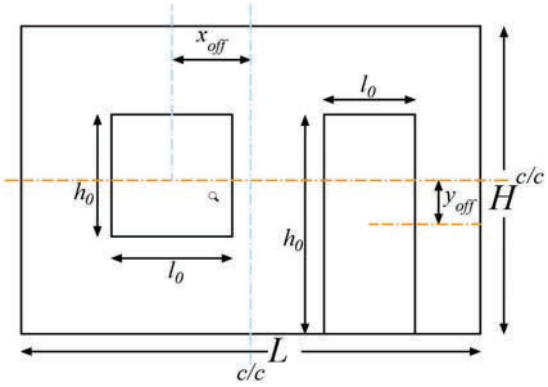

Figure 2: *Opening parameters for Equation (4)*

1.2 OBJECTIVES

Due to a lack of research on the strength and stiffness reduction as a function of the size and location of openings, the current CSA O86 provisions do not allow for any openings in CLT shear walls [9]. To address this knowledge gap, the objective of this study was to investigate experimentally how the size of openings affect the stiffness of CLT panels with different panel thicknesses and aspect ratios.

2 EXPERIMENTAL INVESTIGATIONS

2.1 MATERIALS

CLT panels with two different thicknesses were used in the experiments, namely: 1) 139mm 5-ply grade E1M4; and 2) 175mm 5-ply grade E1M5. The CLT panels were fabricated in accordance with ANSI/APA PRG 320 [10] and were supplied by Structurlam Products Ltd [11]. The wood species used were SPF MSR2100 (major layer)/No. 3 (minor layer). Based on the weight and volume of the CLT panels, the average apparent density of the panels was calculated to be 490 kg/m^3. The moisture content of the wood products was determined to be 12% (±3%) using portable electric resistance meters.

2.2 TESTS ON SINGLE PANELS

Two CLT panels of each layup measuring 1.5 x 3.0m were subjected to testing. Initially, the panels were tested without any opening, and then with gradually increasing opening sizes. The opening sizes were increased in increments of 200mm, up to a maximum size of 1200 x 1200mm, as shown in Figure 3. The panel was fixed at the bottom by three hold-downs, with one placed on each end and one in the panel centre. For ease of preparation, only slots were cut instead of completely removing the material from the opening.

https://doi.org/10.52202/069179-0305

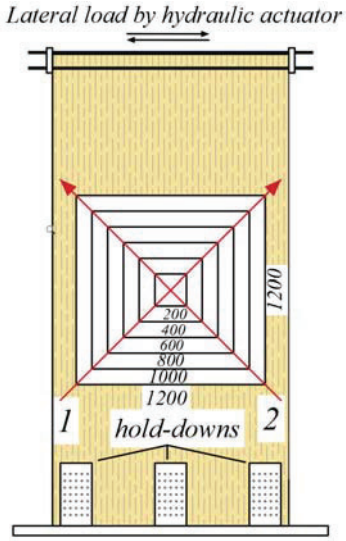

Figure 3: *Size of openings in single panels*

A lateral load was applied at the top end of the panel using a hydraulic actuator. The actuator was attached to steel plates with four pre-stressed rods. For each opening size, the panels were loaded three times to 100kN in both directions. The quasi-static monotonic load was applied at a constant rate of displacement of 10mm/min [12]. To measure the panel distortion, two string pots were used to span diagonally over the opening. In-plane panel movement was prevented by using an HSS profile, which was placed on a Teflon sheet to prevent friction. The experimental setup is illustrated in Figure 4.

Figure 4: *Set-up of single-panel test*

2.3 RESULTS OF SINGLE PANEL TESTS

Figure 5 shows the applied force versus opening distortion for all opening sizes. Figure 6 illustrates the maximum opening distortions as a function of opening size. It can be found that the panel stiffness decreased slightly with increasing opening size, with distortions of around 4mm for opening sizes of up to 800 x 800mm. Only when the opening size reached 1000mm was a significant increase of approximately 10mm observed.

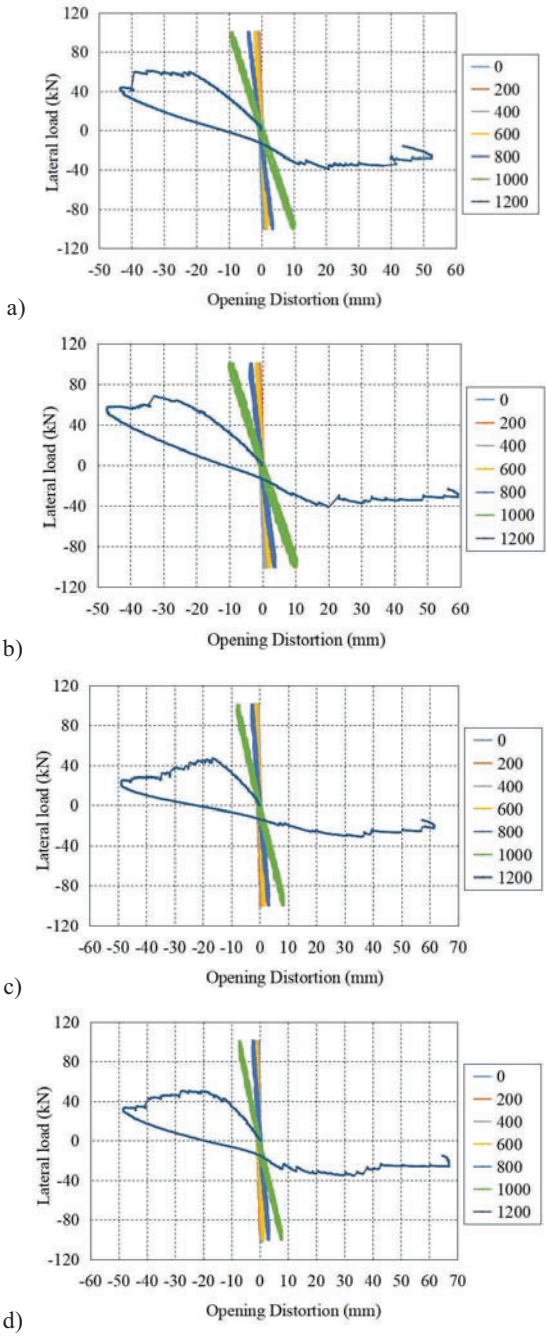

Figure 5: *Lateral load vs Opening distortion curves: (a)139-1; (b)139-2; (c)175-1; (d)175-2*

https://doi.org/10.52202/069179-0305

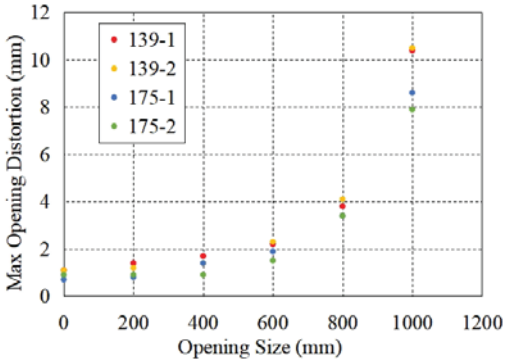

Figure 6: *Maximum opening distortion vs opening size*

The typical failure mode of the panels, when tested with a 1200 x 1200mm opening, is depicted in Figure 7. It be observed that cracks developed in the CLT panels near the corners of the openings, where the stresses peaked.

Figure 7: *Typical failure mode in single-panel test*

2.4 TESTS ON COUPLED PANELS

In the second part of the tests, the impact of different aspect ratios on CLT panels was examined with dimensions of 3 x 1.5 m and 3 x 1 m, corresponding to aspect ratios of 2:1 and 3:1, respectively. Only 139 mm 5-ply CLT panels were utilized for these tests.

Two CLT panels were tested next to each other, initially without any openings and subsequently with openings increasing in size from 150 x 150mm in increments of 150mm. The maximum opening sizes were 750 x 750mm for 1000mm wide panels and 1200 x 1200mm for 1500mm wide panels. To simplify the preparation process, only slots were cut rather than completely removing the material from the openings. The openings were placed eccentrically, with their centers 750mm and 500mm away from the long side of the panels, as depicted in Figure 8.

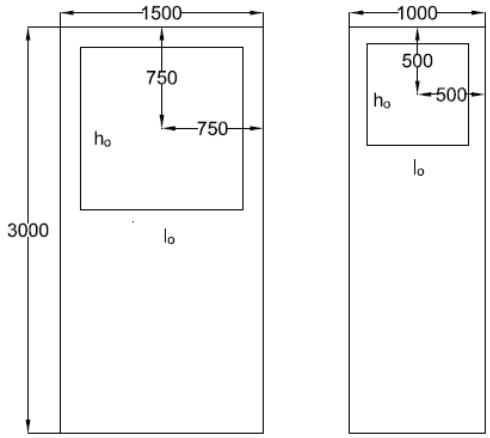

Figure 8: *Size of openings in coupled panels*

A hyperelastic hold-down system, presented by Asgari et al. [13] was used on the outside corners of the panels, and a pin-type shear connector was mounted at the midpoint, as shown in Figure 9. There was no further shear connection between the two panels. A hydraulic actuator was used to apply lateral load to the top of the two CLT panels via pins. A steel frame was used to hold the panels in-plane and to apply a constant dead load to the panels. For each opening size, the panels were subjected to three cycles of lateral loading in both directions, up to 50kN for the 1000mm wide panels and up to 75kN for the 1500mm wide panels. The quasi-static monotonic load was applied at a constant rate of displacement of 10mm/min.

The following parameters were measured during the tests: horizontal panel displacement, individual panel uplifts at both corners, horizontal sliding at the bottom of the panels, and panel distortion. Two string pots were mounted on each panel, spanning diagonally over the openings, to measure the panel distortion.

Figure 9: *Set-up of coupled-panel test*

https://doi.org/10.52202/069179-0305

2.5 RESULTS OF COUPLED PANEL TESTS

Figure 10 illustrates the typical failure mode of the CLT panels when tested with a 1200 x 1200 mm opening. Similar to the single panel test, cracks developed in the panels near the corners of the openings, where the stresses were highest.

Figure 10: *Typical failure mode in single-panel test*

The force versus displacement curves for all opening sizes are depicted in Figure 11, while the panel distortions are illustrated in Figure 12. It is evident that an increase in opening size resulted in a corresponding increase in the maximum displacement, coupled with a decrease in stiffness. Notably, the curves for small to mid-sized openings overlap, indicating that the reduction in stiffness was minimal. The relationship between opening size and maximum distortion is displayed in Figure 13.

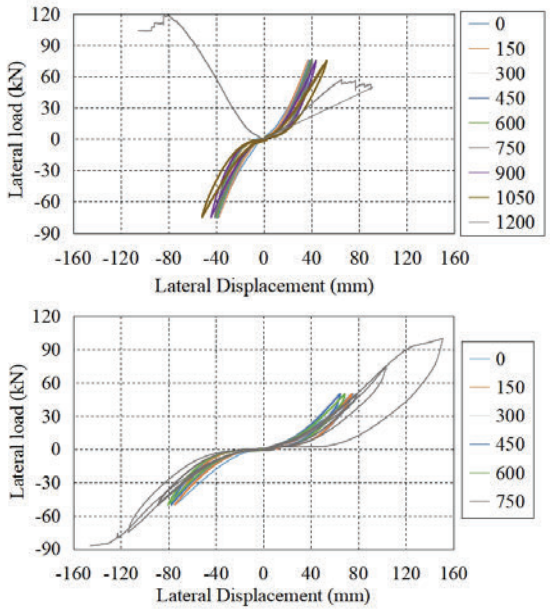

Figure 11:*Load vs displacement curves. Top: 2:1 aspect ratio; bottom: 3:1 aspect ratio*

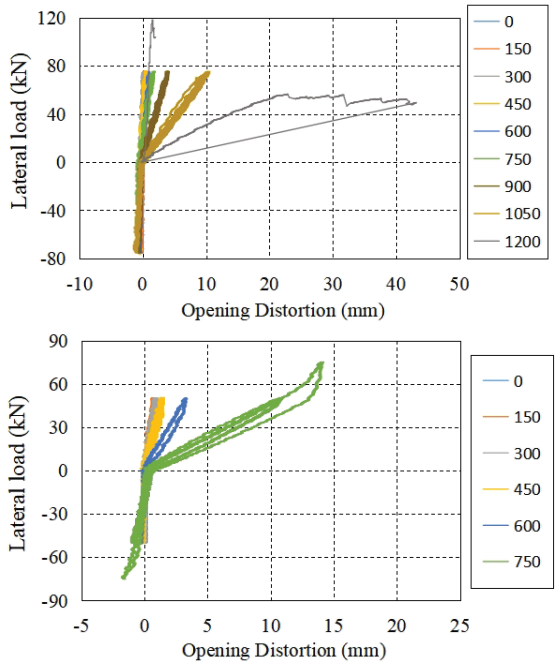

Figure 12: *Opening distortion curves. Top: 2:1 aspect ratio; bottom: 3:1 aspect ratio*

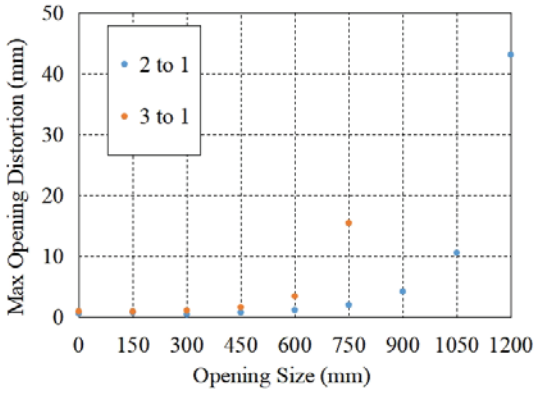

Figure 13: *Maximum opening distortion vs opening size*

3 CONCLUSIONS

The impact of different opening sizes on the in-plane stiffness of CLT panels was investigated experimentally, and the following main conclusions were drawn:

1) Openings do have an impact on the in-plane stiffness of CLT panels, but this impact is minimal for small opening sizes, and only becomes significant for very large opening sizes.

2) From the experimental results of coupled panels, it can be concluded that small openings in CLT shear walls only marginally reduce their stiffness. However, very large openings can reduce the stiffness by up to 35% and significantly reduce the shear resistance, leading to brittle panel failure at small loads.

https://doi.org/10.52202/069179-0305

3) The aspect ratio is a significant factor affecting the stiffness of CLT panels, and panels with different aspect ratios exhibit a considerable difference in stiffness under the same size of CLT panel openings.

4) These findings, once analysed in more depths and used to validate a numerical model for extended parameters studies can guide the development of future design provisions regarding openings in CLT shear walls.

ACKNOWLEDGEMENT

The project was funded by the government of British Columbia through a Forest Innovation Investment grant and a BC Leadership Chair to Dr. Tannert. SEISMIC PERFORMANCE EVALUATION OF REINFORCED WOODEN TEMPLE BASED ON LONG TERM EARTHQUAKE OBSERVATIONS

Toshiaki Sato[1], Yasuhiro Nambu[2], Yuji Miyazu[3] and Masayuki Nagano[4]

ABSTRACT: The seismic performance of structures is known to change over time, and the causes are affected by the surrounding environment such as temperature and humidity as well as damage caused by disturbances such as earthquakes. In terms of structure, seismic performance has been evaluated based on the construction age, mainly the transition of related laws and regulations, but the seismic performance changes over time, considering the material properties that swell and shrink sensitively due to temperature and humidity. the purpose of this study is to quantitatively evaluate the effects of various influential factors using earthquake observation records which are measured over a long period of time at the main hall of wooden temple. The subspace method was applied to the observation record of target temple, and the transition of the natural frequency due to aging was verified as the environment was changed. As a result of the investigation, the natural frequency changed as the temperature up and down, suggesting the effect of swell and shrink of the joint. Further, in the deformation range about less 3 mm, the variation in the natural frequency may have the same effect as the nonlinearity due to the large and small response.

KEYWORDS: System Identification, Subspace Method, Traditional Wooden buildings

1 INTRODUCTION

The seismic performance of structures is known to change over time, and the causes are affected by the surrounding environment such as temperature and humidity as well as damage caused by disturbances such as earthquakes. In terms of structure, seismic performance has been evaluated based on the construction age, mainly the transition of related laws and regulations, but the seismic performance changes over time, considering the material properties that swell and shrink sensitively due to temperature and humidity in case of timber structure. On the other hand, there is still no way to quantitatively evaluate the seismic performance of the wood structure over time, and it can be said that the accumulation of knowledge is indispensable.

Against this background, the purpose of this study is to quantitatively evaluate the effects of various influential factors using earthquake observation records which are measured over a long period of time at the main hall of wooden temple shown in Fig. 1. In this paper, we first organize the system identification method by the subspace methods used in the subsequent studies, and then describe the results of the analysis focusing on the transition of the natural freq-uency together with the identification results by the earthquake observation records.

***Figure 1**: Photo of the target temple*

2 SYSTEM IDENTIFICATION BASED ON SUBSPACE METHOD

2.1 NUMERICAL CALCULATION BY ORDINARY MOESP METHOD

Since the subspace method has the advantage of being applicable to multi-input multi-output (MIMO) systems, verification work of its identification accuracy has been advanced in previous studies, and considering its significance in this study, the Ordinary MOESP method was adopted. In the subspace method, it is considered that

[2] Yasuhiro Nambu, Dr. Eng., Assist. Prof., Kyushu University, Japan, nambu@arch.kyushu-u.ac.jp
[3] Yuji Miyazu, Dr. Eng., Assoc. Prof., Tokyo University of Science, Japan, miyazu@rs.tus.ac.jp
[4] Masayuki Nagano, Dr. Eng., Prof., Tokyo University of Science, Japan, nagano-m@rs.tus.ac.jp

https://doi.org/10.52202/069179-0306

each expression in Eqs. (1) and (2) are satisfied as the state-space representation of the discrete-time linear time-invariant system of *m* input *l* output [1].

$$\mathbf{x}(k+1) = \mathbf{A}\,\mathbf{x}(k) + \mathbf{B}\,\mathbf{u}(k) + \mathbf{w}(k) \qquad (1)$$

$$\mathbf{y}(k) = \mathbf{C}\,\mathbf{x}(k) + \mathbf{D}\,\mathbf{u}(k) + \mathbf{v}(k) \qquad (2)$$

Where, **x** (*k*) denotes the state vector, **u** (*k*) and **y** (*k*) are the input to the system and the output of the system, respectively. **A**, **B**, **C** and **D** are the constant matrix. These vectors and matrices belong to a set of real numbers. **w** (*k*) and **v** (*k*) are unmeasurable vector signals. They are assumed to be zero mean, stationary, white noise vector sequences. The Eqs. (1) and (2) can be organized as

$$\mathbf{Y} = \mathbf{\Theta}\,\mathbf{X} + \mathbf{\Psi}\mathbf{U} + \mathbf{\Xi}\mathbf{W} + \mathbf{V}\,. \qquad (3)$$

Where, **U** and **Y** denote the Input and output block Hankel matrices, respectively, and **X** is matrix composed by state vectors. These are expressed as follows.

$$\mathbf{U}_p = \begin{bmatrix} \mathbf{u}(k) & \mathbf{u}(k+1) & \cdots & \mathbf{u}(k+N-1) \\ \mathbf{u}(k+1) & \mathbf{u}(k+2) & \cdots & \mathbf{u}(k+N) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{u}(k+r-1) & \mathbf{u}(k+r) & \cdots & \mathbf{u}(k+r+N-2) \end{bmatrix}$$

$$\mathbf{U}_f = \begin{bmatrix} \mathbf{u}(k+r) & \mathbf{u}(k+r+1) & \cdots & \mathbf{u}(k+r+N-1) \\ \mathbf{u}(k+r+1) & \mathbf{u}(k+r+2) & \cdots & \mathbf{u}(k+r+N) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{u}(k+2r-1) & \mathbf{u}(k+2r) & \cdots & \mathbf{u}(k+2r+N-2) \end{bmatrix}$$

$$\cdots (4\text{-}1,\ 2)$$

$$\mathbf{Y}_p = \begin{bmatrix} \mathbf{y}(k) & \mathbf{y}(k+1) & \cdots & \mathbf{y}(k+N-1) \\ \mathbf{y}(k+1) & \mathbf{y}(k+2) & \cdots & \mathbf{y}(k+N) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{y}(k+r-1) & \mathbf{y}(k+r) & \cdots & \mathbf{y}(k+r+N-2) \end{bmatrix}$$

$$\mathbf{Y}_\mathbf{f} = \begin{bmatrix} \mathbf{y}(k+r) & \mathbf{y}(k+r+1) & \cdots & \mathbf{y}(k+r+N-1) \\ \mathbf{y}(k+r+1) & \mathbf{y}(k+r+2) & \cdots & \mathbf{y}(k+r+N) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{y}(k+2r-1) & \mathbf{y}(k+2r) & \cdots & \mathbf{y}(k+2r+N-2) \end{bmatrix}$$

$$\cdots (5\text{-}1,\ 2)$$

$$\mathbf{X} = \begin{bmatrix} \mathbf{x}(k) & \mathbf{x}(k+1) & \cdots & \mathbf{x}(k+2r-1) \end{bmatrix} \qquad (6)$$

In respective Eqs. (4) and (5), the scope is divided into two parts, the past and the future based on a certain time for the calculation reasons described later.

The matrix **Θ**, which is designated the expanded observability matrix, and **Ψ** are expressed as follows.

$$\mathbf{\Theta} = \begin{bmatrix} \mathbf{C} \\ \vdots \\ \mathbf{C}\mathbf{A}^{k-1} \\ \mathbf{C}\mathbf{A}^{k} \end{bmatrix},\ \mathbf{\Psi} = \begin{bmatrix} \mathbf{D} & & & \mathbf{0} \\ \vdots & \ddots & & \\ \mathbf{C}\mathbf{A}^{k-2}\mathbf{B} & \cdots & \mathbf{D} & \\ \mathbf{C}\mathbf{A}^{k-1}\mathbf{B} & \cdots & \mathbf{C}\mathbf{B} & \mathbf{D} \end{bmatrix}$$

$$\cdots (7\text{-}1,\ 2)$$

Others shown in Eq. (3) are notes related to noise, but they are not directly used in subsequent calculations, so we will omit them here and proceed with discussions.

In the MOESP method, the expanded observability matrix **Θ** is estimated by using an Eq. (3), and the system matrix **A** and **C** are calculated. First, using the input and output data to execute the LQ decomposition shown in the following equation composed of the block Hankel matrix defined in Eqs. (4) and (5). The Eq. (8) is the LQ decomposition that can be placed in the Ordinary MOESP method is represented.

$$\begin{bmatrix} \mathbf{U}_f \\ \mathbf{Y}_f \end{bmatrix} = \begin{bmatrix} \mathbf{L}_{11} & \mathbf{0} \\ \mathbf{L}_{21} & \mathbf{L}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{Q}_1^T \\ \mathbf{Q}_2^T \end{bmatrix}. \qquad (8)$$

The block matrix $\mathbf{L}_{22}$ obtained by Eq. (8) is applied singular value decomposition as shown in Eq. (9). The block matrix $\mathbf{U}_1\mathbf{\Sigma}_1^{1/2}$ is an estimated value of the expanded observability matrix **Θ**.

$$\mathbf{L}_{22} = \begin{bmatrix} \mathbf{U}_1 & \mathbf{U}_2 \end{bmatrix} \begin{bmatrix} \mathbf{\Sigma}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{\Sigma}_2 \end{bmatrix} \begin{bmatrix} \mathbf{V}_1^{\mathrm{T}} \\ \mathbf{V}_2^{\mathrm{T}} \end{bmatrix} \approx \mathbf{U}_1\mathbf{\Sigma}_1\mathbf{V}_1^{\mathrm{T}} \qquad (9)$$

The system matrix **A** is calculated from the expanded observability matrix **Θ**. The natural frequency f_j ($j = 1 \sim n$) and damping ratio h_j ($j = 1 \sim n$) are calculated using the eigenvalue λ_j of the system matrix **A**.

$$f_j = \frac{\left|\ln \lambda_j\right|}{2\pi\Delta t}, \quad h_j = -\frac{\ln\left|\lambda_j\right|}{\left|\ln \lambda_j\right|} \qquad (10\text{-}1,\ 2)$$

2.2 SETTING CALCULATION CONDITION

In the Ordinary MOESP method, it is necessary to adjust the system number *N* and the number of lines *r* of the block Hankel matrix. In Previous research [2], we find the two indicators shown in the following equations can accurately determine the system number *N* and the number of lines *r* in each time section.

$${}_1e_i = \frac{\sqrt{\left(\sum_{i=1}^{n} \sigma_i^{\,2}\right)^{\frac{1}{2}}}}{\left(\sum_{i=1}^{rl} \sigma_i^{\,2}\right)^{\frac{1}{2}}} \times 100 \qquad (11)$$

$${}_2e_i = \sqrt{\frac{\sum_{i=1}^{N_k} \left({}_rZ_i - {}_{ave}Z_i\right)^2}{N_k}} \qquad (12)$$

Where N_k means the total number of time intervals when the input and output data are divided into multiple intervals on the time axis, and ${}_rZ_i$ is the frequency and damping ratio which identified in time interval *i*. ${}_{ave}Z_i$ represents the average value of all block rows of frequencies and/or damping ratio identified in time interval *i*.

As a result of the preliminary examination, it was determined that appropriate calculation results could be obtained for values exceeding 98% of the index ${}_1e_i$ in each time interval. In addition, since it is necessary to secure a

https://doi.org/10.52202/069179-0306

sufficient number of Hankel rows in order to ensure the accuracy of identification, the upper limit was set to the number of Hankel rows.

In accordance with the above-mentioned identification method, dynamic characteristics can be calculated by using earthquake observation. To investigate the time dependent changes in these characteristics, the observed time history is split into 4 s, and a half of this dividing time is processed for each computation.

3 SEISMIC PERFORMANCE OF WOODEN TEMPLE EVALUATED BY EARTHQUAKE OBSERVATION

3.1 SEISMIC OBSERBATION FOR REINFORCED WOODEN TEMPLE

The target building is a wooden one-story temple the roof is copper tiled, the height of the building is about 9.5 m, the plane is about 14 m × 19 m. The timber, that constructs the main frame, is almost entirely Japanese pine, and parts of the columns are composed of zelkova serrate. The primary structural frame is made with post and beam construction. The main aseismic elements of the vertical plane include traditional mud walls and hanging walls finished with ordinary plaster, and the building was seismically retrofitted in 2013 through 2014 by adding to Plywood. the outline is shown in the Fig. 2. As shown in the Fig. 2, accelerometers are installed at 7 locations in the temple for seismic observation. These are the same as the seismometer arrangement before reinforcement reported in the previous study [3].

Acceleration data from 2012 to 2019 can be obtained. All sensors were able to measure to a limit 1500 cm/s (resolution: 0.01 cm/s) at intervals of 0.01 s, and to record acceleration in three directions. Sensors 1 and 2 observed input motions; the other sensors, located on girders on the roof frame, observed the seismic responses of this target building.

As system identification, the assumed characteristics include that the orthogonal directions, which means the X- and Y-directions shown in Fig. 2, affect each other, therefore cannot be operated independently in each direction. In this paper, the following results are computed for a two input (the records of X- and Y- directions by Sensor-2) and ten output (the records of X- and Y-directions by Sensors 3~7) system. Sensor 1 is not used in this study because Sensor 2 can represent the feature of input motion by previous research [3].

3.2 THE EARTHQUSKE OBSERVATION

Many observational results were obtained during the period from 2012 to 2019, including the issue of trigger settings. In this study, observation records were selected on the condition that PGA in at least one of the two horizontal directions exceeded 10 gal. 44 seismic observation records satisfy these conditions, and the system identification results for these are shown below.

For reference, the observed waveforms in the X and Y directions on July 17, 2016, when the maximum PGA was recorded, are shown in Fig. 3, and the response spectrum obtained from them is shown in Fig. 4.

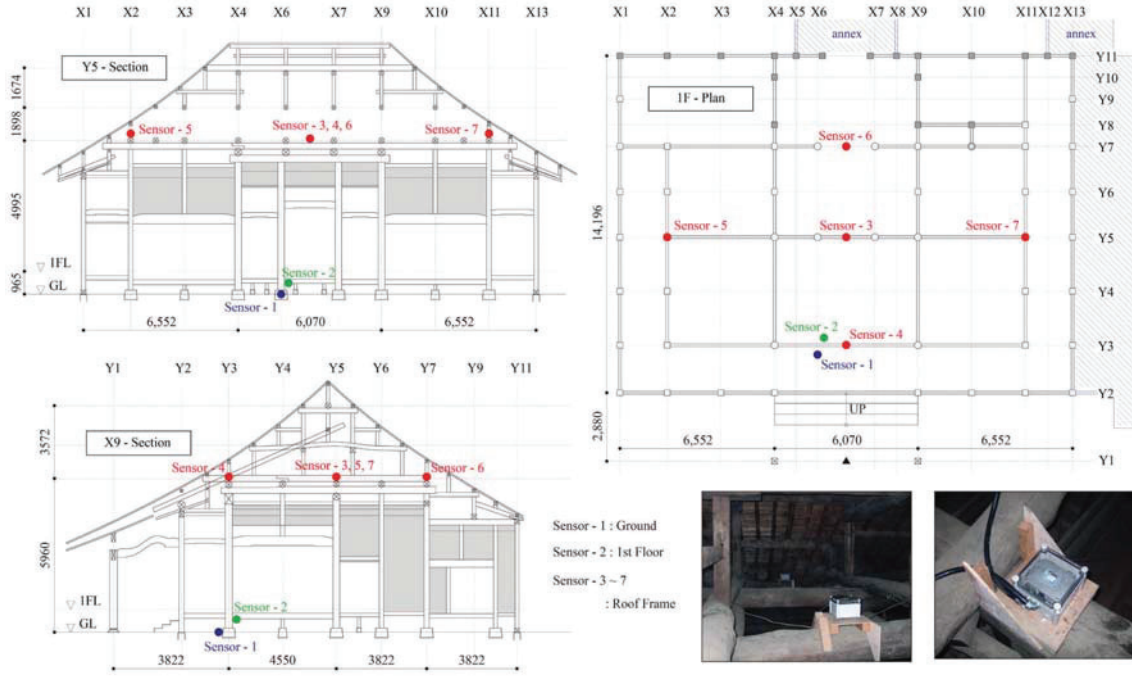

***Figure 2**: Outline of the measuring points on the earthquake observation* [3]

https://doi.org/10.52202/069179-0306

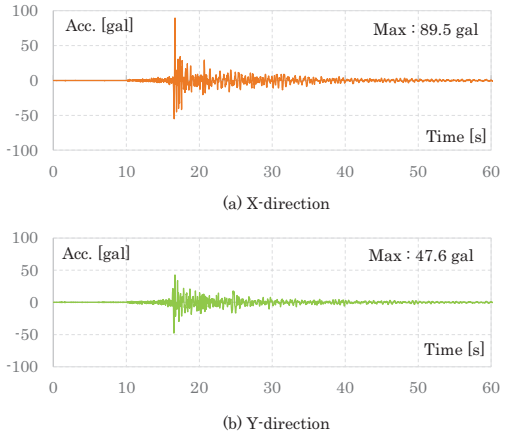

***Figure 3**: Acceleration time history (17th, July, 2016)*

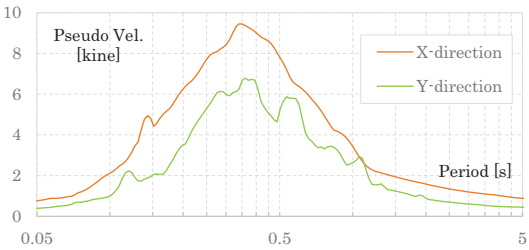

***Figure 4**: Pseudo velocity response spectrum (17th, July, 2016)*

As can be seen in Fig. 3, there is no standard definition of earthquake duration. In this paper, using the effective duration evaluated by the following equation [4] as a measure, we cut off the calculation target interval from each observation record. In addition, in order to remove high-frequency noise that can also be seen in the waveform of Fig. 3, processing was performed using 0.5 through10 Hz bandpass filter.

$$a(t) = \frac{\int_0^{t_0} \ddot{z}^2(t)\,dt}{\int_0^{t} \ddot{z}^2(t)\,dt}$$

Where $a(t)$ means the time history with no dimension of acceleration power, $\ddot{z}$ (t) denotes the acceleration of ground motion, t_0 denotes target time. When $a(t)$ is in the range of

$$0.01 \le a(t) \le 0.95\,,$$

the duration of earthquake is verified the efficiency in this research.

The Fourier spectrum shown in Fig. 4 indicates that the dominant frequency recorded in this earthquake is approximately 3 Hz. Most of the observation records investigated in this study are intraplate earthquakes, which, like this record, are dominated by relatively short periods of 1Hz or more. We add that the target temple also responds clearly to these seismic motions, since it also has a relatively short period.

3.3 UNDERSTANDING THE EFFECT OF NONLINEARLITY

As a result of system identification, Fig. 5 shows the change over time of the natural frequency and story drift for the earthquake that recorded the maximum ground acceleration in the observation record, which discusses Fig. 3 and 4. The story drift is calculated by integration of the acceleration data recorder by Sensor-2 and 3 on each direction.

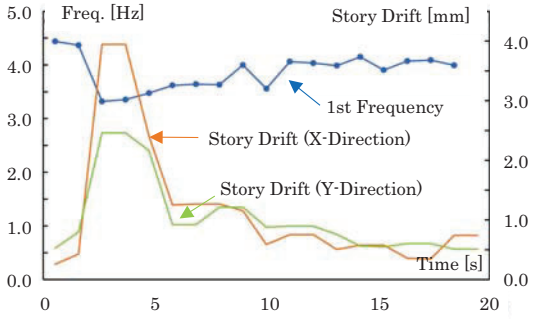

***Figure 5**: Changes in natural frequency and story drift over time estimated by the records on 17th, July, 2016*

Fig. 5 shows that the natural frequency is about 1 Hz as the story drift increases. This is considered to be the result of the nonlinearity of the strain-dependent of a timber structure. In addition, comparing the natural frequency before and after the earthquake, it is also suggested that a decrease of about 0.5 Hz has been observed, causing damage.

In order to confirm the change in vibration properties due to nonlinearity, comparing the vibration mode for each range of story drift corresponding to the identification results shown in Fig. 5. Fig. 6. shows a result comparing the vibration mode of each deformation range. The figure is created by standardizing the maximum value to 1.0 among the eigenvalue mode in each measurement position, and also taking into account the phase difference of each channels.

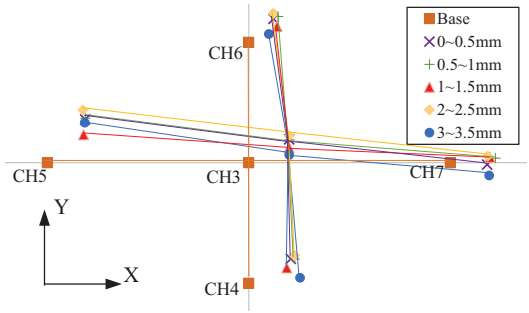

***Figure 6**: Comparison of vibration mode due to difference of story drift estimated by the records on 17th, July, 2016*

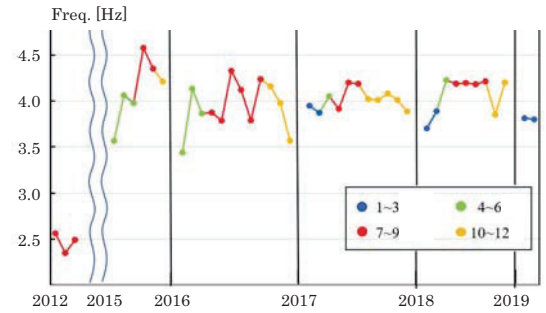
All vibration mode is not the same, but no significant difference is observed as shown in Fig. 6. From the above-mentioned results, it is presumed that the vibration properties itself do not change significantly even if the natural frequency due to nonlinearity is reduced.

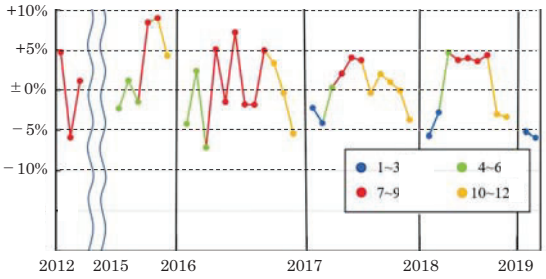
https://doi.org/10.52202/069179-0306

3.4 INVESTIGATING THE TREND FOR LONG OBSERVSTION PERIOD

Following the discussion of short-term natural frequency changes in the same earthquake described above, only long-term changes are investigated. Fig. 7 shows the average values obtained from the identification results of each observation record, arranged in order by observation period. In this figure, the seasons are color-coded.



(a) Long-term change of the natural frequency



(b) the range of changing caused by seasons

***Figure 7**: Changes in natural frequency for Long-period*

From Fig. 7 (a), it can be confirmed that the natural frequency is greatly improved by the seismic reinforcement, and also can be seen that there is a certain amount of periodic variation in each season. In order to clarify the range of seasonal fluctuations, the Fig. 7 (b) shows the results standardized by the average value for before and after seismic retrofit respectively. From this result, it can be seen that the seasonal variation is about 10 % for the natural frequency, and about 20 % for the stiffness assuming that the mass is the same.

4 ANALYSIS OF LONG-TERM STRUCTURAL PERFORMANCE

4.1 CHANGES IN VIBRATION CHARACTERISTICS DUE TO THE SURROUNDING ENVIRONMENT

We investigate the factors that affect the change in the natural frequency of traditional wooden buildings. Fig. 8 shows a comparison between the outside temperature at the location of the target temple, where is Kasukabe-city, Saitama prefecture (near Tokyo), and the natural frequency for each seismic response of story drift. The temperature is the average of the day published by the Japan Meteorological Agency [5]. In the same figure, symbols are displayed separately for each story drift, and the reasons that the multiple results are plotted on the same horizontal axis, is given multiple identification results as the same event as shown in Fig. 5. In addition, the horizontal axis does not show the real time, but the events that occurred in the year are arranged in order of occurrence.

From Fig. 8, it can be seen that the natural frequency decreases as story drift increases, as in the previous result. First, in order to understand the overall trend, focusing on the results of deformation of 0.5 mm or less, which is the most identified result as the equivalent deformation range,

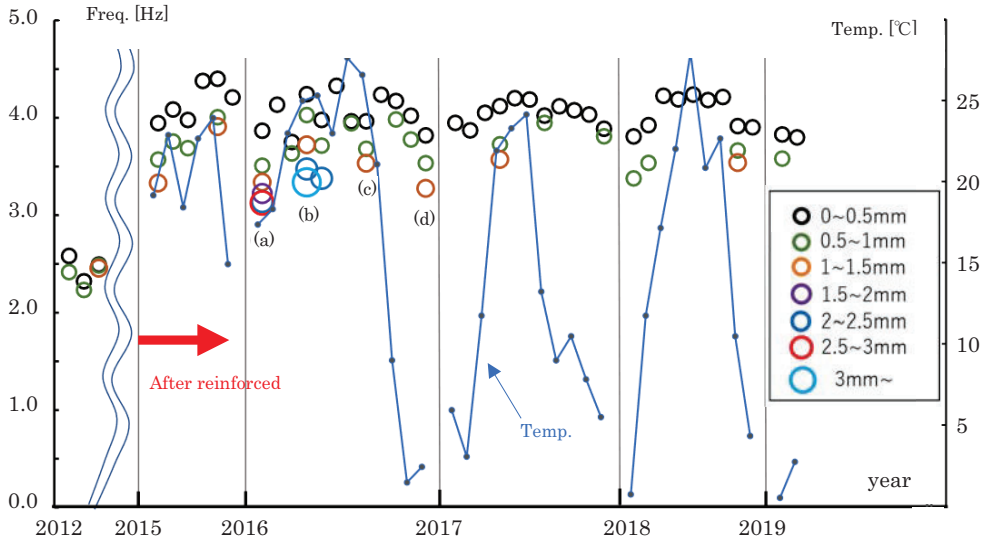


***Figure 8**: Changes in natural frequency for each story drift due to seasonal changes*

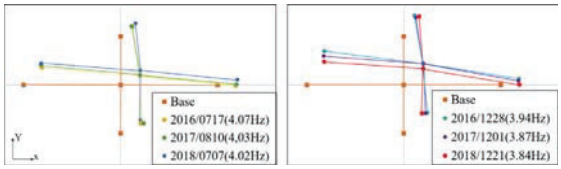
https://doi.org/10.52202/069179-0306

it can be seen that the natural frequency has been gradually decreasing since 2015 after the seismic reinforcement. There are two possible reasons. One is the accumulation of damage caused by earthquakes, and the other is the viscoelastic property of wood. The former was also confirmed in the results of Fig. 5, suggesting that there are factors that accumulate in addition to changes in the natural frequency due to nonlinearity. The latter does not even have method to assess its impact. Although there is a possibility that the result was obtained because it was a traditional wooden building where the properties of wood are likely to appear, it is considered to be a problem that can occur in all timber structures.

Next, focusing on the correspondence between the temperature and the natural frequency of the surrounding environment, it can be seen that the natural frequency clearly increases as the temperature increases, and conversely, the natural frequency decreases as the temperature decreases. It is understood the reason that the wood swelled due to the increase in the amount of moisture in the air accompanying the temperature rise, and conversely, the wood contracted due to drying accompanying the temperature drop. The effect is relatively large, because it can be evaluated that the change corresponding to the decrease in the natural frequency for about five years, which discussed above, is repeated in one year.

Finally, in order to confirm the changes in the vibration properties accompanying these changes in the natural frequency, Fig. 9 shows the comparison results of the eigenmodes for the same seasons during three years from 2016, and Fig. 10 shows the comparison results of the eigenmodes identified for the events (a) to (d) appended to Fig. 8, which means the changes occurring over the course of one year. From the results shown in both figures, it is verified that even if some factors change the natural frequency, there is no significant effect on the vibration characteristics. This view is based on various pre-conditions such as the appropriateness of the arrangement of seismic elements, but it is an important property confirmed in this study.



(a) Hot seasons *(b) Cold seasons*

***Figure 9**: Comparison of vibration mode in hot and cold seasons*

5 CONCLUSIONS

In this paper, the subspace method is applied to the observation records of traditional wooden buildings, and the transition of natural frequency over time is verified along with the changes in the environment. The findings are summarized as follows.

- The natural frequency changed as the temperature up and down, suggesting the effect of swell and shrink of the wood composed the target temple.
- It was confirmed that even if the natural frequency changes depending on the surrounding environment, there is no significant difference in the vibration characteristics.
- In the small deformation range about less 3 mm, the variation in the natural frequency may have the same effect as the nonlinearity due to the large and small response.

ACKNOWLEDGEMENT

We would like to our sincere gratitude toward the chief priest of Jyou - syun - in, Seihou Ishida and sub-chief, Ri-gyou Ishida for their help during this earthquake observation; and former assist. prof. Takenori Hida, Tokyo Univ. of science, for advice about system identification. A part of this study was carried out under support by Junichiro Hara and Naoki Tomiyama, former graduate students, to compute identification results and to organize the data.

GLUED-LAMINATED TIMBER BEAMS WITH LARGE ROUND HOLES: AN EXPERIMENTAL AND NUMERICAL INVESTIGATION

Francesco Mirko Massaro[1], Kjell Arne Malo[2]

ABSTRACT: Timber beams are oftentimes used as joists in timber floors. Especially for small timber buildings like two-story housing for single or few families, it may be necessary to let service pipes pass through the joists to avoid a reduction of the story height. Therefore, there is a need to have large holes in the timber joists, which under the current local guidelines and the future European regulations, leads to the use of timber beams of significant height. In this study, the capacity of glued-laminated timber beams with large round holes is evaluated. The paper presents results from novel experiments performed on beams with round holes positioned in two different configurations. The holes are considered as large, i.e. the diameter of the holes is 50% of the timber beam height or larger. The objectives are, in addition to the experimental investigations, to establish a numerical simulation approach of these experiments which can be used to future studies of possible solutions to the challenge of large holes in timber joists. For comparison, an analytical evaluation of the beams capacity in accordance with the future European regulations is added.

KEYWORDS: timber beams, large holes, glulam, numerical modelling, cohesive zone

1 INTRODUCTION

Timber is one of the most used structural materials because of its excellent mechanical properties. Moreover, due to its advantage of being environmental friendly, there has been a renewed interest in its usage. In the recent years, examples of buildings such as Treet and Mjøstårnet, both in Norway, have shown that timber can be a good material choice also for high-rise structures [1, 2]. However, for the Nordic timber industry the use of timber in houses for single and few families is still more important. The flooring in these smaller building consists usually of traditional joisted floors with simple solutions for ceiling and decking of the floors, as acoustic properties are of little relevance within single apartments. In these buildings, it is preferable to let pipes, used by e.g. water, heating, or ventilation systems, pass through beams in the floors to reduce the height of the building. The design criteria for these types of floors are usually deformations and vibrations, and one or two large holes in the beams, larger than half of the height, do not increase the deformation significantly, as the portion of the beams having reduced bending stiffness will be very small. Nevertheless, it is a very cheap improvement to reduce the spacing of the beams, in areas where the beams have large holes, to compensate for the reduction in stiffness and strength. Therefore, the presence of large holes for pipes in timber beams is very beneficial and leads to effective building systems without unnecessary use of material and space. The presence of holes generates concentrations of shear and tensile stresses orthogonal to grain in proximity of the hole. The exact location of the stress concentrations depends on the acting forces on the member, i.e. on the ratio between the bending moment M and the shear force V in the hole section (see Figure 1).

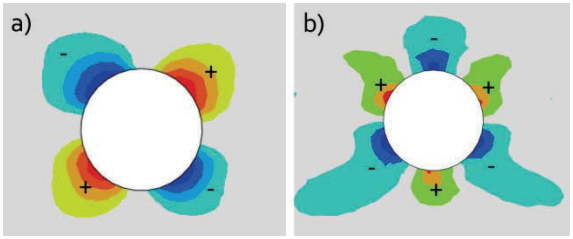

Figure 1: *Stress concentration around circular holes: a) dominant shear (M/V=1h where h is the beam height), b) pure bending (M/V=∞). The symbols + and – indicate tension and compression, respectively.*

Aicher and Höfflin [3] have studied the location of the stress concentrations around a circular hole in a beam subjected to various loading modes, concluding that at approximately 45° from the center of the hole, stress concentrations occur at the edge of the hole.
The strength of timber in tension perpendicular to grain is relatively small and therefore the stress concentrations lead to a reduction of the capacity of the timber element. Consequently, the design of timber members with holes is challenging. Indeed, Eurocode 5 [4] still does not include any normative rule about the presence of holes in timber beams. Nonetheless, there exist national regulations, such as the German National Annex to Eurocode 5 [5], or local guidelines [6] that provide an indication on the maximum hole size. An overview on recent developments on design guidelines can be found in Tapia and Aicher [7].

[1] Francesco Mirko Massaro, NTNU Norwegian University of Science and Technology, Norway, francemm@ntnu.no
[2] Kjell Arne Malo, NTNU Norwegian University of Science and Technology, Norway

https://doi.org/10.52202/069179-0307

Moreover, the future generation of Eurocode 5 will include normative rules, based on Danzer et al. [8], about the design of timber members with holes, although the diameter of the hole, *d*, will be limited to 30% of the timber beam height, *h*, if unreinforced [9]. For joisted floors in small wooden houses, the height of the joists is in the range of 220 mm to 300 mm. Typical water pipes in buildings can have diameter of about 160 mm and thus the limitation on the ratio *d*/*h* increases the necessary beam height significantly with the presence of a hole.

Numerous experiments have been performed on glued-laminated timber beams with round holes over the time, i.a. Johannesson [10], Höfflin [11], Aicher and Höfflin [12], Danzer et al. [13]. However, in these studies the diameter of the holes was always smaller than 50% of the beam height.

Several methods were proposed to analyze the failure load of timber beams with holes, such as i.a. models based on linear elastic fracture mechanics (LEFM) [14], Weibull based models [15, 16], cohesive zone models (CZM) [17]. The use of numerical models with cohesive elements has provided good accuracy in the evaluation of the failure load of timber structural elements, such as for laminate veneer lumber (LVL) beams with round holes [18] and glulam beams with rectangular holes [19].

The main objectives of the present study are to evaluate the experimental capacity and a numerical model of glued-laminated timber beams with large round holes. In this study, a hole is defined as large by having a diameter larger than 50% of the beam height. Thus, novel experiments on timber beams with large round holes were performed. The experimental results were then used to validate the numerical model using cohesive elements with definition of a traction-separation law. Finally, an analytical evaluation of the failure load of timber beams with large round holes, based on the latest draft of the new generation of Eurocode 5, is provided.

2 MATERIAL AND METHODS

2.1 EXPERIMENTS

The experimental investigation was carried out on glued-laminated beams with large holes at the Norwegian University of Science and Technology, Trondheim. The experiments were conducted on K-beams made of Norway Spruce (Picea abies). The K-beams, manufactured by Inntre Kjeldstad AS, are not covered by the EN 14080:2013 standard [20], and therefore they have their own technical approval [21]. Their inner lamellae, classified as LT20 according to the INSTA 142:2009 standard [22], are 17 or 19 mm thick, while the two outermost lamellae are 47 mm thick and are classified as C24 according to the EN 338:2016 standard [23].

Sixty-nine tests were conducted on beams with dimension 36×300×4200 mm^3. Sixty of the tested beams have a hole of 150 to 170 mm diameter, which corresponds to 50 to 56.7% of the beam height. The series name reflects the position and the diameter of the hole: M indicates that the hole is located in a moment-dominated zone, while V indicates that the hole is located in a shear-dominated zone. Moreover, an additional series of nine experiments on K-beams without holes was performed and it is denominated with the letter K. An overview of the performed experiments is given in Table 1 and the geometrical properties are explained in Figure 2.

***Table 1**: Summary of the performed experiments*

Series name	n. of tests	*d* [mm]	l_V [mm]	l_A [mm]	l_L [mm]
M170	9	170	1630	1530	300
V170	10	170	700	600	1230
M160	11	160	1640	1540	300
V160	10	160	700	600	1240
M150	10	150	1650	1550	300
V150	10	150	700	600	1250
K	9	-	-	-	-

The beams were tested with a 3-point bending configuration (see Figure 2), with the supports centered at 100 mm from the beam ends. Prior to testing, the glulam beams were located in a room with the constant climate of 20 °C of temperature and 65% relative humidity (RH) of the air for the time necessary to reach a moisture content (MC) of approximately 12% in the beams.

The load was applied by means of a hydraulic actuator and it was distributed over an aluminum U-profile 140 mm long and 4 mm thick, to avoid local compression deformation (see Figure 2). Moreover, the load was continuously recorded by the test machine together with the displacement of the actuator.

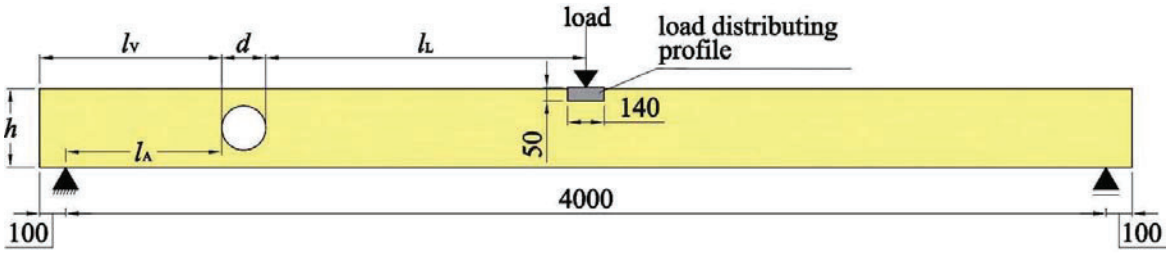

***Figure 2:** Test setup with location of the hole and the load.*

https://doi.org/10.52202/069179-0307

The tests were conducted in displacement control and performed in agreement with the standard EN 380:1993 [24] for the determination of the load at failure. After an initial loading/unloading cycle with the force cycling between ca. 1 and 2 kN, the displacement is increased and then kept constant in order to reach and maintain a loading force of ca. 3 kN. Finally, the displacement is further increased until the failure of the beam is obtained.

2.2 NUMERICAL SIMULATIONS

A numerical model to simulate the behavior of the glulam beams was developed in the FEM software program Abaqus [25].

Timber can be considered as an orthotropic material. However, in the two transversal directions the same material properties were used. Nevertheless, it should be noted that the shear moduli are independent from the normal moduli and thus the material was modeled differently from transversally isotropic. The normal moduli E_x, E_y, E_z and the shear moduli G_{xy}, G_{xz} are chosen according to the K-beams technical approval [21], while G_{yz} as 1/10 of the other shear moduli, and the Poisson's ratios are selected based on Dahl [26] and Massaro et al. [27]. The elastic material properties used in the numerical model are given in Table 2, where the subscript "x" indicates the grain direction. The coordinate system is depicted in Figure 3.

The geometry of the model resembles the geometry of the tested beams, i.e. the model consists of a beam, 4200 mm long and cross-section of 36×300 mm^2. The beam has a hole located according to the geometry given in Table 1 and illustrated in Figure 2.

The beam movements in the y-direction are on the supports on the bottom beam surface, centered at 100 mm from the ends of the beam as displayed in Figure 3b, resembling the experimental supports. The beam is loaded by applying a displacement on a 36×140 mm^2 surface on the middle of the beam top surface, i.e. in the xz-plane (Figure 3a). The loading surface resembles the load distributing area of the experimental configurations.

The behavior in compression parallel to grain is considered to be elastic-perfectly plastic, with elastic limit $f_{c,0}$ (see Table 2). Moreover, the location of the highest transversal tensile stresses around the hole, as determined with an elastic analysis for each configuration, is at the hole edge in a plane at approximatively 40° - 60° from the center of the hole. In correspondence of the highest transversal stress, cohesive layers (layers A and B in Figure 3a), crossing the entire length of the beam, were then introduced in the model. An additional cohesive layer (layer C) is located vertically under the hole, as this area may be subjected to high tensile stress parallel to grain due to bending (see Figure 3a).

A cohesive layer requires the definition of a traction-separation law, i.e. stiffness properties, a damage initiation criterion and a damage evolution phase. The traction-separation law used in this model is a bilinear law, with an initial elastic phase succeeded by a linear softening which starts when the chosen damage initiation criterion is fulfilled (see Figure 4).

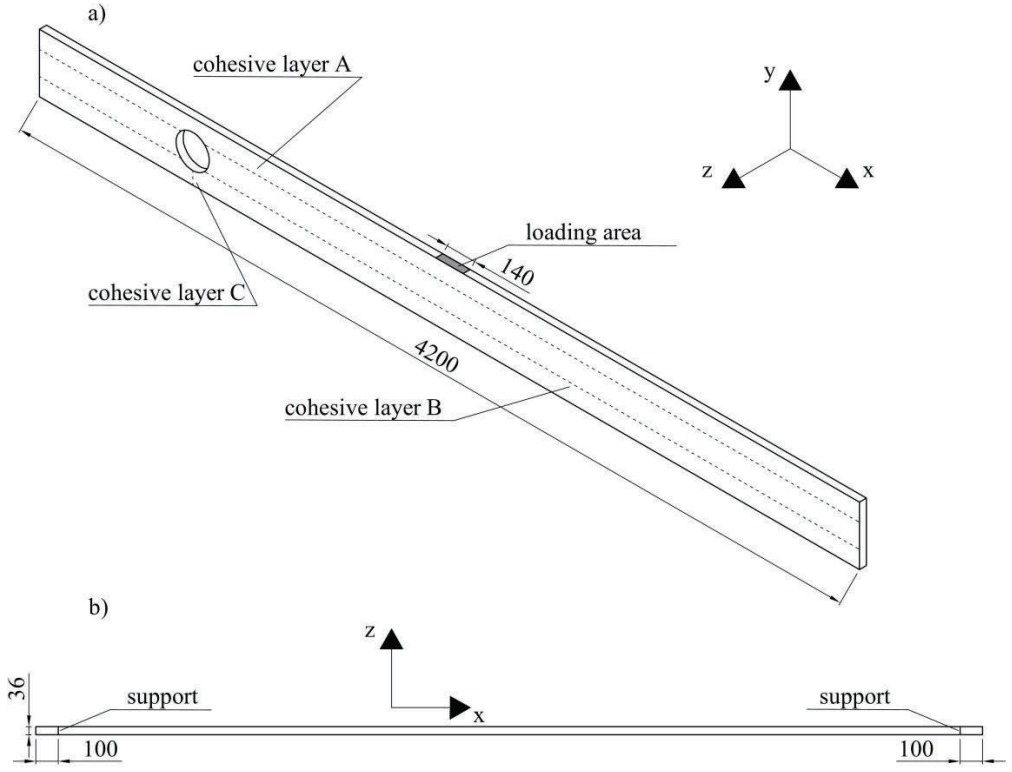

Figure 3: *Geometry of numerical model: a) isometric view and location of the cohesive layers, b) bottom plan view*

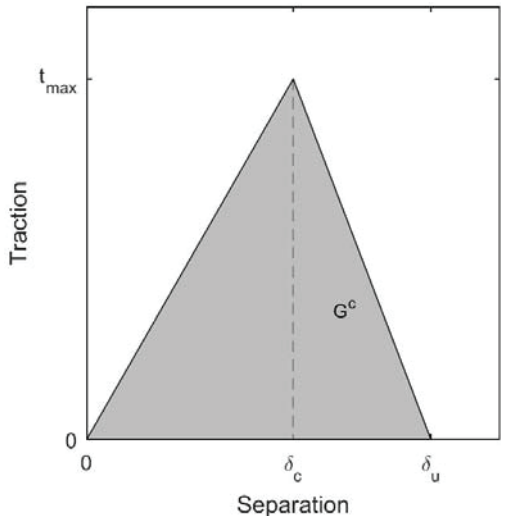

Figure 4: *Traction-separation law*

The elastic stiffness values of the cohesive layers are equal to the stiffness values used for the timber parts. As damage initiation criterion, the maximum stress criterion has been used, i.e. the damage starts when either the tensile stress orthogonal to the cohesive layer or the shear stress in the layer reaches the maximum allowed value. The criterion is expressed as in Equation (1), where t_n, t_s, t_t represent the normal and the two shear tractions, respectively. Note that the angular brackets specify that t_n is a tension stress and can thus only be positive. The subscript max indicates the elastic limit stress in the specific direction. These limit values are chosen as the mean values of the respective strengths.

$$\max\left\{\frac{\langle t_n\rangle}{t_{n\max}};\frac{t_s}{t_{s\max}};\frac{t_t}{t_{t\max}}\right\}=1 \qquad (1)$$

The mean values for shear and tension parallel to grain strength have been obtained from the results of the experiments performed by Treteknisk [28-30] on the K-beams. On the other hand, the tension orthogonal to grain mean strength has been assumed based on Dahl [26] and Massaro et al. [27], while the compression parallel to grain mean strength was based on the K-beams Technical Approval [21, 31].

The damage evolution phase in the layers A and B is controlled by the energy method with linear softening [18, 32]. The critical values of the fracture energy for the opening mode (mode I) and shearing mode (mode II) are chosen as the average of the values reported by Ostapska [33] and Ostapska and Malo [34]. Furthermore, the mixed mode, usually relevant in beams with holes, is here described by Wu's criterion [35, 36] presented in Equation (2).

$$\left(\frac{G_I}{G_{Ic}}\right)^{0.5}+\frac{G_{II}}{G_{IIc}}=1 \qquad (2)$$

In Equation (2), G_I and G_{II} represent the fracture energies for mode I and mode II, respectively, while G_{Ic} and G_{IIc} denote the respective critical values.

The material properties of wood and of the cohesive layers are summarized and given in Table 2.

Table 2: *Material properties of wood and of the cohesive layers used in numerical simulations*

Elastic properties of wood	Normal moduli	E_x	11000 MPa	[21]
		$E_y \equiv E_z$	370 MPa	
	Shear moduli	$G_{xy} \equiv G_{xz}$	690 MPa	
		G_{yz}	69 MPa	[20]
	Poisson's ratios	ν_{xy}	0.5	[26, 27]
		ν_{xz}	0.6	
		ν_{yz}	0.6	
Mean strengths	Tension orthogonal to grain	$f_{t,90}$	2 MPa	[26, 27]
	Tension parallel to grain	$f_{t,0}$	40 MPa	[29, 30]
	Shear	f_v	4 MPa	[28]
	Compression parallel to grain	$f_{c,0}$	26 MPa	[21, 31]
Fracture energies (layers A and B)	Mode I	G_{Ic}	0.24 N/mm	[33, 34]
	Mode II	G_{IIc}	0.79 N/mm	[33]

The elements in the cohesive layer C followed a different damage evolution since they have to represent tensile failure parallel to grain. These elements, if the damage initiation criterion is satisfied, immediately lose their stiffness. This is obtained by imposing $\delta_u \cong \delta_c$ as their damage evolution law (see Figure 4).

Eight-node three-dimensional elements were used in the model: C3D8 (i.e. full integration) for the wooden material and COH3D8 for the cohesive layers with viscous parameter chosen equal to 10^{-3} [18]. Note that the viscous parameter is only necessary to ensure convergence of the analysis and does not have physical meaning. After a sensitivity mesh study, the mesh size has been chosen equal to 20 mm for the timber parts, and equal to 5 mm for the cohesive layers, thus in agreement with Abaqus guidelines [25].

https://doi.org/10.52202/069179-0307

3 RESULTS AND DISCUSSION

3.1 EXPERIMENTAL RESULTS

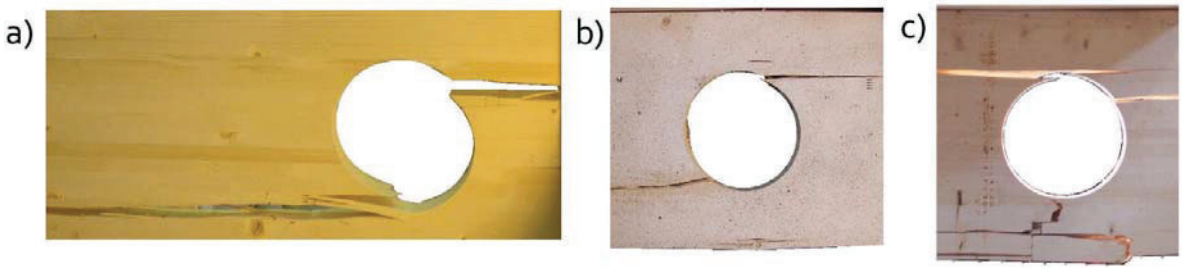

***Figure 5**: Examples of beams at failure: a) Test V170-5; b) Test M150-1; c) Test M150-4*

Figure 5 shows typical examples of beam failure. The cracks were usually initiating either at the top right or at the bottom left of the hole circumference, and then they propagated from there, usually until the beam ends. It should be noted that some beams of the M-series presented additional cracks on the bottom chord of the beam (see e.g. Figure 5c), likely due to bending stresses and thus tension parallel to grain. The failure load F_f, i.e. the maximum load reached in an experimental test, for each tested beam is given in Figure 6, together with the mean value of the series.

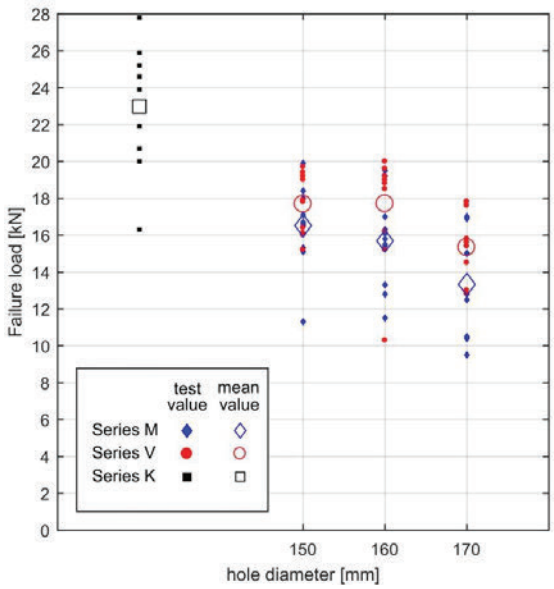

***Figure 6:** Experimental failure loads.*

In Figures 7 and 8, the red dashed lines depict a typical representative outcome of the results of the conducted investigation, described in Chapter 2.1, for the series with the largest holes, i.e. M170 and V170, respectively. The response is given by loading force vs. displacement.

The results show, after the initial loading/unloading phase, a linear increase of the loading force with respect to the deformation applied in agreement with loading procedure described in Chapter 2.1. By increasing the load, the first crack appeared and it gradually spread over the whole beam thickness. Thus, the corresponding load is defined as cracking load (F_{cr}). Afterwards, the crack propagated and new cracks were formed, until a sudden drop in the force occurs corresponding to failure. In some cases, especially in the M-series, the loading force increased again after the first drop, probably because of the presence of knots and finger joints or fiber bridging, but it was followed again by further sudden drops in the force, thus reaching failure.

The distribution of the failure load may be considered lognormal [37]. Thus, the mean and characteristic values of the measured cracking loads, $F_{cr,mean}$ and $F_{cr,k}$ respectively, and failure loads, $F_{f,mean}$ and $F_{f,k}$ respectively, were then determined according to EN14358. The values are reported in Table 3.

***Table 3:** Experimental results: mean and characteristic values. (Values in kN. Coefficient of variation in parentheses.)*

Series	$F_{cr,mean}$	$F_{cr,k}$	$F_{f,mean}$	$F_{f,k}$
M170	11.03 (0.323)	5.37	13.33 (0.220)	8.20
V170	12.70 (0.094)	10.41	15.33 (0.134)	11.50
M160	13.02 (0.169)	9.05	15.69 (0.162)	11.12
V160	15.56 (0.559)	4.35	17.70 (0.206)	11.34
M150	12.70 (0.286)	6.62	16.52 (0.154)	11.85
V150	13.44 (0.221)	8.14	17.68 (0.094)	14.46
K	-	-	22.97 (0.165)	16.00

The results in Table 3 and Figure 6 show that the failure load of the M-series is lower than in the V-series, arguably due to high tensile stress parallel to grain under the hole, in addition to the stress concentrations around the hole. Indeed, the reduction of the mean failure load, from the

reference value for beams without holes (i.e. K-series), ranges between 23% and 33% for the V-series, while for the M-series it ranges between 28% and 42%. The difference between the failure load of the M-series and the V-series is in the order of 2 kN. Moreover, the V-series seems to be less affected than the M-series by the presence of larger holes. Indeed, increasing the diameter of the hole from 150 mm to 170 mm, i.e. from $d/h = 0.5$ to $d/h = 0.57$, the beams of the M-series observe a reduction of the failure load of about 19%, while the reduction is lower for the V-series beams, i.e. approximately 13%.

3.2 NUMERICAL RESULTS

The numerical simulations of the timber beams were performed with the parameters given in Chapter 2.2, and their results are given in Table 4. Additionally, in Table 4, the mean experimental capacity of each configuration, $F_{f,mean}$, and the relative difference with the numerical results are given, showing that the model is in good agreement with the test results and can evaluate the failure load with good accuracy.

Furthermore, the results of the simulations for the M170 and V170 configurations are given in Figures 7 and 8, respectively, in terms of force vs. displacement curves and compared with the experimental results. The force is the load applied in the model, and the deflection is the displacement measured at mid-span. In Figures 7 and 8, the dash-dotted lines represent the experimental results while the continuous lines represent the results obtained from the simulations. Additionally, in the plots the mean failure load obtained from the experiments is depicted with a horizontal dash-dotted line.
The curves in Figures 7 and 8 show good agreement between the experimental and the numerical results. Nevertheless, the stiffness of the simulated beams is slightly higher than in the experiments. The deflection in the experimental investigation is the measured movement of the loading actuator. Thus, the deflection is affected from the flexibility of the test rig, leading to a measured value slightly larger than in the idealized numerical model.

Table 4: *Comparison between numerical and experimental results*

Series	$F_{f,num}$ [kN]	$F_{f,mean}$ [kN]	Relative difference
M170	14.08	13.33	5.6%
V170	15.53	15.33	1.3%
M160	14.81	15.69	5.6%
V160	16.63	17.70	6.0%
M150	15.59	16.52	5.6%
V150	17.69	17.68	0.1%

3.3 COMPARISON WITH REGULATIONS

The new generation of Eurocode 5 [9] includes normative regulations for the evaluation of timber member with holes. However, the diameter of the hole is limited to 30% of the beam height in case of unreinforced holes [9]. Herein, the Eurocode equations are however applied for holes with diameter larger than the limit. According to the new draft of Eurocode 5, the characteristic capacity F_k of a timber beam resembling load conditions and geometry of the tested beams is evaluated by taking into account the three conditions expressed in Equations (3), (4) and (5).

https://doi.org/10.52202/069179-0307

$$F_k = \frac{b \cdot \left(\frac{4 \cdot V_{\text{ref}}}{b \cdot d^2}\right)^{0.2}}{\frac{7}{52 \cdot h} \cdot \left[3 - \left(0.7 \cdot \frac{d}{h}\right)^2\right] \cdot \left[1.1 + 1.3 \cdot \frac{d}{h} - 1.3 \cdot \left(\frac{d}{h}\right)^2\right] + \frac{0.9 \cdot (l_A + d)}{8 \cdot d \cdot h} \cdot \left(\frac{d}{h}\right)^2} \cdot f_{\text{t,90,k}} \; ; \; V_{\text{ref}} = 0.01 \text{ m}^3 \quad (3)$$

$$F_k = \frac{2 \cdot b \cdot (h^3 - d^3)}{6 \cdot (l_A + d) \cdot h} \cdot f_{\text{m,k}} \quad (4)$$

$$F_k = \frac{2 \cdot b \cdot (h - 0.7 \cdot d)}{1.5 \cdot 1.8 \cdot \left(1 + 0.7 \cdot \frac{d}{h}\right) \cdot \left(\frac{0.7 \cdot d}{h}\right)^{0.2}} \cdot f_{\text{v,k}} \quad (5)$$

Equation (3) limits the capacity due to the tensile stresses perpendicular to grain generated by the transfer of bending and shear stresses around the hole, while Equations (4) and (5) limit the capacity because of the bending stresses and shear stresses generated in the residual cross-section, respectively.

The characteristic values of the strength are chosen according to the Technical Approval for K-beams [21], i.e. the tensile strength perpendicular to grain $f_{\text{t,90,k}}$ is chosen as 0.4 MPa, the bending strength $f_{\text{m,k}}$ as 24 MPa and the shear strength $f_{\text{v,k}}$ as 3.5 MPa. By inserting these strength values and the geometric parameters given in Table 1 into Equations (3), (4) and (5), the characteristic capacity F_k is obtained for all tested configurations.

The results are summarized in Table 5, together with a comparison with the experimental results. Furthermore, it is given the relative difference δ between the experimental results and Eq. (3).

Table 5: *Comparison experimental results vs regulations*

Series	F_k [kN] Eq. (3)	F_k [kN] Eq. (4)	F_k [kN] Eq. (5)	$F_{f,k}$ [kN] (exp.)	δ [%]
M170	9.9	12.5	14.6	8.2	+17.3
V170	12.7	27.5	14.6	11.5	+9.3
M160	10.4	13.0	15.6	11.1	-6.8
V160	13.1	28.9	15.6	11.3	+13.6
M150	10.9	13.5	16.6	11.9	-8.2
V150	13.6	30.2	16.6	14.5	-5.8

It can be noted that also for the Eurocode regulations the critical failure mechanism in the beams is splitting perpendicular to grain starting from the edge of the holes, in accordance with the experiments.

The perpendicular to grain splitting failure mechanism, represented by Equation (3), gives a safe estimation for holes of 150 mm, i.e. $d/h = 0.5$. However, for larger holes, it overestimates the characteristic capacity of the beams up to 17%. Indeed, Equation (3) is only valid up to $d/h = 0.3$ for unreinforced holes, and it may need adjusting in order to consider round holes with large diameters.

4 CONCLUSIONS

The objectives of this study were to experimentally evaluate the capacity of glued-laminated timber beams with large round holes and to validate a numerical model for the description of such beams.

Six series of experiments were performed on glued-laminated beams having a hole of diameter varying between 50% and 56.7% of the beam height, for a total of sixty tests. The series differed in the location of the hole: the M-series exhibited a hole in a moment-dominated cross-section, while the V-series presented it in a shear-dominated cross-section. The experiments showcased that the beams have a mean capacity ranging between 13.3 and 16.5 kN for the M-series, and between 15.3 and 17.7 kN for the V-series, respectively. This resulted in a decrease of the capacity of the beam, with respect to a beam without holes, up to 43% when the hole is positioned in a moment-dominated area. On the other hand, the presence of holes in a shear-dominated area has a lower influence, with a drop of the capacity up to 33%.

A numerical model, which resembled the beams geometry, was utilized to study their capacity and fracture process. The model presents horizontal cohesive layers in the location of the predicted fracture planes. An additional vertical cohesive layer was introduced underneath the hole in order to take into account the possibility of longitudinal tensile failure of the beams. The mechanical parameters of the cohesive layers were either chosen according to experimental investigations performed on the beams (Technical Approval) or relevant literature. The model exhibited an overall good agreement. Indeed, the relative difference of the numerical model does not exceed 6%, thus allowing for a proper evaluation of the failure load. Therefore, the numerical model may be used for further studies on the topic of large round holes in timber joists.

Finally, an analytical evaluation of the characteristic capacity of the beams according to the future European regulations was provided. As expected, the splitting verification was the most restrictive and it provided a fair evaluation of the failure load, especially for 150 mm hole diameter. However, the limitations on the size of holes in beams in joisted floors appear to be restrictive, as the beams having circular holes of about 57% of the height

show a residual strength exceeding 57% relative to a beam without any hole.
Furthermore, for a joisted floor having beams with large hole in an area, the spacing between the beams can be halved and the strength of that area becomes unaltered. However, some precautions should be made to avoid drying cracks starting at the hole. Possible actions are painting the hole surface and screw reinforcement.

ACKNOWLEDGMENTS

The authors would also like to acknowledge Atis Degro, Pål Østen Solberg and Noh Weldeab, for their contribution in performing experimental tests and numerical simulations. Furthermore, the supply of the test beams from Inntre Kjeldstad AS is gratefully acknowledged.

ASSESSMENT OF THE FUNDAMENTAL PERIOD OF MULTI-STOREY CROSS LAMINATED TIMBER BUILDINGS

Ebenezer Ussher[1], Angelo Aloisio[2], Roberto Tomasi[1]

ABSTRACT: Cross laminated timber has entered the building industry as an alternative to reinforced concrete with interest for employing them in buildings in high seismic regions because they are lightweight. It is envisaged simplified methods have limitations in predicting design level demands on CLT systems due to the complexities and challenges associated with the material. The objective of this work is assessing the efficiency of proposed analytical methods in predicting the fundamental period (T_1) of building superstructures made of CLT. This is because T_1 is the basis for the equivalent lateral force method in seismic analysis of buildings. The assessment is conducted by comparing predictions from verified numerical modal models with estimates from available empirical formulas. Suggestions are made for the minimum requirements for assessing CLT buildings under dynamic loads.

KEYWORDS: Analytical formulas, buildings, cross-laminated timber, fundamental period, seismic design

1 INTRODUCTION

Timber has been identified as a renewable and sustainable construction material capable of being part of the solution to the global warming menace [1-3]. This is because carbon dioxide ((CO_2) the primary anthropogenic greenhouse gas, accounting for 78% of the human contribution to the greenhouse effect) can be absorbed and stored by timber and timber-related products in their lifetime [1]. This reflects that engineered wood products (EWP) such as cross laminated timber (CLT) has better green credentials than mineral resourced-based construction products including concrete and steel. Development of Fire Engineering tools in recent times have also been at the forefront in erasing the concerns associated with timber as a combustible construction material in the building industry [4]. This has enabled the adaptation of massive EWP and other timber materials as new structural forms to meet sustainable housing demands and challenges.

CLT construction systems are manufactured with three or more layers of lumber arranged and bonded in an orthogonal manner enhancing its split resistance to in-plane loading. Commercially they are available in thicknesses ranging between < 100mm and about 500mm [5,6]. Developed and used in Europe for nearly two decades CLT construction systems have become popular across the globe for putting up low- to medium-rise buildings. CLT products have high stiffness to mass ratios and have similar load carrying characteristics to reinforced concrete (RC) [6]. These make them suitable for building in high seismic-prone regions and in areas with soft soil conditions. Consequently, they have become popular as an alternative to RC for the construction of floors and walls including shear walls [4]. However, among the challenges in respect of using new building systems especially those prefabricated from timber like CLT, is employment of empirical design formulas that are applicable to simple design cases, and which may not work well for those new products. Most design codes and guidelines [7-9] recommend that seismic analysis of buildings whose responses are not significantly influenced by contributions from higher-order modes be conducted using the Equivalent Static Force Procedure (ESFP). Such buildings are required to satisfy some criteria for regularity both in footprint and in elevation. The prediction of the fundamental period (T_1) is therefore the most important parameter in determining the base shear to be proportioned along the height of the building [7,8]. Various formulas have been proposed for predicting the fundamental period (T_1) of buildings as a precursor in determining the horizontal seismic forces under the ESFP. For buildings with heights up to 40 *m* the Eurocode [7] recommends estimating T_1 from Equation (1):

$$T_1 = C_t H^{0.75} \quad (1)$$

where C_t is 0.085 for moment resisting space steel frames, 0.075 for moment resistant space concrete frames and eccentrically braced steel frames and 0.05 for all other structures; and H is the height of the building, in *m*, from the foundation or from the top of a rigid basement. Similar expressions such as given on Equation (1) are outlined in the National Building code of Canada (NBC) [8] and the

https://doi.org/10.52202/069179-0308

Indian standard (IS) – criteria for Earthquake Resistant Design of Structures [9]. However, the NBC [8] suggests estimating the fundamental period for other moment resisting frames as $T_1 = 0.1N$, where N is the total number of storeys above exterior grade to level n. The fundamental period for all other buildings may be obtained from Equation (2), according to the Indian Standard [9], where H is the height of the building in m and d is the base dimension of the building at the plinth level along the considered direction of earthquake shaking in m.

$$T_1 = \frac{0.09}{\sqrt{d}} \tag{2}$$

The objective of this study is to assess the capabilities of existing empirical formulas in various design guidelines in accurately estimating T_1 of CLT buildings. In particular, the study focuses on the so-called platform buildings in which CLT floor framings are supported on load bearing CLT walls; with an erected floor serving as the platform for building the next storey. The assessment is based on using verified numerical models capable of fully representing construction features that exist in actual buildings. Attention is placed on predicting mode shapes and associated modal frequencies. This includes demonstrating whether the discrepancies that can arise out of using simplified assumptions and approaches outlined in various design guidelines for seismic analysis may be acceptable for emerging construction systems.

2 NUMERICAL MODELS

This section describes the scope, assumptions, and calibration of the numerical model techniques employed in this study.

2.1 SCOPE AND ASSUMPTIONS

The numerical models presented in this study represent CLT buildings that are rectangular on plan and satisfy Platform Construction methodology. Building models ranging between 4- and 12-storey heights with footprint and wall locations shown in Figure 1, were considered to match current trend of multi-storey mass timber buildings. Axes of material symmetry (1, 2, 3) of CLT plates are considered to lie parallel to orthogonal axis directions x, y, z that define the length, width and thickness of elements. Linear-elastic small deflection theory is assumed valid since amplitudes of system displacements are several orders of magnitude less than overall building superstructure dimensions.

The limitation of the scope to buildings with rectangular floors was adopted because it illustrates choices of design variables that ensures geometrical regularities for the ESFP in the event of seismic analysis and design without limiting the generality of the adopted concepts. Buildings which are regular in both footprint and elevation are typical for many practical occupancy applications.

2.2 MODELLING TECHNIQUES

The Numerical models were developed using the commercial software package TimberTech [10] whose choice was made because it has the capabilities for simulating direct CLT walls and floors with various connectors to make accurate representation of platform construction arrangements. Furthermore, the program is associated with ease of creating elements and structural systems that facilitates openings for windows, doors, stairs and lift wells.

Successful numerical models depend on accurately simulating the system's geometry and applying the appropriate material properties, boundary conditions and the expected external forces. In developing the geometries of the buildings, the floor plans were laid out with nodes at the locations of both internal and external walls. Thin plates of required thickness and heights representing CLT walls were inserted in between nodes to create loading bearing (including shear walls) and partition walls. Lintels were introduced for window and door openings. CLT floor elements were modelled, supported on both exterior and interior walls along the shorter plan dimension of the buildings. This created a platform upon which upper storeys were added on until the roof. CLT floor elements (180 mm thick) and roof (200 mm thick) were assigned residential and roof live loads respectively. Table 1 and Table 2 respectively summarize CLT type and material properties employed for modelling and analyses with the adoption of a Poisson's ratio of 0.3 for all CLT materials [11]. Figure 2 illustrates an 8-storey FE model with footprint as illustrated in Figure 1.

Table 1: *CLT type and layup configuration used in FE models*

CLT-panel layup	Thickness (mm)
CLT 90 3S (30-30-30)	90
CLT 100 5S (20-20-20-20-20)	100
CLT 120 5S (30-20-20-20-30)	120
CLT 140 5S (40-20-20-20-40)	140
CLT 160 5S (40-20-40-20-40)	160
CLT 180 5S (40-30-40-30-40)	180
CLT 200 5S (40-40-40-40-40)	200

As has been mentioned, TimberTech provides the flexibility of link elements between wall and floor elements. The stiffness applied to the different types of link elements, were estimated from the results of experimental analysis from Gavric et al. [12]. For the angle brackets and hold-downs, a linear relationship between the number of screws and stiffness value is

assumed, and the values for tensile and shear stiffness are estimated by Equation (3): where k_a is the analytical stiffness value from (Gavric et al. 2015), n_a is the number of nails used in the analytical connector, and n_{exp} is the number of nails used in the experiment. Table 3 illustrates estimated hold-down stiffnesses employed along the storey heights of FE models.

Table 3: *Stiffnesses of hold-down anchors in FE analyses*

>9	HD-5	1	2.65

$$K_a = \frac{K_{exp}}{n_{exp}} \tag{3}$$

2.3 NUMERICAL MODEL VERIFICATION

Results from field campaign of ambient vibration measurements of one of the two identical Palisaden student residence buildings on the campus of the Norwegian University of Life Sciences (NMBU) in Ås, Norway, were used to verify the numerical models. The case study building shown in Figure 3 is 8-storey high and matches the configurations of the numerical model described in Figures 1 and 2. Shallow CLT spine elements form structural walls, and horizontal floor and roof slabs which act as structural diaphragms. Except for stair and lift wells on plan, the horizontal floor elements have widths up to 2.5 m and span continuously over 15 m in line with the shorter plan axis dimension. Horizontal floor and roof elements are supported on both exterior and interior CLT walls, reflecting that building configuration conforms to the Platform Construction type.

Figure 3: *Photograph of case study building*

From the lower to the upper storeys the thicknesses of the wall elements decrease, thus the storey masses decrease along the building height, (Figure 1a). CLT floor slab elements have a constant thickness of 180 mm whilst the roof slab elements composed of 200 mm thick CLT plates. The thickness of roof elements indicates that design snow loads are of much significance in Ås, Norway than corresponding design live loads for the floors. Walls designated to act as shear walls are those indicated in Figure 1b. The structure has a central core as shown in Figure 1, which houses a staircase, an elevator and services ducts. The core is surrounded by CLT walls connected to the floor and roof elements thus constituting part of the lateral load transfer system.

Figure 4 compare modal natural frequencies and mode shapes of the numerical model with the results from the field campaign of modes 1–3. As can be seen from Figure 4, modal model results are in good agreement with results from the ambient vibration measurements. Discrepancies between modal model and test results especially between

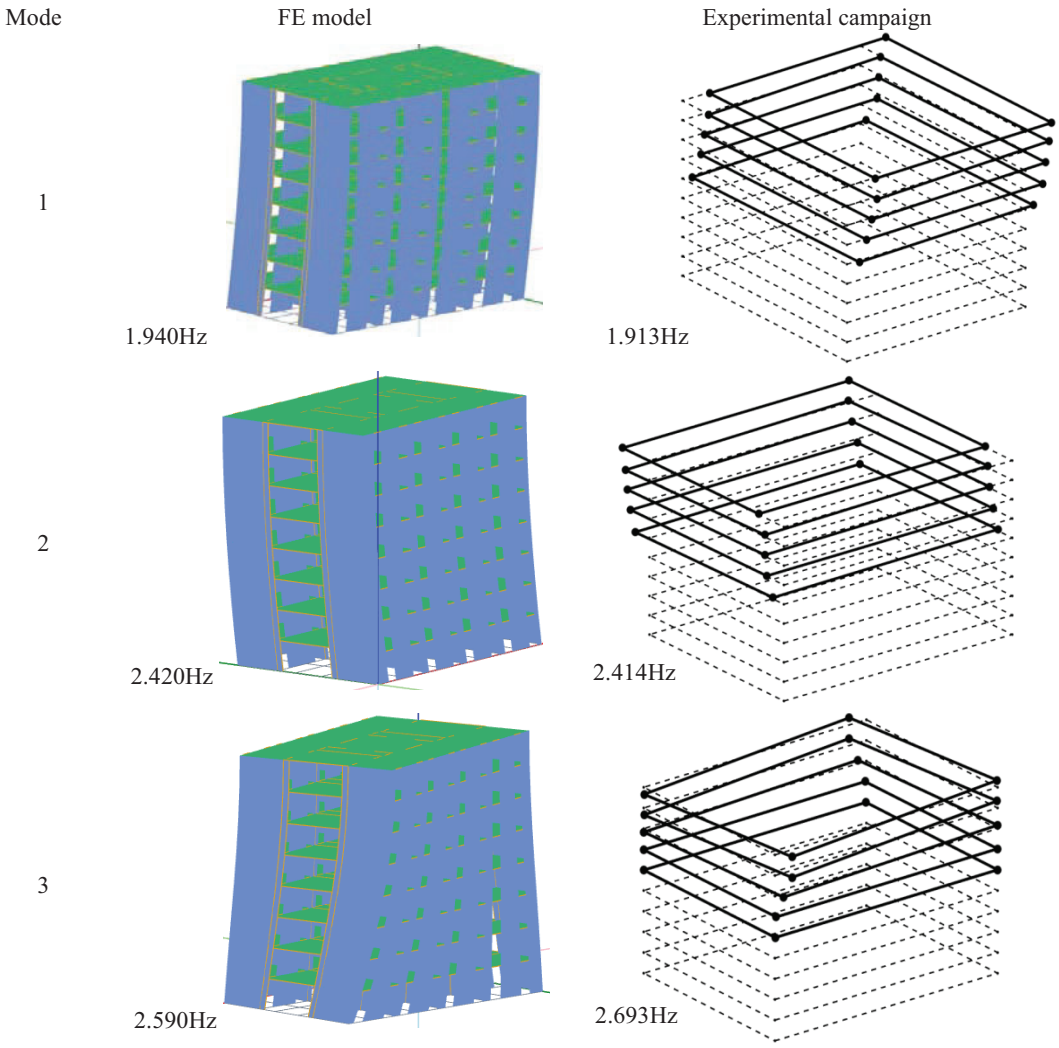

Figure 4: *Comparison of modal frequencies and modal shapes of FE model modal analysis and field campaign of results of the case study building*

mode 3 natural frequencies may be attributed to simplification of the numerical model not accounting for the stiffness due to the end-wall non-CLT materials adjacent to the communal corridor space present in each storey. Presence of non-CLT wall construction elements potentially added to the overall system stiffness consequently influencing low-amplitude ambient vibration measurements. Furthermore, variations between the model and field campaign results may be due to numerical model not accounting for minor differences in material properties and construction imperfections. Also, construction features including door and window openings were simplified and differences between real and model superstructure and wall anchoring conditions were ignored. Overall, the authors consider the obtained balance between the model accuracy and computational efficiency reasonable for extending the presented modelling techniques to assess the reliability and robustness of simplified formulas in estimating T_1.

3 ESTIMATING THE FUNDAMENTAL PERIOD OF CLT PLATFORM-TYPE BUILDINGS

Analytical formulas provided in various design codes [7-9] are employed in estimating T_1 of CLT platform-type buildings. Evaluations are compared with predictions obtained from verified numerical models which offer the needed basis for commenting on the accuracy and

https://doi.org/10.52202/069179-0308

reliability of extrapolating empirical design formulas to systems outside their calibration range.

From Eurocode 8 [7], Equation (1) is applied on the case study building in which C_t is defined by Equation (4)

$$C_t = \frac{0.075}{\sqrt{A_c}} \quad (4)$$

where, A_c is the total effective area of shear walls in the first storey of the building, in m^2 defined by Equation (5):

$$A_c = \sum \left[A_i \left(0.2 + (l_{wi}/H) \right)^2 \right] \quad (5)$$

A_i is the effective cross-sectional area of shear wall i in the direction considered in the first storey of the building, in m^2; H is the building height in m, from the foundation; and l_{wi} is the length of the shear wall i in the first storey in the direction parallel to the applied forces, in m, with $l_{wi} \leq 0.9$. The choice of Equation (4) for calculating C_t is made to reflect the application of CLT shear walls in the case study building and corresponding numerical model. Further comparisons are made with Equation (2) which is part of the Indian Standards [9] provisions for seismic analysis of buildings. From Equation 2, C_t is defined as $C_t = 1/\sqrt{d}$

Table 4 compares model predictions of T_1 of the case building with alternative analytical estimations. As may be observed from Table 4, there are huge discrepancies between the predictions from the Eurocode 8 (Equation (1)) [7] approach and the verified numerical model. However, there appears reasonable variations between the provision from the Indian Standard (Equation (2)) [9] and the numerical model estimates.

Table 4: *Comparison of FE model prediction versus analytical approaches of T_1*

Weak stiffness direction			
Analysis Type	C_t	T_1[s]	%Var
FE	--	0.515	0.000
Eq.-1 [7]	0.068	0.736	42.91
Eq.-2 [9]	0.258	0.548	6.488
Strong stiffness direction			
Analysis Type	C_t	T_1	%Var
FE	--	0.413	0.000
Eq.-1 [7]	0.055	0.587	42.10
Eq.-2 [9]	0.209	0.443	7.236

This suggests that not accounting for both floor plan dimension in addition to the building height in the desired seismic direction affect the accuracy of the formula as may be seen from the Eurocode method versus the Indian design guide formula. For both directions of the building on plan the simplified approach in estimating the fundamental period of the case study building by Equation 2 (from the Indian design guidelines) predicts less than 10% variation from the numerical method. Construction features such as CLT plates edge-to-edge jointing, wall to floor connections, location of shear walls as well as the presence of openings for staircase, lifts, doors and windows all affect the modal stiffness to mass ratios in low amplitude vibration of CLT platform-like buildings. This is demonstrated in the numerical model and providing factors that account for such features in analytical expressions may improve their accuracy for seismic analyses for regular CLT buildings.

4 EFFECT OF BUILDING HEIGHT

Analytical formulas provided in the various design codes [7-9] for the prediction of T_1 for buildings classified as regular in both footprint and elevation, mostly depend on the building height, H in m. As demonstrated in Equations (1) and (2), it is expected that the distribution of stiffness and mass along the height of the building will facilitate over 90% of the energy released in the fundamental mode during seismic action. Therefore, the calibrated numerical model is applied in evaluating effect of building height on T_1 and comparing them with the analytical formulas. Analyses are carried out for four to twelve storeys reflecting a height of between11.8 m and 35.4 m.

Table 5 Compares the FE models prediction of T_1 with analytical provisions based on varying the building height. A couple of inferences may be made from Table 5. First, increasing the number of storeys resulting in increasing the building height results in increasing the fundamental period. This may be attributed to the fact that

Table 5: *Effect building height on T_1 based FE model versus analytical approaches*

Weak stiffness direction			
# of storeys		T_1[s]	
	FE	Eq.-1 [7]	Eq.-2 [9]
4	0.259	0.438	0.274
6	0.385	0.593	0.411
8	0.515	0.736	0.548
10	0.625	0.870	0.686
12	0.735	0.998	0.823
Strong stiffness direction			
# of storeys		T_1[s]	
	FE	Eq.-1 [7]	Eq.-2 [9]
4	0.205	0.349	0.221
6	0.310	0.473	0.332
8	0.413	0.589	0.443
10	0.508	0.694	0.554
12	0.613	0.795	0.664

increasing the storey height results in increases in the systems overall mass without corresponding increases in the overall stiffness. This may be because of changes in wall thickness and uneven distribution of connection details along the building height. Second, numerical predictions compare relatively well with the analytical formula that takes into consideration the building footprint dimension in the direction of ground motion under consideration. Relatively high discrepancies are noted between FE model predictions and the analytical method that considers only the building height.

As the above comparisons between verified numerical models and analytical predictions of T_1 of CLT platform-type buildings demonstrate, it is impossible to judge the suitability of simplified formulas provided in design codes in a generalised manner. The ability of some current simplified representations to estimate T_1 is associated with significant errors whilst others perform relatively better. Implication of this is use of explicit formulas or numerical models not accounting for basic building geometric properties such as floor plan dimension may not be a reliable way of estimating T_1. Additionally, CLT plates have orthotropic representation and slabs, and walls often contain features like intra-plate construction joints. Therefore, design level models should be based on explicit formulas that predict the fundamental frequencies of CLT structures accounting for orthotropic nature of the material and other architectural variables.

5 CONCLUSIONS

Numerical model representations have the capabilities of incorporating construction features that include building plan geometry, material characteristics and other architectural features. This enables the development of viable cost-effective simulations as alternative to expensive field campaigns for determining vibration characteristics of multi-storey CLT buildings. Model techniques also have the advantage of being employed to evaluate the effect of various parameters on a system.

Analyses from the modelling approach presented in this study and compared with analytical methods provided in various design codes point out the limitations in applying simplified analytical formulas for assessing the seismic demands on CLT buildings. Verified numerical analyses prove that in addition to the building height, floor plan dimension in the desired seismic direction should be accounted for in estimating the fundamental period as basis for determining the seismic forces on the structure. This is because the distribution of system mass to stiffness ratios depends on both footprint and the storey height of the building. Furthermore, presented analysis show that construction features influencing modal stiffnesses such as metal shear connectors and tiedown anchors in connections should be accounted for predicting low amplitude vibrations characteristic and forces due to extreme seismic events on CLT buildings.

NUMERICAL MODELLING OF LIGHT TIMBER FRAME WALLS – COMPARATIVE STUDY OF THREE FASTENER REPRESENTATIONS

Lukas Rauber[1], Benno Hoffmeister[2]

ABSTRACT: The lateral load-bearing capacity and stiffness of light timber frame walls (LTFW) depend on the mechanical properties and interaction of their components (frame, sheathing, fasteners and anchorage). The fasteners are decisive for the structural performance (resistance, stiffness) of LTFW. Therefore, numerical modelling focuses on the representation of the fasteners. In this paper, different modelling approaches for fasteners of LTFW are presented and compared with regard to applicability in research and practice – (i) an engineering model with line releases; (ii) a model with oriented springs and (iii) a model with beam elements. The models were validated and compared to experimental results from tests conducted at RWTH Aachen. All models represent the load-bearing capacity closer than the analytical approach of Eurocode 5. The model with line releases is recommended for engineering while the model with oriented springs is recommended for research. The modelling of GFB sheathing needs further investigation.

KEYWORDS: timber frame walls, shear walls, numerical modelling, push-over tests, load-bearing capacity, stiffness

1 INTRODUCTION

Light Timber Frame construction is a resource-efficient construction method with a high degree of prefabrication and short construction times. Light Timber Frame Walls (LTFW) consist of several components (frame, sheathing, fasteners). Frame and sheathing provide a load-bearing element when fastened in shear. The load-bearing behaviour is usually governed by the shear-connection between sheathing and frame as well as by the anchoring or the connection to adjacent building components.

In Europe, the horizontal load-bearing capacity and the displacement of LTFW are calculated according to the "pure shear" model ("Method A") of *Eurocode 5* [1]. This model is based on the lower bound theorem of plasticity theory and assumes that all fasteners are loaded with the same force and parallel to the sheathing edges. In addition, detailing provisions are given to ensure that yielding of the fasteners governs the failure mode of the diaphragm.
In *Eurocode 5* areas containing large openings, like windows or doors, are neglected in the determination of the load-bearing behaviour. It is assumed that wall sections with large openings do not contribute to the load-bearing capacity of the wall [1].

Eurocode 5 does not contain explicit provisions for the calculation of the horizontal stiffness of LTFW [1]. Engineers may calculate the deformation according to the "pure shear" model, by determining the contributions of the individual components – fastener deformation, shear deformation of the sheathing, axial displacement of the frame parts, deformation perpendicular to the grain of the bottom rail and deformation of the anchorage [2].

Test results [3–5] show that prediction of the load-bearing behaviour of LTFW using the "pure shear" model of *Eurocode 5* leads to very conservative results .
For seismic actions LTFW need to be verified according to seismic codes, e.g. *Eurocode 8* [6]. The seismic resistance may be determined assuming ductile and dissipative behaviour represented by a behaviour factor. The application of a behaviour factor of $q > 1.5$ assumes ductile fastener behaviour and requires prevention of brittle failure of other structural wall components. The condition for the achievement of ductile behaviour is the application of so-called capacity design rules. An accurate estimation of the load-bearing behaviour of all structural components is therefore essential for safe seismic design. Due to the lack of adequate provisions for calculating the realistic load-bearing behaviour of LTFW in *Eurocode 5*, non-linear numerical simulations are good alternatives for the calculation of load-bearing capacity and stiffness.

The objective of this contribution is to assess three promising numerical models regarding their applicability in research and engineering. The requirements according to which the models were preselected are the following:

- The model should be able to calculate the load-bearing capacity and the stiffness of LTFW and give more accurate results than the analytical model of *Eurocode 5*.
- The model output can be used as basis for the non-linear analyses of timber frame buildings.
- The model should have reasonable computing time for the application in engineering.

2 NUMERICAL MODELS

The reference structure used with the three presented numerical models is shown in Figure 1. For the frame all models use beam elements with linear-elastic material properties. The studs were hinged to the rails – this is common practice for numerical models of LTFW; whereas in the "pure shear" model of *Eurocode 5* studs and rails are considered contactless. The sheathing was modelled by means of linear-elastic shell elements. The anchorage was represented as a linear-elastic spring.

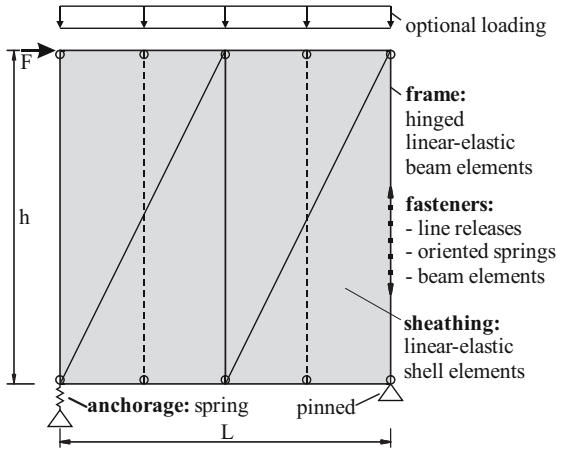

Figure 1: *Basic structure of the numerical models*

The three models differ in the representation of the non-linear fastener behaviour as seen in Figure 2. In model 1 (M1) the connection was modelled using "line releases". Model 2 (M2) used oriented springs to represent the connection between frame and sheathing. In model 3 (M3) flexible beam elements in bending were used according to *Vogt* [3].
M2 (oriented springs) and M3 (Vogt) were implemented in ABAQUS 2019 with "B31" beam elements for the frame and "S4R" shell elements for the sheathing. M1 (line releases) was realized in Dlubal RFEM 5.26 which uses automatic mesh generation.

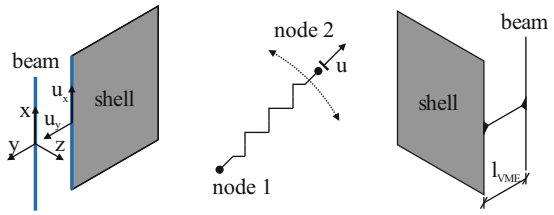

Figure 2: *Different fastener representations of the models*

2.1 LINE RELEASES (M1)

M1 used continuous cartesian spring elements for the representation of the connection between sheathing and frame. RFEM was chosen for the implementation of the model because of the availability and the simple applicability of continuous springs – called "line releases".

The input for line releases is defined as load-displacement per unit length. As shown in Figure 2 a, load-displacement behaviour is represented by continuous springs with degrees of freedom parallel and perpendicular to the sheathing edge. Since cartesian springs only act on their predefined axes, the resulting load-bearing capacity and stiffness are overestimated for oblique load directions [3]. Herein, both spring directions used non-linear curves from tests on connection units as input values as described in chapter 2.4 (0° for u_x and 90° for u_y).
The wall models were solved according to the theory of the third order with large displacements.

2.2 ORIENTED SPRINGS (M2)

M2 used non-linear oriented springs (Figure 2 b) for the representation of the individual fasteners. The model was implemented in ABAQUS.
For modelling the oriented springs "connectors" between sheathing and frame nodes were used with the translational type "axial". With this definition the springs acted in direction of their individual deformation. For modelling the non-linear fastener behaviour, input curves from tests on connection units were used (chapter 2.4).
"Static general" with large displacements (*NLgeom on*) was used as solving method.

2.3 BEAM ELEMENTS (M3)

M3 was also implemented in ABAQUS and used the same elements for frame and sheathing as M2. To model the fastener behaviour, beam elements as described by *Vogt* [3] were used (Figure 2 c).
The fastener elements (*B33*) were connected as "fixed" to frame and sheathing. They used elastic-plastic material behaviour and circular cross-sections to exhibit the same load-bearing behaviour in each load direction.
The fasteners remained elastic until plastic hinges occurred on both ends after the yield point of the material was reached.
To represent the load-bearing capacity of the connection F_f the length of the beam elements was calculated with:

$$l_{VME} = \frac{2 \cdot M_{pl}}{F_f} \tag{1}$$

To represent the stiffness of the connection *K*, a factor s_l was used for reducing *EI* in the numerical definition [3].
The input values for the model presented by *Vogt* [3] used the shear strength $F_{f,Rk}$ and stiffness K_{ser} calculated according to *Eurocode 5*.
For this paper mean values derived from connection tests were used for F_f while *K* was calculated as K_{ser} according to *Eurocode 5* [1].

2.4 INPUT DATA

The input data for the modelling of the fasteners' plastic behaviour was derived from connection tests conducted at RWTH Aachen [4] and the Optimberquake project [7].
At RWTH a test program with a total of 78 connection units was conducted in accordance with *ISO 6891* [8] for the monotonic tests used in this contribution.

https://doi.org/10.52202/069179-0309

The test setup is shown in Figure 3. Structural timber grade C24 was used for the frame part.
Sheathing materials, staple diameters and force grain angles (0° and 90°) were varied. For the validation in this paper only monotonic tests with OSB/3 sheathing (t =15 mm) and staples of diameter 1.8 mm and a length of 65 mm were used.

Figure 3: *Test setup of connection units at RWTH with load acting 0° (left) and 90° (right) to the timber grain*

For the validation with walls tested in the Optimberquake [9] project, tests on connection units [7] performed in this project were used. Relevant for the validation were monotonic tests on OSB/3 sheathing with nails of diameter 2.8 mm and a length of 65 mm. Also relevant were monotonic tests on gypsum fibre board (GFB) with a thickness of 18 mm and staples (⌀ 1.53 mm and length 55 mm).

The non-linear input curves per fastener were derived directly from the test results and used in tabular form for defining fastener load-deformation properties of M1 (line releases) and M2 (oriented springs).
The input values used for the models and the calculation according to *Eurocode 5* are shown in Table 1. M1 and M2 used nonlinear input curves generated from tests on connection units (Figure 4). M3 used mean values of F_f derived from the connection tests. The analytical calculations according to *Eurocode 5* were performed with both mean (m) and characteristic (k) values of F_f.
The E-moduli were set to 11000 N/mm² for the frame components and 380 N/mm² for the sheathing.
In order to simulate the tests at RWTH Aachen the anchorage was simplified by pinned supports. For the Optimberquake walls the spring stiffness of the anchorage was set to 11150 N/mm (from *Vogt* [3]).
The process of the generation of input curves is described in Figure 4. First the mean curves of the monotonic tests were generated per connection variant. Afterwards the curve was scaled down to one fastener for the input of M2 (oriented springs). For M1 (line releases) the input curves still had to be divided by the fastener spacing of the modelled wall to obtain to the load-displacement curves per unit length.

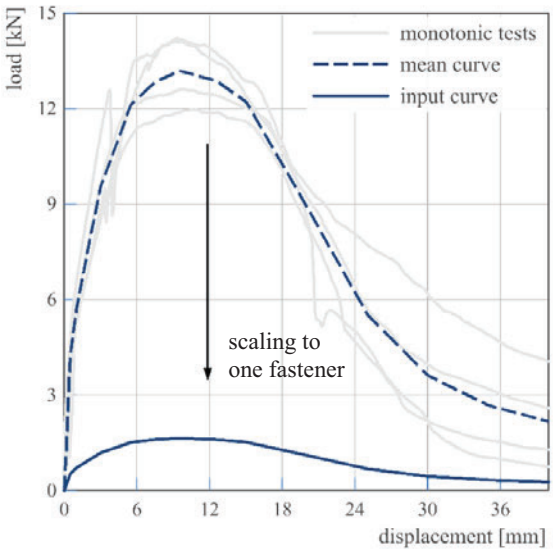

Figure 4: *Generating the fastener input curves from test results*

3 VALIDATION

3.1 TESTS ON WALL ELEMENTS

To validate the models, results of wall tests conducted at RWTH Aachen [4] and the Optimberquake project [9] were used. The tests for the validation are listed in Table 2. All tests were conducted with the monotonic loading protocol according to *ISO 21581* [10].

The experimental investigations conducted at RWTH include tests on standard reference walls as well as newly developed triple-sheathing walls. A total of 12 full scale wall tests were performed at RWTH. Four tests were conducted with and eight without additional vertical loading. In Figure 5 the test setup for a LTFW with vertical loading is shown. A vertical load of 37 kN was applied on each stud (111 kN in total) – representing loads of a four-story building.
All test specimens consisted of C24 frames and OSB/3 sheathing with a thickness of 15 mm which was fastened using resin coated staples (⌀ 1.80 mm and length 65 mm) with a spacing of 75 mm. Specimens with aspect ratios of 1.25 × 2.50 m and 2.50 × 2.50 m were tested.

Table 1: *Input values of the parameters used for the validation of the numerical models for the different tests (see Table 2)*

Test	Fastener parameter		M1 (LR) M2 (OS)	M3 (Vogt)	EC 5 (m)	EC 5 (k)
h-m-xx	K	[N/mm]	non-linear curve from	450	450	450
	F_f	[N]	test series OSB15-st1.80	1609.5	1609.5	908.5
WL-1.1	K	[N/mm]	non-linear curve from	859.5	859.5	859.5
	F_f	[N]	test series na2.8-o18-m	1071	1071	819
WL-2.1	K	[N/mm]	non-linear curve from	643.7	643.7	643.7
	F_f	[N]	test st1.53-g18-m-1	1225	1225	682.7

https://doi.org/10.52202/069179-0309

Table 2: *Test data of timber frame walls used for the validation of the numerical models*

Test	L × h [m]	Sheathing t [mm]	Fasteners ⌀ - length - spacing [mm]	Loading	Project
h-m-02/03	1.25 × 2.50	2 × OSB 15	Staples 1.80 - 65 - 75	horizontal	
h-m-04	1.25 ×2.50	2 × OSB 15	Staples 1.80 - 65 - 75	horizontal + vertical	
h-m-11	1.25 × 2.50	3 × OSB 15	Staples 1.80 - 65 - 75	horizontal	RWTH [4]
h-m-12	2.50 × 2.50	3 × OSB 15	Staples 1.80 - 65 - 75	horizontal	
h-m-13	1.25 × 2.50	3 × OSB 15	Staples 1.80 - 65 - 75	horizontal + vertical	
WL-1.1	2.50 × 2.50	2 × OSB 18	Nails 2.80 - 65 - 75	horizontal + vertical	Optimber-
WL-2.1	2.50 × 2.50	2 × GFB 18	Staples 1.53 - 55 - 75	horizontal + vertical	quake [9]

The anchorage was designed as non-dissipative including sufficient overstrength. The "shear response" according to *Dujic* [11] was ensured for all tests. For this purpose, two anchorages of the type HTT31 of Simpson Strong-Tie as well as horizontal cleats were used at each support.

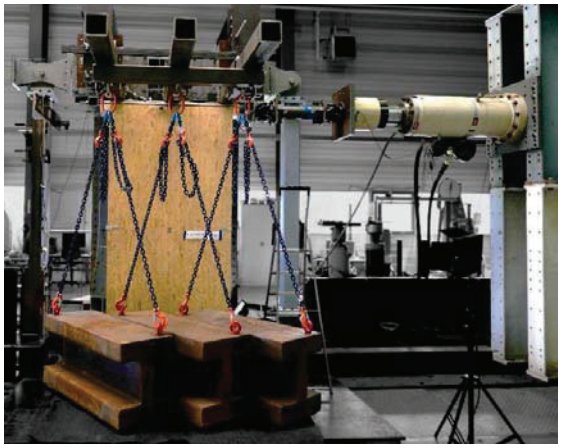

Figure 5: *Test setup for LTFW with vertical loading*

Further test results on LTFW elements from the Optimberquake program [9] were used for validation. Two test setups were selected: (i) specimens with 18 mm OSB sheathing and nails (⌀ 2.80 mm and length 65 mm) and (ii) specimens with 18 mm GFB sheathing and staples (⌀ 1.53 mm and length 55 mm).

3.2 NUMERICAL RESULTS

Figure 6 shows the comparison of the load-bearing capacities (F_{max}) from tests, by numerical models and according to *Eurocode 5* calculated with characteristic (k) and mean test (m) input values.
For M1 and M2 maximum values were used to determine the load-bearing capacity while M3 (Vogt) was evaluated at 60 mm displacement in this paper, since this model does not include decreasing of resistance (Figure 7).

The load-bearing capacity was underestimated for all OSB sheathed test specimens (*h-m-xx* and *WL-1.1*), by the models and by *Eurocode 5* design rules.
F_{max} of the GFB sheathed specimen (*WL-2.1*) was overestimated by all models and *Eurocode 5* when using test data from connection units (*m*).
Comparable tests without (*h-m-02* and *h-m-11*) and tests with vertical loads (*h-m-04* and *h-m-13*) showed no significant difference for F_{max}. The same was the case for the numerical models and the analytical calculations.

The load-displacement curves of the models are compared to the test results of *h-m-02* and *h-m-03* and shown in Figure 7 (left).

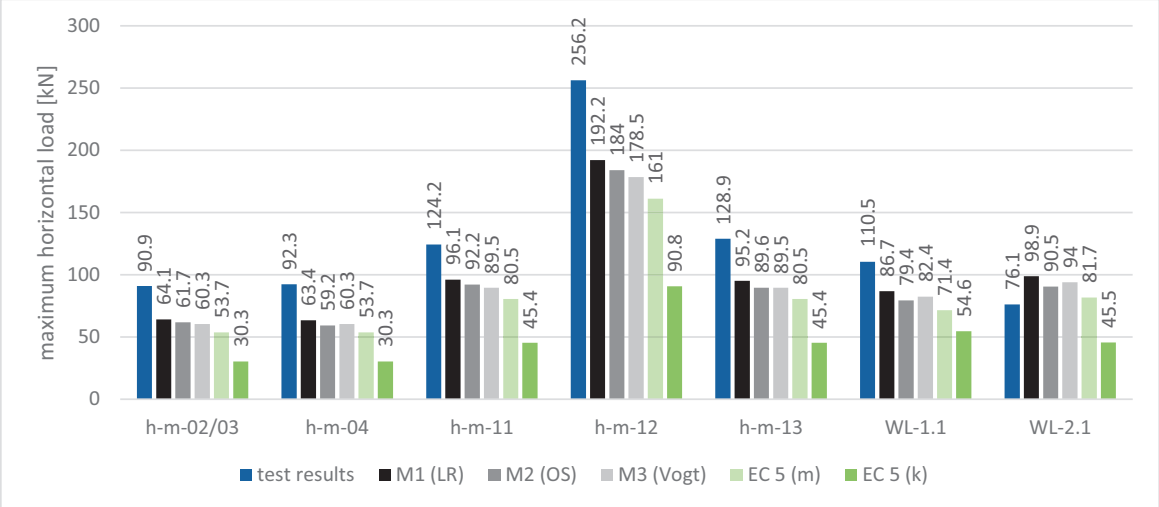

Figure 6: *Bar chart comparison of the load-bearing capacity between mean test results, numerical models and analytical calculation*

https://doi.org/10.52202/069179-0309

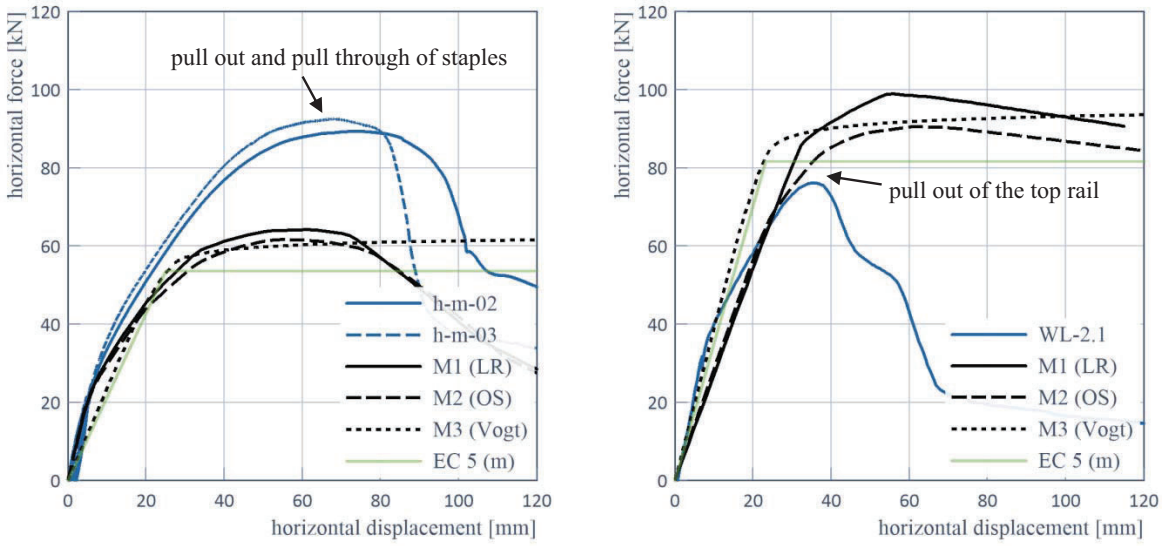

Figure 7: *Load displacement comparison of tests vs models for walls made of OSB with staples (left) and of GFB with staples (right)*

M1 (line releases) and M2 (oriented springs) resembled the scaled non-linear input curves for fasteners (Figure 4) while M3 (beam elements) showed almost ideal elastic-plastic behaviour.

As seen before, all models underestimated the load-bearing capacity of the tests. This model behaviour looked similar for all comparisons to tests *h-m-xx* (OSB and staples) and *WL-1.1* (OSB and nails).

In Figure 7 (right) the load-displacement diagram of specimen *WL-2.1* is shown – the only test with GFB sheathing. F_{max} was overestimated by all models compared to the test result. The initial stiffness was underestimated with M1 and M2 while M3 was closer to the initial stiffness of the test curve.

For the evaluation of the initial stiffness of the tests as well as the model results the calculation of K according to *ISO 21581* [10] was carried out with:

$$K = \frac{0.3\ F_{max}}{u_{40\%F_{max}} - u_{10\%F_{max}}} \qquad (2)$$

The comparison of the evaluated initial stiffnesses of wall tests, models and analytical calculations (according to [2] but also named EC 5) is shown in Figure 8.

For the test series *h-m-xx* (OSB and staples) the following order applies to the stiffness: M1 is the stiffest, followed by M2, M3 and *Eurocode 5*.

Tests on nominally equal walls without (*h-m-02* and *h-m-11*) and tests with vertical loads (*h-m-04* and *h-m-13*) showed no significant difference regarding the initial stiffness. This was also observed for the numerical models and the analytical calculations.

The mean average percentage error (*MAPE*) was used for the comparison between models and test results and was calculated for F_{max} and the initial stiffness by:

$$MAPE = \frac{100\%}{n} \sum_{i=1}^{n} \left| \frac{A_i - F_i}{A_i} \right| \qquad (3)$$

with A_i as the test value and F_i as the model value.

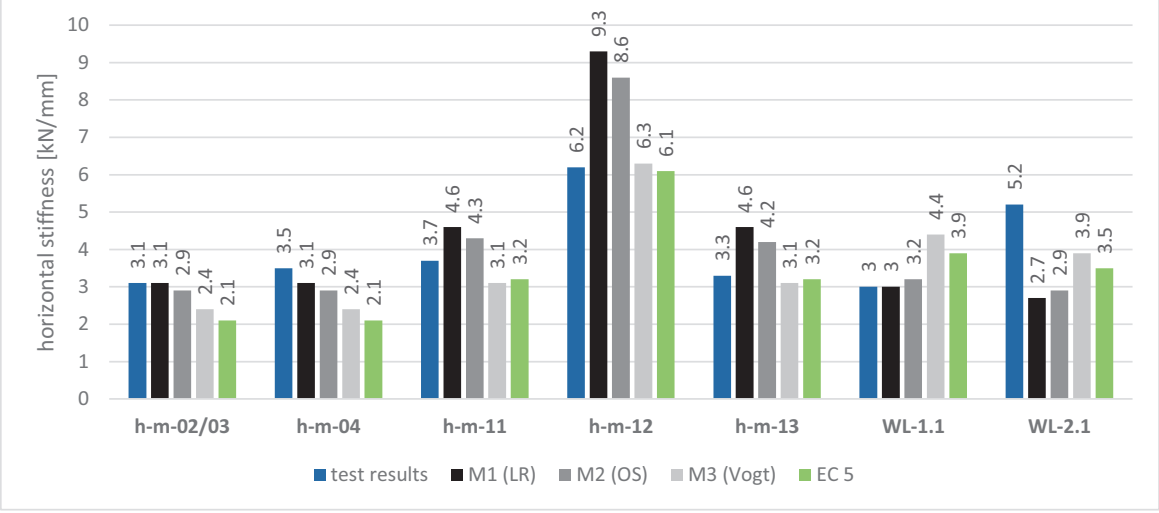

Figure 8: *Bar chart comparison of the stiffness between mean test results, numerical models and analytical calculation*

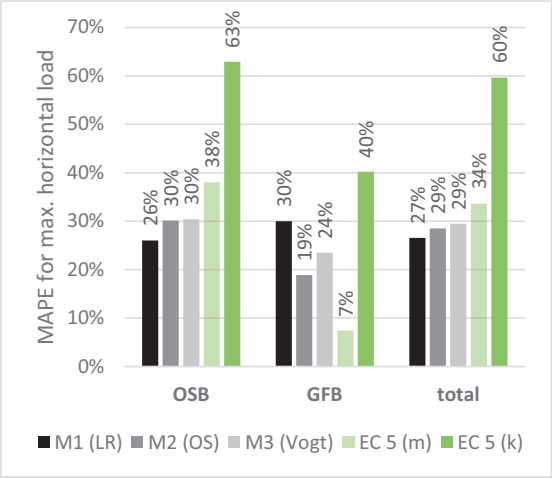
https://doi.org/10.52202/069179-0309



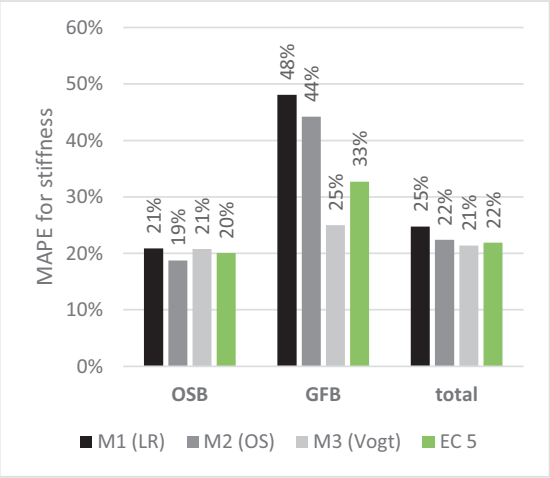


Figure 9: *Comparison of the MAPE of models and Eurocode 5 to test results for F_{max} (left) and for stiffness (right)*

The comparison of *MAPE* between the different models and *Eurocode 5* was evaluated for OSB sheathing, GFB sheathing and the total of all tests. The results are shown in Figure 9 for F_{max} (left) and stiffness (right).
M1 showed the least total error with regard to F_{max}, followed by M2, M3 and EC 5 (mean). For the test with GFB sheathing M1 had the biggest model error, followed by M3, M2 and EC 5 (mean).
With regard to stiffness M1 showed the greatest total error, followed by M2, EC 5 and M3. For OSB sheathing the error is approximately 20% for all models.

3.3 DISCUSSION

The presented numerical models showed a better representation of the load-bearing capacity than the analytical "pure shear" model of *Eurocode 5*.
However, all models show large deviations from the load-bearing capacity as obtained by tests. The differences were significantly higher than expected.

For OSB sheathing the load-bearing capacity was strongly underestimated by all models. This might be due to friction effects between sheathing and frame and/or scale effects of the fastener behaviour – in particular the behaviour of large groups compared to few fasteners in the connection tests – which both might not be represented by the conducted tests on connection units (Figure 3).
For GFB sheathing the load-bearing capacity was overestimated by all numerical models. This might be due to the limited test data from GFB tests – only one connection test and one wall test were used here. Nevertheless, the models' overestimation of load-bearing capacity for GFB is a safety risk for the calculation with these methods. More tests with GFB are needed to calibrate and validate the models.
With regard to stiffness estimation all model results are only as good as the calculation with the model in *Eurocode 5* (calculated with [2]) for OSB test specimens.

In the following the known abilities and limitations of the models are listed and related to the models (named in parentheses).

Abilities

- Calculate the load-bearing capacity and stiffness more accurately than *Eurocode 5* for OSB (all).
- Failure of other wall components (studs, anchorage, sheathing) may also be assessed (all).
- Resulting load-displacement curves may be used as basis for simplified full scale building models (all).
- Wall parts with large openings due to windows and doors can be included in the calculation (all).

Limitations

- Model relies on test results – ideally non-linear test curves – of connection units for best results (all).
- Not applicable for huge and complex engineering models of buildings due to time consuming modelling and long computation time (M2, M3).
- Overestimation of oblique fastener loads and stiffness by using cartesian spring pairs (M1).
- Sheathing failure (e.g. shear and tension) cannot be represented by the models if using linear-elastic material representation. This can lead to overestimation of the load-bearing capacity when sheathing failure occurs for the LTFW (all).
- Seismic behaviour cannot be derived directly because the models' lack the representation of damage (strength reduction) due to cyclic loading (all).

The limitations might be overcome by the following modifications:

- Instead of test data, characteristic values could also be used as model input for safe-sided estimates leading to less model error than *Eurocode 5*.
- M1 could be used in engineering applications, as it requires low computing times and gives reasonable results. The overestimation due to the cartesian spring pair could be overcome by using just the main load direction of the fasteners (u_x) or reducing the second input values (u_y).
- Sheathing stress could be assessed continuously in the models to determine premature sheathing failure.

https://doi.org/10.52202/069179-0309

4 CONCLUSIONS

Three different numerical approaches of fastener representation for LTFW were presented – (i) an engineering model with line releases; (ii) a model with oriented springs and (iii) a model with beam elements.
The comparison of the test results with numerical models demonstrates the difficult venture of modelling load-bearing behaviour of LTFW. The transfer of experimental data from connections to full-scale walls does not lead to the expected (realistic) results.
The results indicate that a scale effect between connection tests to LTFW tests exists. Further research is needed in this regard.

Nevertheless, all models represent the load-bearing capacity of OSB sheathing better than the "pure shear" model given in *Eurocode 5*.
The following conclusions can be drawn with regard to load-bearing capacity:

- All models underestimated the maximum load for the OSB sheathed specimens.
- All models overestimate the maximum load for the GFB specimen. As long as the models cannot represent the load-bearing capacity of GFB sheathed walls, wall tests are recommended.
- Tests and models with and without vertical loading show no significant difference regarding lateral performance.

The following conclusions can be drawn with regard to stiffness:

- The numerical models represent the stiffness of OSB specimens as good as the "pure shear" model.
- No influence from vertical loading is observed for both tests and numerical models.

Model 1 (line releases) shall be particularly interesting for engineers, as it is simple, quick to apply and contains all wall components required for capacity design. However, the effects due to usage of the cartesian spring pair need to be considered.
Model 2 (oriented springs) is suggested for the application in research as it gives valuable output about the individual fastener forces and displacements. Model 3 leads to better estimations than the analytical model of *Eurocode 5* but showed high computational demand and modelling times.

Model 1 (line releases) and model 2 (oriented springs) might be especially interesting for nonlinear pushover analyses of timber frame buildings. Although results are not as good as individual wall tests the models are a less expensive alternative to testing. Both models might also be used to estimate the ductility of LTFW with data from tests on connection units only, but this still needs to be investigated. If the shown model limitations could be overcome, the number of wall tests required to validate the performance would become significantly less in the future.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the financial support of the ZIM research project *HOLZBEBEN* by the BMWI and the FNR research project *HELEPOLIS* funded by BMEL. INCREMENTAL DYNAMIC ANALYSIS OF A FIVE STOREYS CLT BUILDING DESIGNED THROUGH FORCE-BASED METHODS

Franco Benedetti[1], Tomás Valenzuela[2], Alan Jara-Cisterna[3], Alexander Opazo-Vega[4], Víctor Rosales[5]

ABSTRACT: Since the large seismic demands in Chile, there is a high level of uncertainty regarding the seismic safety behavior of timber structures. Besides, in the last decade, there has been a worldwide rise in the construction of cross-laminated timber (CLT) buildings, explained by the ease of industrialization of CLT panels and for being a sustainable material. However, its massification in high earthquake-prone zones is still under development. This research analyzes the seismic fragility of a 5-story CLT building. The aim of this research is to determine the seismic safety level of a CLT midrise building designed by Chilean force-based code regulations by means of Static Nonlinear Analysis and Incremental Dynamic Analysis. For IDA curves, a set of 540 nonlinear time-history analyses were performed using parallel computing tools. The main results show that for the collapse of the building to occur, large pseudo-acceleration values need to be reached. Besides, the collapse margin ratio (CMR) is calculated for the two principal directions, achieving values larger than 3 for 50% collapse probability. These results suggest a large margin of seismic safety of the CLT building designed in this research.

KEYWORDS: Seismic fragility of CLT mid-rise buildings, Timber construction, Incremental Dynamic Analysis.

1 INTRODUCTION

In the last decade, there has been a growing interest in promoting sustainable and industrialized construction materials, in which timber structures have advantages against other materials. In terms of construction systems, CLT is one of the most attractive systems that satisfy all these purposes. It is also a resistant system with good structural performance that has been extensively tested at element [1] and full scale [2] levels.

In general, there is sufficient evidence that shows that CLT can withstand high gravitational load and have an optimal behavior against seismic loads [3]. This last aspect is crucial in a highly seismic country such as Chile. However, in Chile there are no explicit seismic design regulations for CLT. This means, for example, that CLT buildings must meet the same deformation requirements of a reinforced concrete structure. This fact can generate over stiffened and oversized structures that do not take advantage of the deformation capacity that CLT can provide. Additionally, the application of traditional force-based design methods based on the seismic behavior of other structural systems creates uncertainty about the earthquake response and safety of CLT structures. This research aims to quantify through incremental dynamic analyses (IDA) the seismic safety of a panelized CLT mid-rise building designed under the force-based methods approach.

2 PYMELAB BUILDING

The Pymelab building was developed through a collaborative effort between public and private organizations [4]. It was funded by the Production Development Corporation of the Chilean Ministry of Economy (CORFO) and executed by the University of Bío-Bío (Concepción, Chile). It is a project that gathers a large number of SMEs in the timber sector to innovate and create associative support networks. As a result of this collaborative project, a non-habitable 5-story cross-laminated timber building was built (Pymelab Building), providing the timber companies with a living laboratory to test and validate their products and manufacturing capacities.

2.1 BUILDING DESCRIPTION

The 5-story CLT building has a plan dimension of 6.6 m length by 4.2 m width, with 2.5 m of inter-story height. Three representative views of the studied building are shown in Figure 1. On the first three floors, the platform system is employed considering 150 mm thick walls (5 layers CLT panels); while on the upper 2 storeys, the balloon frame system with 100 mm thick walls (3 layers

panels) is used. Besides, following the local industry manufacturing capacity, walls and slabs consider a panelized configuration with panels of a maximum width of 1.2 m (walls) and 1.8 m (slabs). Spline joints are used for the parallel in-plane panel-to-panel connection, and self-tapping screws are employed for the perpendicular wall-to-wall and slab-to-wall connections. The geometry and structural information of the Pymelab structures are presented in Table 1. The structural system is based on the concept of a simple regular prism with stiff and strong corners and concentrated openings in the middle zone of each elevation, providing vertical continuous load paths.

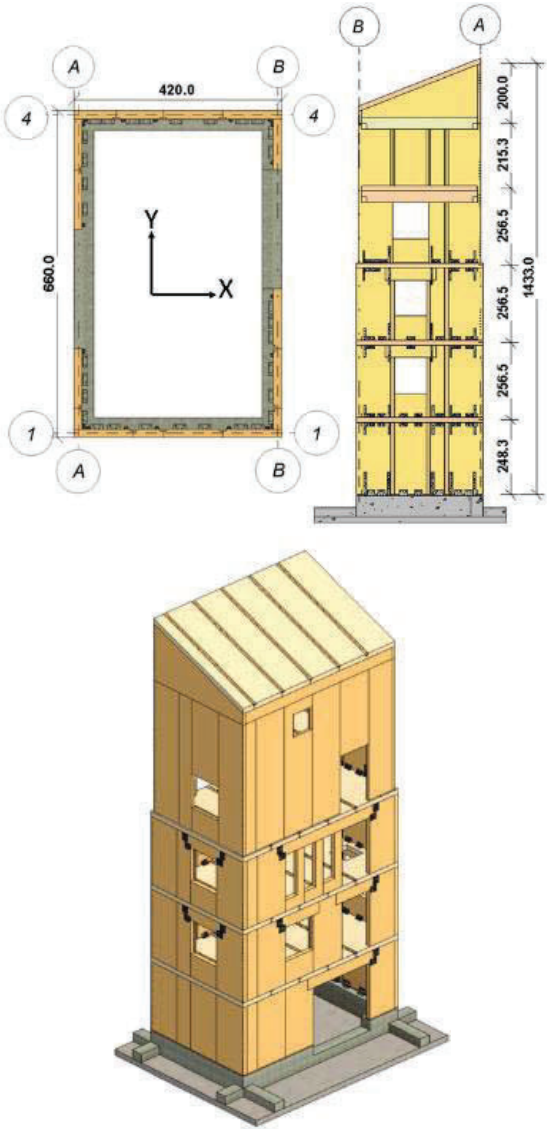

Figure 1: *Floor plan, elevation (top), and 3D view of the general structural configuration (bottom)*

Table 1: *Summary of main properties of the PymeLab building [5]*

Property	Value
N° Stories (Height)	5 (12.5 m)
Story area	27.7 m^2
Wall thickness	165 mm – 100 mm
Slabs thickness	165 mm
N° Metal connectors	2.0 /m^2
Total Wall Ratio (1st story)	10%
CLT Volume	0.34 m^3/m^2

2.2 SEISMIC DESIGN PROCEDURE

For the structural design, the allowable stress design approach was used, following the Chilean seismic code [6], the Chilean structural wood design standard [7], and international recommendations [8]. The mechanical properties of radiata pine CLT panels used in the walls and slabs are listed in Table 2.

Table 2: *Mechanical properties of CLT walls and slabs*

Mechanical properties	Value
Elastic Modulus Ex (3 layers)	2750 MPa
Elastic Modulus Ey (3 layers)	5250 MPa
Elastic Modulus Ex (5 layers)	1755 MPa
Elastic Modulus Ey (5 layers)	6250 MPa
Shear Modulus	324 MPa
Poisson Coefficient	0.3
Density	450 kg/m^3

SAP2000 [9] finite element software was utilized to develop the structural analysis for the design. All connections were considered flexible and modeled using link elements. Non-dissipative elements were modeled as elastic springs, while dissipative elements were modeled as multi-linear springs. Additionally, GAP contact elements were included to simulate the contact between wall-to-wall, wall-to-slab, slab-to-wall, and wall-to-foundation interfaces. Figure 2 displays an elevation of a case study, the graphical representation of the model created in SAP2000, and an example of the deformation of one elevation subjected to lateral seismic loads.

Regarding the seismic design, according to the Chilean code (NCh 433 [6]), the lateral load demand is defined using the maximum seismic coefficient C=0.46, which is established for non-traditional structures and calculated using a load reduction factor R=2. Additionally, the lateral load design must comply with a maximum center of mass inter-story drift of 0.2% under reduced seismic loads. This deformation limit applies to all structural systems regardless of the material used. The seismic demand is applied as lateral forces in the mass center of each floor slab. Additionally, to take into account the accidental torsion at each story level, the mass center where displaced 10% of the plan whith. Lateral forces and weight per story are summarized in Table 3. The seismic weight is determined as the Dead Load plus 25% of the

https://doi.org/10.52202/069179-0310

Live Load, resulting in 2.5 kN/m^2/story and a base shear of 142 kN.

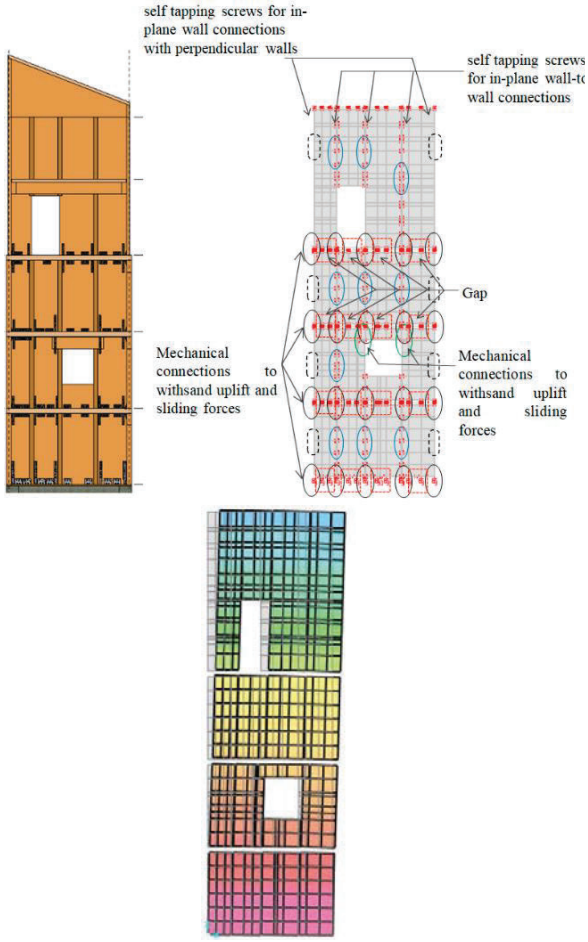

Figure 2: *1-Axis elevation, numerical design model (top), and deformed shape under seismic loads (bottom)*

Concerning the dynamic response, the design periods calculated using the Ritz vector method for the X and Y directions are 0.318 s and 0.274 s, respectively.

Table 3: *Summary of the seismic weight and lateral load demand used in the design stage*

Story	Lateral Force (kN)	Seismic weight (kN)
1	17.9	70.1
2	20.7	68.2
3	22.0	70.2
4	26.3	61.0
5	55.3	44.2

The foundation is a 20 cm thick reinforced concrete mat of 8 m x 6.4 m, stiffened with 0.7 m x 0.4 m beams. The foundation system design was challenging due to the site soil conditions, as well as the slenderness of the building. The soil beneath the mat is a medium-compacted and low-bearing capacity sandy silt. One of the main problems of the foundation is that the structure, being so light and slender, has overturning stability issues. To address this situation, additional weight was added over the foundation to improve the overturning safety, achieving stability safety factors of 1.3 and 1.7 for Y and X directions, respectively.

In terms of connections design, Izzi et al. (2018) [10] recommendations and authors' experience were followed to define the dissipative and non-dissipative connections. The joints that resist the rocking and the wall-in-plane splines are designed to be dissipative to improve the deformation capacity of the system. On the other hand, shear brackets, perpendicular joints, slab-to-wall, and slab-to-slab spline connections were considered non-dissipative.

2.3 STRUCTURAL DETAILING

Due to the panelized configuration of the building, a large number of metal plates and screw connectors are required. Examples of the connectors and metal plates used in this case study include:

Self-tapping screws: used for joints between panels at perpendicular joints. Among the screws used are ESCRC 8x240 screws for perpendicular joints between wall panels, and ESCRC 10x240 screws for joints between walls and slabs.

Angle Brackets: angular-type metal connectors are typically used to resist shear and uplift forces resulting from seismic demands. The angular type brackets used are ABR255 and ABR255SO models fastened with CNA 4x60 annular shank nails.

Hold-Down: HTT31, HTT22e, and HTT5 devices fastened with CNA 4x60 annular shank nails are employed to resist uplift loads and to create vertical load transfer paths.

Spline joints: employed for the in-plane panel-to-panel connection. In this case, radiata pine boards fastened with ESCRC 8x80, ESCRC 8x120, and DSVR312R5LB screws were considered.

Table 4 shows the per-story amount of shear brackets and hold-down connectors used in the Pymelab building.

Table 4: *List of shear and hold-down connectors per story (C: ceiling, F: floor)*

		Shear Brackets		Hold-down

Due to the strict requirements of the Chilean seismic design code (NCh433 [6]), a crowded connector layout is obtained. Figure 3 provides an elevation view and a plan of the metal connector distribution.

3 INCREMENTAL DYNAMIC ANALYSIS APPROACH

Aiming the assessment of the safety level of the seismic design of the Pymelab Building, an incremental dynamic analysis (IDA) has been carried out. To perform this analysis, a robust and detailed model is required in which every deformation mechanism can be properly modeled. Given the model complexities and the large amount of nonlinear time history analyses involved in the IDA, OpenSees [11] models were developed using parallel computing techniques.

3.1 NUMERICAL MODEL DEVELOPMENT

The models consider linear and nonlinear components. Elastic orthotropic shell elements were employed for the CLT boards, and hysteretic nonlinear springs were assigned to the connection elements to simulate their nonlinear mechanical behavior. Moreover, a friction interface was used to represent the contact between walls, slabs, and the foundation. The proposed modeling approach is illustrated in Figure 4, while the mechanical properties of mechanical devices are presented in Table 5. Further details of the modeling process are available in Benedetti et al. (2023) [5].

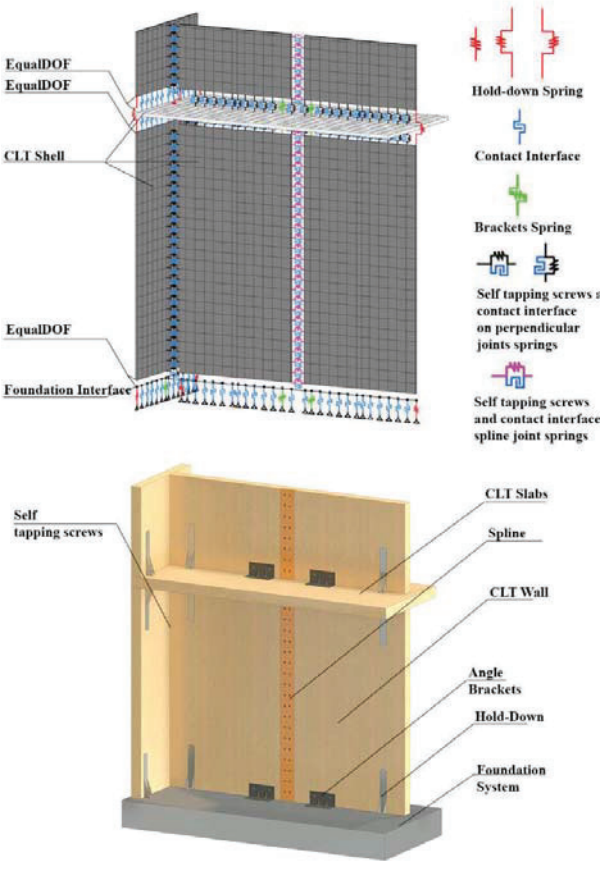

Figure 4: *Cross Laminated Timber (CLT) shear wall components (below) and model implementation (top) [5]*

https://doi.org/10.52202/069179-0310

Table 5: *General mechanical properties of connections in the models*

Connection	Yield displacement Δ_y (mm)	Load capacity F_{max} (kN)	Elastic Stiffness K_e (kN/mm)
Hold Downs (tension)	8.9	72.3	5.88
Shear Brackets (shear)	6.1	110.1	15.15
Shear Brackets (tension)	7.2	88.19	9.83
Metal Plate(shear and tension)	2.4	174.8	42.73

In terms of the parallel modeling approach, several strategies have been developed to segment nonlinear computational domains [12]. However, this study focuses on a static decomposition approach due to its simplicity and straightforwardness. Moreover, the decomposition is conducted with the intent of preventing load imbalances between the processing cores.

Additionally, an iterative approach was employed to address the numerical integration and convergence issues caused by the high nonlinearity of the complex numerical model. An algorithm was used to dynamically and adaptively modify the nonlinear solver, time step (or displacement step), and convergence tolerance, if necessary in order to ease the solving of the analyses [5].

3.2 SEISMIC DEMANDS FOR THE IDA

A combination of Chilean earthquakes and other well-known seismic recordings from around the world were used in the IDA. The seismic response of the structural model was evaluated using 18 acceleration time series, including the horizontal components of the Mw 8.0 Algarrobo 1985, Mw 8.1 México 1985, Mw 6.9 Loma Prieta 1989, and Mw 8.8 Maule 2010 earthquakes. Figure 5 shows the response spectrum of the seismic demands considered, and Table 6 shows their main parameters. To perform the IDA, each seismic record is normalized and scaled according to FEMA recommendations [13].

Table 6: *Main pareameters of the seismic demands employed in the IDA*

Year	M_w	Station	Component	PGA (g)	PGV (m/s)

4 RESULTS AND DISCUSSION

4.1 MODEL VALIDATION

A comparison of the first mode period calculated with OpenSees detailed model with respect to the design model and ambient vibration measurements was performed to validate the model used for the IDA.

To determine the period of the first mode in the IDA numerical model, free vibration tests were conducted under initial conditions that excite the first mode, but are small enough to prevent the response from exceeding the system's yield. The results of the free vibration analysis are presented in Figure 6, showing periods of 0.32 s and 0.28 s for the X and Y directions, respectively.

Moreover, given that the Pymelab building is already built, vibration measurements and modal analysis were carried out with ARTEeMIS software [14]. With this software tool, fundamental vibration modes and

frequencies were identified. Table 7 shows the periods obtained from the measurements, as well as the calculated with both implemented models.

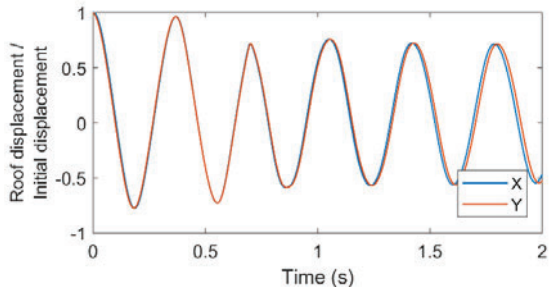

Figure 6: *Free vibration analysis of the IDA model for X and Y directions*

Table 7 periods suggest that the model used for the IDA is able to properly replicate the dominant dynamic response, with differences not larger than 7% with respect to the actual periods. Besides, the design model's and IDA model's fundamental mode periods match closely.

Table 7: *Period comparison among different models and experimental data.*

Model	Tx (s)	Ty (s)
Design model (SAP2000)	0.318	0.274
IDA Model (OpenSeeS)	0.32	0.28
Experimental Data	0.31	0.26

4.2 STATIC NONLINEAR ANALYSIS

Using the IDA OpenSees model, a nonlinear static analysis is performed to analyze the deformation capacity and the overall response of the structure in both directions. The result of the pushover analysis is shown in Figure 7.

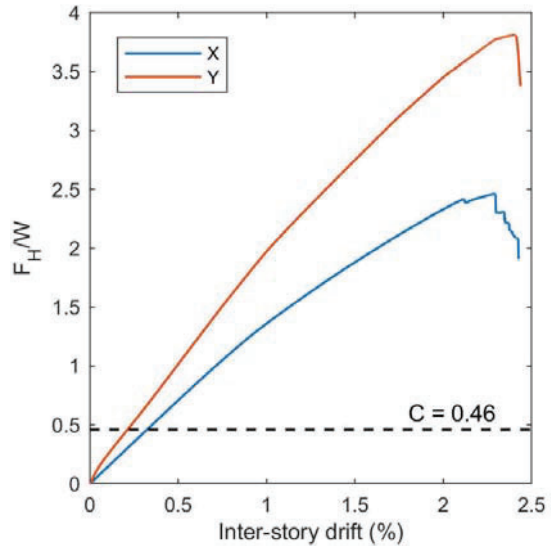

Figure 7: *Static nonlinear curves for X and Y directions*

The capacity curves obtained suggest that the global behavior of the structure for both principal directions is nearly linear during the whole drift range until de maximum capacity is achieved. However, around an inter-story drift of 1%, a break in the curve is observed, which is related to the system's yielding. The elastic stiffness calculated with the first slope of the curves are 155.9 kN/m and 252.1 kN/m for the X and Y directions, respectively.

Notwithstanding that the X-direction is more flexible and weaker than the Y-direction, both reached the maximum capacity and ultimate state at similar inter-story drifts (between 2.3% to 2.4%). Besides, the response of the structure seems to be brittle because of the abrupt drop in the lateral load capacity at the ultimate state.

Additionally, comparing the maximum lateral load capacity with the design seismic coefficient (C=0.46) and base shear, it is observed that the structure's overstrength factors (**Ω**) are 5.4 in the X-direction and 8.3 in the Y-direction (Table 8). Moreover, the system remains in the elastic range for this level of demand.

Table 8: *Maximum capacity (Fmax) and overstrength factor (Ω) in X and Y directions*

Design Base	X-Direction		Y-Direction	
Shear (kN)	Fmax(kN)	Ω	Fmax(kN)	Ω
142.6	763.2	5.4	1181.1	8.3

4.3 INCREMENTAL DYNAMIC ANALYSIS

For the IDA curves construction, a set of 540 nonlinear time-history analyses were performed. The structural damage index considered is the maximum inter-story drift demand, while the first mode elastic pseudo-acceleration spectral coordinate is used as the intensity index.

Using the results of the IDA, fragility curves are calculated for each direction considering four levels of structural damage, which are defined in terms of the inter-story drifts and set at 0.5% for Immediate Occupancy (IO), 1.0% for Operational (O),1.5% for Life Safety (LS), and 2.5% for Near Collapse (NC) (Figure 8). These inter-story drift limits are defined arbitrarily but consistent with the pushover results (Figure 7).

Fragility curves results show that the elastic pseudo-acceleration necessary to reach a 100% probability of achieving the NC state is larger than 7.5 g in and 9.0 g for the X and Y directions, respectively. On the other hand, in the range of elastic pseudo-accelerations between 1.5 g to 2.0 g it is achieved a 100% probability of reaching the IO level.

Moreover, the Collapse Margin Ratio (CMR) is evaluated for different collapse probabilities to determine the level of seismic safety. The CMR values are defined as the ratio between the elastic pseudo-acceleration required to achieve a certain NC state probability (S_{CT}) divided by the maximum expected earthquake demand (S_{MT}). According to Chilean codes (NCh 2745 [15]), S_{MT} demand level can be defined as the elastic design spectrum (S_E) amplified by 1.2 (S_{MT}=1.2S_D). Figure 9 presents the S_E and S_{MT}

https://doi.org/10.52202/069179-0310

demand spectra, as well as the SMT acceleration coordinates obtained for each analysis direction.

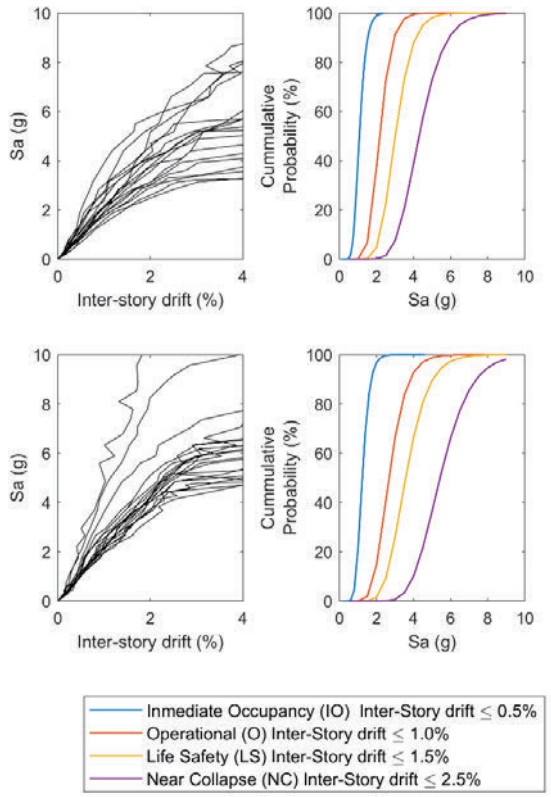

Figure 8: *IDA curves and fragility curves for X-direction (top) and Y-direction (bottom)*

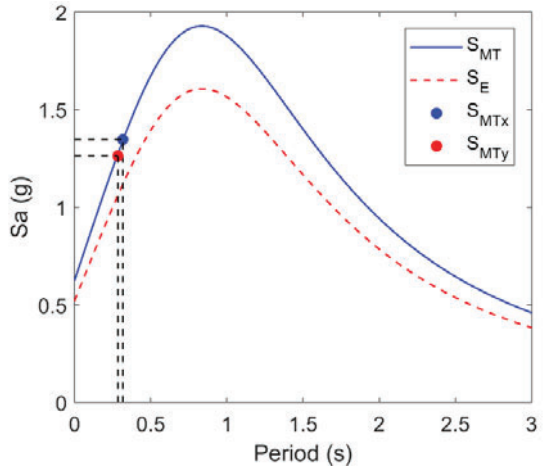

Figure 9: *Maximum considered earthquake spectrum (S_{MT}) and the elastic spectrum (S_a).*

Table 9 presents the obtained CMR values. It is observed that the Y-direction has higher collapse margin ratios due to lower S_{MT} demands and larger S_{CT} at all probability levels considered. However, for both directions, the CMR tends to be high, suggesting that the building's design is able to provide a significant safety margin against earthquake loads (CMR>3 for a 50% NC probability).

Table 9: *Collapse Margin Ratio (CMR) for different NC probabilities*

NC probability	X-Direction			Y-Direction		
	S_{CT}	S_{MT}	CMR	S_{CT}	S_{MT}	CMR
25%	3.63	1.34	2.71	4.62	1.26	3.67
50%	4.30	1.34	3.20	5.45	1.26	4.32
75%	5.05	1.34	3.76	6.46	1.26	5.13

4.4 INTER STORY DRIFT VS ROOF DRIFT RELATIONSHIP

Using the IDA analysis results, it is possible to establish the relationship between the maximum roof drift and maximum inter-story drift. Figure 9 shows the relation obtained and the linear fits for each direction.

The results of Figure 9 show a strong correlation between the maximum roof drift and inter-story drift for the Pymelab building. The linear fits point out that the slope angle is 42° and 36° for the X and Y directions, respectively. These angles suggest that the inter-story drift distribution among the building stories tends to be more uniform X-direction, hinting that the Y-direction could be more prone to concentrated story deformations and eventual soft story mechanisms. Furthermore, linear fit slope angles are close to Gohbarah (2014) [16] findings for reinforced concrete buildings.

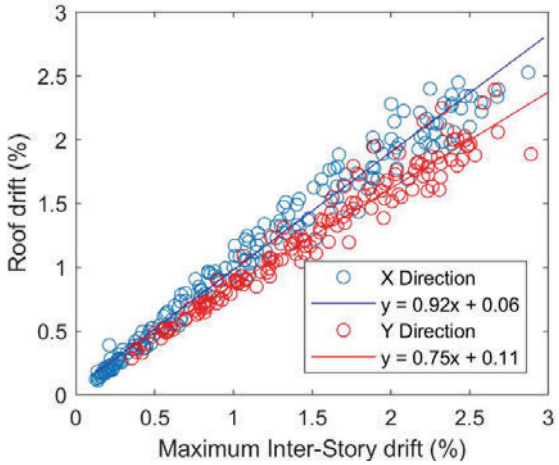

Figure 9: *Relationship between maximum inter-story drift and maximum roof drift of the Pymelab building*

5 CONCLUSIONS

This research analyzes the seismic response and safety of a CLT building designed through traditional force-based methods under seismic codes that do not recognize the intrinsic wooden building characteristics. Complementary, aiming to achieve better earthquake

performance, capacity-based design principles were also considered.

Results appear to show that the building is able to provide significant lateral load strength, but its deformation capacity can be limited. This fact is based on the large overstrength values (Ω >5) and the low displacement ductility ratios (μ<2.5) obtained. The latter might be a consequence of the large seismic force demand considered in the design due to the small load reduction factor (R=2) established by the Chilean code for CLT structures.

Regarding the seismic safety, fragility curves show that the probability of achieving a Near Collapse state is close to 0% for the maximum expected Chilean seismic demand (elastic pseudo-acceleration of 1.36 g). In addition, collapse margin ratio values suggest that the safety margin of the Pymelab Building against earthquake demands is appropriate.

Finally, results suggest that current Chilean force-based design regulations promote safe CLT structures, but it appears that there is still a wide room for the optimization of the designs. Nevertheless, capacity-based design principles should complement the design process in order to promote a suitable failure mode.

ESTIMATION METHOD OF DEGRADATION STATE FOR TIMBER BRIDGES USING VIBRATION ANALYSIS

Daisuke Oikawa[1], Shuya Nemoto[2], Humihiko Gotou[3], Yukari Aoki[4]

ABSTRACT: In this study, a new degradation diagnosis method is developed by vibration analysis. The natural frequency of aging timber bridge is normally decreased due to decay and degradation partially and entirely. In Japan, one of the timber bridges has been in service more than 35 years and its natural frequency is about 8.7Hz. In this study, a numerical bridge model is designed by FEM software considering the decay parts which are end supports and connections between spandrel column and arch rib. When the bridge members are healthy, the Young's modulus is 9.6GPa and the natural frequency is about 12.7Hz. In order to adjust calculated value to the measured value 8.7Hz, the Young's modulus of the bridge model has to be decreased to 4.49 GPa, which is significantly low. Furthermore, we calculated frequencies for each mode parametrically varying the decay parts to find the most affected parts to decrease the natural frequency of the bridge. According to this analysis, the connection between spandrel column and arch rib is the most affected.

KEYWORDS: Glulam timber bridges, Natural frequency, Elastic modulus, Decay, Degradation diagnosis method

1 INTRODUCTION

While degradation diagnosis for timber bridges is important, it is not possible to measure the strength and stiffness by extracting partial members from an existing bridge. In that sense vibration analysis, which makes it possible to measure the natural frequency of an entire bridge by non-destructive test method, is useful. In the real bridges, especially aging ones, decay and degradation would be found at every part especially end support and connection. Thus, when the vibration analysis is adopted as degradation diagnosis, the local decay and degradation should be considered. Unfortunately, a current used vibration method in the literatures[1], [1], [1] can not take into account the local decay.

In this study, we at first evaluate typical modal analysis model using beam/shell element and more exact model using tetrahedral element. Then we adopt the better model to find the effect of the local decay and degradation for the bridges.

3D numerical bridge model (Kajika Bridge in Japan) is created for includes the localized decay and degradation by decreasing Young's modulus. To validate this numerical model, we used for which the natural frequencies obtained by the numerical analysis and by the vibration test are compared.

By this method, we can determine whether natural frequency of the bridge model would decrease or not, that is, how the local decay would affect to the stiffness and strength of the entire bridge. By this method, we can determine whether natural frequency of the bridge model would decrease or not, that is, how the local decay would affect to the stiffness and strength of the entire bridge.

2 MODEL SETTING

In this study, measured data for the existing bridge 'Kajika Bridge' in Ishikawa prefecture in Japan, is used. This bridge shown in Figure.1, 2 is a two-hinged deck arch bridge built in 1987. This bridge has been used as roadway bridge for 35 years till now. In 2019, measurements such as investigations of natural frequencies and of degradation area for the bridge were carried out [1]. Here we numerically simulate the measured condition of the bridge by vibration analysis using FEM tool Salome-Meca[1].

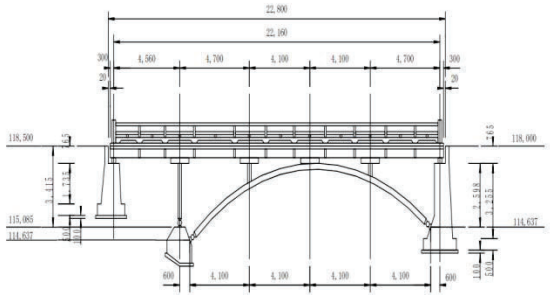

Figure 3: General drawing of Kajika Bridg

Table 1: *Properties of Kajika Bridge*

Location	Ishikawa pref, Japan
Type	Deck arch bridge
Total length	22.8m
Span	16.4m
Traveled way width	3.0m
Design load	Roadway 6tf
Completion	1987-12
Material	Glulam of Hiba (Thujopsis)

3 COMPARISON OF TWO MODELS

In modal analysis for bridges such as truss, arch and so on, which consist of slender members, beam element is generally used, while solid element such as tetrahedral element is not often used because of large calculation load. In this section we compare typical modal analysis model using beam/shell element and more exact model using tetrahedral element for Kajika Bridge.

3.1 CONVERGENCY OF TETRAHEDRAL ELEMENT

Here we investigate convergency of tetrahedral element. In the case of linear element, it needs 6,640,476 elements for natural frequency to be converged to two significant digit, while in the case of quadratic element, it needs 1,596,360 to be converged to two significant digit. Figure. 5 shows convergency for the vibration mode of vertically antisymmetric two sin half-waves, which is the most dominant mode for Kajika Bridge.

According to this result, quadratic element, which can obtain high accuracy with less number of elements, is adopted for the analysis hereafter.

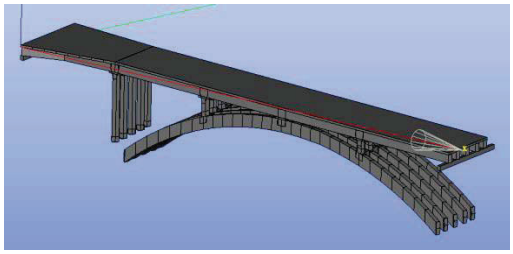

Figure 4: *Numerical Model for Kajika Bridg*e

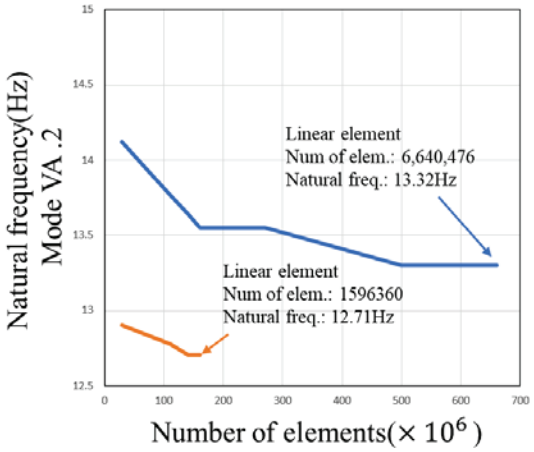

Figure 5: Convergency of tetrahedral element

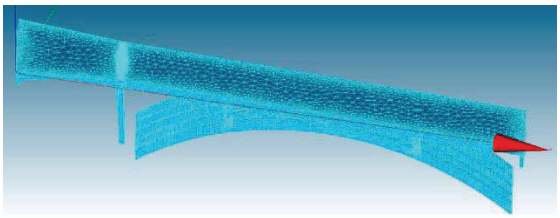

Figure 6: *Mesh of tetrahedral element*

3.2 COMPARISON TO MEASURED VALUE UNDER FITED YOUNG'S MODULUS

Natural frequencies measured in 2004, which is the first year of measurement since the beginning of service in 1987 for Kajika Bridge are shown in Table 2 for the following four dominant modes: H.S.1 is horizontally symmetric one sin half-wave shown in Figure. 6; V.A.2 is vertically antisymmetric two sin half-waves shown in Figure7; V.S.1 is vertically symmetric one sin half-wave shown in Figure.8 and V.S.4 is vertically symmetric four sin half-waves shown in Figure.9

We try to compare accuracy of the tetrahedral element model with beam/shell element model. Beam/shell element mode means the model in which the deck part is modeled by shell element, while the other parts such as arch, longitudinal beam and spandrel column are modeled by beam element shown in Figure 10. Each Young's

https://doi.org/10.52202/069179-0311

modulus of the tetrahedral element model and of the beam/shell element model is fitted to each appropriate value so that the natural frequency for the dominant vibration mode V.A.2 can coincide with the measured value 11.62Hz. Natural frequencies for the other three modes are calculated for the two models as shown in Table. 2. The relative errors for H.S.1 and V.S.1 of the tetrahedral element mode are smaller than those of the beam/shell element model. Although relative error for V.S.4 of the tetrahedral element mode are larger than that of the beam/shell element model. we think that this

Table 2: *Comparison of analysis accuracy*

Vibration mode	Natural frequency Measurement value (2004)	tetrahedral element	beam/shell element
H.S.1	11.62 Hz	4.95 Hz (-4.3%)	4.57 Hz (-13.2%)
V.A.2	5.17 Hz	11.62 Hz (0%)	11.62 Hz (0%)
V.S.1	15.82Hz	15.20 Hz (-3.9%)	14.00 Hz (-11.5%)
V.S.4	19.14Hz	20.77 Hz (8.5%)	18.00 Hz (-5.5%)

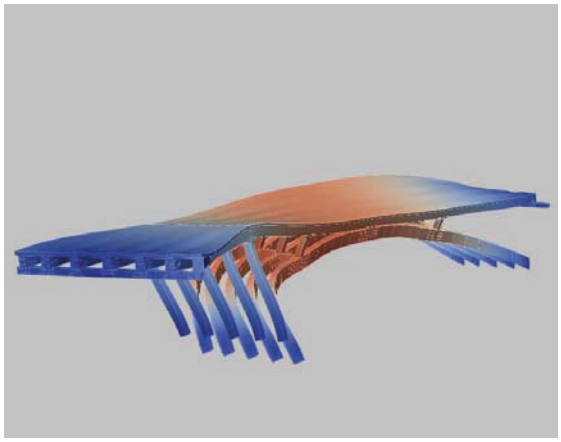

Figure 6: *Horizontally symmetric 1 sin half-wave (H.S.)*

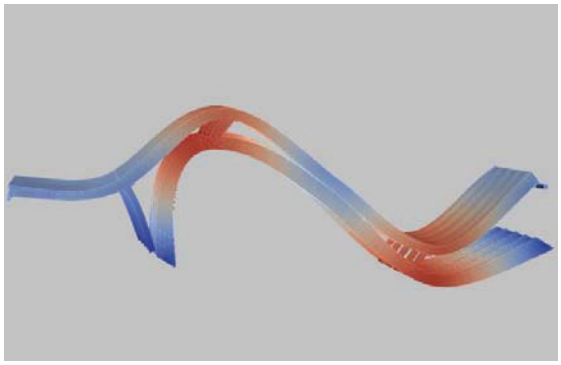

Figure 7: Vertically antisymmetric 2 sin half-waves (V.A.)

because of loss of measurement accuracy in higher mode vibration. According to the above, the tetrahedral element model is more suitable for modal analysis and this model will be used for all analyses hereafter. Incidentally materials for deck parts are orthotropic, while material for arch parts and so other parts is isotropic, since it is difficult to set appropriate othotropic condition corresponding to each local coordinate along the arch rib. Handrails with less influence to structure is not modeled.

4 YOUNG'S MODULUS FITTING TO MEASURED VALUE

The natural frequencies of the four modes for Kajika Bridge measured five times during fifteen years are shown in Table.4. The natural frequency for V.A.2, which is 11.62Hz in 2004, decreases to 8.69Hz in 2019. When we adjust Young's modulus in the tetrahedral element model so that the natural frequency for V.A.2 can be fitted to the value 8.69Hz, the Young's modulus for members of deck part becomes 4.81GPa and that for members of the other parts becomes 4.49GPa. If we assume that Young's modulus for all members decreases uniformly, it follows that Young's modulus for members of Kajika Bridge decreases by 53.23%, drastically. Young's moduluses adjusted in the same fitting manner for the measured values are also shown in Table 3. Figure 11 shows decreasing of the adjusted Young's moduluses for the measurement years. Young's moduluses decrease sharply from 2004 to 2012 and from 2015 to 2017, while Young's modulus decrease gradually in the other periods.

However from the realistic view point, the situation that the Young's moduluses for all members decrease uniformly by 53.23% is unlikely to happen, whether they sharply decrease or gradually decrease depending on periods during fifteen years. We guess that the decrease of the natural frequency is significantly influenced by partial decay of members. In fact the typical examples of partial decay are recognized at easily decayable parts such as ends of arch rib, connection between members and so on, which are shown in Figures 11, 12, 13 and 14. On the other hand, it seems that most of parts except for the decayable parts are not decayed so much by visual inspection.

Therefor we try a new approach fitting natural frequency by adjusting Young's modulus of partially set decay parts instead of adjusting Young's modulus of all members in the following section.

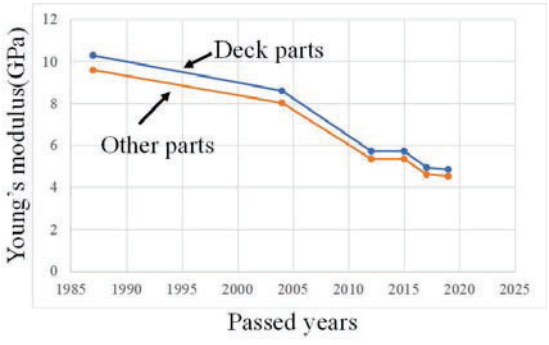

Figure 11: *Reduction in Young's modulus by passing age*

Figure 14: *Decay of connection between spandrel column and arch rib*

5 EVALUATION OF DECAY EFFECT

Here we numerically simulate the measured condition of the bridge by vibration analysis using FEM tool Salome-Meca considering decayed areas such as connection between longitudinal beam and sleeper beam, connection between spandrel column and arch rib, and end supports corresponding to the measurement. The numerical model with decayed areas is shown in Fig.15, 16.

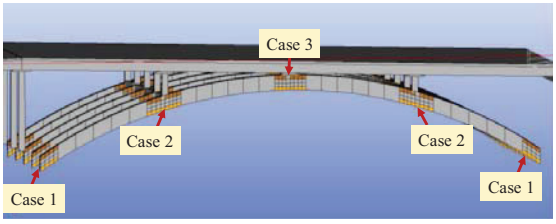

Figure 15: *Bridge model with decayed areas*

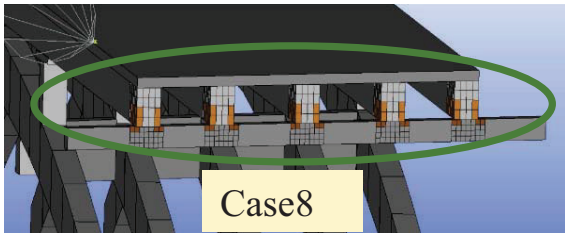

Figure 16: *Bridge model with decayed areas(sleeper beam)*

6 NUMERICAL ANALYSIS METHOD

In this study, the FEM model for the bridge is meshed by tetrahedral solid elements and the ends of each arch rib are hinged at the middle line of the section. The following two types of analyses are carried out.

6.1 COMPARISON BETWEEN MEASURED DATA AND NUMERICALLY DERIVED DATA

According to the measurement in 2019, the dominant natural frequency of Kajika bridge is 8.69Hz. In the numerical estimation, we firstly assume the model with only healthy areas whose Young's modulus is 9.6GPa (without decay), secondly we set the decayed areas whose Yong's modulus is 96MPa (Reduction 0%) and thirdly we gradually reduce the Young's modulus for the healthy areas (from 10% to 50%) with the same Young's modulus 96MPa for the decayed areas, until the natural frequency of the model would be enough close to the measured value.

6.2 EFFECT ESTIMATION FOR LOCAL DECAY PARTS

The case study has been conducted to identify the most significant part affecting the natural frequencies. The following cases shown in Table 4 are considered. It should be noted that the decay part for analysis 6.1 includes all cases, that is, the combination of Case 7 and Case 8.

Table 4: *Cases considering decay parts*

	Decay parts
Case 1	End supports

7 RESULTS AND DISCUSSION

The results of the analysis 6.1 are shown in Table 5. The dominant vibration mode of the arch bridge has vertically in-plane two sine half-waves as shown in Figure 3. While the measured natural frequency for Kajika bridge is 8.69Hz, that of numerical model with the decay parts and the healthy parts whose Young's modulus remains 9.6GPa (Reduction 0%) is 11.79Hz, which is about twice as large as the measured value. When Young's modulus of healthy parts is reduced by 40%, the calculated natural frequency is close to the measured value. And when the Young's modulus is reduced by 45.59%, the calculated natural frequency almost coincides with the measured value. At this time, the Young's modulus of this bridge is 5.22GPa which is less than half of the model without

https://doi.org/10.52202/069179-0311

decay. This estimation is smaller than expected and not realistic.

The results of the analysis 6.2 are shown in Table 6. According to the results, Case 2, 4, 6, and 7 shows the lower frequencies. The decay parts in these cases includes connection between spandrel column and arch rib. Therefore, the connection has significant influence on natural frequencies.

Case8	12.67	0.31%

8 CONCLUDING REMARKS

In this study, we carried out vibration analysis to estimate the proper Young's modulus and the most significant decay part affected to decreasing of the natural frequency for the bridge model with the considered local decay, comparing calculated values to the measured value. Basing on the results of the study, the following conclusions are made:

1) According to numerical comparison between tetrahedral element model and beam/shell element model, it is found that tetrahedral element mode gives more fitted natural frequencies for each dominant vibration mode than beam/shell element model.
2) As a result of simplified analysis, in which Young's moduluses for all members decrease uniformly, the adjusted value of Young's modulus becomes 53.23% to the original, while it is unlikely to happen.
3) In order to adjust the calculated natural frequency to the measured value, the Young's modulus of the healthy parts of the bridge has to be 5.22GPa, which is significantly low and still not realistic.
4) The decay at connection between spandrel column and arch rib has significant influence on natural frequencies of the bridge.

It is difficult to estimate which is more significant, reduction of Young's modulus for healthy parts or influence of decay parts. In the further study, the decay parts should be more parametrically studied considering conditions such as size, position, level of decay and so on.

TECHNICAL DESGIN GUIDE FOR TIMBER-CONCRETE COMPOSITE FLOORS – A CANADIAN APPROACH

Samuel Cuerrier Auclair[1], Christian Dagenais[2], Sylvain Gagnon[3]

ABSTRACT: FPInnovations, a not-for-profit research organisation for the Canadian forest sector and affiliated industries, developed a technical design guide for timber-concrete composite (TCC) floors meeting multi-design requirements. It provides the design criteria along with the calculation methods to control the elastic and long-term deflection, the vibration induced by human walking and the structural resistance, as well as guidance for the fire-resistance design and the behaviour of the shear connection. The technical guide has been used to develop design provisions that are expected to be implemented in the next 2024 edition of CSA O86. This paper presents a summary of this Canadian design method.

KEYWORDS: Timber-concrete composite (TCC), multi-criteria design, floor vibration, fire resistance, shear connector

1 INTRODUCTION

A timber-concrete composite (TCC) system consists of two distinct layers, a timber layer and a concrete layer, joined together by shear connectors; typically, the concrete slab is the top layer. The properties of both materials are better exploited as a composite element, since tension forces from bending are mainly resisted by the timber while compression forces from bending are resisted by the concrete. This construction technique is used to strengthen and stiffen timber floors of existing and new constructions, especially in multi-storey buildings and long-span applications. When the two materials are well connected together, the load-carrying capacity and the bending stiffness are significantly increased compared to a traditional timber floor system [1]. The concrete layer is usually a reinforced concrete slab. The timber part can be solid wood lumber, glued laminated timber (Glulam), structural composite lumber (SCL), cross-laminated timber (CLT), nail-laminated timber (NLT) or made of other engineered wood products. The shear connectors can be discrete fasteners (e.g., nails, screws, or notches cut in the wooden part) or shear connectors transferring the load to a larger surface (e.g., embedded plates, glue). A combination of different shear connectors is also possible.

The development of the TCC system was initiated after the First World War to find an alternative for reinforced concrete and steel, because of a lack of availability of steel. Several connection systems were patented [2, 3]. In the 1930's, this construction technique was applied to bridges mainly located in the U.S.A. [4]. In the 1950's, TCC building structures appeared in Australia and New Zealand [5]. It was ignored in most parts of the world until the 1990's, when TCC structures started to be used when refurbishing old historical buildings in European cities, in order to meet the new requirements regarding sound insulation and fire-resistance [6].

TCC systems can be a cost-competitive solution in the construction of buildings with floors having longer spans, since the mechanical properties of the two materials would be used efficiently. Furthermore, the additional mass from the concrete can improve the acoustic performance, compared to that of a timber floor system alone. Nevertheless, TCC floors are not commonly used in buildings in Canada, due to the absence of technical guidelines in the Canadian wood engineering design standard CSA O86-19 [7].

2 OBJECTIVES

The objectives of this paper are to present the multi-criteria design guide for TCC floors in Canada written by FPInnovations [8]. The criteria considered in the design are:

1) the elastic and the long-term deflections,
2) the vibration performance due to human normal walking,
3) the ultimate limit state design (bending and shear resistance) and,
4) the structural fire resistance.

The methodology used to verify those criteria are based on the gamma-method (γ-method) which was developed by Möhler [9] in 1956 by applying a sinusoidal load on a composite beam.

3 EVALUATION OF THE EFFECTIVE BENDING STIFFNESS

Using the γ-method, available in Annex B of the Eurocode 5 [10], the effective bending stiffness of the composite system can be evaluated. The γ-method assumes a uniformly distributed shear stiffness, K, between the two connected components, being timber and concrete. If the spacing of the shear connector is not constant along the span, an effective spacing needs to be estimated as follows:

$$s_{eff} = 0.75s_{min} + 0.25s_{max} \quad (1)$$

where s_{min} is the spacing of the shear connector near the supports in mm and s_{max} is the connector spacing in the mid-span section in mm. The uniformly distributed shear stiffness is then calculated as follows:

$$K = \frac{nk}{s_{eff}} \quad (2)$$

where n is the number of rows of the shear connectors and k is stiffness of a single shear connector in N/mm.

The tension contribution of the concrete must be neglected to be in-line with the concrete design standard in Canada (CSA A23.3) [11]. Figure 1 shows the nomenclature used and the cross-section with the associated axial deformation used for the calculation.

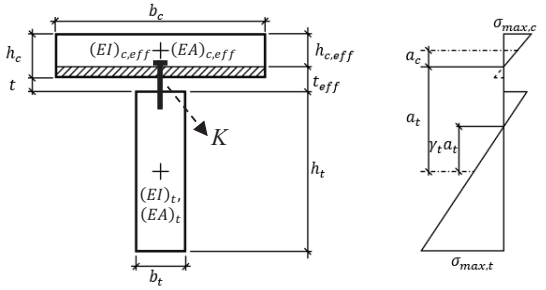

Figure 1: *Cross-section and axial deformation of a TCC beam neglecting the concrete solicited in tension*

$$(EI)_{eff} = (EI)_{c,eff} + (EI)_{t,eff} + \gamma_c(EA)_c a_c^2 + \gamma_t(EA)_t a_t^2 \quad (3)$$

Where,

$$\gamma_c = 1 \text{ and } \gamma_t = \frac{1}{1 + \frac{\pi^2(EA)_t}{KL^2}} \quad (4)$$

$$h_{c,eff} = \min\left(\sqrt{\alpha^2 + \alpha(h_t + 2h_c + 2t)} - \alpha; h_c\right) \quad (5)$$

$$\alpha = \frac{\gamma_t(EA)_t}{E_c b_c} \quad (6)$$

$$(EA)_{c,eff} = E_c b_c h_{c,eff} \text{ and } (EI)_{c,eff} = \frac{E_c b_c h_{c,eff}^3}{12} \quad (7)$$

$$a_c = \frac{\gamma_t(EA)_t r}{(EA)_{c,eff} + \gamma_t(EA)_t} \text{ and } a_t = r - a_c \quad (8)$$

$$r = \frac{h_t}{2} + t + h_c - \frac{h_{c,eff}}{2} \quad (9)$$

Where $(EI)_{eff}$ is the effective bending stiffness in N-mm^2. $(EI)_{c,eff}$ and $(EA)_{c,eff}$ are the effective bending stiffness and the axial stiffness of the concrete slab by neglecting the portion in concrete in N-mm^2 and in N, respectively. $(EI)_t$ and $(EA)_t$ are the bending stiffness and the axial stiffness of the timber component in N-mm^2 and in N, respectively.γ_c and γ_t are the composite factor of the concrete and wood component, respectively. E_c, b_c and h_c are the modulus of elasticity, the effective width and the thickness of the concrete slab in MPa, mm and mm, respectively. h_t is the height of the wood component in mm. a_c and a_t are the distance between the centroid of the concrete slab and the timber to the neutral axis of the concrete slab in mm, respectively. L is the span of the TCC floor in mm. t is the gap between the concrete slab and the timber component in mm. r is the distance between the centroids of the concrete slab and the wood component in mm.

4 SHEAR CONNECTION PROPERTIES

The type of shear connection between the timber and concrete components greatly influences the structural properties of TCC floors. A wide range of connection systems are available, ranging from mechanical connectors such as bolts [12], lag screws [13], or self-tapping screws (STS) [14], glued-in perforated steel plates [15], composite connectors [16], adhesive bonds [17], notched connections [18], or steel kerf plates [19].

When possible, the shear resistance of the shear connector should be estimated with the appropriate Clause 12 in CSA O86-19 [7]. When not possible, the shear resistance needs to be estimated through laboratory testing.

CSA O86-19 [7] does not give equation to estimate the slip modulus of connectors. Thus, this property needs to be evaluated in a laboratory. The testing need to be performed in accordance with the standard ISO 6891 [20].

5 ELASTIC AND LONG-TERM DEFLECTIONS

5.1 ELASTIC DEFLECTIONS

In Canada, the deflection limit for timber structure under serviceability loads are prescribed by CSA O86-19 [7]. Estimating the elastic deflection is relatively straightforward, the effective bending stiffness is estimated using the standard-term properties of each

https://doi.org/10.52202/069179-0312

material and using the serviceability limit state slips modulus of the shear connector. Once this, effective bending stiffness is estimated, the instantaneous deflection can be estimated with the serviceability load combination considered.

5.2 LONG-TERM DEFLECTION

The long-term deflection is estimated by the superimposition principles. Two portions of the total deflection can be defined:

1) the elastic deflection due to transient load evaluated with the previous subsection and
2) the long-term deflection, which includes the elastic and creep portion, due to quasi-permanent and permanent loads.

The second portion is evaluated by dividing the stiffness properties of each material (e.g., timber, concrete and shear connector) by their respective creep modification factors. Creep modification factors are numerically equivalent to the creep coefficient by adding 1 to the value. Once the stiffness of each material is modified, the long-term effective bending stiffness can be estimated to calculate the long-term deflection due to quasi-permanent and permanent loads.

6 VIBRATION PERFORMANCE DUE TO WALKING

Human normal walking excites the floor through its footstep. Significant efforts were made towards understanding the nature of footsteps [21-24]. Based on their findings, it can be concluded that the footstep force generated by walking comprises two components [22]. One component is a short duration impact force induced by the heel of each footstep on the floor surface where the duration of the heel impact varies from about 30 ms to 100 ms depending on the conditions and the materials of the two contact surfaces (that of the floor and the footwear of the walking person), and on the weight and gait of the person. The other component is the walking rate, a series of footsteps consisting of a wave train of harmonics, at multiples of about 2 Hz.

To understand how TCC floors behave under walking vibration, FPInnovations tested three different laboratory floors:

1- NLT-concrete composite slab floor with a nail plate as shear connectors;
2- CLT-concrete composite slab floor with self-tapping screws as shear connectors;
3- Concrete slab - glulam beams composite floor with self-tapping screws as shear connectors.

The three floors have been tested according to the ISO 18324 [25] and ISO 21136 [26] in order to evaluate their natural frequency, damping ratio, static deflection under a concentrated load and their vibration performance under a subjective evaluation. From these tests, design criteria to limit the span due to vibration induce by walking has been developed. More information on the tested laboratory TCC floors can be found in [27].

Using the subjective evaluation results of the three tested TCC floor along with their calculated natural frequencies and deflections, the following design criterion was derived using the method described in ISO 21136 [26].

$$\frac{f_1}{d_{1kN}^{0.14}} \geq 5.75 \tag{10}$$

where f_1 is the fundamental natural frequency in Hz and d_{1kN} is the static deflection under a 1 kN point load in mm. Assuming a simple span floor with a centre point load, Equation (10) can be rewritten as follows to limit the span.

$$L \leq 0.329 \frac{\left((EI)_{eff}^{1m}\right)^{0.264}}{m_L^{0.207}} \tag{11}$$

where L is the maximum allowable clear span in meter for the vibration criterion. $(EI)_{eff}^{1m}$ is the effective bending stiffness of the floor calculated with Equations (3) considering the standard-term material properties for 1-meter-wide floor in N-m^2 and m_L is the structural mass only of the 1-meter-wide floor in kg/m.

Figure 2 illustrates the verification of the proposed design criterion for TCC floors using the limited laboratory data and the field floor data. Each symbol represented a subjectively rated TCC floor.

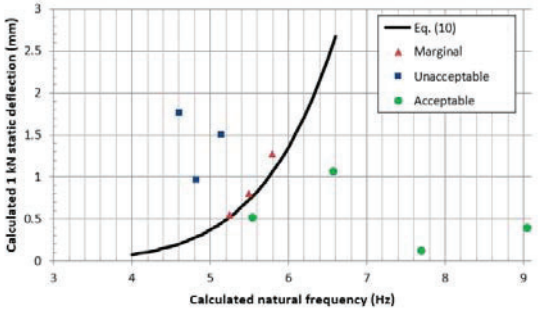

Figure 2: *Verification of the proposed design criterion for controlling vibration of TCC floors*

7 ULTIMATE LIMIT STATE DESIGN

TCC floors are made of three components: timber, concrete and shear connectors, where each of them can limit the strength of the floor. In the following section, equations are developed to evaluate the bending moment and the shear resistance of the whole TCC floors by considering the component that would fail first.

The shear connector can be 1) brittle or is not allowed to yield or 2) ductile and is allowed to yield. In these two different scenarios, the resisting equations are not the same. In the first scenario, the γ-method is used to estimate the force in each component. The TCC floor

design resistance is achieved when the first component achieved its ultimate resistance. The second scenario assumes that each connector has yielded which changes the equilibrium cinematic compared to the γ-method. Consequently, an elasto-plastic model (EPM) [28] is used to estimate the force on each component and the TCC floor ultimate resistance is achieved when the timber or the concrete achieved its ultimate resistance. It should be noted that the shear connector under serviceability load must remain in its elastic behaviour which is verified with the γ-method.

If the connector is ductile and the resistance of the TCC floor is limited by the γ-method, the floor will likely be brittle. Comparatively, if the resistance is limited by the EPM, the floor will have inelastic deformation before collapse. Figure 3 shows typical load-deflection curve of TCC floor. The γ-method will limit the resistance of the floor if the floor fails in the first circled portion and the EPM will limit the resistance of the floor if the floor fail in the second circled portion.

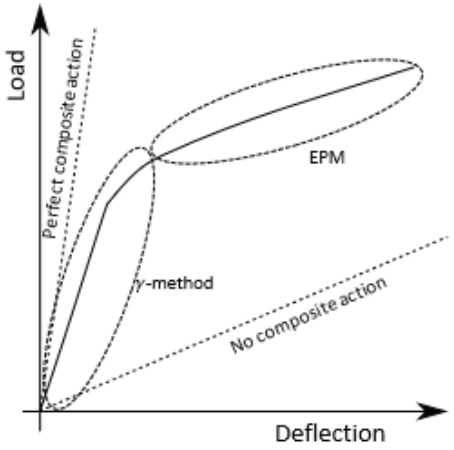

Figure 3: *Failure mechanism of TCC floors*

If not all the connectors have yielded when the floor fails, that situation is not directly accounted either in the γ-method and the EPM. However, in the γ-method the shear stiffness of the connectors is usually reduced when calculating the ultimate resistance of the floor which partially accounts this situation. Moreover, in the EPM the total shear load given by all the yielded connectors is estimated with their design resistance. Due to repeatability effect, the total shear load given by the connectors in the EPM gives a smaller probability of failure compared to a single shear connector. Consequently, in the design calculation, the EPM gives a conservative design value if all the connectors have yielded.

7.1 BENDING RESISTANCE

7.1.1 Gamma method

A bending moment applied on a composite floor (M) induced a bending moment (M_i) and an axial force (N_i) on each layer where i is used to either represent the timber component, t, or the concrete component, c. According to the γ-method, the axial force and the bending moment on each layer is calculated with the following formulae:

$$N_i = \frac{\gamma_i (EA)_i a_i}{(EI)_{eff}} M \tag{12}$$

$$M_i = \frac{(EI)_i}{(EI)_{eff}} M \tag{13}$$

The maximum axial stress on a given component is equal to the following equation:

$$\sigma_{max,i} = \frac{M}{b_i h_i (EI)_{eff}} \left(\frac{6(EI)_i}{h_i} + \gamma_i (EA)_i a_i \right) \tag{14}$$

However, for the timber element, only looking the maximum stress is not sufficient. The interaction between the axial force and the bending moment need verification with the following combined efforts interaction in accordance with CSA O86-19 [7]:

$$\frac{T_{f,t}}{T_{r,t}} + \frac{M_{f,t}}{M_{r,t}} \leq 1.0 \tag{15}$$

Where $T_{r,t}$ and $M_{r,t}$ are the tension and bending moment resistance, respectively, for the timber element evaluated with the CSA O86-19 [7] and $T_{f,t}$ and $M_{f,t}$ are the tension and bending moment force resisted by the timber component. The bending moment resistance of a TCC floor limited by the timber can be determined by substituting Equations (12) and (13) into Equation(14):

$$M_{r,\gamma,t} = \frac{(EI)_{eff} T_{r,t} M_{r,t}}{\gamma_t (EA)_t a_t M_{r,t} + (EI)_t T_{r,t}} \tag{16}$$

The bending moment resistance of a TCC floor limited by the concrete component is determined by ensuring that the maximum axial stress of the concrete does not exceed $0.9\phi_c f_c'$ which is in consistent with CSA A23.3-19 [11]. However, ensuring that the concrete never exceeds $0.9\phi_c f_c'$ with a triangular stress distribution is very conservative since concrete is able to have some inelastic deformation.

$$M_{r,\gamma,c} = 0.9\phi_c f_c' S_c \tag{17}$$

$$S_c = \frac{(EI)_{eff}}{E_c (0.5h_c + \gamma_c a_c)} \tag{18}$$

As a result, the bending moment resistance of a TCC floor when the shear connectors are brittle or not allowed to yield is:

$$M_{r,\gamma} = \min\left(M_{r,\gamma,t}; M_{r,\gamma,c}\right) \tag{19}$$

7.1.2 Elasto-plastic model

The bending moment resistance evaluated with the γ-method assumes that each component has a linear elastic behaviour. However, if the connector yields before failure

https://doi.org/10.52202/069179-0312

of the timber or the concrete element, bending moment resistance given by the γ-method may overestimate the resistance which is why bending moment resistance needs to be limited as a function of the connection's strength determined from the EPM ($M_{r,EP}$). When calculating the resistance with the EPM, the connectors must exhibit a ductile behaviour.

To consider the ductility of the connectors, Frangi & Fontana [28] proposed a method which accounts the strength of the connectors. The principles of this method are similar to the method in CSA S16-19 [29] for calculating the bending moment resistance of a steel-concrete beam, with some minor differences. When the connectors are allowed to yield, the following equation needs to be respected:

$$M_r = \min\left(M_{r,\gamma,t}; M_{r,\gamma,c}; M_{r.EP}\right) \tag{20}$$

where $M_{r,EP}$ is the bending moment resistance evaluated with the EPM developed by Frangi & Fontana [28] describes in this section. They developed the equations to evaluate the bending moment resistance considering that the timber fails first, while a part of the concrete is in tension, which is usually the case. However, to consider all possible scenarios, the equations for the bending resistance in the event that the concrete fails first or when the entire thickness of the concrete is in compression were also developed.

Based on the assumption that all connectors have yielded at the collapse mechanism, the maximum shear force that can be transferred to each layer is calculated from the design connector strength ($V_{r,conn}$) and the number of connectors (m) located between the critical cross-section and one point of zero moment:

$$N_c = N_t = N = mV_{r,conn} \leq \min\left(T_{r,t}; 0.9\phi_c f_c' A_c\right) \tag{21}$$

If $mV_{r,conn} \geq \min\left(T_{r,t}; 0.9\phi_c f_c' A_c\right)$, it means that the concrete or the timber will reach its resistance before that all the connectors have yielded. In that case, $N = \min\left(T_{r,t}; 0.9\phi_c f_c' A_c\right)$, $h_{c,eff} = h_c$, $\sigma_{b,t} = \sigma_{b,c} = 0$, when evaluating $M_{r,EP}$ with Equation (31).

If the bending moment resistance of the composite floor is governed by the timber design strength, the bending stress applied on the timber $\sigma_{b,t}$ is calculated as follows:

$$\sigma_{b,t} = \left(1.0 - \frac{N}{T_{r,t}}\right)\frac{6M_{r,t}}{b_t h_t^2} \tag{22}$$

If a part of the concrete is in tension, $h_{c,eff}$ and $\sigma_{b,c}$ are calculated as:

$$h_{c,eff} = \sqrt{\frac{NE_t h_t}{E_c \sigma_{b,t} b_c}} \leq h_c \tag{23}$$

$$\sigma_{b,c} = \frac{N}{b_c h_{c,eff}} \leq 0.45\phi_c f_c' \tag{24}$$

Note that E_t in the EPM is equal to $12(EI)_t/(b_t h_t^3)$. If the limitation of Equation (23) is not respected, then the entire thickness of the concrete is in compression and $h_{c,eff} = h_c$ and $\sigma_{b,c}$ is calculated as:

$$\sigma_{b,c} = \frac{E_c h_{c,eff}}{E_t h_t}\sigma_{b,t} \leq \left(0.9\phi_c f_c' - \frac{N}{b_c h_{c,eff}}\right) \tag{25}$$

If the limitation of Equation (24) or (25) is not respected then the bending moment resistance of the composite floor is governed by the concrete strength. If a part of the concrete is in tension, $h_{c,eff}$, $\sigma_{b,c}$ and $\sigma_{b,t}$ are calculated as follows:

$$h_{c,eff} = \frac{2N}{0.9\phi_c f_c' b_c} \leq h_c \tag{26}$$

$$\sigma_{b,c} = 0.45\phi_c f_c' \tag{27}$$

$$\sigma_{b,t} = \frac{E_t h_t b_c (0.9\phi_c f_c')^2}{4E_c N} \leq \left(1.0 - \frac{N}{T_{r,t}}\right)\frac{6M_{r,t}}{b_t h_t^2} \tag{28}$$

If the limitation of Equation (26) is not respected then the entire thickness of the concrete is in compression and $h_{c,eff} = h_c$ and $\sigma_{b,c}$ and $\sigma_{b,t}$ are calculated as follows:

$$\sigma_{b,c} = 0.9\phi_c f_c' - \frac{N}{b_c h_{c,eff}} \leq \frac{N}{b_c h_{c,eff}} \tag{29}$$

$$\sigma_{b,t} = \frac{E_t h_t}{E_c h_c}\left(0.9\phi_c f_c' - \frac{N}{b_c h_{c,eff}}\right) \leq \left(1.0 - \frac{N}{T_{r,t}}\right)\frac{6M_{r,t}}{b_t h_t^2} \tag{30}$$

Once N, $h_{c,eff}$, $\sigma_{b,c}$ and $\sigma_{b,t}$ are known, the bending moment resistance of the composite floor is calculated as follows:

$$M_{r,EP} = N\left(\frac{h_t}{2} + t + h_c - \frac{h_{c,eff}}{2}\right) + \sigma_{b,c}\frac{b_c h_{c,eff}^2}{6} + \sigma_{b,t}\frac{b_t h_t^2}{6} \tag{31}$$

7.2 SHEAR RESISTANCE

7.2.1 Gamma method

The shear resistance of a TCC floor can be dictated by the strength of the connectors, the timber or the concrete. From the Eurocode 5 [10], the shear flow at the connection interface (τ_{conn}) is evaluated with the following formulae:

$$\tau_{conn} = \frac{\gamma_t (EA)_t a_t}{(EI)_{eff}} V \quad (32)$$

V is the applied shear force on the whole TCC section. The applied shear force at one connector (V_{conn}) is afterwards evaluated with the following equation:

$$V_{conn} = \frac{\tau_{conn} s}{n} = \frac{\gamma_t (EA)_t a_t s}{n(EI)_{eff}} V \quad (33)$$

Where s is the tributary spacing of the considered shear connector and n is the number of rows of shear connectors. Equation (33) can be rewritten to estimate the shear resistance of the whole composite floor dictated by the connection shear resistance with the γ-method ($V_{r,\gamma,conn}$) as follows:

$$V_{r,\gamma,conn} = \frac{n(EI)_{eff}}{\gamma_t (EA)_t a_t s} V_{r,conn} \quad (34)$$

where $V_{r,conn}$ is the design connection shear resistance.

The vertical shear stress in the timber and concrete elements according to the classical beam theory (and the theory of mechanically jointed beams [10]) is calculated as follows:

$$\tau_{max,i} = \frac{V(EQ)_i}{(EI)_{eff} b_i} \quad (35)$$

where,

$$(EQ)_i = \frac{y_i}{h_i}\left(\frac{6(EI)_i}{h_i}\left(1 - \frac{y_i}{h_i}\right) + \gamma_i (EA)_i a_i\right) \quad (36)$$

y_i is the position at which the shear stress is evaluated. Knowing that the shear stress is critical at the neutral axis evaluated as $y_{NA,i} = h_i/2 + \gamma_i a_i$ the maximum stress within a layer is then:

$$\tau_{max,i} = \begin{cases} \dfrac{0.5E_i\left(\frac{h_i}{2} + \gamma_i a_i\right)^2}{(EI)_{eff}} V, & y_{NA,i} < h_i \\ \dfrac{E_i h_i \gamma_i a_i}{(EI)_{eff}} V, & y_{NA,i} \geq h_i \end{cases} \quad (37)$$

If there is no neutral axis in the layer, the shear stress is maximal at the interface, as dictated from the second expression in Equation (37).

In Canada, the verification according to design standard is based on the force instead of the stress. According to the theory of mechanically jointed beams, the shear force in each component is calculated with the following equation:

$$V_i = \frac{(EI)_i + 0.5\gamma_i (EA)_i h_i a_i}{(EI)_{eff}} V \quad (38)$$

Equation (38) can be rewritten to estimate the shear resistance of the whole composite floor dictated by the timber shear resistance or the concrete shear resistance with the γ-method as follows:

$$V_{r,\gamma,t} = \frac{(EI)_{eff}}{(EI)_t + 0.5\gamma_t (EA)_t (h_t + t) a_t} V_{r,t} \quad (39)$$

$$V_{r,\gamma,c} = \frac{(EI)_{eff}}{(EI)_c + 0.5\gamma_c (EA)_c (2h_c - h_{c,eff} + t) a_c} V_{r,c} \quad (40)$$

where $V_{r,t}$ is the design shear resistance of the timber component and $V_{r,c}$ is the design shear resistance of the concrete slab. It must be noted that in Equations (39) and (40) the gap, t, have been added in the equation to ensure that the total vertical shear force can be resisted by the concrete and the timber component.

The shear resistance of the whole TCC floors is reached when the first component reaches its strength. Thus, the following equation gives the shear resistance of the whole TCC floors ($V_{r,\gamma}$).

$$V_r = \min\left(V_{r,\gamma,conn}; V_{r,\gamma,t}; V_{r,\gamma,c}\right) \quad (41)$$

If the connector resistance is reached before the shear resistance of the timber or the concrete, that doesn't necessarily mean failure of the TCC floor if the connectors exhibit a ductile behaviour [28,30,31]. When the capacity of the ductile shear connector is reached, it will transfer its forces to the concrete and timber elements until one of them fail. As a conservative design, Equation (41) may be used to evaluate the shear resistance of the TCC floor when the connector is ductile. However, if the designer wants to benefit on the ductility of the connector, the following equation can be used:

$$V_r = \min\left(V_{r,\gamma,t}; V_{r,\gamma,c}; V_{r,EP,t}; V_{r,EP,c}\right) \quad (42)$$

where $V_{r,EP}$ is the shear resistance following the EPM. Although the shear connectors are ductile, the shear resistance limited by the shear connector, $V_{r,\gamma,conn}$, must be higher than the serviceability shear load in order to limit the fatigue phenomena and ensuring accuracy in the deflection calculation.

7.2.2 Elasto-plastic model

More details for the shear resistance calculated with the EPM is given in the design guide for TCC floors in Canada written by FPInnovations [8].

8 STRUCTURAL FIRE-RESISTANCE

This section addresses the structural fire-resistance of a TCC floors subjected to a standard fire from underneath and does not address all the other subjects related to the

https://doi.org/10.52202/069179-0312

fire safety, such as the separating function of floor assemblies. In order to develop and validate a calculation method to predict the time of structural fire-resistance for a TCC floor, FPInnovations [32, 33] tested three different TCC floors exposed to a standard fire such as that specified in CAN/ULC-S101 and ASTM E119. The span of these three floors was 4815 mm with an applied live load of 2.4 kPa. One of the floors consisted of a series of nine screw-laminated 2x8 "beams" (38 x 184 mm, on the edge), where each build-up beams consisted of five pieces of lumber boards. Conventional truss plates were used as shear connectors into 89 mm reinforced concrete as shown in Figure 4a. A second floor consisted of a 5-ply (175 mm) E1 stress grade CLT and 89 mm concrete, connected using self-tapping screws driven at 45° into the CLT, as shown in Figure 4b. The third floor consisted of 5¼" x 16" (133 x 406 mm, on flat) laminated veneer lumber (LVL). Lag screws were used as shear connectors, as shown in Figure 4c, to 89 mm concrete topping. All of these floors were fully exposed to the standard fire from underneath (i.e. timber components were exposed to fire).

a) 2x8 screw laminated wood with a truss plate

b) CLT with self-tapping screws

c) LVL with lag screw

Figure 4: *TCC floors under construction for fire-resistance testing*

Based on the data gathered from the tested TCC floors exposed to the CAN/ULC S101 standard fire, it was found that the shear connectors have little to no impact on the heat transfer into the assembly. Even the lag screws' larger diameter did not create a significant increase in heat transfer through the assembly as the shear connector becomes exposed to fire from underneath. Consequently, as long as the connector is not exposed to fire (i.e., remains in the reduced timber cross-section), it can be assumed that the shear resistance and the shear stiffness of the connector are not affected. However, when the timber element is exposed to fire on its side and underneath (e.g. timber beam), the wood that covers the shear connector on the side must be at least 35 mm to remain thermally thick (i.e. to limit heat transfer up to the connector). When the wood cover is less than 35 mm, the temperature into the connection can increase significantly and then greatly affect its mechanical properties.

When the connector becomes exposed to fire from underneath, its shear resistance should be estimated using the appropriate design provisions as a function of its residual penetration depth into the timber. If it is not possible to estimate the shear resistance with those design provisions, its strength may be reduced proportionally to its remaining depth. This design assumption may not be applicable for all shear connectors. Consequently, applying this assumption is at the judgment of the structural engineer of record.

When no test data are available, the reduced shear stiffness of the shear connector could be proportional to the loss of strength. This assumption may not be applicable for all shear connectors, but has been validated with self-tapping screws inserted with an angle of 45°, lag screws and truss plates in the following references [32, 33]. It is at the judgment of the structural engineer of record to apply or not this hypothesis in function of the shear connector.

Table 1 gives the structural failure times obtained from these three tested floors and those predicted using the methodology proposed herein.

Table 1: *Fire-resistance of TCC floors – Test data vs. calculation method*

	NLT-Concrete	CLT-Concrete	LVL-Concrete
Shear connector	Truss plate	Self-tapping screws	Lag screws
Test failure time (min)	>214*	214	191
Predicted failure time	247	198**	165

*Test was stopped when the CLT-concrete floor failed. No failure was reached for the NLT-concrete floor.
**Using the effective charring model from Annex B of CSA O86-19 [7]

The predicted structural fire-resistance failure times are calculated using laboratory shear connector test results (stiffness and resistance). The shear connector properties were proportionally reduced linearly as a function of its remaining penetration depth once it was exposed to fire. The predicted times are conservative for the CLT-concrete and LVL-concrete composite floors. For the NLT-concrete floor, the predicted failure time seems realistic, but it is uncertain whether the estimation is conservative, or not, since the test was stopped after 214 min; time at which the CLT-concrete floor failed first (CLT and NLT were tested simultaneously in the same furnace).

Figure 5 shows the predicted deflection as a function of time for the LVL-concrete composite floor with two different assumptions. One predicted curve assumes that the stiffness of the connectors is reduced proportionally to its remaining penetration depth and the other curve uses the stiffness of the connectors based on shear test results conducted at different remaining penetration depths into

the LVL. The deflection was estimated by reducing the thickness of the wood through time and the shear connector stiffness which impacted the calculated $(EI)_{eff}$. For the LVL-concrete composite floor with lag screws as shear connectors, the estimated deflection and residual resistance are conservative when assuming that the properties of the shear connector are reduced proportionally to its remaining penetration depth. The predicted deflection is also quite accurate when compared to the experimental results using shear connector properties being modified based on experimental shear test results.

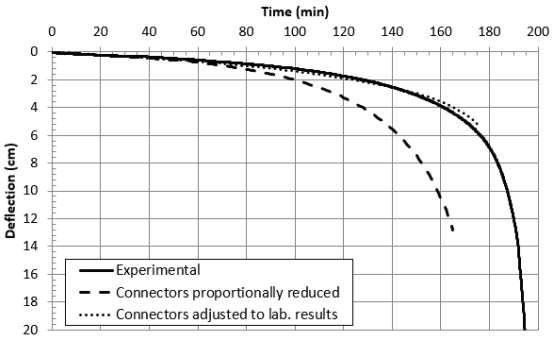

Figure 5: *Comparison between the experimental and the predicted deflections in function of time curves*

From these tests, it is concluded that when the composite floor is made with a timber slab (bottom), the timber effectively protects the concrete (top) from the thermal effects from fire underneath. Consequently, the strength of the TCC slab floor can be calculated by simply reducing the timber cross-section due to charring and the connector properties as a function of its remaining penetration depth. However, when the floor is made with timber beams instead of a timber slab, the concrete located between beams becomes fully exposed to fire and its fire resistance shall be calculated in accordance with the applicable design provisions found in the NBC [34].

9 CONCLUSIONS

With the information currently available in the literature and laboratory test results, FPInnovations developed a design guide for timber-concrete composite floors with a focus on the Canadian design code. This paper presents a summary of this design method.

At the time of writing this paper, design provisions were developed for implementations in the next 2024 edition of CSA O86. The methodology presented in the technical guide was used to develop the provisions, which have been slightly modified based on CSA O86 Task Group members. Limitations are also proposed, such as simple span TCC floors and TCC floors consisted of slab elements only.

ACKNOWLEDGEMENT

FPInnovations would like to thank its industry members and Natural Resources Canada (Canadian Forest Service) for their financial supports of this work.

AN ENGINEERING MODEL FOR THE DESIGN OF CUT-BACKS IN RIBBED PANELS

Medhanye Biedebrhan Tekleab[1], Manfred Augustin[2], Gerhard Schickhofer[3]

ABSTRACT: This paper deals with the modelling and analysis of ribbed panels with 'cut-back' ribs. A critical point in the design of these members is on the determination of the occurring forces and stresses - in particular in tension perpendicular to grain - at the end of the ribs, potentially inducing a splitting failure. Thus, ribbed panels with cut-back ribs in practice always have to be reinforced by appropriate methods (e. g. self-tapping screws or glued-in rods). The open question for the designer is on the determination and the intensity of the design force for the reinforcement.

In this contribution a pure analytical solution procedure based on a simple engineering model has been used. A detailed discussion on modes of load resistance and corresponding deformations has been made, taking into account effects of geometrical & mechanical properties of the components, cut-back length, component-interface properties and load intensity. As a result, simple expressions for the prediction of forces in the reinforcement under transverse loading situations were obtained. All results and discussions may also be applied to systems of beam-beam as well as plate-plate composites with cut-backs and notches of the lower component respectively.

KEYWORDS: CLT, GLT, Stiffening, ribbed-panels, cut-back ribs, shear connection, relative slip, splitting, linear elastic analysis, reinforcement, stresses perpendicular to grain

1 INTRODUCTION

With the increased demand and use of CLT and LVL plates as slabs in structural timber systems, panels with longer spans are desired. One possibility to fulfil the requirements regarding strength, serviceability and economical aspects of long span plates is through the application of wooden ribbed panels. Such structural components consist usually of equally spaced ribs (e.g. glulam) and a plate (e.g. CLT or LVL). These ribs are in general eccentrically glued to the plate along their upper edge (interface line or contact surface).
Ribbed panels/plates with ribs having depths commonly used in practice are regarded as stiffened panels/plates. With relatively deeper ribs, the case of 'folded plates/structures', consisting of a system of rectangular cover plate and a sequence of parallel equidistant ribs may come into picture.

2 LOAD-CARRYING BEHAVIOUR

Ribs oriented in the longitudinal direction to increase the flexural stiffness of the plates are due to constructional and economical reasons shorter in length than the longitudinal dimension of the cover plate, i.e. there is a 'cut-back' at the end of the ribs. Such ribs are not supported at the transverse edges of the structural system. The ribs therefore are taking part in the load-carrying process of the complete structural system via distributed 'interaction' forces along the interface lines, i.e. interaction shear forces parallel to the interface line & interaction transverse normal forces in the direction orthogonal to the mid-plane of the ribbed panel.
Apart from the usual design of ribbed panels in ULS and SLS this detail requires a special consideration.
To get an overview about the phenomenon as well as to calibrate the developed model tests were driven. In Figure 1 the used test configuration is shown, while in Figure 2 the potential failure mode is depicted.

3 PRACTICAL CONSIDERATIONS

When designing ribbed panels, the usual loadings have to be taken into consideration. In addition, effects from changing moisture contents may occur but are usually neglected in the verification as well as in this paper. While shear forces at the interface are covered (up to a certain limit) by the glue-line, the tension stresses perpendicular tend to induce a splitting-failure at the end of the cut-back. In practise, the resulting tension force has to be taken by appropriate reinforcements (e. g. self-tapping screws or glued-in rods) because of the magnitude and sensitivity of this strength. Currently no specific model for the design of cut-back reinforcements is known.

There have been many studies that directly or indirectly dealt with reinforcements of notches in beam members (see section 5.4) which are to some extent comparable with cut-backs in ribbed panels. Results of such studies have been included in guidelines and standards and are used by practicing engineers. Most studies, if not all, however mix 'transverse tensile stress resultant' as given, for example, in the DIN 1052:1988 [5] formula $F_{t,90} = 1.3\,[3(1-\alpha)^2 - 2(1-\alpha)^3]\,V$, which is only valid for unreinforced cases or equivalent, 'force in a given reinforcing screw' referring to any reinforced system irrespective of crack extent or system strength and 'required screwing/reinforcing force' for cases with pre-specified crack extent or intended system strength.

From the viewpoint of practice, one may not definitely speak about avoiding splitting at the end of the cut-back; one may even say cracking at its vicinity is inevitable. Once splitting happens there, the (local) shear resistance will be lost. This effect keeps increasing as crack line grows as a result of load increase.

To cover the requirements in practice, a model for the determination of design forces for the reinforcement of cut-backs in this paper is developed based on a beam model enabling a transparent and understandable design.

4 STRUCTURAL MODELLING

The structural system will be modelled as a plate system with rib stiffeners. The rectangular plate is assumed simply supported along both (parallel) transverse edges and extends to 'infinity' in the other direction (Figure 3).

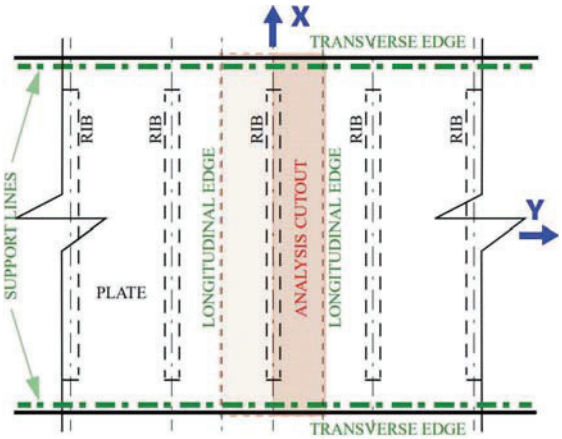

Figure 3: *Plan view of the structural system*

Due to an assumed independence of the load distribution on the transverse Y-coordinate it becomes possible to reduce the investigation to a suitable analysis 'cut out', applying symmetry conditions along the longitudinal edges of the structural model. The representative analysis 'cut out' will consist of one full rib and a strip of the covering plate composed as T-shaped model (Figure 4). Due to symmetry this model may further be reduced to half of the rib and plate flange. Figure 5 shows sectional views of uncracked and partly cracked interfaces, respectively.

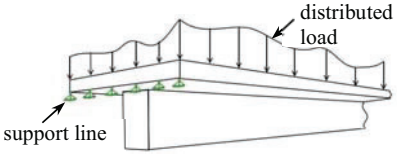

Figure 4: *Symmetric T-shaped model*

https://doi.org/10.52202/069179-0313

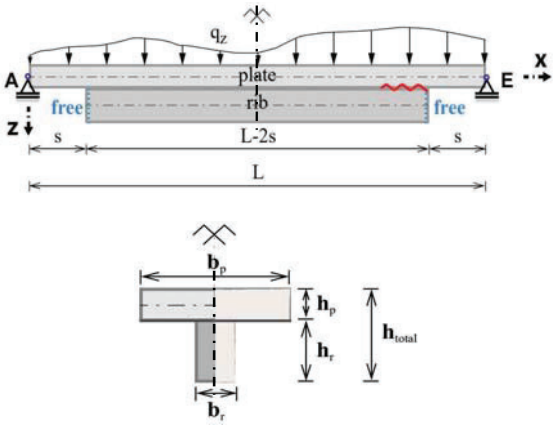

Figure 5: *Sectional views: uncracked interface (rib left side) and cracked interface (rib right side) at the cut-back*

The first question of interest is how the (linear elastic) structural behavior changes if the support conditions switch from the 'standard situation' where ribs are supported alongside the cover plate to the 'non-standard situation' where ribs are of the same length as the cover plate but are not supported, i.e. cut-back length s = 0. The second question of interest is how this change of behavior will further be affected if the cut-back length 's' becomes greater than zero, i.e. s > 0 as shown in Figure 10.

5 SOLUTION APPROACH

There will be an interaction of interface shear stress with interface normal stress in resisting applied system loading. For the sake of simplicity, special cases of no relative slip (rigid shear connection) and unrestricted relative slip (without shear connection) have been considered in the current study. Moreover, for simplicity, only bending deformations are considered. Figure 6 shows a substitute system of a general two-element system (cut-back length s = 0) that will help to understand the solution approach implemented. In the 'substitute system' both elements are first considered supported with a follower step that counterbalances the forces at the free edge of the lower structural element.

In the intermediate step of the 'substitute system' where both elements are supported, the load share between the elements depends on their flexural stiffnesses for the case of a system with unrestricted relative slip (without shear connection) as given by Equations (1) and (2).

$$q_{z,1} = \frac{E_1 I_1}{E_1 I_1 + E_2 I_2}\, q_z \tag{1}$$

$$q_{z,2} = \frac{E_2 I_2}{E_1 I_1 + E_2 I_2}\, q_z \tag{2}$$

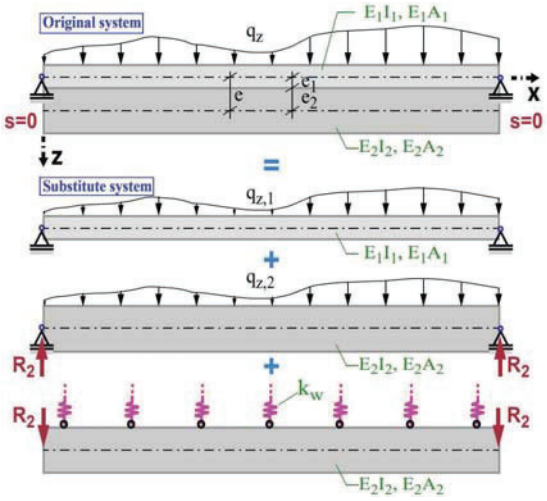

Figure 6: *Substitute system and load sharing*

For the case of the system with no relative slip (rigid shear connection), the load share between the elements will depend on the axial stiffnesses of the elements in addition to their flexural stiffnesses. The load share in such a case is given by Equations (3) and (4) and the axial force at a section resulting from the stiffness of the interface in shear by Equation (5).

$$q_{z,1} = \frac{E_1 I_1 + \rho\, e_1\, e}{E_1 I_1 + E_2 I_2 + \rho\, e^2}\, q_z \tag{3}$$

$$q_{z,2} = \frac{E_2 I_2 + \rho\, e_2\, e}{E_1 I_1 + E_2 I_2 + \rho\, e^2}\, q_z \tag{4}$$

$$N_x = -\rho\, e\, \frac{\partial^2 w}{\partial x^2} \tag{5}$$

where

$$\rho = \frac{E_1 A_1 \cdot E_2 A_2}{E_1 A_1 + E_2 A_2} \tag{6}$$

It should be noted that for structural components commonly used in practice, the rib contribution towards the system resistance remains almost unaffected when the interface is taken as shear rigid. This is true because the axial stiffness in general has a very small effect when compared with the flexural stiffness.

As far as design of cut-back reinforcement against splitting is concerned, the relative transverse displacement between the plate and rib becomes relevant. For the development of a solution method, a step-by-step procedure based on the superposition of different intermediate steps is proposed.

5.1 ZERO CUT-BACK LENGTH, s = 0

As part of the solution, the plate will be analysed and the rib stiffening effects will be introduced as boundary conditions for the plate structure as shown in Figure 7. The basic case where ribs are of the same length as the

https://doi.org/10.52202/069179-0313

cover plate but unsupported (cut-back length s = 0) will be considered first.

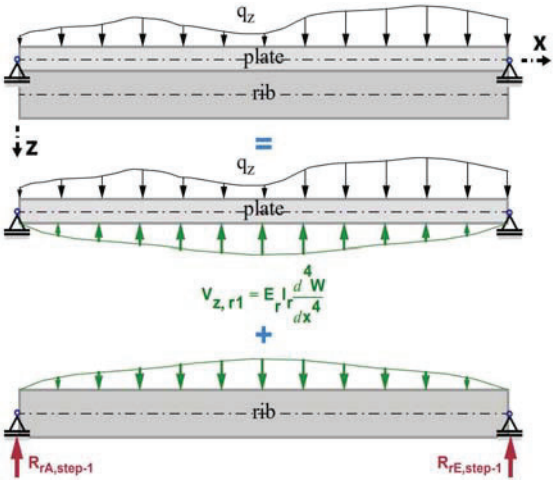

Figure 7: *Intermediate structural system: rib-effect as boundary condition*

The orthotropic plate differential equation with 'w' representing the transversal plate bending deformation (downward positive) is given as follows:

$$K_x \frac{\partial^4 w}{\partial x^4} + 2\left(K_\nu + 2K_{xy}\right)\frac{\partial^4 w}{\partial x^2 \partial y^2} + K_y \frac{\partial^4 w}{\partial y^4} = q_z(x,y) \quad (7)$$

where w is the transverse deformation, $q_z(x,y)$ is the transverse distributed loading, K_x and K_y are bending stiffnesses, K_ν is coupled bending stiffness, and K_{xy} is torsional stiffness (for CLT, $K_\nu = 0$ due to cracks & gaps).

5.1.1 First step

As a first step in the solution procedure, Equation (7) can easily be solved taking the following plate boundary conditions into account. In this particular step the ribs, together with the plate, will be considered as simply supported representing a standard simply supported system.

at x = 0 and x = L_r:

$$\begin{aligned} w &= 0 \\ \partial^2 w/\partial x^2 &= 0 \end{aligned} \quad (8)$$

at y = 0:

$$\begin{aligned} \partial w/\partial y &= 0 \\ V_z = -\left[K_y \frac{\partial^3 w}{\partial y^3} + \left(K_\nu + 4K_{xy}\right)\frac{\partial^3 w}{\partial x^2 \partial y}\right] &= \frac{1}{2} E_r I_r \frac{\partial^4 w}{\partial x^4} \end{aligned} \quad (9)$$

at y = b/2:

$$\begin{aligned} \partial w/\partial y &= 0 \\ V_z = \left[K_y \frac{\partial^3 w}{\partial y^3} + \left(K_\nu + 4K_{xy}\right)\frac{\partial^3 w}{\partial x^2 \partial y}\right] &= 0 \end{aligned} \quad (10)$$

where V_z = transverse shear force along the edge parallel to X-axis, E_r = rib elastic modulus, I_r = rib moment of inertia and L_r = length of the rib.

In order to fully solve Equation (7), a particular solution w_{part} and a homogeneous solution w_{hom} will be introduced and superposed.

$$w_{p1} = w_{r1} = w_{part} + w_{hom} \quad (11)$$

in which w_{p1} = plate transversal deformation and w_{r1} = rib transversal deformation, both from step-1.

In the following equation, the particular solution w_{part} is shown for a strip acting just like a beam under a constant loading $q_z(x)$ and fulfilling the aforementioned boundary conditions.

$$w_{part} = \frac{q_z}{24\,K_x}\left(x^4 - 2L_r x^3 + {L_r}^3 x\right) \quad (12)$$

When Equation (12) is expressed in Fourier series form, it is given by:

$$w_{part} = \frac{4\,q_z {L_r}^4}{\pi^5\,K_x} \sum_{1,3,5\ldots}^{\infty} \frac{1}{m^5} \sin\frac{m\pi x}{L_r} \quad (13)$$

and w_{hom} should fulfil the following homogeneous equation:

$$K_x \frac{\partial^4 w}{\partial x^4} + 2\left(K_\nu + 2K_{xy}\right)\frac{\partial^4 w}{\partial x^2 \partial y^2} + K_y \frac{\partial^4 w}{\partial y^4} = 0 \quad (14)$$

For a single span system with hinged end-supports, one can choose a solution for w_{hom} of the type

$$w_{hom} = \sum_{1,3,5\ldots}^{\infty} Y_m \sin\frac{m\pi x}{L_r} \quad (15)$$

where Y_m is a function of y only.

For cases where $\left(K_\nu + 2K_{xy}\right)^2 < K_x K_y$, just like in the case of CLT plates, substituting w_{hom} into Equation (14) and solving for Y_m gives:

$$\begin{aligned} Y_m = \frac{q_z {L_r}^4}{K_x}\big(&e^{\varphi y}(A_{m1}\cos\psi y + B_{m1}\sin\psi y) \\ &+ e^{-\varphi y}(C_{m1}\cos\psi y + D_{m1}\sin\psi y)\big) \end{aligned} \quad (16)$$

where

$$\begin{aligned} \varphi &= \frac{m\pi}{L_r}\sqrt{\frac{1}{2}\left(\sqrt{\frac{K_x}{K_y}} + \frac{K_\nu + 2K_{xy}}{K_y}\right)} \\ \psi &= \frac{m\pi}{L_r}\sqrt{\frac{1}{2}\left(\sqrt{\frac{K_x}{K_y}} - \frac{K_\nu + 2K_{xy}}{K_y}\right)} \end{aligned}, \quad (17)$$

The constants A_{m1}, B_{m1}, C_{m1}, and D_{m1} can be found from fulfilling the aforementioned boundary conditions of the plate at y = 0 and y = b/2. For plates with $K_\nu = 0$, the expressions for the constants A_{m1}, B_{m1}, C_{m1}, and D_{m1} are given in ANNEX-A.

https://doi.org/10.52202/069179-0313

5.1.2 Second step

The second step will involve balancing/zeroing the end shear of the rib, i.e. re-applying the rib-end reaction forces of the intermediate structural system in the opposite direction. Since this force will result in a fast decaying interface tensile stress (Figure 11) and later be mostly carried by reinforcements very close to the supported edges, it results in very small deformation of the plate. It is thus possible to consider the effects of the tip-loaded rib alone on a beam-on-elastic foundation model.

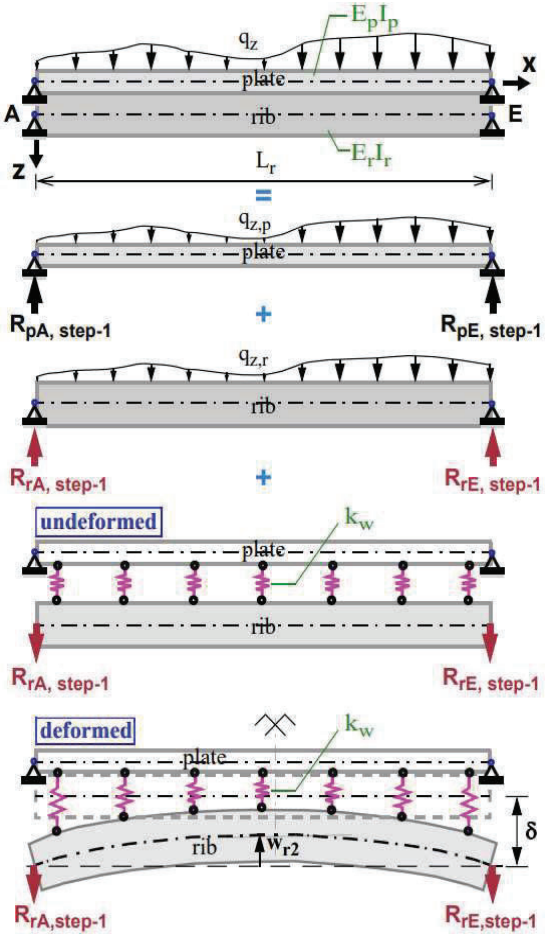

Figure 8: *Rib-end shear balancing*

The following equation results from equilibrium considerations of the rib:

$$E_r I_r \frac{\partial^4 w_{r2}}{\partial x^4} = k_w(\delta - w_{r2}) \tag{18}$$

where k_w = interface transversal stiffness, δ represents rib-tip transverse deformation of step-2, obtained from force equilibrium equation as given by Equation (19), $R_{r1} = R_{rA,step\text{-}1} = R_{rE,step\text{-}1}$ is the rib-tip reaction force from step-1 and w_{r2} is rib deformation under rib-tip action R_{r1} (see deformed system, Figure 8).

$$\delta = \frac{1}{L_r}\left(\frac{R_{r1}}{k_w} + \int_0^{L_r/2} w_{r2}\ dx\right) \tag{19}$$

As part of the second step in the solution procedure, the above differential equation can be solved considering the following rib boundary conditions:
at x = 0 and x = L_r:

$$\begin{aligned} w_{r2} &= 0 \\ \partial^2 w_{r2}/\partial x^2 &= 0 \end{aligned} \tag{20}$$

The resulting rib transverse deformation will then be given by:

$$\begin{aligned} w_{r2} = \delta &+ e^{\lambda x}(C_1 \cos\lambda x + C_2 \sin\lambda x) \\ &+ e^{-\lambda x}(C_3 \cos\lambda x + C_4 \sin\lambda x) \end{aligned} \tag{21}$$

where

$$\begin{aligned} C_1 &= -\frac{1 + e^{\lambda L_r}\cos\lambda L_r}{1 + e^{2\lambda L_r} + 2e^{\lambda L_r}\cos\lambda L_r}\delta, \\ C_2 = C_4 &= -\frac{\sin\lambda L_r}{2(\cos\lambda L_r + \cosh\lambda L_r)}\delta, \\ C_3 &= -\frac{1}{2}\left(1 + \frac{\sin\lambda L_r}{\cos\lambda L_r + \cosh\lambda L_r}\right)\delta, \end{aligned} \tag{22}$$

$$\lambda = \sqrt[4]{\frac{k_w}{4\,E_r I_r}} \tag{23}$$

The fast-decaying elastic foundation reaction given by $V_{z,r2} = k_w(\delta - w_{r2})$ can also be represented by a Fourier series as follows:

$$V_{z,r2} = \sum_{1,3,5\ldots}^{\infty} E_m \sin\frac{m\pi x}{L_r} \tag{24}$$

where

$$E_m = \frac{32m^3\pi^3 e^{\lambda L_r}\lambda^4 E_r I_r(\cos\lambda L_r + \cosh\lambda L_r)}{(m^4\pi^4 + 4\lambda^4 {L_r}^4)(1 + e^{2\lambda L_r} + 2e^{\lambda L_r}\cos\lambda L_r)}\delta \tag{25}$$

The resultant tensile force of the decaying elastic foundation reaction can then be determined. One is able to compute the total rib boundary effect on the plate and repeat the calculations to determine the plate total deformation.
In the shown form, the mutual deformations of both structural components affect the distribution of forces in the elastic foundation. Since the deformations in the plate at the end of the rib are small, as a simplification, the plate can be assumed rigid. This leads to the structural system of a beam/rib-on-elastic foundation from which the resultant tensile force and the reinforcement force in the region of the cut-back can be determined analytically (Figure 9). The computation of the resultant tensile force of the decaying elastic foundation reaction of such a beam is shown in ANNEX-B.

https://doi.org/10.52202/069179-0313

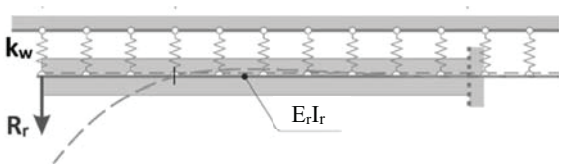

Figure 9: *Model for the cut-back based on a beam on an elastic foundation*

5.2 NON-ZERO CUT-BACK LENGTH, s > 0

The presented structural model can also be used to compute the transverse tensile stress resultants for 'cut-back' lengths larger than zero. Similar to the s = 0 case two intermediate steps are involved in the solution procedure.

5.2.1 First step

The first step in the modelling considers a simply supported system (system span length equal to rib span length) with symmetrical end moments obtained by simple mechanics (Figure 10). The rib restraining force/reaction and the corresponding bending contribution of the rib will then be computed.

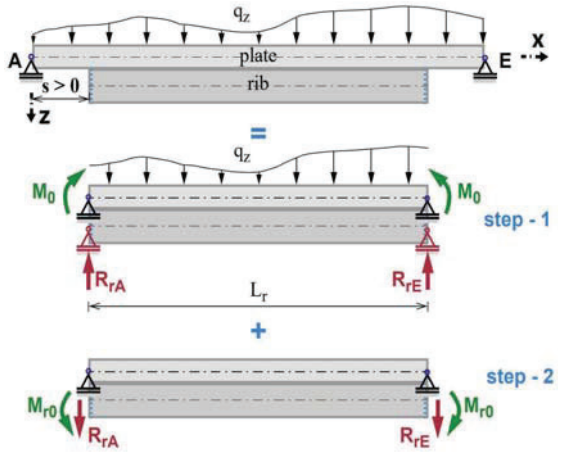

Figure 10: *step-by-step solution procedure*

5.2.2 Second step

The second step will deal with a rib-tip loaded system that counterbalances the restraining force/reaction and corresponding bending contribution. These are believed to be the main causes for the possible relative displacement between the structural components. It can also be treated as a beam on an elastic foundation.

The resulting interface tensile stress distributions which depend on the interface stiffness against splitting are shown in Figure 11 and Figure 12 for cases with no interface crack and partly cracked, respectively. As can be seen from both figures, the larger the interface tension stiffness is the faster the decay would be. This fact can be related to the need for relatively stiff reinforcement at the cut-back disturbance zone edge.

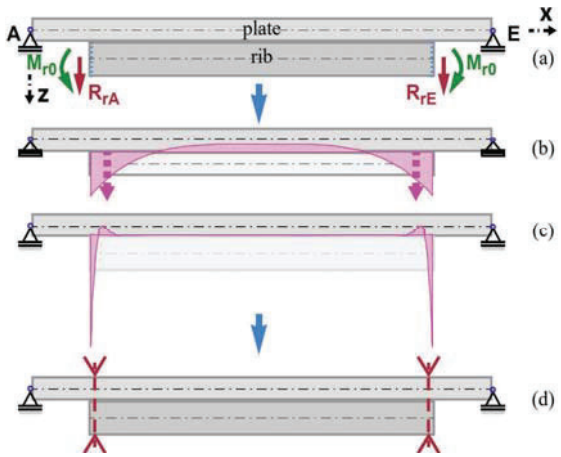

Figure 11: *No interface crack: (a) rib-tip actions, (b) transverse stress distribution for smaller interface stiffness, (c) transverse stress distribution for larger interface stiffness and (d) reinforcement*

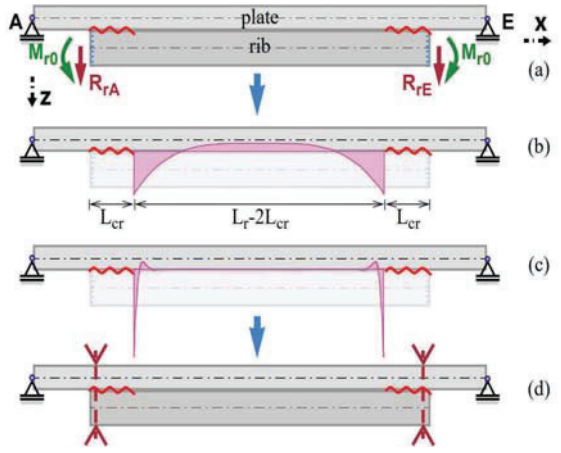

Figure 12: *Partly cracked interface (with L_{cr} = crack length): (a) rib-tip actions, (b) transverse stress distribution for smaller interface stiffness, (c) transverse stress distribution for larger interface stiffness and (d) reinforcement*

5.3 CALCULATION OF THE FORCE IN THE REINFORCEMENT

The tensile stress resultants (up to the first root) and its distance from the end of the rib can be computed as functions of the applied rib-tip force $R_r = R_{rA} = R_{rE}$ and the moment $M_r = M_{r0} = \left(E_r I_r / \left(E_r I_r + E_p I_p\right)\right) M_0$ as given by Equations (27) & (28) (see ANNEX-B.1 and ANNEX-B.2). The rib-tip moment M_r is expressed as:

$$M_r = \frac{E_r I_r}{E_r I_r + E_p I_p} \cdot M_0 = \frac{M_0}{1 + \frac{1}{\gamma_r}} \qquad (26)$$

It should also be noted that in the following analysis the rib is assumed to be long enough to have enough decay

length for any edge effect, i.e. to avoid effects of one edge on the other.

$$F_{t,90;R_r} = \left(1 + e^{-\frac{\pi}{2}}\right) R_r \approx 1.21\, R_r \; (for\; x_1 = \frac{\pi}{2\,\lambda}) \quad (27)$$

$$F_{t,90;M_r} = \sqrt{2}\, e^{-\frac{\pi}{4}}\, M_r \lambda \approx 0.645\, M_r \lambda \; (for\; x_1 = \frac{\pi}{4\,\lambda}) \quad (28)$$

In a simultaneous presence of both actions R_r and M_r at the rib-tip, one can compute the combined tensile stress resultant as a rough estimation leading to satisfactory results from the resulting combined stress distribution of the decaying interface tensile stress using Equation (30). In particular this procedure gives results numerically close to the exact solution if the interface stiffness is large. The resultant transverse tensile force for this case is given approximately by Equation (29).

$$\begin{aligned} F_{t,90;R_r+M_r,\text{large }\lambda} &\approx \frac{V}{1+\frac{1}{\gamma_r}} \left(1 + e^{-\pi/2} + \sqrt{2}\, e^{-\pi/4}\, \lambda\, s\right) \\ &\approx \frac{V}{1+\frac{1}{\gamma_r}} \left(1.21 + 0.645\, \lambda\, s\right) \end{aligned} \quad (29)$$

For general cases, however, the actual transverse tensile stress resultant caused by a simultaneous loading by the rib-tip actions R_r and M_r can be obtained from Equation (30) (see ANNEX-B.3). It represents the tensile stress resultant of the total decaying function up to the first root (zero-point) under the assumption that $M_r \approx R_r \cdot s$.

$$F_{t,90;R_r+M_r} = \frac{V}{1+\frac{1}{\gamma_r}} \left(1 + a \cdot e^{-b}\right) \quad (30)$$

where

$$a = \sqrt{1 + 2\,\lambda\, s\,(1+\lambda\, s)};\; b = \tan^{-1}\left(1 + \tfrac{1}{\lambda\, s}\right) \ldots \text{ [rad]}$$

5.4 COMPARISON WITH KNOWN APPROACHES (VALID FOR BEAMS)

A comparison of results from different approaches (beam theory, DIN 1052-1:1988 [5], Henrici ([6],[7]), draft prEN 1995-1-1:2021 [4]) that dealt with 'transverse tensile stress resultant' and the results from the current study have been made. In this context it has to be mentioned, that these studies are valid, from a strict point of view, only for notched beams with rectangular cross-sections, but since no alternatives are known they were used for the comparison.

The expressions used in the following comparison are given by Equations (31) to (35). In the comparison, since no proven methods for the determination of the interface normal stiffness k_w are known yet, the assumption of a constant transverse stress distribution along the rib-depth: $k_w = b_r \cdot E_{90,mean}/h_r$ has been used for the current study.

$$F_{BT} = [3(1-\alpha)^2 - 2(1-\alpha)^3]\, V \quad (31)$$

$$F_{DIN} = 1.3\; [3(1-\alpha)^2 - 2(1-\alpha)^3]\, V \quad (32)$$

$$F_{Hen} = \kappa_\beta\, \kappa_s\, \kappa_\alpha\; V \quad (33)$$

$$F_{Tek} = \frac{V}{1+\frac{1}{\gamma_2}} \left(1 + a \cdot e^{-b}\right) \quad (34)$$

$$\begin{aligned} F_{prEN} = (0.9 + 0.5(2\alpha-1)^2) \cdot (1+2\beta) \\ \cdot (3(1-\alpha)^2 - 2(1-\alpha)^3)\, V \end{aligned} \quad (35)$$

where
$\alpha = h_1/h_{total}$ (valid for beams only),
$\kappa_\beta = 1 + 2\beta$,
$\kappa_s = 1 + (s_0 - 1)[1.44(1-\alpha)(1-2\alpha) - 0.1]$,
$\kappa_\alpha = 1.5\big(1 - 0.7(1-\alpha)(3(1-\alpha)^2 - 2(1-\alpha)^3)\big)$,
$s_0 = \sqrt[4]{E_0/E_{90}}$ (in the comparison, $s_0 = 1.81$ is used [6]),
$\gamma_2 = E_2 I_2 / E_1 I_1$,
$\beta = s/h_{total}$
V … vertical force
F_{BT} … force using beam theory
F_{DIN} … force using DIN 1052-1:1988 [5]
F_{Hen} … force using Henrici ([6],[7])
F_{Tek} … force from this study (see Equation (30))
F_{prEN} … force using prEN 1995-1-1:2021 [4]

Figure 13 shows the comparison for the case of $s/h_{total} = 0.2$ and Figure 14 for the case of $s/h_{total} = 0.4$, where s = cut-back length, h_1 = depth of upper element, h_{total} = total depth of the system and V = beam reaction force. For CLT-GLT ribbed panels, the practical range for the h_1/h_{total}-ratio lies between 1/3 and 1/4 [11]. This range is represented by the gray shaded regions in Figure 13 and Figure 14. It can be observed from Figure 13 and Figure 14 that the 'transverse tensile stress resultant' decreases with an increase in the h_1/h-ratio, i.e. the stiffening effect from the lower-beam and its contribution to the system strength decreases.

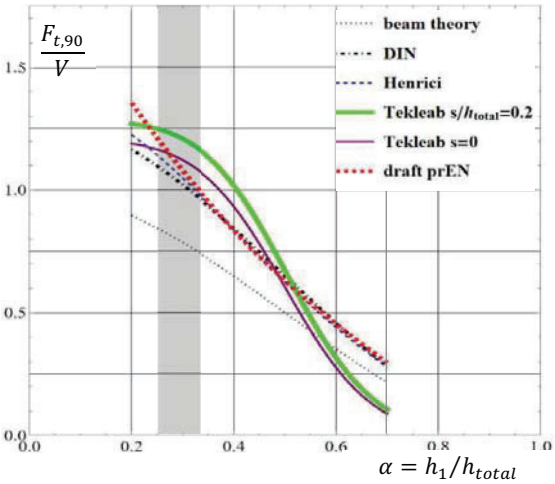

Figure 13: *Transverse tensile stress resultants for $s/h_{total} = 0.2$*

https://doi.org/10.52202/069179-0313

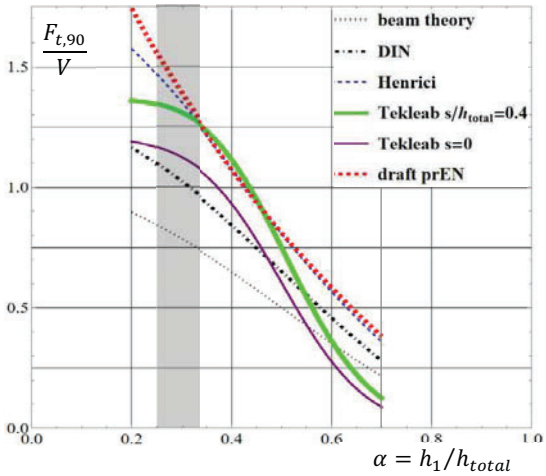

Figure 14: *Transverse tensile stress resultants for s/h_{total} = 0.4*

One can easily recognise from the graphical comparisons that the beam theory and DIN results do not directly include cut-back length effects in addition to the perpendicular to grain stiffness effects.

Figure 15 shows the effect of the cut-back length *s* on the transverse tensile stress resultant ratio, $F_{t,90}/R_r$, of a system example. It can be seen that with an increasing distance from the supporting line, the transverse stress resultant increases. Due to restrictions of the model this tendency will be valid only for small β-values. Further studies regarding the scope of application are necessary.

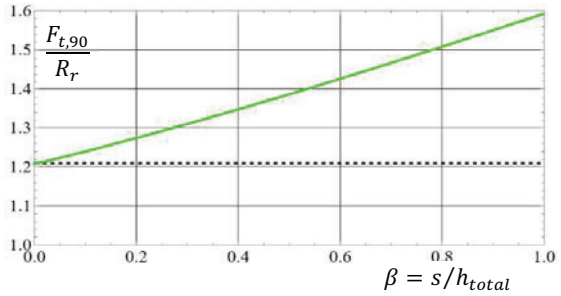

Figure 15: *cut-back length effect on tensile stress resultant*

The discussions so far dealt with 'transverse tensile stress resultants' of unreinforced cases. It is evident that the 'force in a reinforcement' is influenced by the tensile load-carrying of the timber and its stiffness as well as the stiffness of the reinforcement. Further efforts on the area will deal with this topic.

6 APPLICATION EXAMPLE

As an example (see Figure 16), a ribbed plate consisting of a glulam rib b_r/h_r = 160/280 mm and a 5-layer CLT panel with layer thicknesses of 40-20-20-20-40 mm (h_p = 140 mm) and width b_p = 800 mm has been considered. The system is a single span simply supported beam with length L = 10.0 m and cut-back length s = 200 mm. The materials used for the 7-layer combined glulam rib are T21 for the two lower layers & T14 for the upper five layers and GL24h* for the CLT panel. The system is loaded by its own weight $g_{1,k}$ = 1.0 kN/m², a permanent load $g_{2,k}$ = 2.0 kN/m² and a live load q_k = 3.0 kN/m². It is reinforced with self-tapping screws of ϕ10/400 mm at 'cut-backs' with an end distance of 50 mm.

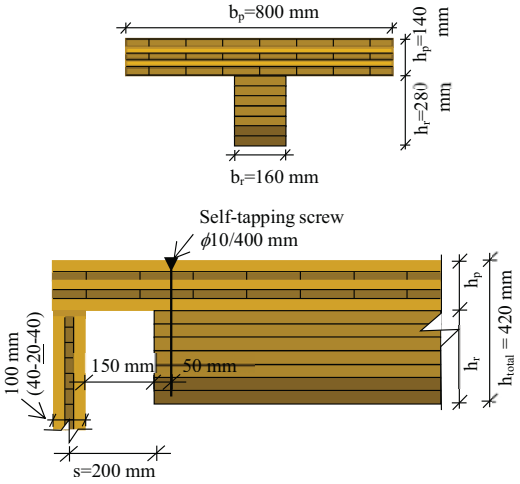

Figure 16: *cross-section (upper) and cut-back details (lower)*

In order to determine the force in the given screw, one will first obtain the following quantities:

$$q_d = [1.35 \cdot (1.0 + 2.0) + 1.50 \cdot 3.0] \cdot 0.800 = 6.84\ kN/m$$

$$A_d = \frac{q_d\, L}{2} = \frac{6.84 \cdot 10.0}{2} = 34.2\ kN$$

$$V_d = A_d - q_d \cdot s = 34.2 - 6.84 \cdot 0.200 = 32.8\ kN$$

$$E_p I_p = 1.96 \text{ x } 10^{12}\ N\ mm^2$$

$$E_r I_r = 3.48 \text{ x } 10^{12}\ \text{N mm}^2$$

$$\rightarrow \gamma_r = \frac{E_r I_r}{E_p I_p} = \frac{3.48\ x\ 10^{12}}{1.96\ x\ 10^{12}} = 1.78$$

$$R_{r,d} = \frac{V_d}{1 + \frac{1}{\gamma_r}} = \frac{32.8}{1 + \frac{1}{1.78}} = 21.0\ kN$$

$$M_{r,d} = R_{r,d} \cdot s = 21.0 \cdot 0.200 = 4.20\ kNm$$

$$k_w = \frac{b_r \cdot E_{90,mean}}{h_r} = \frac{160 \cdot 300}{280} = 171 N/mm^2$$

$$\lambda = \sqrt[4]{\frac{k_w}{4 \cdot E_r I_r}} = \sqrt[4]{\frac{171}{4 \cdot 3.48x10^{12}}} = 0.00187\ [1/mm]$$

- $R_{r,d}$ and $M_{r,d}$ considered solely and added up

$$F_{t,90,d;R_r+M_r,\lambda} \approx 1.21 \cdot 21.0 + 0.645 \cdot 1.87 \cdot 4.20 \approx 30.5\ kN$$

- $R_{r,d}$ and $M_{r,d}$ considered simultaneously

$$a = \sqrt{1 + 2 \cdot 1.87 \cdot 0.2 \cdot (1 + 1.87 \cdot 0.2)} = 1.42$$

$$b = tan^{-1}\left(1 + \frac{1}{1.87 \cdot 0.2}\right) = 1.31$$

$$F_{t,90,d;R_r+M_r} = 21.0\ (1 + 1.42 \cdot e^{-1.31}) = 29.0\ kN$$

For comparison:

- DIN 1052-1:1988 [5]

$$\alpha = h_{ef}/h_{total} = 140/420 = 1/3$$

$$F_{t,90,d} = 1.3 \cdot V_d \cdot [3(1-\alpha)^2 - 2(1-\alpha)^3]$$

$$F_{t,90,d} = 1.3 \cdot 32.8 \cdot \left[3\left(1 - \frac{1}{3}\right)^2 - 2\left(1 - \frac{1}{3}\right)^3\right] = 31.6\ kN$$

- with DIN 1052 adapted for ribbed panels:

for the composite cross-section: $e_{z,s}$ = 273 mm (from the lower edge), $(EI)_{ef} = 2.08 \cdot 10^{13} Nmm^2$,

$$F_{t,90,d} = 1.3 \cdot V_d \cdot \frac{b_r}{6} \cdot \frac{\mathrm{E_r}}{(EI)_{ef}} \cdot (3 \cdot z_s \cdot h_r^2 - h_r^3)$$

$$F_{t,90,d} = 1.3 \cdot 32.8 \cdot \frac{160}{6} \cdot \frac{12500}{2.08x10^{13}} \cdot (3 \cdot 273 \cdot 280^2 - 280^3) = 28.9\ kN$$

Verification of the reinforcement:

The design resistance per screw is computed applying the following values (screw data from an approval):

- for the verification of the withdrawal resistance: with the withdrawal strength $f_{ax,90,k}$ = 10.0 N/mm², the modification factor k_{mod} = 0.80 and the partial safety factor γ_M = 1.30 for the reinforcement (joint); since the smaller penetration depth is in the CLT plate it becomes crucial for the design.

$$F_{ax,Rd} = k_{mod} \cdot \frac{f_{ax,90,k} \cdot d \cdot l}{\gamma_M} = 0.80 \cdot \frac{10.0 \cdot 10.0 \cdot 140}{1.30} = 8{,}615\ N = 8.62\ kN$$

- for the verification of the screw tensile strength: tensile strength of the screw $F_{tens,k}$ =32.0 kN and the related partial safety factor γ_{M2} = 1.25.

$$F_{tens,d} = \frac{F_{tens,k}}{\gamma_{M2}} = \frac{32{,}000}{1.25} = 25{,}600\ N = 25.6\ kN$$

- design resistance per screw:

$$\mathrm{R}_{ax,d} = \min\{F_{ax,Rd}; F_{tens,d}\} = \min\{8.62\ kN; 25.6\ kN\} = 8.62\ kN$$

with n_{ef} = n, the required screws to cover the force:

$$n_{req} = \frac{\mathrm{F}_{t,90,d;R_r+M_r}}{R_{ax,d}} = \frac{29.0}{8.62} = 3.36$$

Applied at each cut-back: 4 x Ø 10/400 mm screws.

The rules regarding spacings and end distances etc. have to be met. Special conditions for the detailing of the reinforcement at the 'cut-back' can be found in ([1], [2]).

7 CONCLUSIONS AND OUTLOOK

Ribbed timber panels are interesting possibility to expand the range of application in timber engineering due to the possibility of realizing floors with larger spans. Because of technical and economic reasons, the ribs of such floor systems are often 'cut-back', i. e. end at a distance from the supports.

The ends of ribs in this case have to be reinforced by appropriate methods (e. g. self-tapping screws). As known to the authors no explicit rules for this mentioned design situation are known or given in relevant standards. Since no alternatives are given, one may use the equations given in the National Annexes to EN 1995-1-1 in Germany and Austria, mentioned for the first time in DIN 1052:1988 [5] for reinforced notches of rectangular cross-sections. It is, however, evident that this approach doesn't cover the given situation of ribbed panels with 'cut-backs' and is thus not valid for this case.

In the current study, simplified expressions for the 'transverse tensile stress resultants' (of unreinforced cases) based on a simple engineering approach applying a beam on elastic foundation were derived. With the developed equations one can easily calculate the force to be covered by the reinforcement. Since a general approach was used, the presented modelling, analysis and results can also be applied to plate-plate and beam-beam composites. The usual verifications like verifications of bending and shear stresses in ULS as well as deflection and vibration in SLS have to be done. This is important because due to the limited load-carrying capacity of the CLT, too high β-values will not be possible.

In addition to the presented results the interface tensile stiffness, the consideration of shear-deformation effects, interaction of interface shear stress with interface normal stress, non-linear interface behaviour, crack length etc. will be part of the ongoing analysis and experimental research. Moreover, the range of application (regarding α- and β-values) is under investigation. In particular, tests with different lay-ups (γ_r-values and h_p/h_{total}-values) and different β-values are in preparation.

ACKNOWLEDGEMENT

This research work was financed by the Austrian Research Promotion Agency (FFG) and is part of an ongoing study and experimental research on ribbed timber panels being carried out at the competence centre holz.bau forschungs gmbh, Graz, Austria.

LATERAL DEFORMATION AND KINEMATIC MODES OF MULTI-PANEL BALLOON-TYPE CLT SHEARWALL SYSTEM

Dalu Xing[1], Ghasan Doudak[2], Daniele Casagrande[3]

ABSTRACT: Balloon-type Cross-Laminated Timber (CLT) shearwall systems have been widely used as lateral load resisting systems (LLRS) in several mid- and high-rise timber buildings. Contrary to platform-type shearwalls, balloon framing contains continuous panels along multiple storeys in the vertical direction, which helps avoid perpendicular-to-grain compression failure in the floors. Despite some of the advantages associated with this type of construction, design provisions have not yet been introduced to various timber codes and standards, mainly due to the scarcity in research on their behaviours. This paper presents a numerical analysis model with the aim of investigating the lateral deformation and kinematic modes of balloon-type CLT shearwall systems. A finite element (FE) model is proposed, and a discussion on various key parameters affecting the behaviour of the shearwall, including aspect ratios (*h/b*), stiffness of the connectors, vertical loads and the number of panels, is presented.

KEYWORDS: Balloon-type, Cross-laminated timber, Aspect ratio, Multi-panel, Kinematic behaviour

1 INTRODUCTION

Numerous research projects and case studies have highlighted the ability of cross-laminated timber (CLT) shearwalls to resist lateral wind and seismic loads in timber buildings, mainly due to their high in-plane strength and stiffness. When the wall aspect ratio (i.e., height-to-length) is limited between 2:1 to 4:1, it has been demonstrated that CLT shearwalls are capable of dissipating energy through rocking behaviour and engagement of panel-to-panel connections as well as mechanical boundary anchors (hold-downs and angle brackets). This aspect ratio range is usually suitable for platform-type construction, where the wall extends between two consecutive floors. The development of analytical and experimental models for platform-type CLT shearwalls, including establishing the lateral behaviour and kinematic modes of multi-panel shearwall systems, has been undertaken by several researchers [1,2,3,4]. In terms of manufacturing, transportation and installation, it is sometimes desirable to produce longer panels that can extend multiple storeys along the height of the building. Another benefit of this so-called balloon-type construction is the avoidance of having accumulated axial load in the wall that could cause perpendicular-to-grain compression failure in the floors [5].

Balloon-type CLT shearwall systems have already been adopted in several construction projects, such as the Arboratum Project [6], which employs a CLT shearwall core with aspect ratios of the panels ranging from 5:1 to 20:1. Another example is the Arbora Condos in Montreal [7], which contain shearwall panels spanning 7 storeys with aspect ratios between 3:1 and 11:1. Despite the presence of these type of buildings in practice, research activities investigating the performance of balloon-frame CLT shearwalls have been scarce. Some studies have focused on predicting the lateral deformation of a two-panel balloon-type CLT shearwall system [8,9], while others have investigated the impact of ledger beams on the wall performance [10,11].

It is important to note that there are currently no design provisions for balloon-frame CLT shearwalls in various codes and standards (e.g., CSA O86 [12] and Eurocode 5 [13]), mainly due to a lack of fundamental research output involving this system. The review of available research clearly indicates that more research towards developing an understanding of the behaviour of multi-panel balloon-type CLT shearwall systems is necessary.

The current research aims at contributing to the gaps in knowledge in this field by investigating the lateral deflection and kinematic modes of balloon-type multi-panel CLT shearwall systems through a numerical FE approach.

2 SENSITIVITY ANALYSIS

2.1 MODEL DESCRIPTION

A finite numerical element (FE) model has been adopted to conduct sensitivity analyses with the aim of understanding the impact of key parameters governing the

mechanical behaviour of multi-panel balloon-type shearwall systems subjected to lateral loads. The proposed FE model consists of shearwalls with a total height, a total width and a panel width of h, B and b, respectively, subjected to lateral point force F stemming from wind or seismic loads applied at the diaphragm level of each storey. The panels are assumed to be connected to the foundation by hold-downs with axial stiffness, k_{hd}, along the vertical direction, while the panel sliding along the horizontal direction is restricted. Adjacent panels are connected to each other by means of uniformly placed vertical joints with total shear stiffness k_{vj}. Vertical uniformly distributed gravity loads, q, are assumed to be applied at each floor level. Figure 1 shows a two-panel model with a height representing three storeys.

The numerical analysis is carried out using the commercially available FE software package SAP2000 [14]. A total of 548 different models were developed based on a series of varying parameters, including panel aspect ratio h/b, stiffness of hold-down and vertical joints, vertical loads and the number of panels.

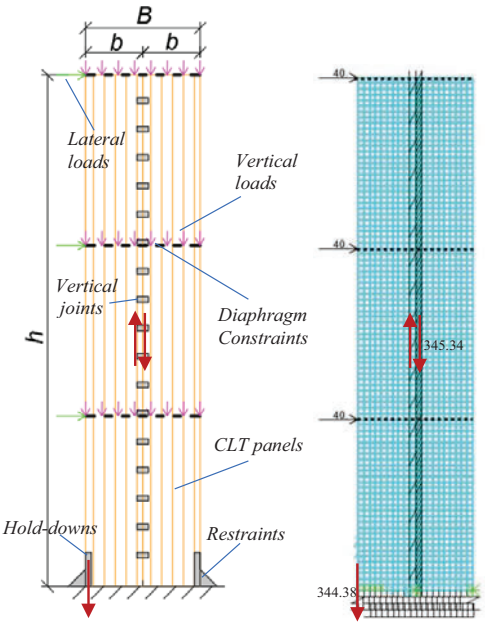

Figure 1: *Two-panel three-storey CLT shearwall model*

2.2 MODEL CONFIGURATION AND PARAMETERS

The FE model adopts thick-shell type elements to simulate the behaviour of the shearwall panels. The mesh size was selected to be 100 mm × 100 mm, based on a mesh sensitivity analysis. It should be noted that when the meshing size was reduced from 100 mm × 100 mm to 10 mm × 10 mm, the difference in the total lateral deformation was within 3%.

Equivalent material properties of the CLT panels were determined using the method proposed by Brandner et al. [15], as presented in Equations (1) and (2) for the effective modulus of elasticity along the vertical, $E_{0,eff}$, and lateral, $E_{90,eff}$, directions, respectively.

$$E_{0,eff} = \frac{E_0 t_0 + E_{90} t_{90}}{t} \quad (1)$$

$$E_{90,eff} = \frac{E_0 t_{90} + E_{90} t_0}{t} \quad (2)$$

where

E_0 is the modulus of elasticity parallel to grain,
E_{90} is the modulus of elasticity perpendicular to grain,
t_0 is the total thickness of vertical layers,
t_{90} is the total thickness of lateral layers,
t is the total thickness of the panel.

For the purpose of the sensitivity analysis, E_{90} is assumed equal to $E_0/30$ [12,16], and E_0 is assumed to be the same in both the longitudinal and transverse layers. The effective in-plane shear modulus, G^*, was estimated according to the method proposed by Bogensperger et al. [17].

Link elements were assumed to simulate the behaviours of hold-downs, vertical joints and foundation supports. Additionally, restraints are applied at the bottom of each panel to restrict their lateral sliding. In order to ensure the same lateral displacements at the top of the panels, a diaphragm constraint at the floor level was imposed.

Table 1 summarises the input parameters used in the sensitivity analysis, while Table 2 indicates the range of aspect ratios investigated.

Table 1: *Values of the basic parameters of models*

Parameter	Symbol	Values
Storey number	n (-)	1; 2; 3; 4
Number of panels	m (-)	1; 2; 3; 4
Lateral load per storey	F (kN/m)	20
Vertical load per storey	q (kN/m)	0; 20
Stiffness of foundation	k_f (1) (kN/m)	1.0×10^6
Panel thickness	t (mm)	175 (5 layers)
Young's modulus and shear modulus	E_0(2), G_0(3) (MPa)	12000; 690
Stiffness of hold-down	k_{hd} (kN/mm)	10; 25; 50; 100
Stiffness of unit vertical-joint	k_{vj}/h (kN/mm/m)	3; 7.5; 15

Note: (1), (2), and (3) refer to the values adopted by [1], [12] and [18], respectively.

Table 2: *Aspect ratio (h/b) matrix in the sensitivity analysis*

	h = 3m	h = 6m	h = 9m	h = 12m
b = 0.25m	12			
b = 0.5m	6	12		
b = 0.75m	4	8	12	
b = 1m	3	6	9	12
b = 2m	1.5	3	4.5	6
b = 3m	1	2	3	4
b = 6m		1	1.5	2
b = 9m			1	1.3
b = 12m				1

The naming convention of the models follows a format where, for example, for "*M12/1 - P3 - VL20 - H10V3*", "*M12/1*" indicates a model (*M*) with a panel aspect ratio of 12 to 1, "*P3*" refers to the number of panels being three, "*VL20*" highlights a value of vertical load (*VL*) equal to 20 kN/m/storey, and "*H10V3"* indicates that the values of

https://doi.org/10.52202/069179-0314

the stiffness of hold-downs (H) and the unit stiffness of vertical-joint (V) are 10 kN/mm and 3 kN/mm/m, respectively.

2.3 VALIDATION OF THE MODEL

The methodology proposed in this paper is verified against the shearwall test conducted by Chen and Popovski [8], which consists of a two-panel balloon frame CLT shearwall, as shown in Figure 2. The panels consist of 5-ply CLT (Grade E1) with dimensions of each panel equal to 4125 mm (height) × 420 mm (width). Two sets of hold-downs are placed at both outer corners, and five pairs of panel-to-panel joints (half in the front and half in the back) are used to attach the two panels with an equal spacing distance of 825 mm. Lateral restraints are used to prevent sliding. A uniformly distributed gravity load with a magnitude of 2.1 kN/m is applied on the top of two panels. A concentrated horizontal load is applied at the top of the wall.

Model input parameters were consistent with those used in the study and included modulus of elasticity in the longitudinal layers are E_0 = 11700 MPa and E_{90} = 390 MPa, while the transverse layers were assigned values of E_0 = 9000 MPa and E_{90} = 300 MPa [12]. As a result, the effective moduli of elasticity obtained using Equation (1) and (2) are calculated to be $E_{0,eff}$ = 7140 MPa, and $E_{90,eff}$ = 3834 MPa, respectively. The shear modulus G is assumed equal to 731 MPa, and hence the effective shear modulus G^* is calculated equal to be 380.47 MPa [17].

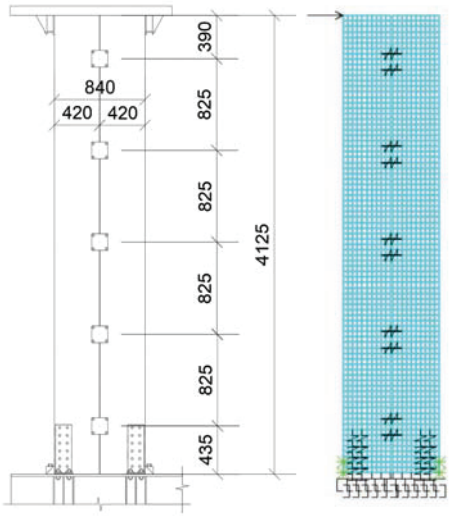

Figure 2: *Shearwall configuration (left) [8] and FE model (right)*

The results of the comparison (Figure 3) clearly show the ability of the proposed model to mimic the behaviour of the shearwall. Discrepancies are likely related to the values of the assumptions associated with the mechanical properties of the connectors, which have been simplified to bi-linear curves in the FE modelling analysis.

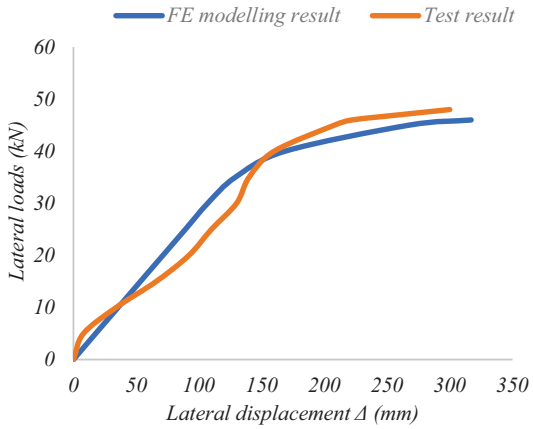

Figure 3: *Result comparison between FE modelling and test [8]*

3 RESULTS AND DISCUSSION

The results from sensitivity analysis are discussed in the context of the total lateral stiffness, K, defined as the ratio between total lateral loads, ΣF, and the total lateral displacement at the top of the shearwall, Δ_{total}. The relative rocking deformation, r, is defined as a percent ratio that the rocking deformation, $\Delta_{rocking}$, constitutes relative to the total deformation, Δ_{total}, ($r = \Delta_{rocking}/\Delta_{total} \times 100\%$). The discussion also includes the kinematic behaviours that are expressed in terms of coupled-panel (CP) behaviour, which involves rotation of the individual panels about their respective centres of rotation, single-wall (SW) behaviour, where the entire shearwall rotates about one centre of rotation at its end, and intermediate (IN) behaviour that falls between the CP and SW behaviours [1].

3.1 IMPACT OF PANEL ASPECT RATIO

The conducted sensitivity analysis of multi-panel balloon-type CLT shearwall systems shows that aspect ratio h/b significantly impacts the lateral deformation and kinematic modes of the walls. As expected, the results from all cases show that $1/K$ increases with increasing aspect ratio h/b, as shown in Figure 4 for the models *M h/b-P2-VL20-H10V3*.

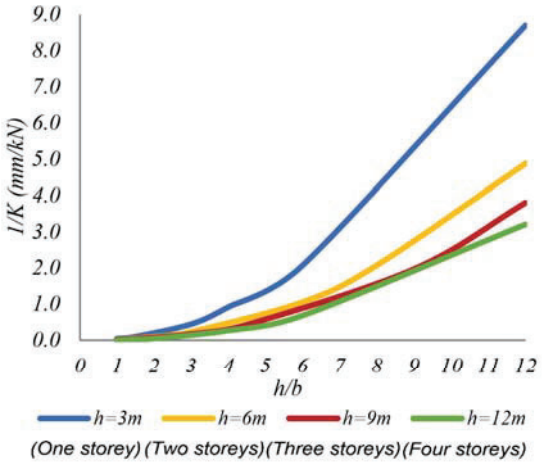

Figure 4: *Relationship between 1/k and h/b for the models M h/b-P2-VL20-H10V3*

Figure 5 shows the relationship between the relative rocking deformation *r* and panel aspect ratio *h/b,* for wall height equal to 6 m. Similar results were also obtained for wall heights equal to 9 m and 12 m. The results reveal consistent tendencies for walls with higher stiffness of hold-downs and vertical-joint to exhibit less rocking. This can be attributed to the restraining effect of the hold-down with higher stiffness, as well as the contribution of the vertical joints with higher stiffness to cause the panels to behave more in SW mode.

It can also be noted that the rocking behaviour is dominant in the range of aspect ratios between 3 and 6, which could be attributed to a largely shear-driven behaviour when the aspect ratio is low (≤ 2), and flexural-driven behaviour for high aspect ratios.

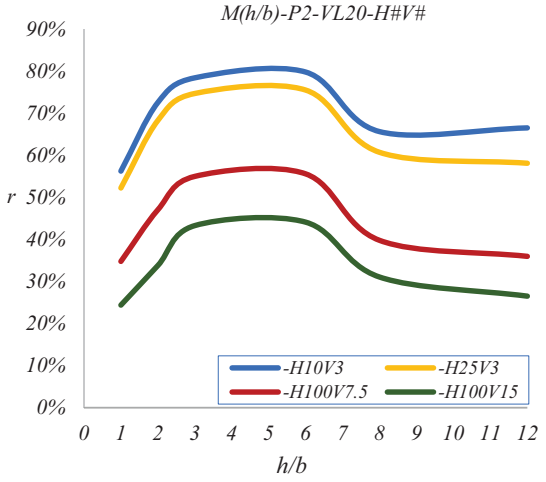

Figure 5: *Relationship between h/b and r when h equals 6 m and vertical load equals 20 kN/m for two-panel models*

3.2 IMPACT OF CONNECTION STIFFNESS

Due to the large range of stiffness values found in the results for connection stiffness, an approach involving normalised lateral stiffness, K_{hd}^* and K_{vj}^*, defined as the ratio between the total lateral stiffness of the wall, *K*, and the value of stiffness related to specific hold-down stiffness, k_{hd}, equals 10 kN/mm in Equation (3), or the specific unit vertical-joint stiffness of k_{vj}/h, equal to 3 kN/mm/m in Equation (4), respectively, is used in this study. The normalised vertical joint stiffness k_{vj} * is defined as a ratio between the value of unit vertical-joint stiffness and the specific value equal to 3 kN/mm/m in Equation (5).

$$K_{hd}^* = \frac{K}{K_{(k_{hd}=10kN/mm)}} \quad (3)$$

$$K_{vj}^* = \frac{K}{K_{(k_{vj}/h=3kN/mm/m)}} \quad (4)$$

$$k_{vj}{}^* = \frac{k_{vj}/h}{3} \quad (5)$$

Figure 6 presents the relationship between the normalised total lateral stiffness K_{hd}^* and hold-down stiffness k_{hd} for $b = 1\ m$, $b = 2\ m$, and $b = 3\ m$, without the application of vertical loads. Generally, it is found that the relationship between K_{hd}^* and k_{hd} is non-linear, and the rate of increase becomes less significant following an increasing hold-down stiffness.

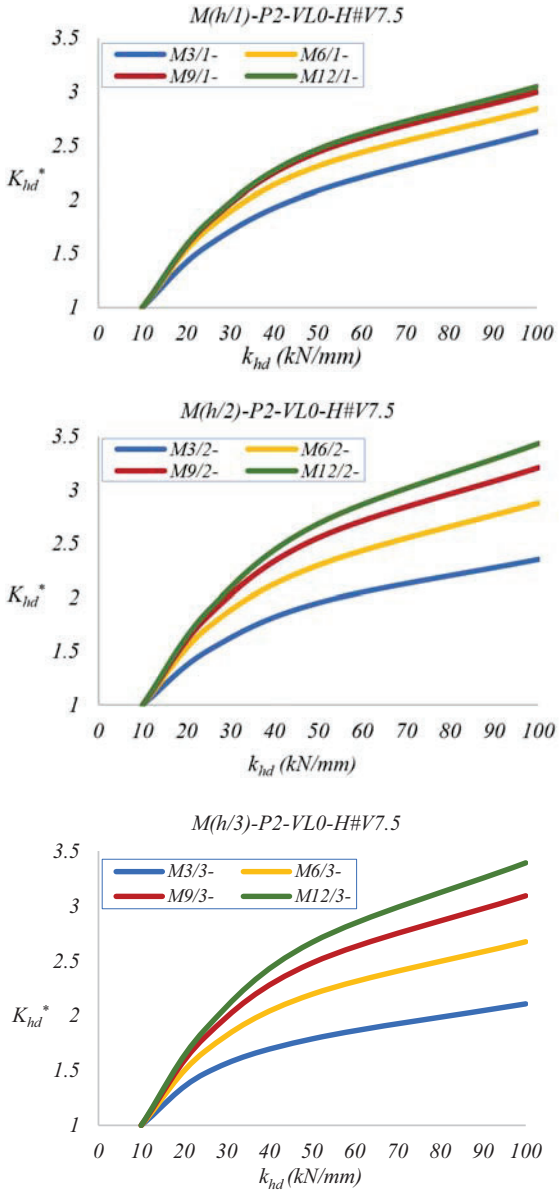

Figure 6*: Relationship between* k_{hd} *and normalised total lateral stiffness* K_{hd}^* *when* k_{vj}/h *equals 7.5 kN/mm/m, and there is no vertical load for two-panel models*

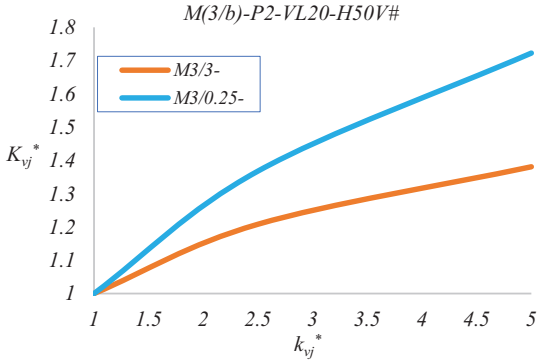
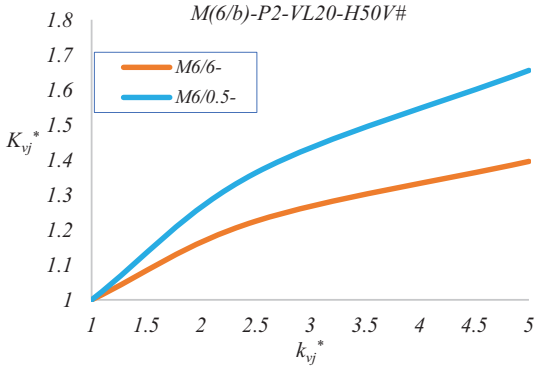
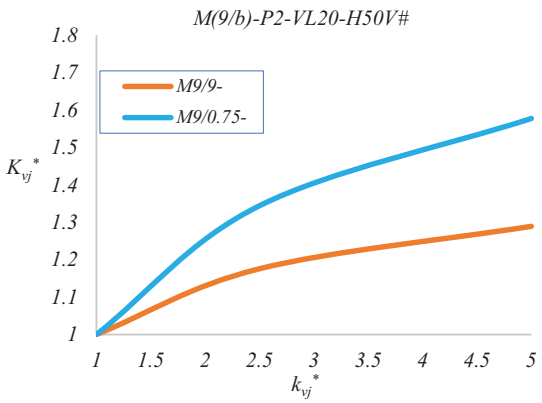
Figure 7 presents the relationship between K_{vj}^* and the normalised vertical-joint stiffness k_{vj}^* for $h = 3\ m$, $h = 6\ m$, $h = 9\ m$ and $h = 12\ m$, including the application of vertical loads. Generally, the trends are consistent with those observed for the hold-down stiffness. When the aspect ratios of panels are low (e.g., 1:1, as in models

https://doi.org/10.52202/069179-0314

M3/3-, M6/6-, M9/9- and *M12/12-*), K_{vj}^* increases less significantly than those with higher aspect ratios following the growth of the stiffness of vertical joints.







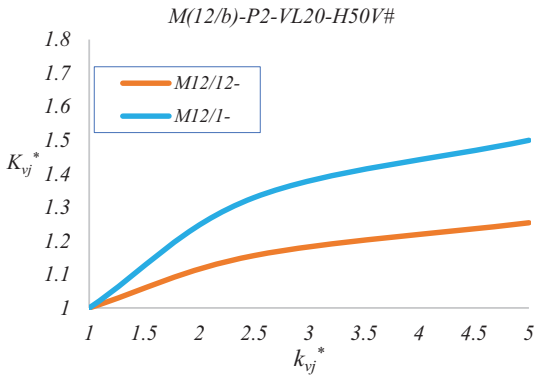


***Figure** 7: Relationship between normalised vertical-joint stiffness k_{vj}^* and normalised total lateral stiffness K_{vj}^* when k_{hd} equals 50 kN/mm, and vertical loads equal 20 kN/m for two-panel models*

Table 3 illustrates the percentage of two-panel models with CP mode as a function of an increase in hold-down stiffness (includes 72 models), while Table 4 presents the percentage of two-panel models with SW mode when the unit stiffness of vertical joints is varied (includes 96 models). It can be observed that similar to what was found from research on platform-type shearwalls, balloon-type construction tends to be more dominated by CP mode when the stiffness of hold-downs increases, while SW mode is more prevalent when the stiffness of unit vertical-joint increases.

***Table 3:** Percentage of the CP mode using different values of the hold-down stiffness*

k_{hd} (kN/mm)	Percentages of the CP mode#
10	16.7%
25	41.7%
50	68.1%
100	88.9%

#: The percentage of CP mode is calculated by

$$\frac{No.\,of\ the\ models\ shown\ as\ CP\ mode}{No.\,of\ the\ total\ models\ (=72)} \times 100\%.$$

***Table 4:** Percentage of the SW mode using different values of the vertical-joint stiffness*

k_{vj}/h (kN/mm/m)	Percentages of the SW mode#
3	21.9%
7.5	46.9%
15	69.8%

#: The percentage of SW mode is calculated by

$$\frac{No.\,of\ the\ models\ shown\ as\ SW\ mode}{No.\,of\ the\ total\ models\ (=96)} \times 100\%.$$

The relationships between the hold-down or unit vertical-joint stiffness and the percentage of rocking deformation are depicted in Figure 8 and Figure 9, respectively. It can be noted that the shearwalls with higher aspect ratios are more sensitive to hold-down stiffness, while the ones with lower aspect ratios are more sensitive to the unit vertical-joint stiffness. This may be attributed to the fact that when the panel aspect ratio is higher, hold-down stiffness has a more significant influence on the distribution between rocking deformation and flexural deformation, while when the aspect ratio is lower with panels performing more rigidly, vertical-joint stiffness has more impact on the distribution between rocking deformation and shear deformation.

https://doi.org/10.52202/069179-0314

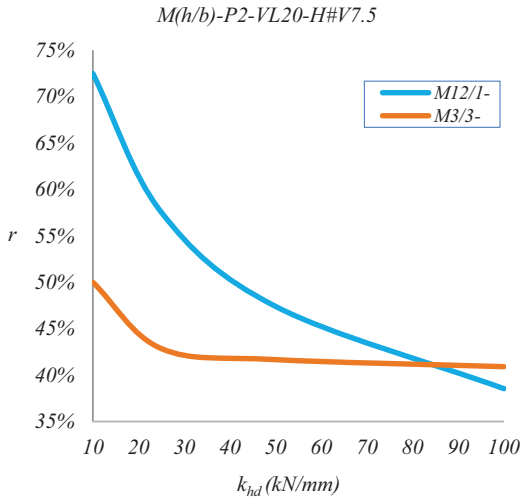

***Figure 8**: Relationship between k_{hd} and r when k_{vj}/h equals 7.5 kN/mm/m, and vertical loads equal 20 kN/m for two-panel models*

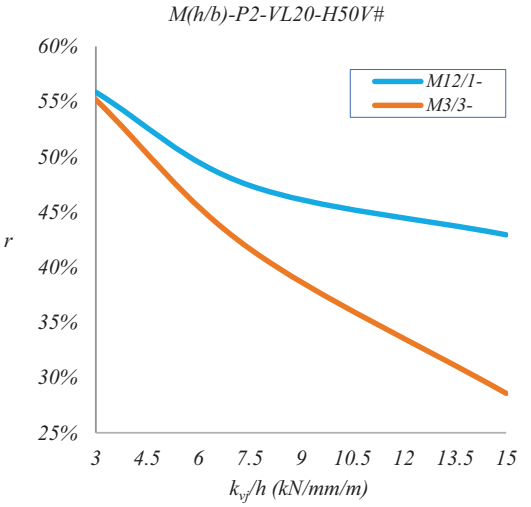

***Figure 9**: Relationship between k_{vj}/h and r when k_{hd} equals 50 kN/mm, and vertical loads equal 20 kN/m for two-panel models*

3.3 THE IMPACT OF VERTICAL LOADS

Models with vertical loads show higher total lateral stiffness K compared with those with no vertical loads applied. Figure 10 compares the average total lateral stiffness between the cases that include or exclude the vertical loads when aspect ratios vary from 3 to 12 for two-panel models. It is noted that although the averaged total lateral stiffness is positively affected by the increase in vertical loads, the effect is much less pronounced when the panel aspect ratio increases. It is also found that the presence of vertical loads yields more cases with CP mode. For example, when a vertical load of 20 kN/m/storey is applied, the number of cases with CP mode increases from 130 out of 288 (45.1%) to 180 out of 288 (62.5%).

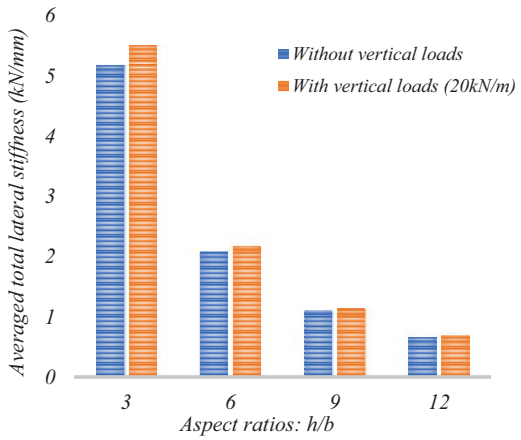

***Figure 10**: Impact of vertical loads on the averaged total lateral stiffness with varying aspect ratios when b equals 1 m for two-panel models*

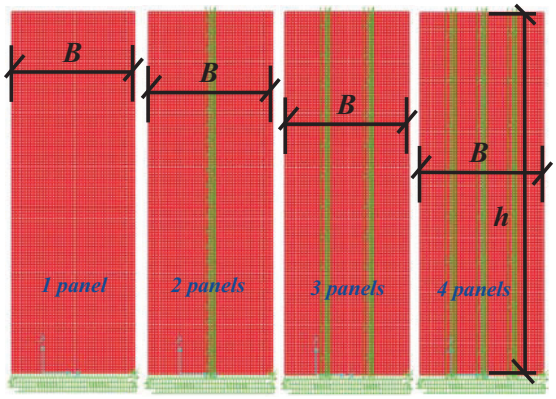
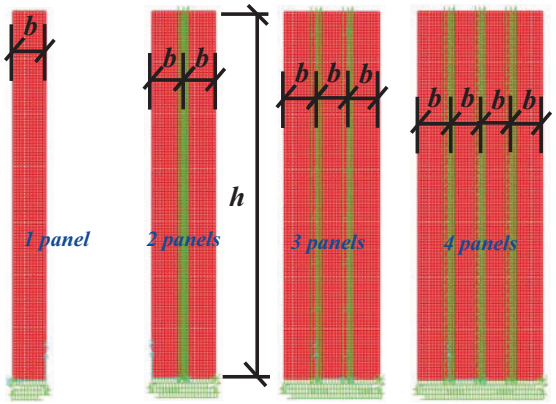
3.4 THE IMPACT OF THE NUMBER OF PANELS

This part of the analysis considers two conditions, namely a fixed ratio of h to B, and a fixed ratio of h to b, as shown in Figure 11.



(a) Varying panel number with fixed h/B (12:4)



(b) Varying panel number with fixed h/b (12:1)

***Figure 11:** Analysis of multi-panel behaviours*

https://doi.org/10.52202/069179-0314

The analysis for the fixed h/B ratio found that increasing the number of panels resulted in a decrease in the total lateral stiffness of the wall (Figure 12). In comparison, the models with higher relative stiffness $\tilde{k}$ defined as a ratio between k_{hd} and k_{vj} ($\tilde{k} = k_{hd}/k_{vj}$) showed a much larger reduction in stiffness than those with lower relative stiffness values.

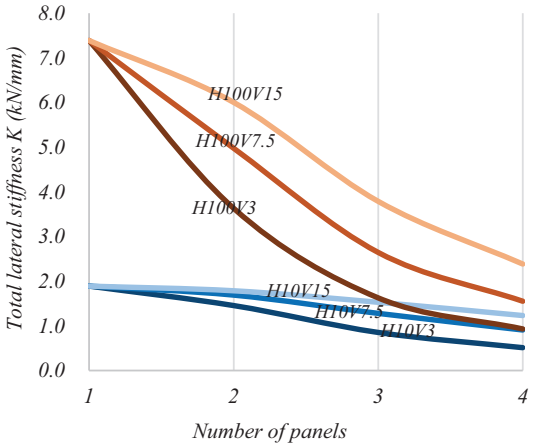


Figure 12: *Relationship between the number of panels and K when h/B is fixed to be 12:4 and vertical loads equal to 20 kN/m*

It can be observed from the results that the number of panels affects the percentage of rocking deformation, with the general tendency for a higher percentage of rocking behaviour when more panels are used, as illustrated in Figure 13.

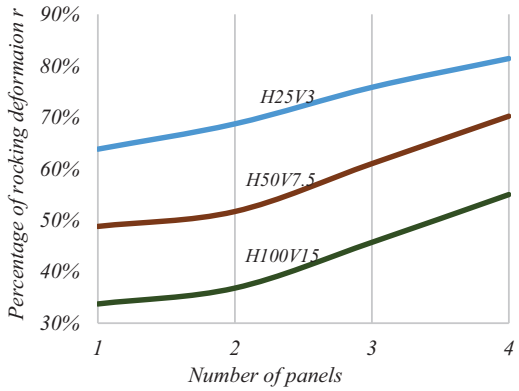

Figure 13: *Relationship between the number of panels and r for the models with CP mode when h/B is fixed to be 12:4 and vertical loads equal to 20 kN/m*

With respect to the kinematic modes, the models with CP mode tend to maintain that behaviour following an increase in the number of panels. However, models with SW mode could shift to IN behaviour when more panels are added. Figure 14 shows an example from model *M h/b -P# - VL20 - H25V15*, where when the number of panels increases from 2 to 4, the kinematic mode changes from SW to IN.

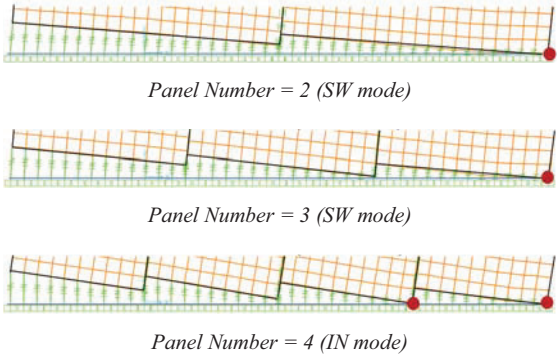

Figure 14: *Kinematic modes of the models with varying panel numbers.*

The analysis found that the total lateral stiffness tends to increase when the number of panels is increased while maintaining a constant ratio of *h/b*.

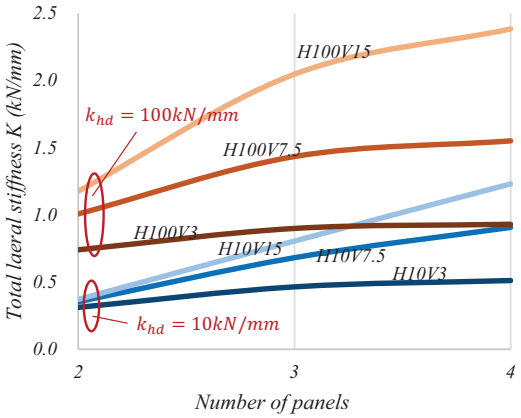

Figure 15: *Relationship between the number of panels and K when h/b is fixed to be 12:1 and vertical loads equal to 20 kN/m*

Similar to the result from the condition with a fixed *h/B* ratio, a higher percentage of rocking deformation is observed for systems using more panels with a fixed *h/b* ratio.

4 CONCLUSIONS

Analysis of the lateral deformation and kinematic modes of multi-panel balloon-type CLT shearwall systems is presented in this paper. A multi-panel shearwall model is proposed, and the effect of key parameters on the behaviour of the shearwall is presented and discussed.

The results highlight the importance of the panel aspect ratio (*h/b*) and the stiffness of connectors. It is found that the total lateral stiffness of the wall is higher when panels with lower aspect ratio, hold-down and vertical joints with higher stiffness and larger vertical loads are adopted. Increasing the number of panels for a shearwall system with a fixed total height-to-width ratio (*h/B*) results in lower total lateral stiffness, while increasing the number of panels with a fixed panel aspect ratio (*h/b*) results in higher total lateral stiffness.

The results also indicate that the lateral flexural deformation for balloon-type shearwalls should not be

https://doi.org/10.52202/069179-0314

ignored. In general, a higher aspect ratio, higher stiffness of hold-downs and vertical joints, and fewer number of panels all lead to a higher percentage of flexural deformation.

Finally, it is found that balloon-type CLT system with higher relative stiffness in the connections and higher vertical loads tends to be dominated by CP mode.

SEISMIC ASSESSMENT OF BALLOON-FRAMED CLT BUILDING WITH SELF-CENTERING HOLD-DOWN

Yuxin Pan[1], Md Shahnewaz[2], Carla Dickof[3], Thomas Tannert[4]

ABSTRACT: Balloon-framed cross-laminated timber (CLT) construction has a number of advantages when compared to platform-type construction. To date, however, only limited studies are reported on the performance of the former during earthquake shaking, and the seismic design provisions of many buildings codes only apply to the latter. Applications of innovative self-centering, energy-dissipation devices in balloon-framed CLT building are not yet well understood either. This study assesses the seismic performance of a balloon-framed CLT building with friction-based self-centering hold-downs (HD). A three-dimensional nonlinear finite element model was developed with the connections calibrated with test data. A tri-hazard ground motion selection approach was adopted to select and scale proper earthquake motions for the building site in Vancouver, Canada. The impact of the choice of hold-down on the seismic performance and damage potential of the building was assessed through nonlinear time history and incremental dynamic analyses. At design level, the building had an maximum drift of 0.67%, which met the 2.5% design limit. For comparison, a second building model with traditional HD was established and analysed, where larger drift was observed. The results confirmed the good seismic performance of the self-centering HD for balloon-framed CLT building.

KEYWORDS: Cross-laminated timber, seismic fragility, nonlinear modelling, resilience

1 INTRODUCTION

Most recent cross-laminated timber (CLT) projects applied a platform-type approach where each floor serves as a platform for erecting the walls of the next floor [1]. The platform construction has several disadvantages, mainly, it requires high compression resistance of the base floor in perpendicular-to-grain direction, and it requires more time for on-site assembly [2]. Balloon-framed construction, in which the walls are continuous from the base to the roof with floors can solve these problems. However, limited studies on balloon-framed construction are available and the design guideline for balloon-frame construction is not specified in Canadian Standard for Engineering Design in Wood CSA O86 [3].

A shake table tests on a 2-storey balloon-framed building with post-tensioned CLT rocking walls was conducted at UCSD laboratory [4]. It was observed that the building performed well at the maximum considered earthquake level. Li et al. [5] conducted a series of reversed cyclic tests on the balloon-framed shear walls and developed analytical equations for estimating the wall resistance. FPInnovations [6] in Canada proposed a mechanics-based model to predict the deflection and resistance of the balloon-type CLT building with an aspect ratio up to 12:1. Shahnewaz et al. [7] conducted static monotonic and cyclic tests on 2-storey balloon-framed CLT shear walls and identified that the rocking behavior of the CLT was not affected by the ledgers. Zhang et al. [8] developed 3D ETABS model for tall balloon-framed CLT building (12-story and 18-story) to investigate the influence of different connections on the overall characteristics of the building. Recently, Pan et al. [9] studied the collapse risk of a 2-storey school building retrofitted with balloon-framed CLT shear walls and found the building designed with the seismic reduction factors of that from the platform system can meet the requirement.

Another challenge for balloon-framed construction is the design of the tall walls' base connections, which require larger shear and overturning resistances. Common CLT buildings experience damage due to yielding and nail withdrawal of steel connectors (e.g., spline joint, hold-down, shear connections) during earthquake excitations, while the wall panels exhibit almost rigid behaviour [10]. With the increase of the wall height, larger demands will be posed to the base connectors, therefore, high-performance connectors are needed to accommodate this demand. Amongst the several high-performance connectors that have been developed in recent years [11],

a friction-based self-centering device used as hold-down (HD), commercially available under the trademark 'Tectonus', has shown great energy dissipation while causing low damage. Hashemi et al. [12] conducted large-scale experimental test conducted on a rocking CLT wall with this self-centering HD device and demonstrated that this novel device showed excellent behaviour and can achieve a damage-avoidant and seismic-resilient design.

This paper aims to assess the seismic performance of a balloon-framed CLT building with such self-centering device through nonlinear time history analysis (NLTHA).

2 BUILDING DESCRIPTION

The 4-storey, 16 m tall CLT building, located in Vancouver, Canada, has a dimension of 36.8 m×11.4 m and story height of 3.6 m, as shown in Figure 1. The building is the new office centre for Fast + Epp. It was designed with a live load of 2.4 kPa and a superimposed dead load of 2.5 kPa. The 2015 version of National Building Code of Canada (NBCC) [13] was used for the seismic design for a Class B Vancouver site (rock conditions). The CLT walls were designed with different thickness - 139 mm and 190 mm for the long direction, and 245 mm for the short direction. The walls are balloon-framed with ledgers at the middle. Seismic design reduction factors R_d and R_o of 2.0 and 1.5, respectively were used for the lateral system design which corresponds to the requirement for rocking platform CLT wall [3]. CLT is also utilized throughout the building for the floors, stairwells, elevator cores, as well as the demising firewall.

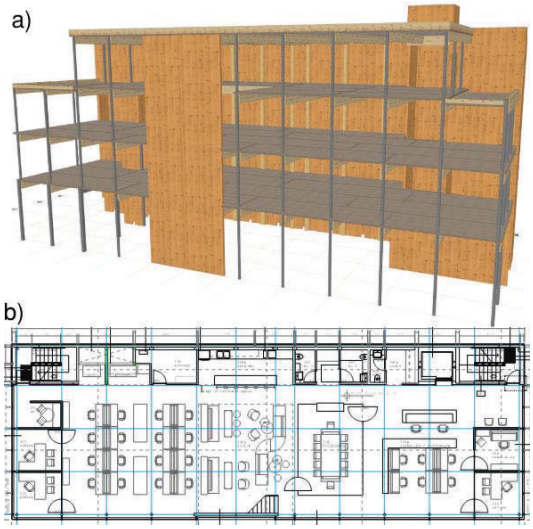

Figure 1: *3D isotropic a) and plan b) view of the building*

The walls are balloon-framed for every two storeys connected with ϕ 8 × 130 mm fully threaded screws installed in horizontal half-lap joints. The vertical panel-to-panel connections are provided with 19 mm ×200 mm D. Fir plywood surface spline joints using both partially threaded screws and smooth shank nails at a spacing of 500 mm and 64 mm, respectively. Base connections include concrete shear keys (SK) for each panel and two Tectonus HD at both ends of the coupled walls. For SK, a concrete upstand of 250 mm height and 300 mm width was designed with 4-15M U-bars embedded.

The Tectonus HD act as shock absorbers for the building during an earthquake, providing energy dissipation and damping through the earthquake cycles, with the ability to snap back to its original position once shaking ends. The Tectonus connectors remain damage-free, a feature that might allow immediate return to occupancy after a significant earthquake, without facing uncertain delays expected with conventional systems. Figure 2 shows a photo of the installed Tectonus device and a typical "flagshaped" hysteresis curve with self-centering characteristics. The design parameters are as follows: F_{slip}=350 kN, F_{ult}=700 kN, $F_{restoring}$=350 kN, $F_{residual}$=165 kN, and Δ_{ult}=15 mm.

In the original design, a steel braced frame was placed in the short direction of the building. As this study focused on the impact of the self-centering HD device, the building was modified by replacing the brace system with a coupled balloon-framed CLT shear wall. A total of 12 Tectonus HDs were used in the updated building model for assessment.

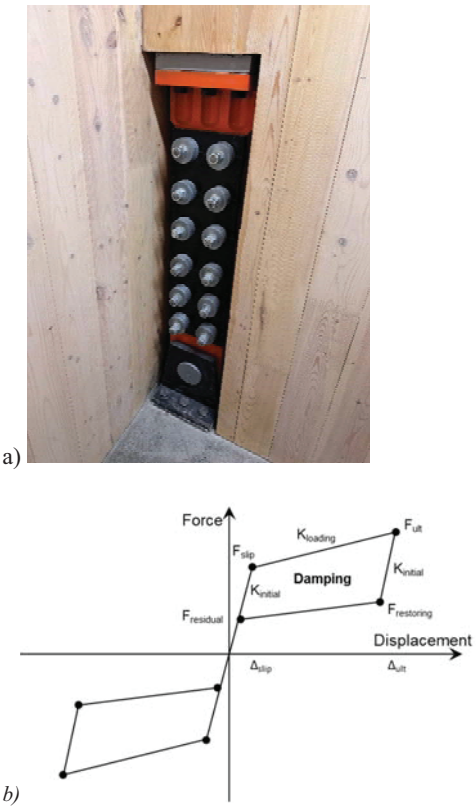

Figure 2: *Tectonus HD device: a) photo, b) hysteresis curve*

https://doi.org/10.52202/069179-0315

3 MODELING

A nonlinear three-dimensional (3D) model of the building was developed in OpenSees [14]. Isotropic elastic shell elements were used to model the CLT wall panels and nonlinear spring elements (either zeroLength or twoNodeLink) were used to simulate the connections, as seen in Figure 3. Pinching4 model and SelfCentering models were used and calibrated to model the nonlinear behaviour of the connections, including cyclic degradation and pinching at large deformation.

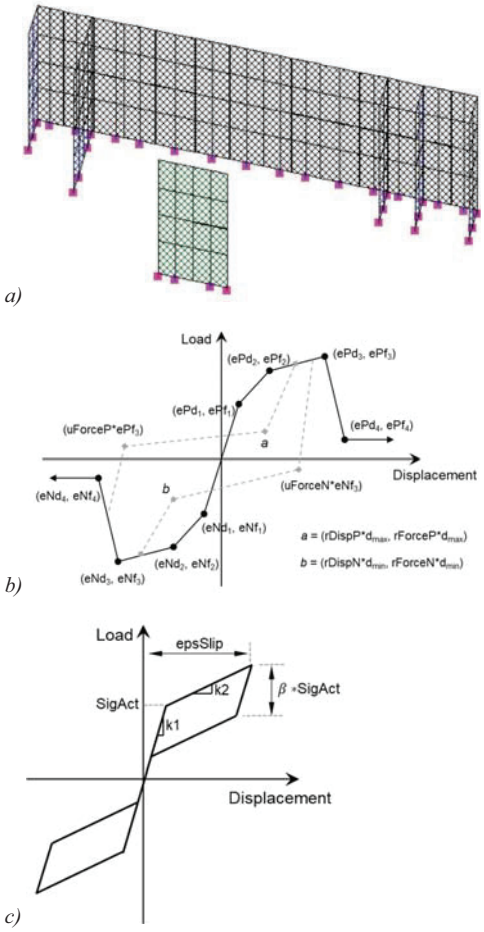

Figure 3: *Numerical model in OpenSees: a) 3D model of the building, b) Pinching4 material model, c) SelfCentering material model for connections*

For comparison purpose, a second building model with conventional dowel-type HD was established and modelled. The HD was manufactured with customized stell plate (975 mm high, 370 mm wide, 102 mm long at base, and 28 mm thick) and attached with 32 fully threaded ϕ12×120 self-tapping screws. It was tested at the UNBC lab with the same peak capacity of 700 kN.

All the connections were calibrated with experimental data available in the literature or conducted at UNBC lab. Considering the limitation of the SelfCentering model where the unloading stiffness has to be the same with the loading stiffness (different in actual behavior of the Tectous HD), an energy equivalent assumption was made: by controlling the *Frestoring* in Figure 2 (i.e., β in Figure 3b), the total energy enclosed by the numerical backbone curves was almost the same as the area enclosed by the design parameter.

Figure 4 shows the first two preliminary mode shapes of the developed model. The building had a fundamental period T of 0.8 sec in the short direction (East-West) and 0.5 sec in the long direction (North-South). The sliding and rocking behaviour of the CLT panels can be identified. The obtained information will be used to select proper ground motion input records that represent the seismicity for the nonlinear dynamic analysis.

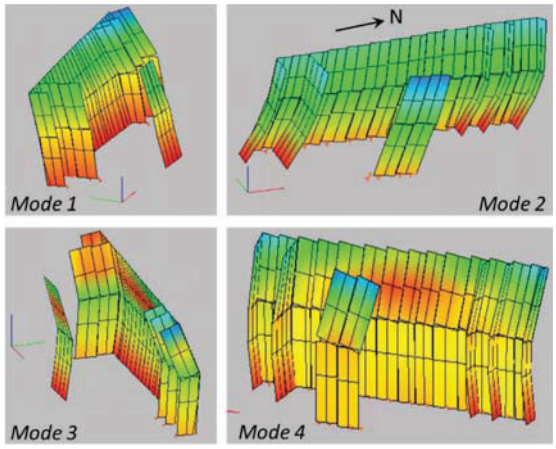

Figure 4: *Mode shapes of the building model*

4 ANALYSIS

To assess the seismic performance of the two buildings, NLTHA was performed on their models. This procedure requires proper selection and scaling of representative ground motions. For the building site of Vancouver, which is located in the complex Cascadia Subduction Zone, there are three types of earthquake hazards: 1) shallow crustal earthquakes, 2) subduction inslab earthquakes, and 3) subduction interface earthquakes. By conducting a probabilistic seismic hazard analysis for the site using Canada's 5th Generation Seismic Hazard Model, the contributions from each hazard are 8%, 72%, and 20%, respectively. As per the NBCC, a total of 21 pairs (two horizontal components) of ground motion records, 7 from each earthquake type, were selected from global databases and matched to the design spectrum of the building over a period range of 0.2T to 2.0T. Figure 5 shows the response spectra of selected motions matched to the design spectrum.

https://doi.org/10.52202/069179-0315

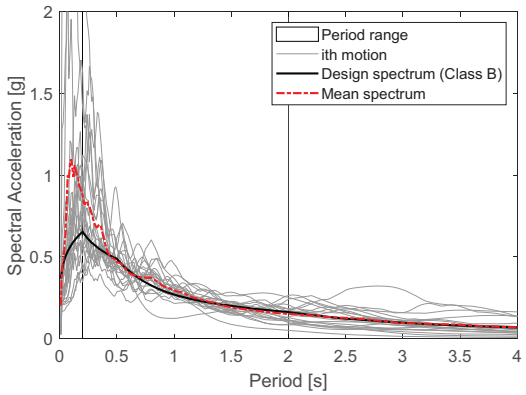

Figure 5: *Ground motion selection and scaling*

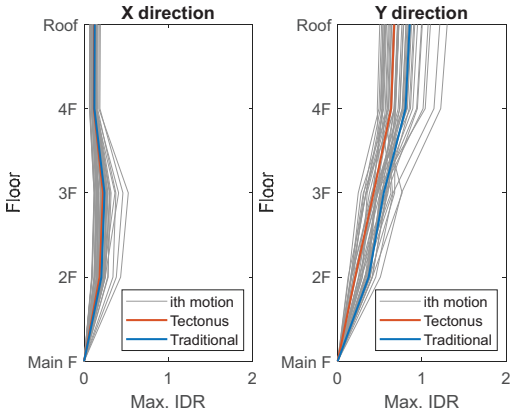
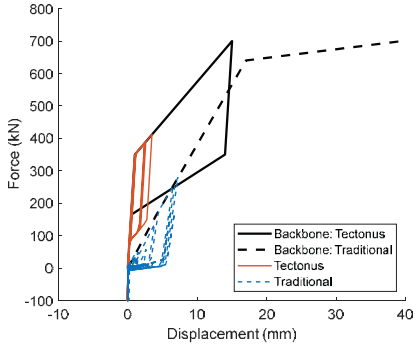
With the established models and the selected motios, NLTHA were conducted at the design intensity level for two building models. Figure 6a compares the maximum drifts at both directions of the buildings. For the Tectonus one, the maximum drift on average were 0.22% at the second story for the long direction and 0.67% at the roof floor for the short direction, which were far below the 2.5% drift limit specified in NBCC for normal importance category buildings. It was observed that the Tectonus HD had negligible impact on drift in the strong long direction, but decreased 30% drift for the short direction when compared to the conventional HD. It is worth mentioning that although the two HD devices had the same peak capacity, the initial stiffness were different, therefore, different seismic performance at design intensity levels were expected. This can be seen in Figure 6b. Due to lower initial stiffness, traditional HD showed twice the displacement at 32% lower force than the Tectonus HD.



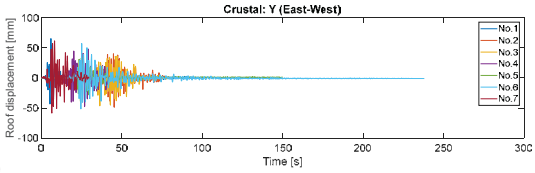
a)



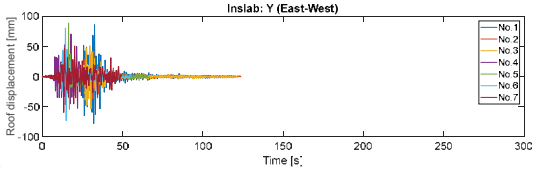
b)

Figure 6: *Comparison of two building models at design intensity level: a) drift, b) HD hysteresis*

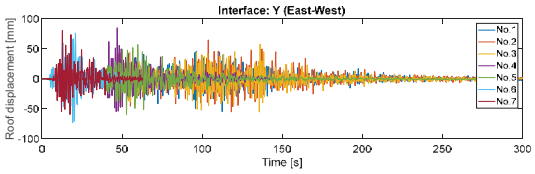
For illustration, roof displacement time histories in the short direction of the building with Tectonus HD are presented in Figure 7, are categorized for each earthquake type. The average of the maximum roof displacements for the long and short directions were 24 mm and 64 mm, respectively, where the maximum displacement of 89 mm was observed from one subduction inslab motion – the Michoacan motion in the short direction.



a)



b)



c)

Figure 7: *Roof displacement time histories in the short direction of the building model with Tectonus HD: a) crustal, b) subduction inslab, c) subduction interface*

Hysteresis curves of the Tectonus building model and representative connections subjected to the Michoacan subduction inslab motion (No. 4 at station Caleta De Campos) at design level are presented in Figure 8. Highly nonlinear behaviour including stiffness and strength degradation, as well as pinching can be observed. It can be seen that the horizontal panel-to-panel spline connection was the primary source for energy dissipation.

https://doi.org/10.52202/069179-0315

The spline connections in both directions of the building showed large relative displacements and dissipated large amount of the energy. This was followed by the Tectonus HD. The rocking behaviour for this design level shaking resulted in 2 mm uplift and almost 400 kN tension force. The vertical floor-to-floor half-lap connections were capacity protected, and therefor showed almost linear behaviour.

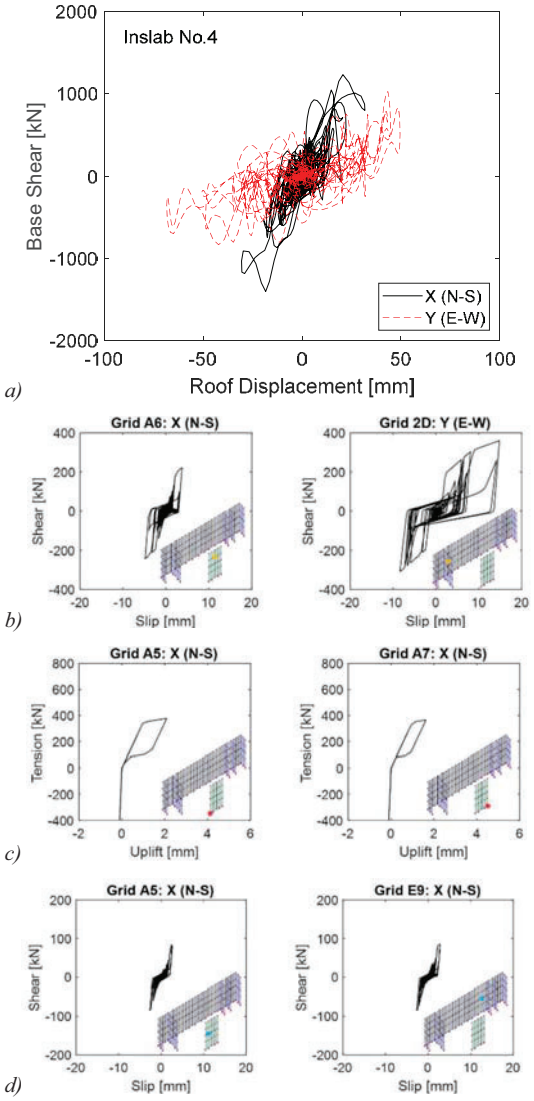


Figure 8: *Nonlinear hysteresis curves during subduction inslab motion: a) global curve, b) horizontal panel-to-panel spline joint, c) Tectonus HD, and d) vertical floor-to-floor half-lap joint*

5 CONCLUSIONS

In this study, a 3D finite element model for a balloon-framed CLT building was developed and calibrated with test data. The building was equipped with a resilient friction-based self-centering device as HD – the first in Canada. For comparison, a second building model designed with conventional dowel-type HD was also developed. The SelfCentering and Pinching4 material models in OpenSees were used for modelling the connections. Twenty-one pairs of ground motion records were selected based on the seismic hazard of the building site for the nonlinear time history analysis. Based on the analysis results, both building models met the drift limit of 2.5% specified in NBCC at the design level. The model with the Tectonus HD showed lower drift compared to the traditional one. Further studies on the collapse capacity and damage fragility of the building model will be conducted to have a comprehensive understanding of the effectiveness of the Tectonus HD for seismic resilience design.

ACKNOWLEDGEMENT

The project was supported by Government of Canada through a Canada Research Chair and by Natural Resources Canada (NRCan) through the Green Construction Wood (GCWood) program.

STUDY OF THE EFECT OF SEISMIC REINFORCEMENT USING CFRTP STRANDS ON WOODEN BUILDINGS

Koji Kubo[1], Nobuji Sakurai[1], Yuya Takaiwa[2]

ABSTRACT: In this study, we conduct seismic reinforcement work using CFRTP (Carbon Fiber Reinforced Thermo-Plastics) strands on an actual wooden building, conduct microtremor measurement before and after the work, and grasp the change in natural vibration characteristics. Additionally, the numerical analysis before and after the work confirm that to what extent yield strength is raised by the seismic reinforcement. These results reveal that the effectiveness of the seismic reinforcement using CFRTP strands on wooden buildings is not a bad influence on the period of the actual building.

KEYWORDS: Wooden architecture, Microtremor measurement, Seismic performance

1. INTRODUCTION

We can raise yield strength by seismic reinforcement members as a result of conducting seismic reinforcement on wooden buildings. Moreover, we can raise stiffness. The rising of stiffness changes the natural period. In consequence, there is a possibility that the building resonates with seismic motion of the periodic band which used to not resonate before seismic reinforcement. Accordingly, in seismic reinforcement design, we need to grasp the possible spectral shape in the area as a result of surveys of the fault around the site and historical earthquake. On the other hand, if there are seismic reinforcement members raise yield strength and not change stiffness, we can keep resonance with the periodic band unchanged before and after the seismic reinforcement. However, conventional seismic reinforcement members of wooden buildings, for example, plywood, reinforcing bar brace, and diagonal brace, raise not only yield strength but also stiffness. Therefore, we developed a seismic reinforcement method for wooden buildings using CFRTP strands that having high yield strength, and moreover, low stiffness at large deformation. Carbon fiber composite materials are advanced materials used in a wide range of fields of engineering, and are also gathering attention in the field of construction [1]. In the previous study, the authors developed an end fixing structure for CFRTP strands having toughness [2][3][4]. We showed that CFRTP stands have high yield strength at large deformation, moreover, have low stiffness as a result of conducting an in-plane shear test on wooden frame reinforcement walls using CFRTP strands [5]. In this study, we conduct seismic reinforcement work using CFRTP strands on an actual wooden building, conduct microtremor measurement before and after the work, and grasp the change in the natural vibration characteristic. Additionally, the numerical analysis before and after the work confirm that to what extent yield strength is raised by the seismic reinforcement. The purpose of this study is that these results reveal the effectiveness of the seismic reinforcement using CFRTP strands on wooden buildings.

2. TARGET BUILDING

2.1 OUTLINE OF THE BUILDINGS

The “shumaku” displayed in Natural Museum of Ethnology since 1999 is a reproduction of a facility that was built around 1920 for Korean Peninsula travelers to eat and sleep. In order to exhibit, the original roof was changed from thatching to copper plate. The planar shape is L-shaped, and the floor plan is composed of accommodation rooms such as Japanese “Hatagoya” and “Uchiniwa” (cooking area).

Photo 1: *Appearance of the target building (Before reinforcement)*

https://doi.org/10.52202/069179-0316

2.2 OUTLINE OF STRUCTURE

The frame by the wooden framework construction method is constructed with 150mm × 150mm columns, 150mm × 200mm beams, 90mm × 150mm rails, and walls are plywood Shinkabe:japanese traditional column-exposed wall. The wooden frame members are all made of pine, and the column bases are Ishibadate:Japanese traditional construction method, columns set up on stones instead of anchoring to the ground. The roof truss is copper roofing using Japanese roof truss. Table 1 shows the building weight. Figure 1 shows roof truss frame and framing elevation.

Table 1: *Building weight.*

Floor		height H (m)	weight W(kN)	area A(m^2)	W/A (kN/m^2)
1		3.270	114.61	61.76	1.85

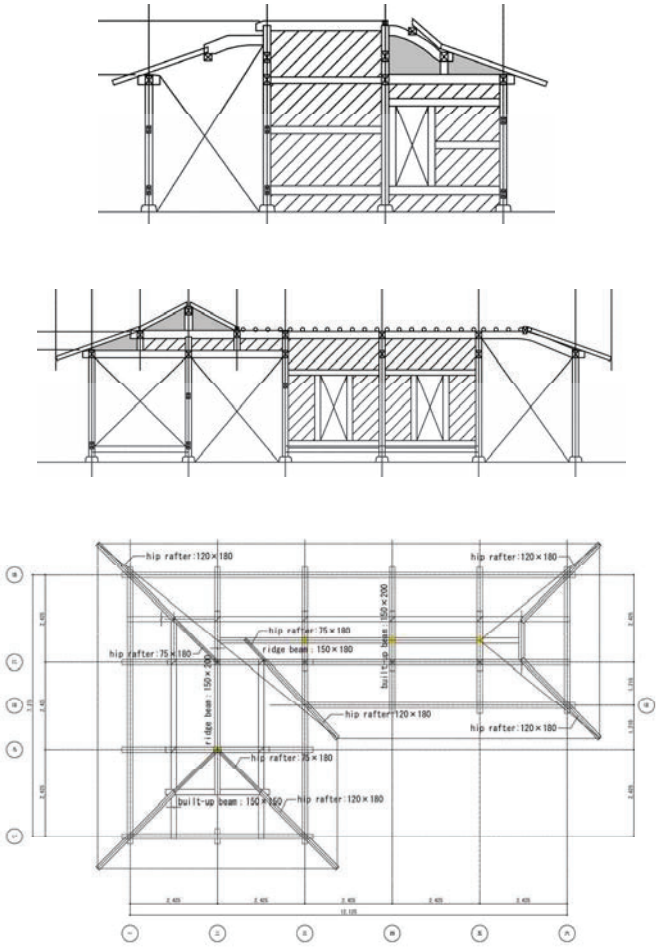

Figure 1: *roof truss flame plan, framing elevation*

2.3 OUTLINE OF REINFORCEMENT

We needed to conduct a reinforcement to maintain the exterior and the interior of the building. Therefore, we selected reinforcement members installed on the current wall. We adopted CFRTP strands made of carbon fiber composites as seismic reinforcement members and conduct seismic reinforcement. CfRTP strands were arranged in well balanced manner on the structure of each frame (top and bottom of girts), and the entire building was considered so that there was no behavior of twisting. The seismic reinforcement work was completed at the end of March 2022.

Photo 2: *Appearance of the target building (After reinforcement)*

Photo 3: *Appearance of the target building (After reinforcement)*

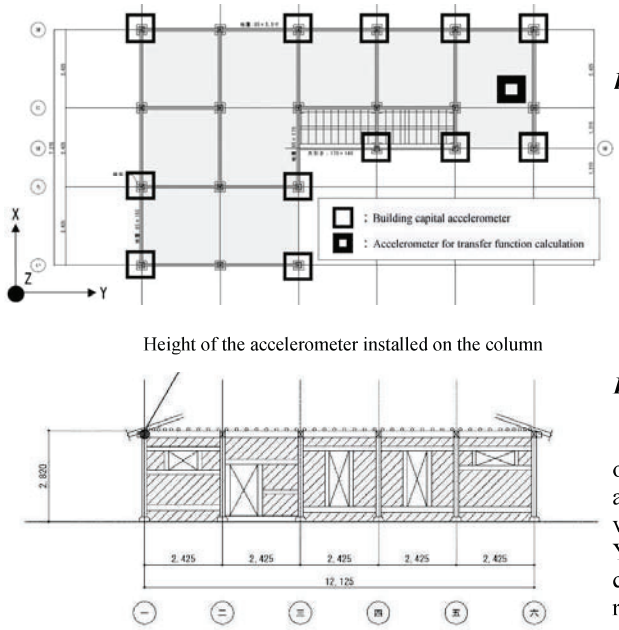
3. MICROTREMOR MEASUREMENT

3.1 OUTLINE OF THE MEASUREMENT

The eigenfrequency and vibration mode shape are estimated by measurement. Figure 2 shows the measurement position. The measurement was performed at the capital and ground level using a 3-axis accelerometer:RS-ONE.
Data for 180 seconds was sampled at a sampling frequency of 100 Hz.



Height of the accelerometer installed on the column

Figure 2: *measurement position*

3.2 MEASUREMENT RESULT

Figure 3, 4 (Before reinforcement) and Figure 5, 6 (After reinforcement) show analysis results.

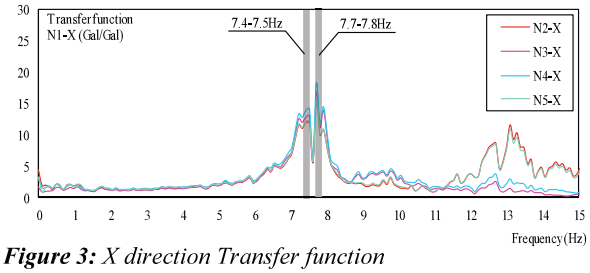


Figure 3: *X direction Transfer function*

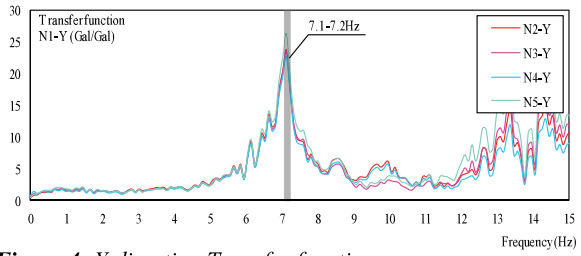

Figure 4: *Y direction Transfer function*

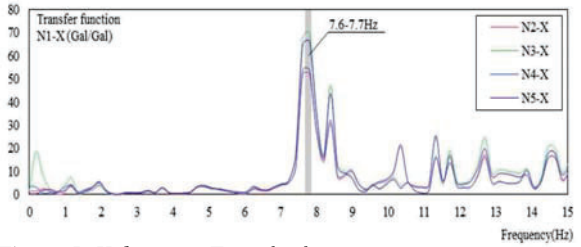

Figure 5: *X direction Transfer function*

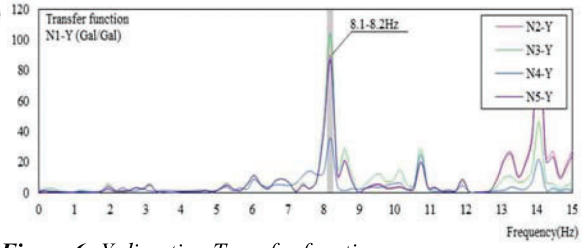

Figure 6: *Y direction Transfer function*

Before reinforcement, it had a natural vibration mode of X component around 7.4 - 7.5 Hz and Y component around 7.1 – 7.3 Hz. After reinforcement, it had a natural vibration mode of X component around 7.6 - 7.7 Hz and Y component around 8.1 – 8.2 Hz. There is almost no change in the periodic band before and after reinforcement.

4. ESTIMATION OF STIFFNESS AND YIELD STRENGTH

We calculated stiffness and ultimate horizontal yield strength before and after seismic reinforcement by numerical analysis, and compared the change of stiffness before and after seismic reinforcement.

https://doi.org/10.52202/069179-0316

4.1 OUTLINE OF THE ANALYSIS MODEL

This analysis model express horizontal diaphragm stiffness in pole plate level contributed by roof truss. We replaced seismic reinforcement members arranged on the wall with wire braces. Figure 7 shows analysis model.

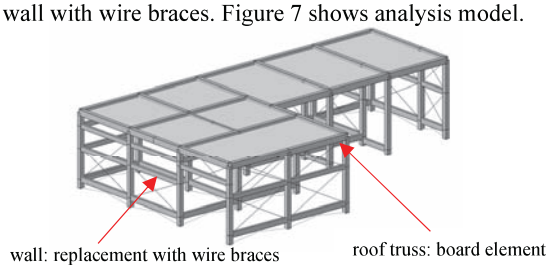

Figure 7: *analysis model*

4.2 EIGENVALUE ANALYSIS

We conducted eigenvalue analysis before and after seismic reinforcement. Table 2 is comparative table of analysis result and microtremor measurement result. Figure 8 and 9 show primary mode.

Table 2: *Eigenfrequency (Hz)*

	Microtremor measurement		Analysis result	
	X direction	Y direction	X direction	Y direction
Before reinforce -ment	7.40	7.10	0.001	0.005
After reinforce -ment	7.60	8.10	2.535	2.805

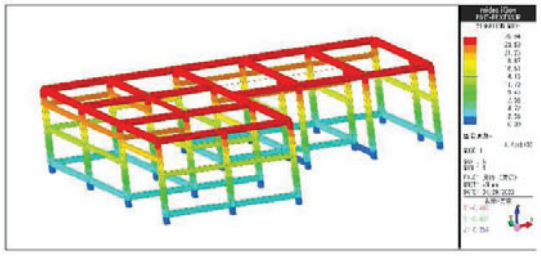

Figure 8: *Primary mode chart (Y direction before reinforcement)*

Figure 9: *Primary mode chart (Y direction after reinforcement)*

4.3 STATIC ELASTIC ANALYSIS

We conducted static elastic analysis before and after seismic reinforcement, and compared horizontal stiffness and ultimate horizontal yield strength. We adopted ultimate horizontal yield strength in 1/15 rad. Figure 10 and 11 show load-deformation relationship. Table 3 shows ultimate horizontal yield strength.

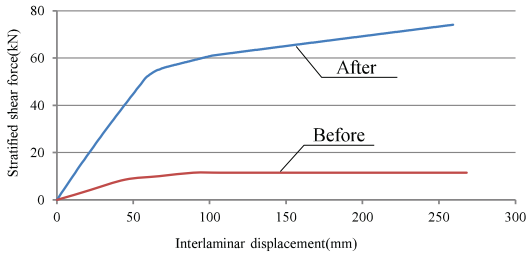

Figure 10: *X direction Load-deformation relationship*

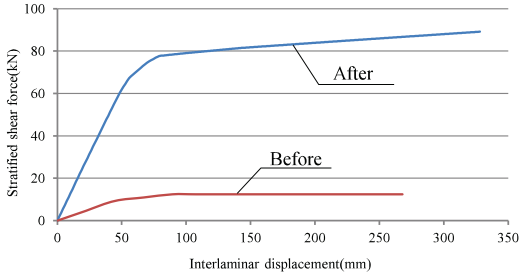

Figure 11: *Y direction Load-deformation relationship*

Table 3: *ultimate horizontal yield strength*

	Horizontal Stiffness (kN/mm)		Ultimate horizontal yield strength (kN)	
	X direction	Y direction	X direction	Y direction
Before reinforce -ment	0.083	0.090	11.5	12.50
After reinforce -ment	1.010	1.236	70.42	78.87

According to analysis results, we can see that stiffness and ultimate horizontal yield strength increased greatly from before reinforcement. By contrast, according to results of microtremor measurement, we can see that eigenfrequency is about the same. Therefore, we suggest that initial stiffness is almost unchanged.

https://doi.org/10.52202/069179-0316

5. EFFECT ON THE BUILDING BY CHANGE OF STIFFNESS

There's a wide variety of seismic reinforcement from high-stiffness members to low-stiffness members. We need to grasp the period of the building, to attenuate the effect on the building by the change of stiffness.

5.1 SEISMIC REINFORCEMENT WITH DIFFERENT STIFFNESS REINFORCEMENT MEMBERS

In the case of seismic reinforcement using high-stiffness members, the natural period fluctuates due to increasing stiffness. In consequence, there is a possibility that the building resonates with seismic motion of the periodic band which used to not resonate before seismic reinforcement.

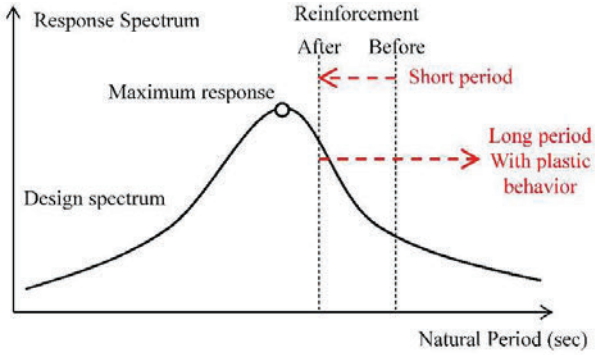

Figure 12: *Seismic reinforcement using high-stiffness members (Steel material brace, plywood, diagonal brace etc.)*

By contrast, seismic reinforcement using low-stiffness members raise yield strength without change of stiffness. In consequence, we can keep the same periodic band which the building resonates before and after seismic reinforcement.

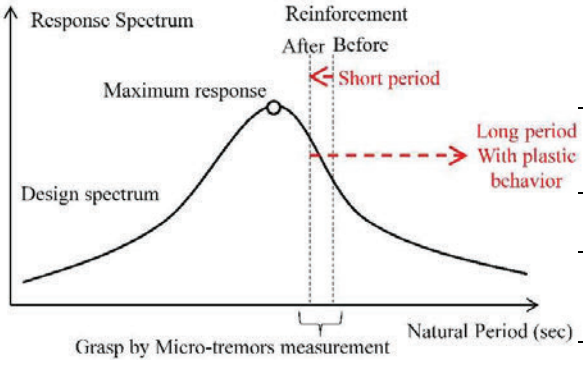

Figure 13: *Seismic reinforcement using low-stiffness members (CFRTP strand proposed by this study)*

5.2 COMPARATION WITH HIGH STIFFNESS MEMBERS

We compared by analysis seismic reinforcement with high-stiffness against low-stiffness members, and considered the change of eigenfrequency after reinforcement. We employed high-stiffness wire braces as high-stiffness members, and CFRTP strands as low-stiffness members. We calculated eigenfrequency and horizontal stiffness in 1/120 rad. Figure 14 and 15 show load-deformation relationship. Table 4 is comparative table of eigenfrequency and stiffness.

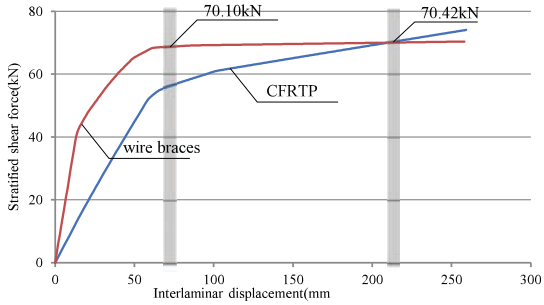

Figure 14: *X direction Load-deformation relationship*

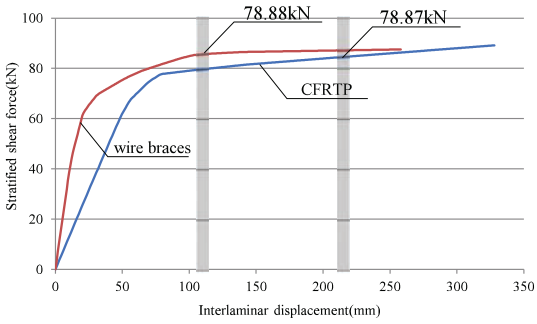

Figure 15: *X direction Load – deformation relationship*

Table 4: *Comparative table of eigenfrequency*

Reinforceme -nt members	CFRTP strand		Wire brace	
Direction	X direction	Y direction	X direction	Y direction
Horizontal stiffness	0.945	1.236	1.963	2.403
Eigenfreque-ncy	2.535	2.805	2.776	3.112

https://doi.org/10.52202/069179-0316

Figure 16 shows mode chart after seismic reinforcement with high-stiffness members.

Figure 16: *Primary mode chart (Y direction after reinforcement)*

Analysis results demonstrated that eigenfrequency of high-stiffness members is up 1.10 times in X direction, and 1.11 times in Y direction than low-stiffness members. We confirmed that horizontal stiffness of high-stiffness members is up around 2 times in both direction than low-stiffness members.

6. CONCLUSIONS

We confirmed that horizontal stiffness calculated by actual measurement value of microtremor measurement is almost unchanged before and after reinforcement. Numerical analysis demonstrated that yield strength after reinforcement is up than before reinforcement. We employed high-stiffness wire braces and low-stiffness CFRTP strands as seismic reinforcement members, and confirmed differences in stiffness between the two by numerical analysis. According to the result, we confirmed that eigenfrequency of using wire braces is higher than using CFRTP strands in the case that each ultimate horizontal yield strength is almost the same. We presume that CFRTP strands employed as seismic reinforcement members in this study are high-yield strength and low-stiffness members. The building reinforced with these seismic reinforcement members function as fail safe in large deformation. Moreover, we confirmed that seismic reinforcement with CFRTP strands have no negative effect on periodic characteristic of the existing building.

ACKNOWLEDGEMENT

The owner of the target wooden building, National Museum of Ethnology gave us huge help.
We would like to express our gratitude to them.

SHEAR FAILURE MECHANISM III IN CROSS LAMINATED TIMBER – NUMERICAL INVESTIGATIONS OF FRACTURE BEHAVIOUR

Henrik Danielsson[1], Erik Serrano[2]

ABSTRACT: The paper deals with numerical investigations of load-bearing capacity and fracture behaviour of Cross Laminated Timber at in-plane shear loading. Focus is on shear failure mechanism III, *i.e.* failure in the crossing areas between flatwise bonded laminations, and on evaluating test methods for that failure mode. In current design provisions, this failure mode is characterised by the rolling shear strength, $f_{v,R}$, and the torsional shear strength, $f_{v,tor}$, and therefore testing including both transverse (rolling) shear and torsional shear is needed. Two such test set-ups are investigated, one aiming at evaluating torsional shear strength and one aiming at evaluating rolling shear strength. Full 3D finite element analyses applying a cohesive zone model approach were used to study the strength and fracture behaviour. Failure criteria for structural design, material strength parameters, and the suitability of the two test configurations to determine strength parameters are discussed in relation to findings from the numerical investigations. One main conclusion from the investigation is that expected test results using the torsional test set-up are less size dependent as compared to test results using the transverse set-up. The numerical analyses suggest a very small influence from tensile loading perpendicular to the crossing area, for both test set-ups.

KEYWORDS: CLT, in-plane shear, failure mechanism III, fracture mechanics, finite element modelling

1 INTRODUCTION

Prediction of load-bearing capacity of Cross Laminated Timber (CLT) at in-plane shear loading (see Figure 1) is relatively complex and involves three potential shear failure mechanisms (FM): Gross shear failure (I), net shear failure and (II) and shear failure at the crossing areas between bonded laminations of adjacent layers (III).

This paper deals with investigations regarding load-bearing capacity and fracture behaviour for shear FM III, based on 3D finite element (FE) models including a cohesive zone modelling approach to describe the fracture behaviour at the crossing area between flatwise bonded laminations. The numerical studies include test configurations for determination of strength parameters to be used for structural design: one test set-up for torsional shear loading and one for uniaxial shear force loading.

The influence of test specimen geometry, test specimen size and lamination growth ring pattern on the fracture over the crossing area and on the load-bearing capacity is studied.

The purpose of the work presented is to gain knowledge of the fracture behaviour of CLT at in-plane shear loading, specifically for combined rolling and longitudinal shear over the crossing areas.

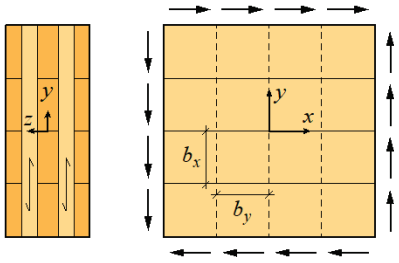

Figure 1: *CLT at in-plane shear loading*

For the applied cohesive zone modelling approach, the behaviour is governed by the material strength, the stiffness, the fracture energy, and the shape of the curve

describing the stress versus deformation relationship within the fracture process region. For rolling shear, very little information is found in the research literature regarding fracture properties at the local scale. For the present application, with combined longitudinal and rolling shear loading, the lack of available information is even further emphasized.

2 FAILURE CRITERIA FOR DESIGN

FM III is in general relevant for CLT elements without edge-bonding, involving shear stresses acting in the *xy*-plane (see Figure 1) and over the crossing areas between adjacent laminations of different layers. These shear stresses represent both longitudinal shear and rolling shear in the two bonded laminations.

For structural design of CLT, both *pure in-plane shear* loading and in-plane shear loading at *beam loading conditions* is relevant. The following failure criteria have been proposed in [1, 2] to be used for structural design:

$$\frac{\tau_{tor}}{f_{v,tor}}+\frac{\tau_{zx}}{f_{v,R}} \le 1.0 \quad \text{and} \quad \frac{\tau_{tor}}{f_{v,tor}}+\frac{\tau_{zy}}{f_{v,R}} \le 1.0 \qquad (1a, 1b)$$

Here τ_{tor} is a shear stress due to torsion by relative rotation between the laminations and τ_{zx} and τ_{zy} are the shear stresses due to relative translation between the laminations (see Figure 2). The corresponding strength parameters are the rolling shear strength, $f_{v,R}$, and a torsional shear strength parameter, $f_{v,tor}$.

In structural design, the two shear stress components τ_{zx} and τ_{zy} are commonly assumed to have uniform distributions over the crossing areas. The torsional stress τ_{tor} is calculated from the polar moment of inertia, $I_{P,CA}$, of the bonded area according to

$$\tau_{tor}=\frac{M_{tor}}{I_{P,CA}}\frac{b_{max}}{2} \qquad \text{with} \qquad I_{P,CA}=\frac{b_x b_y}{12}\left(b_x^2+b_y^2\right) \qquad (2)$$

where M_{tor} is the torsional moment, b_x and b_y are the widths of the laminations, and where $b_{max} = \max\{b_x, b_y\}$. The stress τ_{tor} according to Equation (2) refers to the maximum value at the four mid-points of the sides of the crossing area, see Figure 2, and can also be expressed as

$$\tau_{tor}=\frac{M_{tor}}{W_{P,CA}} \qquad \text{with} \qquad W_{P,CA}=\frac{b_x b_y}{6 b_{max}}\left(b_x^2+b_y^2\right) \qquad (3)$$

where $W_{P,CA}$ represents a corresponding torsional section modulus.

As pointed out in [3], it is from the view of continuum mechanics confusing that the shear stress components in Equations (1a) and (1b) are evaluated against two different strength values: $f_{v,R}$ for stress components τ_{zx} and τ_{zy}, and $f_{v,tor}$ for the torsional shear stress τ_{tor}. The torsional shear strength should in this this sense be seen as representing a structural property, rather than a material property.

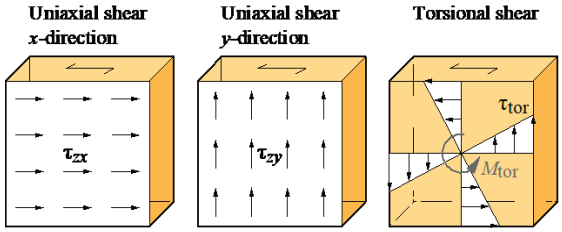

Figure 2: *Illustrations of assumed shear stress distributions*

Alternative approaches for verification of the load-bearing capacity for shear FM III are outlined in [3] and further discussed in [4]. This approach is based on consideration of only the rolling shear strength of the laminations, which would make it possible to abandon the torsional shear strength parameter, $f_{v,tor}$. This is motivated by the relatively large difference in material strength between rolling shear and longitudinal shear. For orthogonally bonded laminations, a material point on one side of the bonding area loaded in longitudinal shear will have a neighbouring material point on the other side of the bonding area which is loaded in rolling shear. By this reasoning, a *maximum stress* criterion based on the rolling shear strength of the lamination was suggested in [3], according to the illustration in Figure 3 (which is based on an assumed strength ratio as $f_v/f_{v,R} = 2.0$).

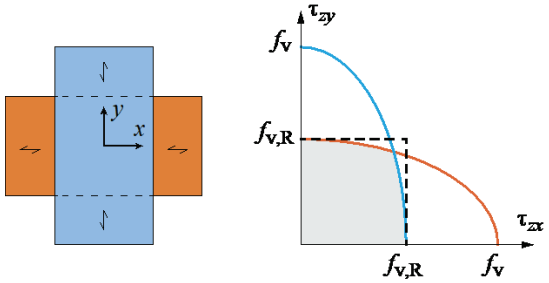

Figure 3: *Suggested maximum stress criterion from [3], based on only rolling shear strength $f_{v,R}$ (dashed lines)*

3 ANALYTICAL MODELS

Simple analytical models can be formulated for approximate estimation of the load-bearing capacity of a crossing area loaded in either pure uniaxial shear or in torsion. A system of two rigid surfaces, connected by a shear-flexible medium, is considered. Two different failure/yield surfaces are considered here. These are denoted A and B and are based on a quadratic stress interaction and on a maximum stress criterion, according to Equations (4) and (5), respectively. The yield surfaces are illustrated in Figure 4, with f_s representing the shear strength.

Surface A: $$\sqrt{\tau_{zx}^2+\tau_{zy}^2} \le f_s \qquad (4)$$

Surface B: $$\max\left\{\tau_{zx}, \tau_{zy}\right\} \le f_s \qquad (5)$$

https://doi.org/10.52202/069179-0317

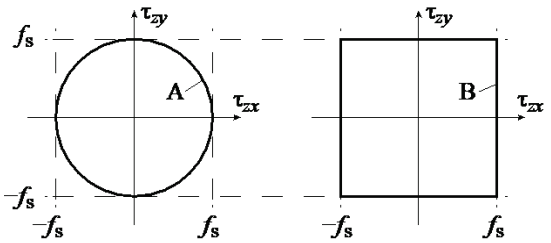

Figure 4: *Failure/yield surfaces A and B*

Expressions for the elastic and ideally plastic load-bearing capacities for a square area loaded in uniaxial shear or in torsion are given in [4] for the respective failure/yield surfaces. These elastic/plastic limits are used below, for comparison to results obtained by numerical analyses.

4 NUMERICAL MODELLING

Test configurations for determination of the rolling shear strength, $f_{v,R}$, and the torsional shear strength parameter, $f_{v,tor}$, were studied by numerical methods. The numerical models are based on non-linear FE-modelling and a cohesive zone approach, including strain softening after reaching the local material strength, for modelling of the fracture initiation and propagation over the crossing area.

The studied test configurations include situations of torsional loading and uniaxial shear force loading. For these test configurations, numerical parameter studies were carried out in order to investigate the influence of specimen geometry (lamination sizes) and the influence of the growth ring pattern of the laminations on the load-bearing capacity and fracture behaviour.

The software Abaqus [5, 6] was used for the numerical analyses. The timber laminations were modelled as linear elastic parts with orthotropic stiffness properties according to Table 1 and considering a cylindrical coordinate system, LRT. Linear 3D brick elements (C3D8 in Abaqus) were used for the timber laminations. The bonding between the laminations was modelled as a surface-to-surface contact. The contact formulation was assigned as hard contact in compression normal to the contact surface. For the two in-plane shear directions and for the normal direction in tension, a cohesive behaviour was implemented. This behaviour is defined by local material strengths for the two in-plane shear directions (f_{s1} and f_{s2}), the tensile strength for loading perpendicular to the contact surface (f_n), the fracture energy (G_f) and a softening law defining the descending part of the local stress versus deformation response. The initial stiffness for the contact formulation in the two shear directions and in the normal direction is further defined by the stiffness values k_{s1}, k_{s2} and k_n, respectively.

For the parameters defining the contact formulation and the softening behaviour, reference values were chosen in accordance with the reference values used in [4]: $f_{s,1} = f_{s,2} = 3.0$ MPa, $f_n = 5.0$ MPa, $G_f = 1.2$ Nmm/mm^2 and $k_{s1} = k_{s2} = k_n = 100$ N/mm^3. For the softening, a linear relation between deformation and decreasing stress was assumed.

Table 1: *Material stiffness parameters used for the timber laminations*

Modulus of Elasticity	E_L	12 000	MPa
	E_T	400	MPa
	E_R	600	MPa
Shear modulus	G_{LT}	750	MPa
	G_{LR}	600	MPa
	G_{TR}	75	MPa
Poisson's ratio	ν_{LT}	0.50	-
	ν_{LR}	0.50	-
	ν_{TR}	0.33	-

In order to study the influence of the choice of damage initiation criterion, two different criteria were used. A maximum stress criterion according to

$$\max\left\{\frac{\langle\sigma_n\rangle}{f_n}, \frac{\tau_{s1}}{f_{s1}}, \frac{\tau_{s2}}{f_{s2}}\right\} = 1.0 \tag{6}$$

and a criterion considering quadratic stress interaction according to

$$\left(\frac{\langle\sigma_n\rangle}{f_n}\right)^2 + \left(\frac{\tau_{s1}}{f_{s1}}\right)^2 + \left(\frac{\tau_{s2}}{f_{s2}}\right)^2 = 1.0 \tag{7}$$

were considered. For these criteria, σ_n represents the normal (tensile) stress over the crossing area while τ_{s1} and τ_{s2} represent the two in-plane shear stresses. For all analyses presented below, equal values for the two in-plane shear strengths are assumed and a notation as $f_{s1} = f_{s2} = f_s$ is hence used below.

For comparison of results, a non-dimensional brittleness ratio is defined according to b/l_{ch}, where b is a characteristic length of the considered body and where the material characteristic length is defined according to

$$l_{ch} = \frac{G_{TR} G_f}{f_s^2} \tag{8}$$

where G_{TR} is the rolling shear stiffness, G_f the fracture energy and f_s the local material shear strength. With reference values for these parameters as given above, the characteristic material length is $l_{ch} = 10$ mm.

4.1 TORSIONAL SHEAR LOADING

For pure torsional loading, the test set-up suggested in EN 16351:2021 [7] (as an alternative method) for determination of the torsional shear strength parameter $f_{v,tor}$ is considered.

The specimen geometry is shown in Figure 5, while the applied boundary conditions and considered lamination growth ring patterns are illustrated in Figures 6 and 7, respectively. For the back surface of the lamination with grain direction parallel to the x-direction, displacements were prescribed as $u_x = u_y = u_z = 0$. The front surface of the lamination with grain direction parallel to the y-direction, was constrained by a kinematic coupling to the surface midpoint which was used as a reference point. For this reference point, boundary conditions were implemented such that the displacements $u_x = u_y = u_z = 0$ and the loading was applied by a prescribed rotation θ_z.

https://doi.org/10.52202/069179-0317

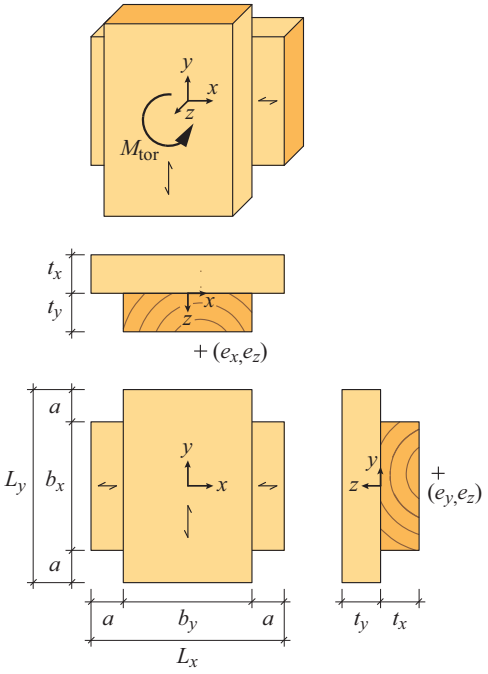

Figure 5: *Definition of geometry for pure torsional loading*

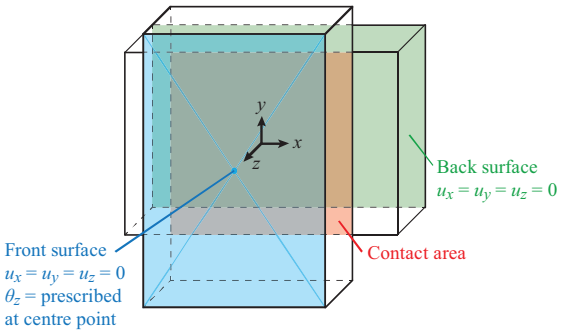

Figure 6: *Boundary conditions for pure torsional loading*

According to EN 16351:2021, no restraints from compression or tension in the direction of the rotation axis should be introduced. The influence of boundary conditions was studied by releasing the constraint of the displacement in the *z*-direction for the front surface, *cf.* Figure 6.

The lamination lengths (here denoted L_x and L_y) should according to EN 16351:2021 furthermore be such that the laminations extend a minimum of 30 mm on each side of the tested crossing area. No further instructions are given regarding the absolute or relative size of the laminations.

Torsional tests of single crossing areas are reported in [8, 9], for six test series with different lamination growth ring patterns and crossing area sizes: 145×100 mm², 145×150 mm² and 145×200 mm². Those tests gave an overall mean torsional strength of 3.46 MPa, with test series mean values varying between 3.00 MPa and 4.13 MPa, without a clear trend regarding the size influence on the load-bearing capacity.

Numerical results for models loaded in pure torsional shear are expressed by the *apparent* torsional shear stress as defined according to Equations (2) and (3), using the resulting torsional moment over the crossing area M_{tor} as found from the FE-analyses.

An initial parameter study was carried out, aimed at investigating the influence of model parameters on the numerical results. Based on the reference values of material strengths, fracture energy and lamination stiffness properties as defined above, a parameter study on the influence of the initial stiffness of the contact area was performed. Stiffness values $k_{s1} = k_{s2} = k_n$ in the range from 10 N/mm³ to 4 000 N/mm³ were used. The lamination geometry was defined by setting $b = b_x = b_y = 120$ mm, $t_x = t_y = 30$ mm and $a = 30$ mm, and the growth ring pattern RB was considered. The element mesh was chosen to obtain roughly cubically shaped elements with a side length of approximately $t_x/6 = 5$ mm.

The calculated maximum load increases slightly with increased crossing area stiffness. The reference stiffness (100 N/mm³) gives however only a 0.7% difference in maximum value compared to a stiffness of 4 000 N/mm³. Since the numerical stability is enhanced using moderate crossing area stiffness values, the reference stiffness of 100 N/mm³ was considered as a reasonable trade-off between numerical stability and accuracy.

The influence of the element size on the results was also studied. Decreasing the element side length by a factor 2.0 (from 5 mm to 2.5 mm) gave only a 0.2% difference in maximum load. The difference in overall torsional stiffness of the specimen was influenced to a greater extent by that element refinement: a reduction of the stiffness by 1.5% was found. An approximate element side length of 1/6 of the lamination width was used for results presented below and relating to torsional loading, since it was considered as a reasonable trade-off between numerical efficiency and accuracy.

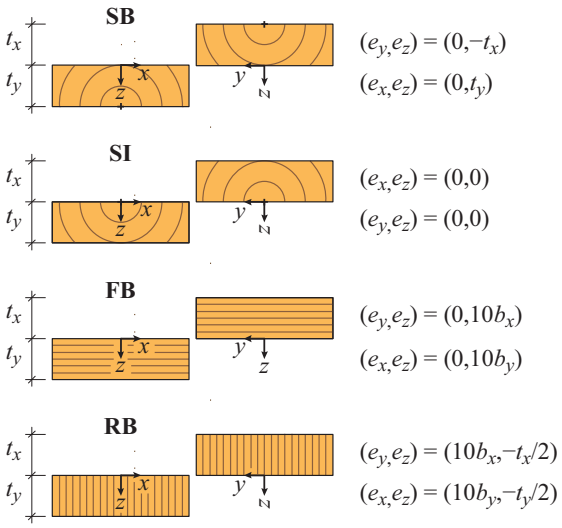

Figure 7: *Considered growth ring patterns for pure torsional loading*

https://doi.org/10.52202/069179-0317

Results for analyses considering the two different criteria for damage initiation according to Equations (6) and (7) are shown in Figure 8. For both criteria, results are presented for assumptions of material tensile strength as either $f_n = 5.0$ MPa (reference value) or $f_n = 2.5$ MPa and for boundary conditions as prescribed by EN 16351:2021, *i.e.* with $u_x = u_y = 0$ but disregarding $u_z = 0$ for the surface with prescribed rotation (denoted EN in Figure 8). The results relate to a specimen with geometry $b_x = b_y = 120$ mm, $t_x = t_y = 30$ mm, $a = 30$ mm and with growth ring pattern RB according to Figure 7.

Using the maximum stress criterion (MS) according to Equation (6) compared to the quadratic interaction criterion (QT) according to Equation (7) gives an increase of the maximum apparent torsional stress of about 6%. Within the two groups of curves (three curves in each group), representing the two criteria, very similar or identical results were found. Identical results for the torsional shear stress were found for material tensile strengths $f_n = 2.5$ MPa, 5.0 MPa and 50 MPa (not shown in Figure 8) for the maximum stress criterion. A very small influence of the material tensile strength was also found for the damage initiation criterion based on quadratic traction (QT), with differences being below 0.2% for load-bearing capacity. The change of boundary conditions regarding free/restricted movement in the z-direction has also a very small influence on the load-bearing capacity, for both damage initiation criteria.

The response in terms of the apparent torsional stress versus prescribed rotation is shown in Figure 9 for $b_x = b_y = 120$ mm, $t_x = t_y = 30$ mm, $a = 30$ mm, growth ring pattern RB, reference values for materials strengths and using the damage initiation criterion based on maximum stress. For these results, a slightly refined mesh was used with approximate elements side lengths as $t_x/8$. In subfigures a), b) and c), the stress distributions over the crossing area are illustrated by the maximum value of the two shear stress components τ_{zx} and τ_{zy} acting in the plane of the crossing area, at three instants during loading: a) at initiation of softening, b) about midway between initiation of softening and maximum load and c) at maximum load.

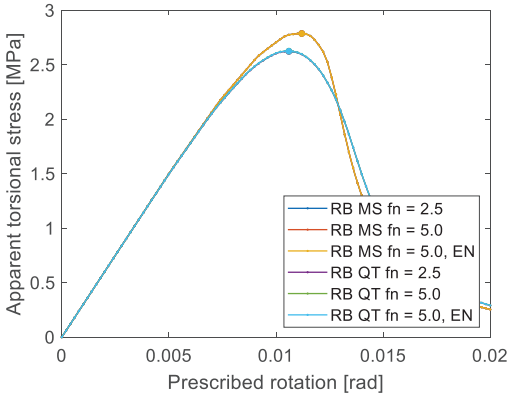

Figure 8: *Apparent torsional stress versus prescribed rotation for different choices of criteria for initiation of softening (MS and QT), for different material tensile strengths f_n, and for different boundary conditions*

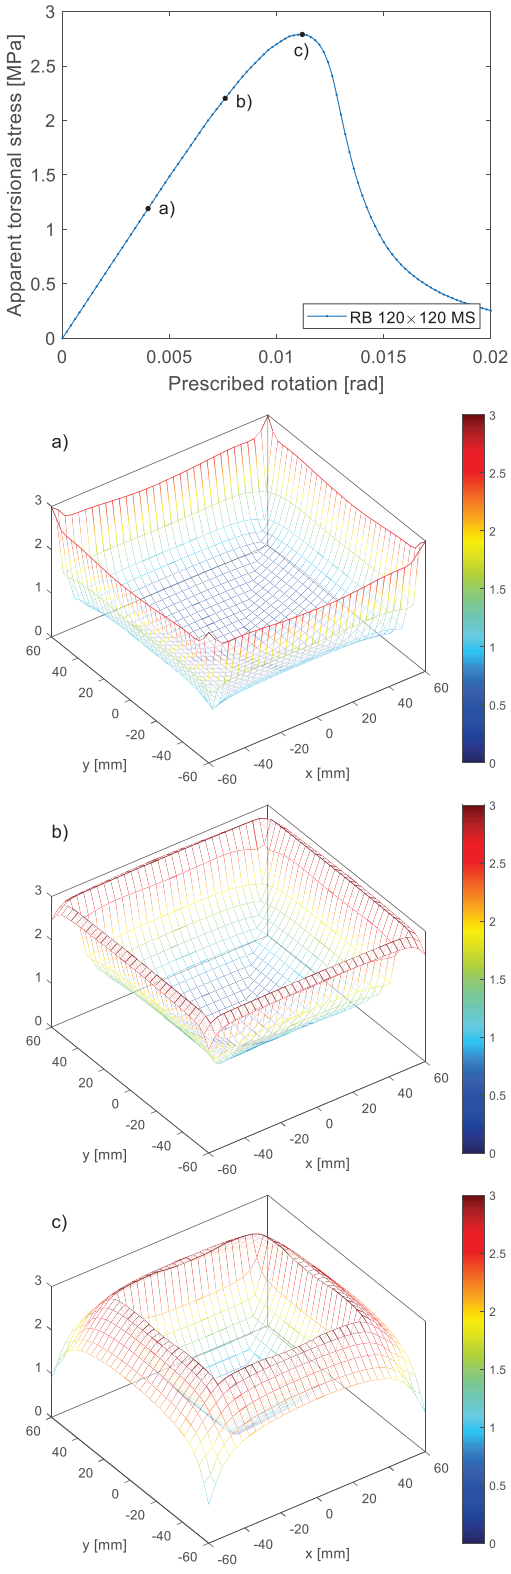

Figure 9: *Apparent torsional stress versus rotation for geometry RB 120×120 with damage initiation criterion from Equation (6) and stress distributions for $\tau = \max(\tau_{zx},\tau_{zy})$ at instants a), b) and c) during loading*

Results in terms of apparent torsional strength are given in Figure 10, based on a specimen geometry with $b = b_x = b_y$, $L_x = L_y = 1.5b_x$, and $t_x = t_y = b_x/4$ and for lamination widths b within the range of 5 mm to 200 mm. Results for all geometries, and all growth ring patterns as illustrated in Figure 7 and considering the damage initiation criteria according to Equation (6) are given. In addition, results for growth ring pattern RB, and initiation criterion according to Equation (7) are also shown. For the specimen geometries considered here, the demand $a \geq 30$ mm given in EN 16351:2021 is not fulfilled for laminations widths $b < 120$ mm.

The same results are shown in Figure 11, but now expressed as the relationship between the brittleness ratio b/l_{ch} and the normalised torsional strength, $\tau_{tor,max}/f_s$. The considered lamination widths b give brittleness ratios b/l_{ch} in the range of 0.5 to 20.

The differences in load-bearing capacity between the different growth ring patterns is fairly small and there is no strong influence of the specimen size for practically relevant dimensions of the laminations.

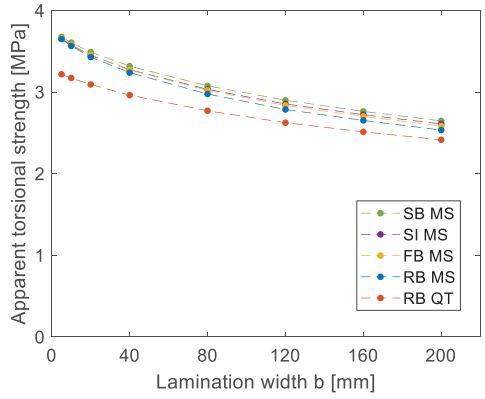

Figure 10: *Apparent torsional shear strength, $M_{tor,max}/W_{P,CA}$ according to Equation (3), for different growth ring patterns and lamination widths $b = b_x = b_y$*

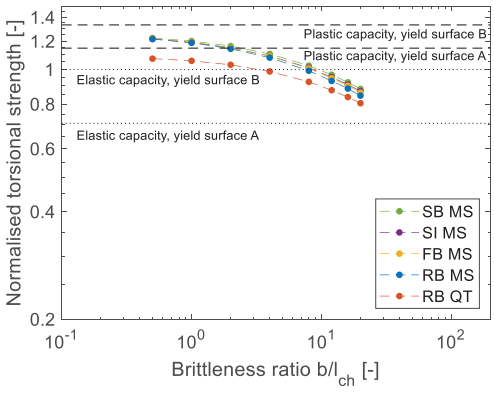

Figure 11: *Normalised torsional strength, $\tau_{tor,max}/f_s$, as influenced by brittleness ratio for different growth ring patterns and considering damage initiation criteria according to Equations (6) and (7)*

The influence of the individual lamination widths, and hence the size and shape of the crossing area, was studied. Results for different widths b_y (20 mm to 220 mm) of the lamination oriented in the y-direction, for a fixed width $b_x = 120$ mm of the lamination oriented in the x-direction, are shown in Figure 12. These results are based on lamination thicknesses $t_x = t_y = 30$ mm, $a = 30$ mm, growth ring pattern RB according to Figure 7 and damage initiation according to Equation (6).

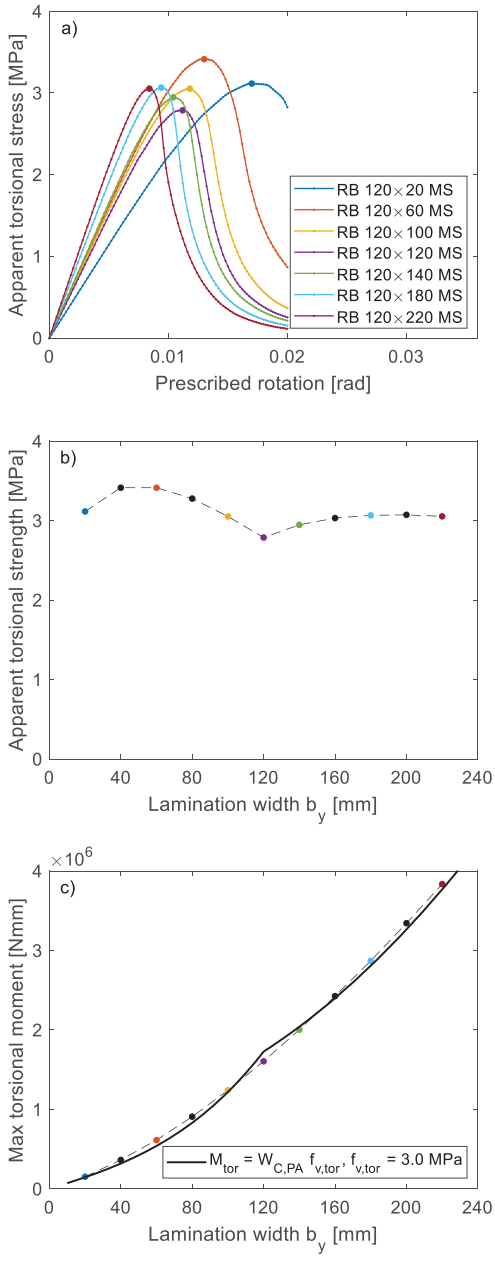

Figure 12: *Results for $b_x = 120$ mm and different lamination widths b_y in terms of a) torsional stress versus rotation, b) apparent torsional strength and c) maximum torsional moment*

https://doi.org/10.52202/069179-0317

Results presented in Figure 12 relate to specimens with 11 different geometries. Results in terms of apparent torsional stress versus rotation are shown in Figure 12a) for seven of these analyses, while results in Figures 12b) and c) are given for all 11 geometries.

The differences in the apparent torsional strength according to Figure 12b) can be explained by essentially two effects; a size effect and an effect of the change of the specimen shape. The two geometries with laminations $b_x \times b_y$ = 120×80 mm^2 and $b_x \times b_y$ = 120×180 mm^2 are equal in shape with a ratio of 1:1.5 between the side lengths of the crossing area. The difference in apparent torsional strength, 3.28 MPa for 120×80 mm^2 and 3.07 MPa for 120×180 mm^2, is hence related to a size effect and, possibly to the effect of changed stiffness ratio between the crossing area torsional stiffness and the rolling shear stiffness of the laminations.

The maximum torsional moments are shown in Figure 12c), where also the torsional moment capacity according to the design criteria from Equations (1) – (3) is given for an assumed torsional strength parameter $f_{v,tor}$ = 3.0 MPa. The ratio between the numerically found values of the maximum torsional moment and the capacity according to the design criteria varies between 0.93 and 1.14 for this assumption.

In order to further study the influence of the shape of the crossing area, a number of analyses were carried out for geometries with a fixed value of the torsional section modulus defined in Equation (3), $W_{P,CA}$ = 576 000 mm^3 (as for b_x = b_y = 120 mm), by varying both lamination widths, b_x and b_y. Also for these analyses, geometries with lamination thicknesses $t_x = t_y = 30$ mm and $a = 30$ mm were considered and results are presented in Figure 13.

Results in terms of stress versus rotation response are given in Figure 13a) for six out of the 11 geometries considered. The apparent torsional strength is shown in Figure 13b) and the maximum torsional moment in Figure 13c).

From the present results, a maximum load-bearing capacity appears to be found for a side length ratio of the crossing area of about 1.8. Equal lamination widths (here $b_x = b_y = 120$ mm) and hence a square shape of the crossing area gives the lowest load-bearing capacity among the geometries considered here. The difference between the highest and lowest capacities (found for geometries 174×90 mm^2 and 120×120 mm^2, respectively) is 15%.

The maximum torsional moments are shown in Figure 13c), where also the torsional moment capacity according to the design criteria from Equation (1) – (3) is given for an assumed value $f_{v,tor}$ = 3.0 MPa. The ratio between the numerically found values of maximum torsional moment and the design criteria varies between 0.93 and 1.07.

The results presented in Figures 12 and 13 concern specimen geometries with a large span of the aspect ratio of the crossing area side lengths: ratios up to 1:6 for results presented in Figure 12 and ratios up to 1:3 for results presented in Figure 13. The numerical results in terms of the maximum torsional moment are yet in fairly good agreement with the load-bearing capacities given by the design criteria from Equations (1) – (3), with the torsional moment capacity being proportional to the value of $W_{P,CA}$, defined in Equation (3).

The shear stress distribution over the crossing area (as found from the FE-analyses) varies during loading, as illustrated in Figure 9, due to initiation of local softening and development of fracture process zones. Although the stress distribution at maximum load does not agree very well with the assumed stress distribution according to the design approach (see Figure 2), similar load-bearing capacities are predicted.

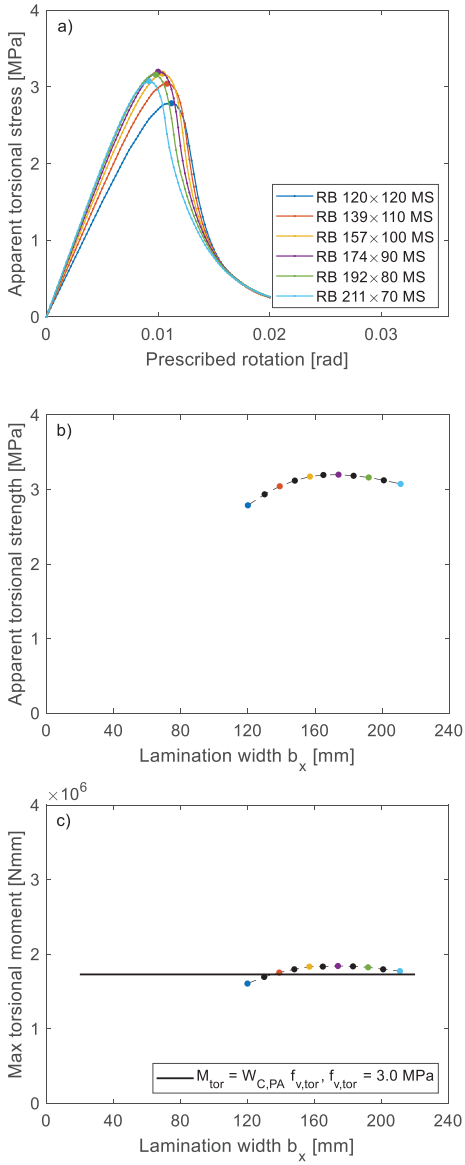

Figure 13: *Results for different laminations widths $b_x \times b_y$ with constant value of $W_{P,CA}$ = 576 000 mm^3 in terms of a) torsional stress versus rotation, b) apparent torsional strength and c) maximum torsional moment*

4.2 UNIAXIAL SHEAR LOADING

For the load case of *pure uniaxial* shear, a test set-up introducing shear over two crossing areas (by compression loading) of a symmetrical test specimen is considered, as illustrated in Figure 14.

Such tests are for example reported in [10], with specimens cut from CLT with lay-up 40-20-40 and testing a crossing area of 150×150 mm^2. Tests of six nominally equal samples gave a mean rolling shear strength $f_{v,R}$ = 1.39 MPa with CoV = 13%.

The numerical results presented here relate to the influence of specimen size and the influence of the growth ring pattern of the laminations, considering material stiffness properties according to Table 1 and boundary conditions according to Figure 15. For the FE-model, the symmetry with respect to the z-direction was considered and only half of the specimen was modelled. The parameters describing the contact formulation and the softening behaviour were according to the reference values stated in Section 4. A study of the influence of the choice for the tensile material strength f_n was carried out and results showed a very small influence on the load bearing capacity for strength values of 2.5 MPa and 50 MPa, compared to the reference value of 5.0 MPa.

For the study of the influence of the specimen size, geometry parameters were chosen according to: $b_x = b_y$, $t_x = t_y = b_x/4$, $L_x = b_x$ and $a = b_x/6$. For this basic geometry, the lamination widths $b = b_x = b_y$ were varied from 5 mm to 200 mm. Three different growth ring orientations were considered for this loading situation, see Figure 16.

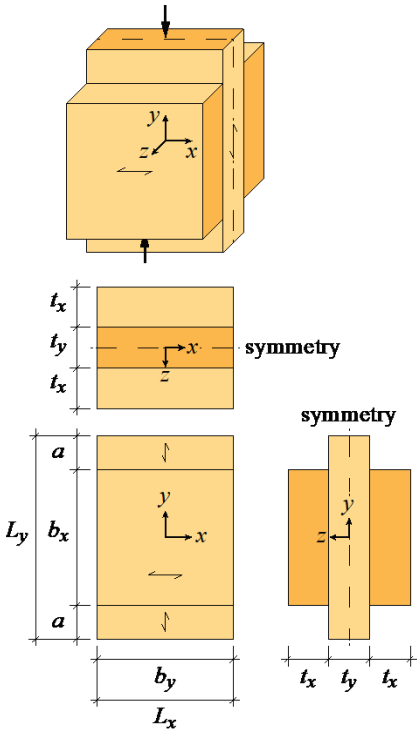

Figure 14: *Definition of geometry for pure shear loading*

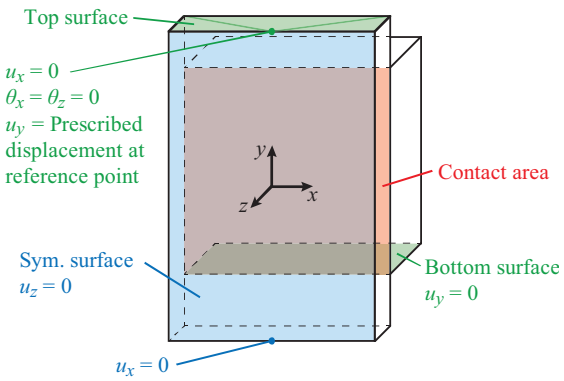

Figure 15: *Boundary conditions for pure shear loading*

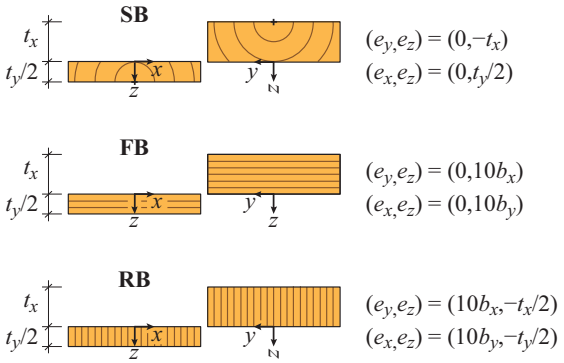

Figure 16: *Considered growth ring patterns for pure shear loading*

Results in terms of *apparent* shear strength, defined as the mean shear stress over the crossing area at maximum loading, are given in Figure 17. The same results are shown in Figure 18, as the relationship between the brittleness ratio b/l_{ch} and the normalised shear strength.

For growth ring pattern RB, results are presented for damage initiation criteria according to Equations (6) and (7). The differences are overall very small, indicating a uniaxial shear stress distribution over the crossing area with little influence from τ_{zx} on the results.

As the specimen size is decreased, the mean shear stress at maximum load approaches the material strength f_s. For a small size of the crossing area, the fracture process zone is relatively large and the behaviour approaches the case of an ideally plastic behaviour over the crossing area. For a uniform stress distribution, the elastic/plastic capacities for yield/failure surfaces A and B are all equal (f_s).

The numerical results show a strong influence of the specimen size for lamination widths $b = b_x = b_y$ above approximately 100 mm. For these specimen sizes, the trend of the numerical results resembles the size influence predicted by LEFM (the dashed line in Figure 18), with load-bearing capacity inversely proportional to the square root of the size. The size influence found from the numerical analyses presented in Figure 18, considering pure uniaxial shear, is stronger than found for the case of torsional loading with results presented in Figure 11.

https://doi.org/10.52202/069179-0317

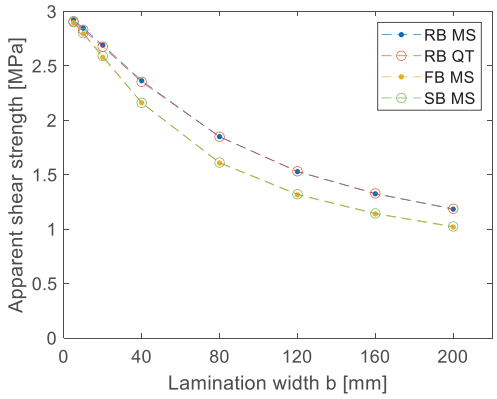

Figure 17: *Apparent shear strengths for different growth ring patterns and lamination widths $b = b_x = b_y$ and considering damage initiation criteria according to Equations (6) and (7)*

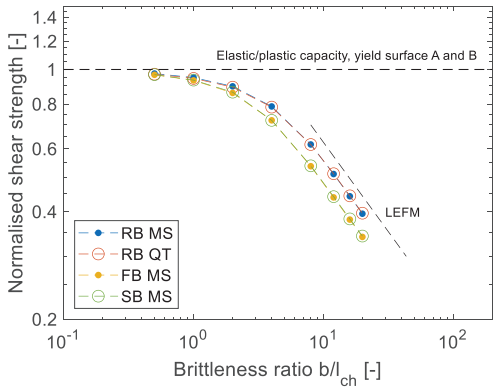

Figure 18: *Normalised shear strength as influenced by brittleness ratio for different growth ring patterns and considering damage initiation criteria according to Equations (6) and (7)*

The response in terms of mean shear stress versus prescribed displacement is shown in Figure 19, for a specimen with geometry according to $b_x = b_y = 120$ mm, $t_x = t_y = 30$ mm, $a = 20$ mm and with growth ring pattern SB according to Figure 16. The stress distribution for the shear stress component τ_{zy} over the crossing area is illustrated for three instants during loading: a) at initiation of softening, b) about midway between initiation of softening and maximum load and c) at maximum load.

The stress distribution before initiation of softening is very uneven, with a high stress concentration along the edge of the crossing area close to the support. At increased loading, a fracture process zone develops and its front moves in the y-direction at increasing load. At maximum load, a small traction-free crack has formed and the stress at the opposite side of the crossing area is approaching the material strength.

During the complete course of loading, the distribution of the shear stress τ_{zy} is very uniform with respect to the x-direction.

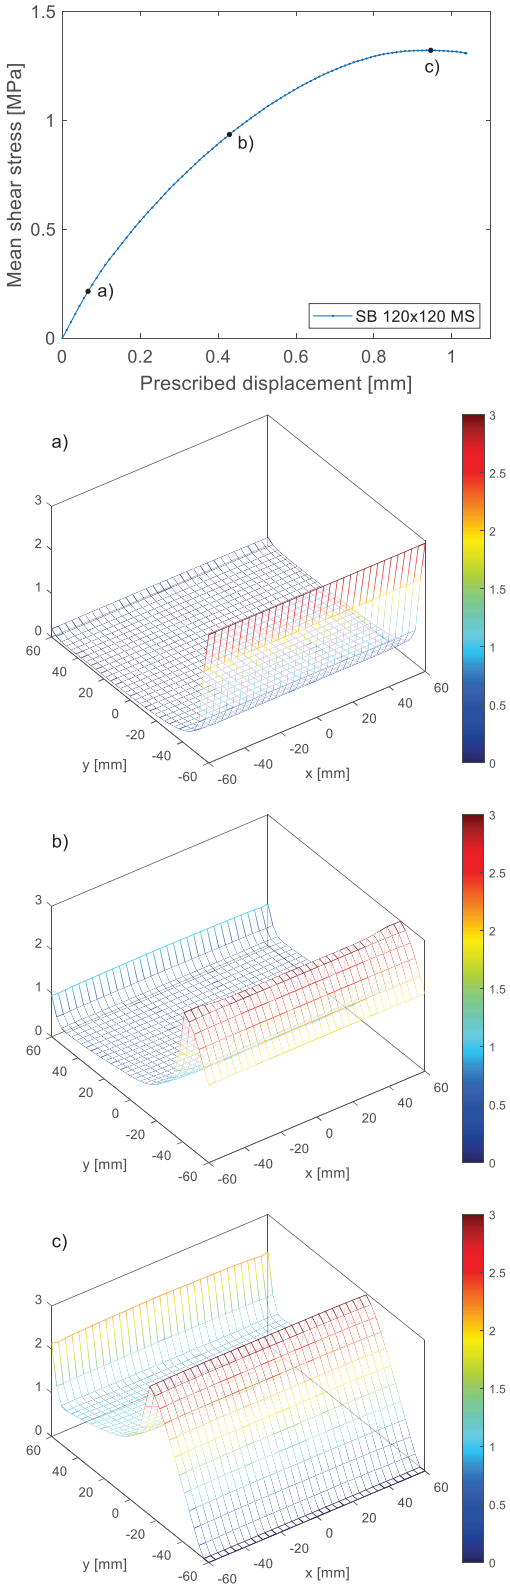

Figure 19: *Load versus displacement for geometry SB 120×120 with damage initiation criterion from Equation (6) and stress distributions for τ_{zy} at instants a), b) and c) during loading*

5 DISCUSSION AND CONCLUSIONS

The general failure criteria for shear failure mechanism III according to Equations (1a) and (1b) are appealing in the sense that they represent criteria which are easy to use for structural engineers. The concept of using two different strength parameters, the rolling shear strength $f_{v,R}$ and the torsional shear strength $f_{v,tor}$, is however somewhat confusing from the view point of continuum mechanics.

Numerical results for pure torsional loading, based on a cohesive zone modelling approach and use of a damage initiation criterion based on maximum stress values and a single shear strength parameter, f_s, are presented in Figures 12 and 13 for different crossing area sizes and shapes. The numerical analyses gave maximum torsional moments which agree reasonably well with predictions of the design approach according to Equations (1) – (3). This agreement regarding load-bearing capacity is not obvious, since the basic concepts of the numerical modelling approach and of the mechanical model underlying the design approach are very different.

Selecting appropriate values for material parameters (especially material strengths and fracture energy) for the present type of numerical analyses is furthermore not obvious, this issue is discussed in *e.g.* [4]. For the reference values of material parameters used in this work, load-bearing capacities as found for the numerical analyses for both torsional and uniaxial shear loading do however roughly agree with test results as presented in *e.g.* [8–10].

The investigations presented here are limited to consideration of one single crossing area which is loaded in *either* pure torsion *or* uniaxial shear. For practical design situations involving in-plane shear of CLT, such as in-plane beam loading, there is typically a large number of crossing areas within the member with combined torsion and uniaxial shear loading. Proposed design approaches for CLT beams, as presented in [1–2, 11], are based on models considering linear elastic behaviour and do not account for gradual damage and strain-softening over the crossing areas during increased loading. To gain better understanding of the mechanical behaviour, further numerical analyses considering full-sized CLT beams modelled with softening contact are suggested.

Considering the specific test set-ups studied here, one important conclusion is that the set-up for uniaxial shear loading according to Figure 14 should be expected to give results for the rolling shear strength which are highly dependent on the specimen size (see Figure 18), especially for practically relevant lamination dimensions with $b > 100$ mm. The numerical results for the test set-up for torsional loading according to Figure 5 do not show the same strong size influence on the load-bearing capacity (see Figure 11). A drawback of torsional testing may however be that the tests are rather complicated to carry out and that torsional testing machines might not be considered as standard test equipment. From the numerical investigation presented, neither of the test set-ups appear to be influenced by tensile loading perpendicular to the crossing area.

ACKNOWLEDGEMENTS

The financial support from FORMAS for the project *Strength and fracture analysis of cross laminated timber* (grant 2019-01354) is gratefully acknowledged.

The financial support for the project *InnoCrossLam* is also gratefully acknowledged. The project *InnoCrossLam* is supported under the umbrella of ERA-NET Cofund ForestValue with Swedish support from Vinnova, FORMAS and the Swedish Energy Agency. ForestValue has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N° 773324.

The computations were enabled by resources provided by *Lunarc* – the center for scientific and technical computing at Lund University.

ANALYTICAL STUDY ON P-Δ EFFECT ON MEDIUM-RISE WOODEN BUILDINGS

Shogo Aoki[1], Naohito Kawai[2], Takafumi Nakagawa[3]

ABSTRACT: In recent years, medium to high rise buildings up to about 10 stories of wooden structure have become a reality in Japan. However, analytical research is still insufficient. In this report, we aim to clarify the influence of the P-Δ effect by pushover analysis, capacity spectrum method, and time history response analysis for wooden buildings of 3 to 5 stories, and to obtain basic data for seismic design method. The result was that the influence of the P-Δ effect on the seismic performance of the medium-rise wooden buildings was small according to the capacity spectrum method, but the increase rate may reach 22 % in time history response analysis, so future examination is required.

KEYWORDS: Wood frame construction, Capacity spectrum method, Time history response analysis

1 INTRODUCTION

1.1 BACKGROUND

In recent years medium to high rise buildings up to about 10 stories of wooden structure have become a reality in Japan. In addition, by using wood as a structural material for sustainable forest management, we can expect to reduce climate change. In other words, wooden structures are good for the environment. Demand for medium to high rise wooden buildings that use a large amount of wood is increasing. However, analytical research is still insufficient.

For conventional low-rise wooden buildings up to about three stories, the safety limit deformation angle against large earthquake motion is considered to be about 1/30. On the other hand, the problem is pointed out whether large deformation is allowed even in medium to high rise wooden buildings such as 5-10 stories.

Among the discussion on whether or not the safety limit deformation angle should be reduced for medium to high rise wooden buildings, there is an opinion that the influence of the P-Δ effect cannot be ignored in medium to high rise wooden buildings because the vertical load is large. However, in theory, there should be no big difference between low-rise wooden buildings and high-rise wooden buildings as far as the ratio to the seismic force is concerned.

1.2 PURPOSE

In this study, we examine the P-Δ effect of medium-rise wooden buildings, for which analytical research is insufficient. The P-Δ effect is the effect of additional bending moment due to the axial force of vertical members and horizontal displacement of the story. In this report, we aim to clarify the influence of the P-Δ effect for wooden buildings, and to obtain basic data for seismic design method. Specifically, 3- to 5-story building models by wood frame construction are created and are analysed using an analysis software, wallstat [1]. And the influence of the P-Δ effect is discussed from the difference of earthquake response between the models with and without P-Δ effect.

2 ANALYSIS MODEL

The analysis models are 3- to 5-story building models by wood frame construction. The floor plan is shown in Fig. 1, and the appearance of 3- to 5- story models are shown in Figs. 2 to 4.

Any construction method can be used for the purpose of this study as the P-Δ effect only depends on the vertical load and the deformation angle. The reason for using wood frame construction method is to make the models simple as the main structural elements against seismic force is shear walls in wood frame construction, and deformation state of one floor does not affect the performance of other floors. The height of each floor was set to 3 maters. We prepared two types of analysis models, the standard model and the soft first story model. For the standard models, the sufficiency rate, the ratio of the allowable strength of a story to the requirement by allowable stress design, is 2 for all the story. For the soft first story models, the sufficiency rate of 1st story is 3, and that of 2nd story or higher is 6.

3 ANALYSIS METHOD

3.1 ANALYSIS SOFTWARE

The analysis model is created using wallstat ver.4.3.13. Originally, it was an analysis software for the conventional wooden framework construction method, but we created a model by replacing it with the wood frame construction. At that time, not all studs and joists were modelled. The studs were modelled at the position of columns of the conventional wooden framework construction method. We use the presence or absence of gravity to determine whether the P-Δ effect should be considered in the design.

3.2 INPUT EXTERNAL FORCE

There are three types of external forces to be input. The first is a pushover analysis so that the deformation angles between the layers are equal in each layer. This is done to confirm the validity of the analysis using wallstat by comparing with the load-displacement relationships of input shear wall data. The second is a pushover analysis using distribution coefficient Ai which is provided in the Building Standard Law (BSL) of Japan as seismic shear force distribution. Using the result of second push over, the maximum response displacement against strong ground motion is calculated using equivalent linearization method or the method known as capacity spectrum method [2, 3] and the response spectrum of type 2 ground stipulated in the BSL. The third is time history response analysis. Five artificial seismic waves conforming to the response spectrum of type 2 ground stipulated in the BSL are input, and the response displacement is calculated.

4 DATA OF ANALYSIS MODEL

4.1 BUILDING MATERIALS

The Young's modulus and flexural strength of wood were set to 1.24×10^4 N/mm^2 and 40.0 N/mm^2, respectively, referring to the material for design [4].

Table 1: *Young's modulus and flexural strength of wood*

Young's modulus	1.24×10^4 [N/mm^2]
Flexural strength	40.0 [N/mm^2]

4.2 BUILDING WEIGHT

Weights were set as shown below with reference to the material of trial design [5].

4.3 JOINTS OF BUILDING MATERIALS

Tension & compression springs and rotational springs are set between stud and beam and between beams. The load-displacement relationships of these joints are set as shown in Tables 5 and 6. The tension spring is assumed to be a joint with an allowable strength of 100 kN. The joint at the top or the bottom of each stud is assumed to have no moment resistance, so the stiffness of the rotational spring is close to 0 Nmm.

Table 5: *Tension & compression springs*

4.4 SHEAR WALLS AND FLOOR STRUCTURES

The structure was set to be shown in Table 7 and 8 based on References [6] and [7]. The values of viscous dumping ratio of all the shear walls and floor structures are set to be 2%. The stiffness values in the table are those for the wall length of 0.91 meters and are converted to the stiffness of the wall length in the model automatically in the software. Floor structures are assumed rigid enough. In the models, the stiffness and the strength are the same as those of the shear walls at the first story. Fig. 8 shows the hysteresis characteristics of the shear wall.

5 PUSHOVER ANALYSIS RESULTS

5.1 SUMMARY

Pushover analysis is performed so that the story deformation angle is equal in each layer. This is to confirm the validity of the analysis using wallstat.

5.2 STANDARD MODEL ANALYSIS RESULTS

Figs. 9 and 10 shows the result of pushover analysis on 5-story models as the samples. The "assumed wall" with gravity is theoretical solution considering the P-Δ effect. The results of the pushover analysis were generally in agreement with that, and it was confirmed that the P-Δ effect was included in the same degree as the theory.

6 RESPONSE PREDICTION BY CAPACITY SPECTRUM METHOD

6.1 OVERVIEW

Capacity spectrum method is a simple prediction method for elasto-plastic response proposed in a 1976 paper by Akenori Sibata et al. The idea of capacity spectrum method is to consider a steady vibration at a certain displacement, replace it with an equivalent linear response, and predict the response using the response spectrum. In the case of a multi-story building, it is necessary to replace it with an equivalent one-degree-of-freedom system. We calculated acceleration response spectrum and displacement response spectrum according to the Building Standard Law of Japan [8]. We used Equations (1) and (2).

$$S_a = \frac{\sum_{i=1}^{N} m_i \cdot {\delta_i}^2}{(\sum_{i=1}^{N} m_i \cdot \delta_i)^2} \cdot Q_B \tag{1}$$

$$S_d = \frac{\sum_{i=1}^{N} m_i \cdot {\delta_i}^2}{\sum_{i=1}^{N} P_i \cdot \delta_i} \cdot S_a \tag{2}$$

m_i: Mass of i-th story (kg)
δ_i: Displacement relative to the ground on i-th story (m)
Q_B: Base shear (N)
P_i: Load on i-th story (N)

6.2 STANDARD MODEL ANALYSIS RESULTS

Table 9 shows the values of maximum relative story displacement and story deformation angle by capacity spectrum method. The rate of increase in interlayer displacement due to the P-Δ effect of the standard model was -4.64 % to 8.68 %. Figs. 21 to 26 show the analysis results of the standard models.

7 TIME HISTORY RESPONSE ANALYSIS

7.1 STANDARD MODEL ANALYSIS RESULTS

Table 11 shows the average values of maximum story displacement and story deformation angle by time history analysis using five artificial seismic waves. The rate of increase in interlayer displacement due to the P-Δ effect of the standard model was -34.4 % to 22.2 %. Figs. 33 to 38 show the analysis results of the standard models.

8 CONCLUSION

We aim to clarify the influence of the P-Δ effect by pushover analysis, capacity spectrum method, and time history response analysis for wooden buildings of 3 to 5 stories, and to obtain basic data for seismic design method. In the pushover analysis, it was confirmed that the analysis using wallstat was appropriate by comparing the load deformation relationship of the wall assumed with the analysis result. The increase rate of relative story displacement due to the P-Δ effect was up to 8.97% for the capacity spectrum method and up to 22.2% on average for 5 artificial seismic waves in the time history response analysis. Looking at the results of the capacity spectrum method, it can be said that the effect of the P-Δ effect on the seismic performance of medium-rise wooden buildings is small. However, the rate of increase may reach 22.2% in the time history response analysis, so future examination is required.

DETERMINATION OF THE EFFECTIVE WIDTH OF CROSS-LAMINATED TIMBER RIB PANELS USING DIGITAL IMAGE CORRELATION

Miriam Kleinhenz[1], Martin Viertel[2], Thomas Demschner[3], Andrea Frangi[4]

ABSTRACT: The effective width of cross-laminated timber rib panels is analysed. The floor system consists of cross-laminated timber plates rigidly bonded to glued-laminated timber ribs by means of screw-press gluing. Ultimate-load tests were performed on four different cross-sections. Digital image correlation was used to visualize and monitor the strain distribution on top of the cross-laminated timber plates at midspan. The longitudinal strain distributions along the cross-laminated timber width were obtained for the determination of the effective width. The experimental results are compared to numerical results of a finite element model and to Eurocode 5 estimations. The longitudinal strain distributions show good agreement and confirm digital image correlation as a suitable measurement technique.

KEYWORDS: Massive timber rib panel, cross-laminated timber, effective width, optical measurement technique, finite-element modelling, strain distribution

1 INTRODUCTION

Long-span floor systems are required for building types such as commercial office buildings, residential buildings, schools, and industrial buildings. As a long-span floor system with spans up to 16 m, cross-laminated timber rib panels consist of cross-laminated timber (CLT) plates connected to glued-laminated timber (glulam) ribs. Full composite action is provided by a rigid connection between the composite components by means of screw-press gluing [1] (Figure 1).

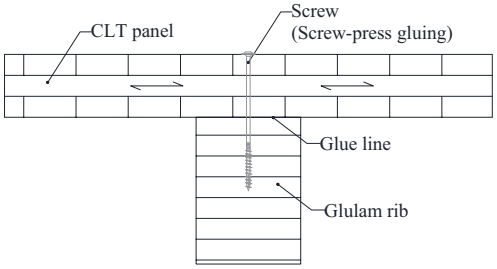

Figure 1: *Cross-section of cross-laminated timber rib panels.*

For such ribbed cross-sections, the assumption that the cross-section remains plane is incorrect. The simple beam theory according to Euler-Bernoulli is not applicable because the strains in the flange vary with the distance from the rib due to the in-plane shear flexibility of the flange. This leads to a non-uniform distribution of the longitudinal strains along the CLT width.
In a research project, ultimate-load tests were performed for the analysis of the structural behaviour. The system's stiffness and the resulting effective width were analysed [2]. This paper focuses on the strain distributions on top of the CLT plate being monitored during the ultimate-load tests using digital image correlation (DIC). The longitudinal strains obtained from the DIC measurements are compared to the numerical results of a finite element (FE) model. Both methods were validated by the measurements at midspan of a linear variable differential transformer (LVDT). Of both methods, the resulting effective widths are compared to the estimated effective width of Eurocode 5 [3].

2 SIMPLIFIED DESIGN METHOD

For simplified structural analysis, the effective width defines an equivalent cross-section that provides the same maximum bending stress and effective bending stiffness as the actual cross-section [4]. Figure 2 illustrates how the non-uniform stress distribution over the entire CLT width is replaced by a uniform stress distribution in the region of the effective width b_{ef}. Equation (1) shall apply:

$$\sigma_{x,max}(z) \cdot b_{ef} = \int \sigma_x(y,z)dy \qquad (1)$$

where $\sigma_{x,max}(z)$ is the maximum longitudinal bending stress distribution along the thickness of the CLT plate at rib centre, b_{ef} is the effective width, and $\int\sigma_x(y,z)dy$ is the integral of the longitudinal bending stresses along the thickness and along the width of the CLT plate.
The chapter on CLT design in the final draft [5] for a revised version of the European design standard for timber structures EN 1995-1-1 (Eurocode 5) [3] proposes simplified equations to estimate the effective width for

ribbed plates build up from CLT plates. In the case of uniformly distributed loads, Equation (2) determines the effective width of Eurocode 5 $b_{ef,EC5}$:

$$b_{ef,EC5} = b_{rib} + \sum b_{ef,i} \tag{2}$$

$$= b_{rib} + b_{f,i} \cdot (0.5 - 0.35 \cdot \left(\frac{b_{f,i}}{l}\right)^{0.9} \cdot \left(\frac{(EA)_x}{(GA)_{xy}}\right)^{0.45})$$

where $b_{ef,i}$ is the effective width at each side of the rib width b_{rib}, $b_{f,i} = (b - b_{rib})$ is the clear rib distance, l is the span, and $(EA)_x/(GA)_{xy}$ is the ratio per meter width between the in-plane stiffness of the longitudinal CLT layers and the shear stiffness in plane of the gross CLT cross-section. The geometry is explained in Figure 3.

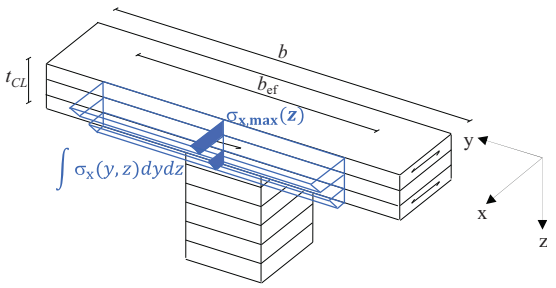

Figure 2: *Determination of the effective width.*

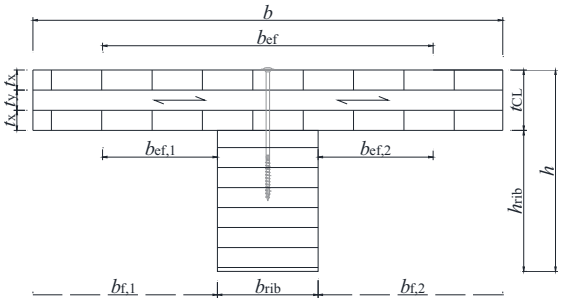

Figure 3: *Geometry of the cross-section.*

For the verification of stresses, the calculation method of rigidly bonded components (Bernoulli-beam) is applied. The calculation method is based on the assumption of full composite action between the CLT plate and glulam rib. The neutral axis is located in the centre of gravity of the composite cross-section z_s, determined by Equation (3):

$$z_s = \frac{\sum_{i=1}^{n+1}(E_i \cdot A_i \cdot a_i)}{\sum_{i=1}^{n+1}(E_i \cdot A_i)} \tag{3}$$

where E_i is the mean value of the modulus of elasticity of component i, A_i is its cross-section area, and a_i is the distance to its centroid from a selected origin.
The effective bending stiffness of the composite cross-section about the y-axis $(EI)_{ef}$ is defined by Equation (4):

$$(EI)_{ef} = \sum_{i=1}^{n+1}(EI)_i = \sum_{i=1}^{n+1}\left(\frac{E_i \cdot b_i \cdot h_i^3}{12} + E_i \cdot b_i \cdot h_i \cdot z_i^2\right) \tag{4}$$

where $(EI)_i$ is the bending stiffness of component i, E_i is the mean value of its modulus of elasticity, b_i is its width, h_i is its height, and z_i is the distance of its centroid to the global centre of gravity z_s.
The effective width b_{ef} defines the width b_i of n-longitudinal CLT layers (n = 1 for top CLT layer, n = 2 for second CLT layer etc.). Therefore, it is involved in both the determination of the global centre of gravity z_s, and the effective bending stiffness of the composite cross-section $(EI)_{ef}$. The rib is considered as (n+1)-component.

3 EXPERIMENTAL INVESTIGATIONS

3.1 CROSS-SECTIONS

Four cross-sections were tested, as presented in Figure 4 (A, B, C, and D), including T-sections (one CLT plate as top flange) and box-sections (CLT plates as top and bottom flanges). Twelve test specimens were tested using three replicates per cross-section (A1-A3, B1-B3, C1-C3, and D1-D3).

3.2 TEST SETUP AND PROCEDURE

The ultimate-load tests were performed as four point bending tests in accordance with EN 408 [6]. The test setup had a span l of 5.20 m (Figure 5). The span complies with the length of the horizontal furnace of later performed full-scale fire tests [2]. The test specimens were simply supported with a CLT width b of 0.933 m. Cross-sections B and D were tested without gypsum plasterboards. For bending at two points, two hydraulic cylinders applied the load uniformly with steel profiles of 200 mm depths along the test specimen's width.

3.3 MEASUREMENTS

Table 1 lists the measurements per test specimen. Load cells measured the applied cylinder forces F_{cyl}. At failure time, the maximum load per cylinder $F_{cyl,max}$ was on average 107 kN. The deflection w at midspan, as described in Figure 5, was recorded by the LVDT as w_{LVDT}. The maximum deflection $w_{LVDT,max}$ was on average 41 mm. The failure led in the linear-elastic load-deflection behaviour to a significant load drop.
An Optotrak Certus position sensor (NDI) was installed to record the local deflection on the front of the test specimen. NDI markers were fixed on the surface of the test specimen, which allowed for a 3D tracking of these markers throughout the testing. Their locations are shown in Figure 5. One NDI marker was located at the bottom edge at midspan. The LVDT at midspan confirmed the accuracy of this NDI measurement. To determine the local effective bending stiffness in the shear-free zone, further markers were placed on the front side of the test specimen below the force application points at a distance l_1 of 1.26 m according to EN 408 [6].

https://doi.org/10.52202/069179-0319

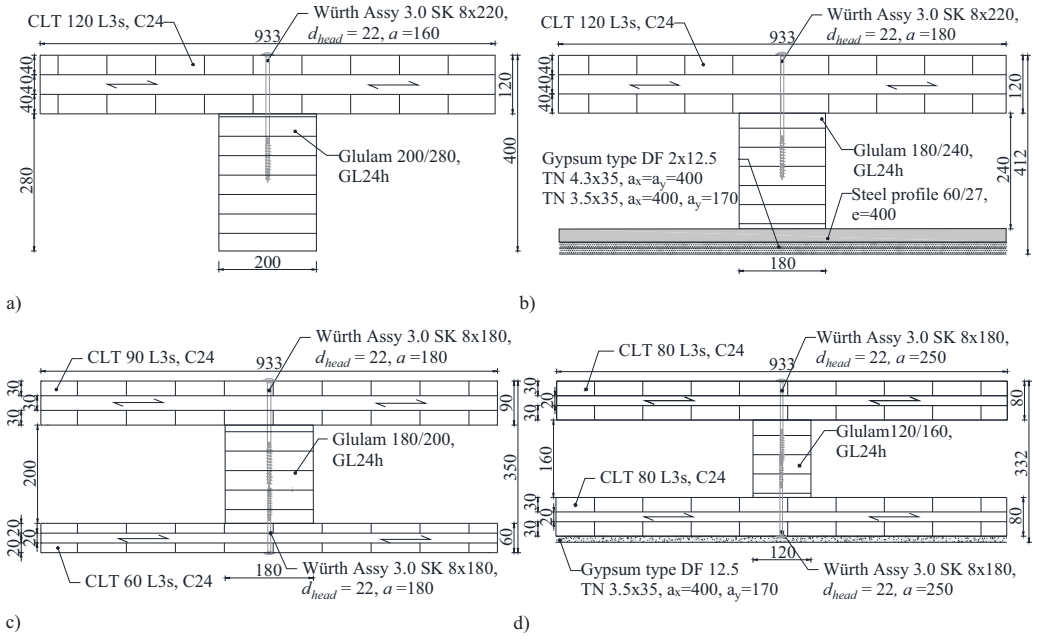

Figure 4: *Cross-section types of the experimental program, in [mm]: a) T-section (A); b) T-section initially protected (B); c) Box-section (C); d) Box-section initially protected (D).*

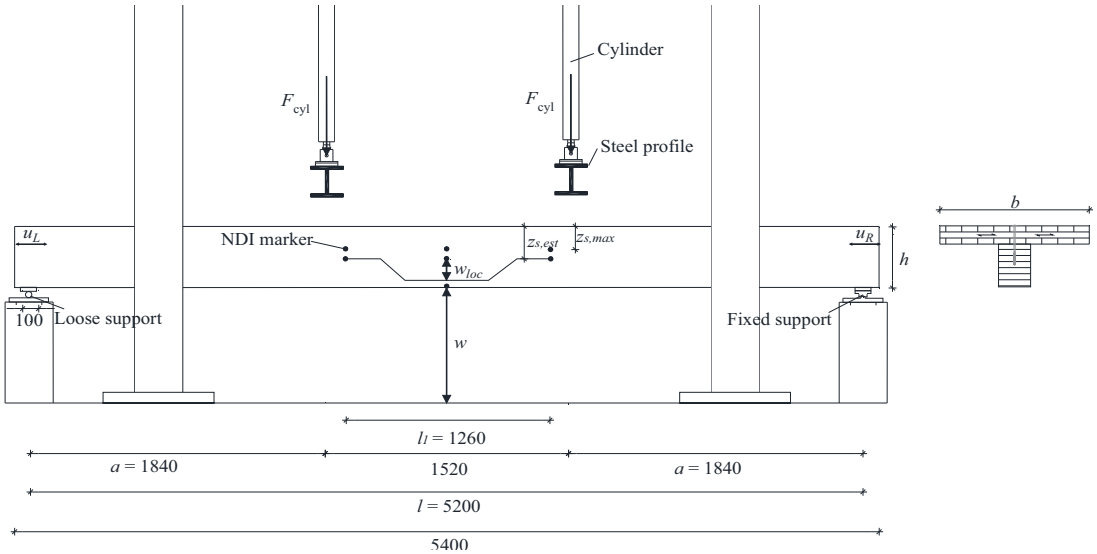

Figure 5: *Test setup in accordance with EN 408* ***[6]****.*

Over the height of the test specimen, these markers were located at two estimated positions of the neutral axis (= global centre of gravity): at $z_{s,max}$ for the maximum system (width b), and at $z_{s,est}$ for the estimated system according to Equation (2) (width $b_{ef,EC5}$). As the actual position can be assumed to be within these limits, the mean on both cases was calculated as local deflection w_{loc}. At failure, the maximum local deflection $w_{loc,max}$ was on average 2.2 mm.

3.4 EXPERIMENTAL RESULTS

3.4.1 Experimental effective bending stiffness

A linear regression was used to determine the slope of the load-deflection curve $\Delta F/\Delta w_{loc}$ [7]. In accordance with EN 408 [6], the experimental effective bending stiffness was calculated as local effective bending stiffness $(EI)_{ef,l}$ according to Equation (5):

$$(EI)_{ef,l} = \frac{a \cdot l_1^2}{16} \frac{\Delta F}{\Delta w_{loc}} = \frac{a \cdot l_1^2}{16} \frac{(2\Delta F_{cyl})}{\Delta w_{loc}} \quad (5)$$

https://doi.org/10.52202/069179-0319

* Selected test specimens for the DIC technique.

where l_1 is the gauge length for the determination of modulus of elasticity, and a is the distance between support and force application, as shown in Figure 5.
Table 1 lists the local effective bending stiffness $(EI)_{ef,l}$ per test specimen; on average 18.1 MNm^2.

3.4.2 Experimental effective width

Due to the correlation between the effective bending stiffness $(EI)_{ef}$ and the effective width b_{ef}, the experimental effective widths $b_{ef,test}$ per test specimen were calculated by equating Equation (4) to the local effective bending stiffness $(EI)_{ef,l}$ of Table 1. A solve-function of nonlinear equations was used. Table 1 lists the experimental effective widths $b_{ef,test}$ per test specimen. Here, the experimental effective width $b_{ef,test}$ defines the width b_i of the longitudinal CLT layers of the top and bottom CLT plate.
Figure 6 presents the results in relation to the CLT width b. In addition, estimated effective widths of Eurocode 5 $b_{ef,EC5}$ were calculated according to Equation (2). Since no formula is given for loading in bending at two points, the formula for uniformly distributed loads was used. For box-sections, an average value of the top and bottom CLT plate is given. While the experimental effective width $b_{ef,test}$ was on average 80% of the CLT width, it would have been estimated at 60% by Eurocode 5 ($b_{ef,EC5}$).

3.4.3 Maximum experimental bending stress

Based on the calculation method of rigidly bonded components, the maximum experimental bending stress on top of the top CLT plate $\sigma_{max,test}(z_{bot})$ is calculated according to Formula (6):

$$\sigma_{max,test}(z_{top}) = \frac{M_{max} E_{CLT}}{(EI)_{ef,l}} \cdot (z_1 + \tfrac{h_1}{2}) \qquad (6)$$

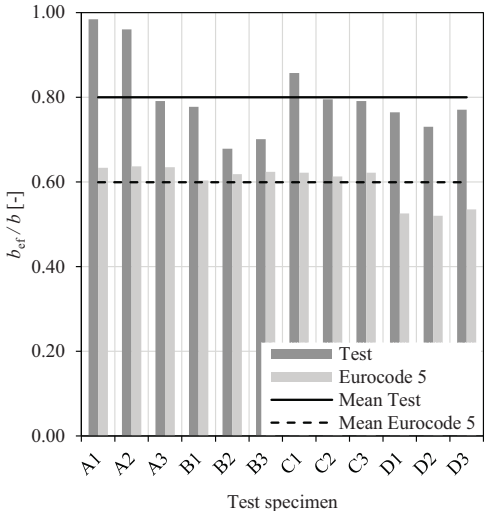

Figure 6: *Experimental and by Eurocode 5 estimated effective width of the tests specimens in relation to the CLT width.*

With

$$M_{max} = F_{max}/2 \cdot a \qquad (7)$$

where E_{CLT} is the modulus of elasticity of the top CLT plate, $(EI)_{ef,l}$ is the local effective bending stiffness (Table 1), and h_1 and z_1 are the height and the distance to the global centre of gravity z_s according to Equation (3) of the top CLT layer, and a is the distance between support and force application, as shown in Figure 5. The ultimate load F_{max} includes the self-weight of the test specimen (see Table 1). The modulus of elasticity of the top CLT plate E_{CLT} and the dimensions of the single CLT plates and glulam ribs have been measured in advance and were

https://doi.org/10.52202/069179-0319

taken from [7]. Table 1 lists the maximum experimental bending stress on top of the top CLT plate $\sigma_{max,test}(z_{bot})$ per test specimen. At failure, the compressive stress value was on average 22 N/mm^2. The top side of the top CLT plate was under compression.

4 DIGITAL IMAGE CORRELATION

4.1 TEST SETUP AND PROCEDURE

In [8], LVDTs were installed at midspan side by side along the CLT width to measure the deformations on the CLT surface. Digital image correlation (DIC) is an optical measurement technique to capture relative 3D changes in sequential images. In this research project, the DIC technique was used at midspan to obtain the strain field distributions on top of the CLT plate of four selected test specimens (A2, B1, C1, and D3). Therefore, a rectangular area of interest of around 1.17 m^2 (0.90 m x 1.30 m) was observed between the two cylinders of the test setup (Figure 7). In the area of interest, a regular, black speckle pattern was applied with a paint roller on top of a white undercoat (speckle size: 1.8 mm). The contrast between speckle and undercoat improves the analysis' accuracy [9,10]. To improve the analysis' quality, LED floodlight illuminated the area of interest.

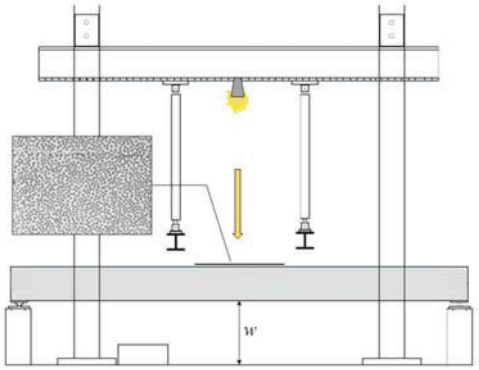

Figure 7: *Test setup in accordance with EN 408* ***[6]*** *including the measurements of the digital image correlation at midspan (area of interest).*

Digital images were simultaneously taken using a set of two cameras, type FLIR, Grasshopper 3, 12.3 MP. The resolution obtained was 4096x3000. The cameras were attached to the universal testing machine by an additional support frame with a distance to the area of interest of approximately 2.20 m. The baseline between the cameras and the distance between the cameras and the test specimen were checked after calibration of the DIC system. Digital images were taken during the ultimate-load tests (frame rate: 30 fps). In a zero-displacement test, the correlation error was checked in dependency of the speckle size, and the subset size. A subset size of 45 pixels on average was used for the image correlation. Displacements were calculated from the digital images by the comparison of virtual subsets containing a certain amount of pixels in original and deformed states at different instants of time. Therefore, a reference image was chosen that was taken in the unloaded phase. Since the projection error did not exceed the value of 0.1, the test specimen's movement or its distance to the cameras remained small. For the calculation, the origin of a coordinate system was set in the centre of the test specimen, thus in the middle of the area of interest. The software VIC-3D Digital Image Correlation Version 9.1.6 [11] was used for calibration, collection of digital images, running the correlation, and calculation of the displacements.

4.2 VALIDATION

The DIC measurements of the four selected test specimens were validated by comparing the maximum vertical displacements $w_{DIC,max}$ at the centre of the area of interest with the maximum deflections measured by the LVDT $w_{LVDT,max}$ (Figure 8). The results show perfect correlation.

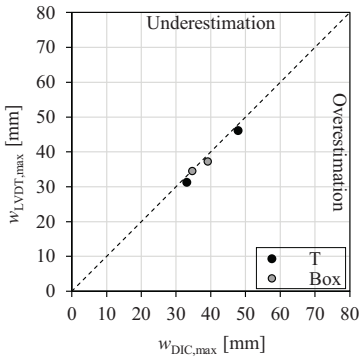

Figure 8: *Maximum deflections - Experimental results measured by the digital image correlation (DIC) and by the linear voltage displacement transducer (LVDT).*

5 NUMERICAL INVESTIGATIONS

5.1 FINITE ELEMENT MODEL

The modelling framework is developed using the Python programming language [12] and Abaqus Unified FEA software suite for finite element analysis [13]. The cross-section of a T-section was sketched and extruded to one deformable part. A geometric symmetry simplification was considered in the form of a vertical symmetry plane in the middle of the cross-section in longitudinal direction and a vertical symmetry plane at midspan (Figure 9). The support was defined as roller support. The generated part was partitioned into flange and rib. The flange was partitioned into the CLT layers, the material orientations of which were defined by local coordinate systems. The contact interactions between flange and rib, and the CLT layers were considered as rigid. The flexible-in-shear multi-layered FE model was loaded as four point bending test. As in the test setup, the mechanical load was applied uniformly at the position of the cylinder along the CLT width over a depth of 200 mm. A gravity load could be activated using a gravity acceleration of 9806.65 mm/s^2. Based on a sensitivity study [14], a mesh of 20x20 mm^2 was chosen. The incompatible mode eight-node brick element (C3D8I) was used for the analyses. Material properties were discussed as linear-elastic and orthotropic using the material properties of Table 2 for the nine engi-

[2)] Values based on Bodig and Jayne [15].

neering constants. The materials were assigned to the CLT layers as CLT and to the rib as glulam. The shear modulus in-plane of the gross CLT cross-section G_{xy} and the rolling shear modulus of CLT G_r were determined according to Equation (8) and Equation (9):

$$G_{xy} = min\left(\frac{650}{1 + 2.6 \cdot \left(\frac{t_l}{b_l}\right)^{1.2}}; 450\right) \quad (8)$$

$$G_r = min\left(30 + 17.5 \cdot \left(\frac{b_l}{t_l}\right); 100\right) \quad (9)$$

where t_l is the thickness of the lamination, and b_l is either the width of the lamination, the distance between the edge and a groove or the spacing between grooves within the lamination [16,17]. The latter was taken as average distance between grooves of the edge-bonded laminations, declared as 150 mm by Stora Enso.
The FE model was generated for each test specimen of the ultimate-load tests based on the specified dimensions, density, and the determined local modulus of elasticity as modulus of elasticity in x-direction E_x of the single components (CLT plates and glulam ribs), taken from [7]. The maximum load per cylinder $F_{cyl,max}$ was applied per test specimen (Table 1).

5.2 VALIDATION

The gravity load was deactivated in the FE model and the deflection at midspan was requested in the middle of the bottom edge in the post-processing. The FE model was validated by comparing the maximum numerical deflections $w_{sim,max}$ to the maximum deflections measured by the LVDT $w_{LVDT,max}$ (Figure 10). The results show good correlation with a coefficient value of 0.96.
Then, the gravity load was activated in the FE model. The flexible-in-shear multi-layered FE model resulted in a non-uniform stress distribution along the CLT width. On top of the CLT plate at midspan, the stress value in longitudinal direction at rib centre was requested from the created output database. Figure 11 presents per test specimen the maximum longitudinal stress values

https://doi.org/10.52202/069179-0319

$\sigma_{x,max,sim}(z_{top})$ of the FE model in comparison to the maximum experimental bending stresses $\sigma_{max,test}(z_{top})$ (Table 1). The results show good correlation with a coefficient value of 0.91.

6 RESULTS

6.1 STRAIN DISTRIBUTION

6.1.1 Digital image correlation

The DIC technique measured displacements on top of the top CLT plate. The software VIC-3D Digital Image Correlation Version 9.1.6 [11] was used for the determination of strains. The in-plane strains, i.e. longitudinal strains $\varepsilon_{xx,DIC}$, were calculated from the displacements as engineering strains. The accuracy was influenced by cracks and damages on the surface. Therefore, the longitudinal strains were averaged over the best illuminated region of the area of interest. Figure 12 presents the strain fields at failure of the selected test specimens. It should be noted that the region could only cover around 0.90 m of the CLT width b of 0.933 m.

Then, the averaged longitudinal strains $\varepsilon_{xx,DIC}$ were smoothed over the CLT width by taking the mean over a window length of 100 mm. Figure 13 presents the smoothed longitudinal strain distribution $\varepsilon_{xx,DIC}$ along the CLT width of the four selected test specimens (A2, B1, C1, and D3) at failure time. The strains result in compressive strains between 0.0006 and 0.0014. The results indicate a non-uniform stress distribution along the CLT width of the ribbed cross-sections.

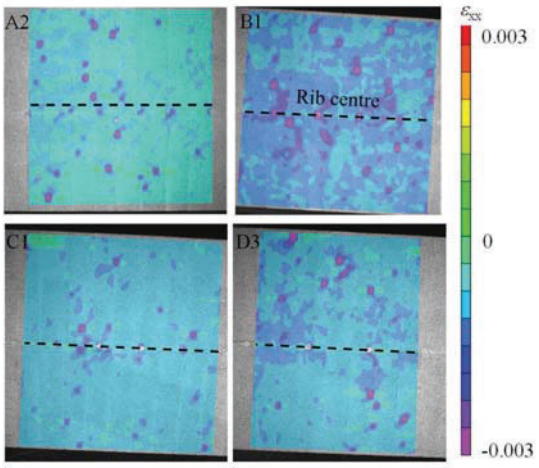

Figure 12: *Strain field on top of the top CLT plate at midspan - Longitudinal strains measured by the digital image correlation (DIC) of the four selected test specimens (Digital image at failure, contour range: -0.003 – 0.003 [-]).*

6.1.2 Finite element model

The gravity load was deactivated in the FE model. For comparison with the DIC results, the strains in longitudinal direction $\varepsilon_{xx,sim}$ along the CLT width were requested on top of the top CLT plate at midspan from the created output database (Figure 13). The strains result in compressive strains between 0.0008 and 0.0016. The flexible-in-shear multi-layered FE model resulted in a non-uniform stress distribution along the CLT width.

6.2 MAXIMUM STRAIN AND STRESS

The strains on top of the top CLT plate vary with the distance from the rib due to the in-plane shear flexibility of the flange. At rib centre, both the maximum longitudinal strain as well as the maximum stress value occur. Table 3 lists the results at midspan based on the DIC measurements and the FE model. The maximum longitudinal strain value at rib centre $\varepsilon_{xx,max}$ resulted on average in -0.00116 for the DIC measurements and in -0.00147 for the FE model. Figure 14 compares the maximum stress values on top of the top CLT plate at rib centre $\sigma_{x,max}(z_{top})$ between the FE model and the DIC measurements. The maximum stress value in longitudinal direction $\sigma_{x,max,sim}(z_{top})$ was requested from the created output database, as in Figure 11. The maximum stress value of the DIC measurements $\sigma_{x,max,DIC}(z_{top})$ was calculated by multiplying the maximum longitudinal strain value at rib centre $\varepsilon_{xx,max,DIC}$ with the modulus of elasticity of the top CLT plate $E_{CLT,}$ taken from [7]. The maximum stress value on top of the top CLT plate at rib centre $\sigma_{x,max}(z_{top})$ resulted in a compressive stress of on average 15.7 N/mm² for the DIC measurements and 19.8 N/mm² for the FE model.

[1)] Values taken from [7].

6.3 EFFECTIVE WIDTH

In this paper, longitudinal strains ε_{xx} were obtained at midspan only on the top side of the top CLT plate; for both the DIC technique and the FE model. Equation (10) shall apply in accordance with Equation (1) and Figure 2:

$$\varepsilon_{xx,max}(z_{top}) \cdot b_{ef,top} = \int \varepsilon_{xx}(y, z_{top})dy \qquad (10)$$

where $\varepsilon_{xx,max}(z_{top})$ is the maximum longitudinal strain value on top of the top CLT plate at rib centre, and $\int\varepsilon_{xx}(y,z_{top})dy$ is the integral of all longitudinal strains along the width of the CLT plate on top of the top CLT plate.

The effective width on top of the top CLT plate $b_{ef,top}$, is determined according to Equation (11):

$$b_{ef,top} = \frac{\int \varepsilon_{xx}(y, z_{top})dy}{\varepsilon_{xx,max}(z_{top})} \qquad (11)$$

The effective widths on top of the top CLT plate $b_{ef,top}$ were calculated for the four selected test specimens (A2, B1, C1, and D3) based on the longitudinal strains of the FE model and based on the DIC measurements. Table 3 lists the results in relation to the CLT width b. Figure 15 shows the comparison between the two models. Both the results of the DIC measurements and the FE model show

https://doi.org/10.52202/069179-0319

a low deviation between the results of maximum 4%. For the DIC results, the effective widths on top of the top CLT plate $b_{ef,top}$ resulted on average in 88% of the CLT width for all test specimens (CoV = 1%). For the numerical results, a distinction can be made between T-sections (86% of the CLT width) and box-sections (80% of the CLT width).

7 DISCUSSION

7.1 STRAIN DISTRIBUTION

The strain distributions along the CLT width on top of the top CLT plate are compared between DIC measurements and the FE model. The strain distributions show complete compression along the CLT width, as expected for the system of a simply supported beam under positive moment. The DIC results are in a range close to the expected range of the numerical results of the FE model. The DIC results of the T-sections (A2, B1) show good agreement in the shape of the strain distribution in comparison to the FE results. The DIC results of the box-sections (C1, D3) show a less pronounced decrease in strains with the distance from the rib centre. The composite system exhibited a lower shear lag effect as estimated by the FE model. Especially, the thinner top CLT plates of the box-sections proved to be less flexible in plane. The strain distributions at midspan might have been effected through a clinching effect of the steel profiles of the experimental test setup.

7.2 MAXIMUM STRAIN AND STRESS VALUE

The best fit can be seen for test specimen B1. Here, not only the shape of the strain distribution but also the maximum longitudinal strain value at rib centre $\varepsilon_{xx,max}$ comply between the DIC technique and the FE model. The FE model overestimates the maximum longitudinal strain value at rib centre $\varepsilon_{xx,max}$ by only 15%. For specimen A2, however, the FE model overestimates the value by 55%.

The maximum stress values on top of the top CLT plate at rib centre $\sigma_{x,max}(z_{top})$ are calculated from the maximum longitudinal strain value at rib centre $\varepsilon_{xx,max}$. Figure 14 outlines the overestimation by the FE model by up to 55%. The average error is 4.4 N/mm^2 (RMSE).

7.3 EFFECTIVE WIDTH

The effective widths on top of the top CLT plate $b_{ef,top}$ are in good agreement between the DIC technique and the FE model for the T-sections. The FE model underestimates the effective widths of the box-sections by 10%. This is based on the more pronounced non-uniform strain distribution along the CLT width. The small deviation between the results of the individual models (CoV ≤ 4%) illustrates the small influence of the material properties on the strain distribution. As outlined in [7], the effective width b_{ef} mainly depends on the stiffness of the floor system, e.g. the ratio of clear rib distance to span $b_{f,i}/l$, which was about 0.15 of the tested system.

Figure 15 puts the results in relation to the mean value of the estimated effective width of Eurocode 5 $b_{ef,EC5}$, taken from Figure 6. The effective width by Eurocode 5 $b_{ef,EC5}$ shows the approach on the safe side with an estimate of 60% of the CLT width on average.

Figure 15 puts the results in relation to the mean value of the experimental effective width $b_{ef,test}$, taken from Figure 6. The experimental effective width $b_{ef,test}$ was on average 80% of the CLT width. The higher deviation between the experimental results (CoV = 11%) illustrates the sensitivity of the experimental results based on the local deflections of less than 3 mm (see Table 1). The mean value of 80% of the CLT width complies well with the numerical investigations presented in [18]. There, the effective width would have been determined around 75% of the CLT width (Abb. 20, MM_Bsp3s_q).

The effective widths on top of the top CLT plate $b_{ef,top}$ of the DIC measurements and the FE model lay slightly above the mean value of the experimental effective width $b_{ef,test}$. It should be noted that the effective width b_{ef} of the entire flange or system is expected to be smaller than the effective width on top of the top CLT plate $b_{ef,top}$.

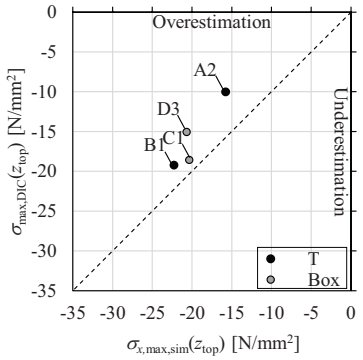

Figure 14: *Maximum stress values on top of the top CLT plate - Numerical results (sim) in comparison to results based on the DIC measurements (DIC).*

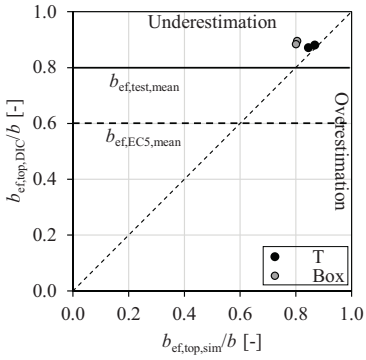

Figure 15: *Effective width - Results on top of the top CLT plate based on the FE model (sim) in comparison to the ones based on the DIC measurements (DIC); incl. mean values of the experimental and by Eurocode 5 estimated effective width.*

8 CONCLUSIONS

The DIC analysis allows visualizing the strain field on top of the CLT plate. In comparison to strain gauges and LVDTs, entire field measurements are possible. The proposed paper investigates DIC as a suitable measurement technique for the determination of the

effective width b_{ef}. The investigations apply to a floor system with a ratio of clear rib distance to span $b_{f,i}/l$ of about 0.15. The strain and stress distributions along the CLT width on top of the top CLT plate are compared between DIC measurements and the FE model. The DIC measurements and the numerical results of the FE model were validated against the experimental results of four tested cross-sections. Based on the DIC results, the composite system exhibited a lower shear lag effect as estimated by the FE model.

Although the in-plane stiffness was underestimated by the FE model, the results of the effective width on top of the top CLT plate $b_{ef,top}$ show good agreement between the DIC measurements and the FE model. Furthermore, the results comply with the effective width b_{ef} of the experimental results, which is on average 80% of the CLT width. Eurocode 5 gives an estimate on the safe side of 60% of the CLT width on average.

The numerical investigations formed the basis for thermo-mechanical investigations [7]. The aim was the determination of the effective width in fire over the entire height of the CLT plate. The 3D FE model resulted in a non-uniform, temperature-dependent strain distribution along the CLT width [19]. The temperature-dependent longitudinal bending stresses were taken along the CLT width and along the thickness of the longitudinal CLT layers per specified time step. A parametric study analysed the effective width in fire $b_{ef,fi}$ for a parameter range expected in practice.

MODELLING OF OSB SANDWICH PANELS WITH ORIGAMI-INSPIRED CORE

Jan Pełczyński[1], Kamila Martyniuk-Sienkiewicz[2], Anna Al Sabouni-Zawadzka[3]

ABSTRACT: This research is focused on the development, and experimental and numerical testing of wood-based sandwich panels with both covers and a core made of oriented strand boards (OSBs). The core shapes are inspired with an origami pattern. Wood-based sandwich panels are structural elements that maintain essential features of wood, such as lightness, while having an increased load-bearing capacity and stiffness. Thanks to these properties, they find application in high-rise and residential construction. Laboratory tests presented in this study are aimed at determining selected material properties of the boards, namely the Young's moduli in the longitudinal and transverse direction. The experimentally identified parameters are afterwards used as orthotropic coefficients in the numerical analysis of six sandwich panels, differing in the core type and the thickness of the core boards. The numerical models are prepared in the Abaqus environment and analysed using the finite element method (FEM). Two types of models are built for each panel: a 3D shell model of the whole panel and a 3D solid submodel of a section of the panel. The submodels are aimed at the detailed analysis of stress distributions in the areas of the connections between the covers and the core.

KEYWORDS: Sandwich panel, OSB, FEM, Submodelling

1 INTRODUCTION

Modern civil engineering faces many problems that force engineers to seek for new, creative solutions, both within materials and structures. Due to the rapidly progressing urbanisation and the increasingly frequent requirement to strive for sustainable solutions, scientists have started to pay more attention to wood, which has been used in the construction for centuries. One of the first steps toward the improvement of this natural material was the development of wood-based products such as oriented strand board (OSB), laminated veneer lumber (LVL), glued or cross-laminated timber (GLT or CLT). These materials can be used in multi-storey buildings thanks to their improved load-bearing capacity and good elastic properties while maintaining a low weight.

OSBs consist of slender strands of wood which are bonded together using water-resistant resins [1]. The boards have usually three layers of strands, which are oriented perpendicularly to one another, and the strands of outer layers are mostly oriented along the main axis of the board. OSBs are widely used as engineering products in the construction industry due to their favourable mechanical properties [2].

The research on OSB has focused mainly on the determination of its physical and mechanical properties, using both the numerical and experimental studies. Zhu et al. [3] investigated material properties of OSB by performing experimental tests covering in-plane behaviour of the boards as well as their properties in the perpendicular direction. They proved that OSB is an orthotropic material with better mechanical properties along the main strands orientation direction. Moreover, they proposed an elastic-plastic constitutive model of OSB, which they implemented in the finite element (FE) analysis. Islam et al. [2] conducted laboratory tests on OSB samples in order to determine various technical parameters of the boards, e.g. ultimate strengths, Young's modulus, shear modulus, and Poisson's ratio. They tested samples which were cut from the board along three directions: transverse, diagonal and longitudinal. Hrázský and Král [4] studied the effect of density and glue amount changes on the mechanical behaviour of OSB. They determined bending strength, modulus of elasticity and tensile strength of OSBs of different thicknesses, varying in density and the amount of glue. Plenzler et al. [1] performed experiments aimed at determining elastic and strength properties of the layers of commercial OSB panels. They confirmed that the physical and mechanical properties of the face and core layers of OSB differ significantly. Feraboli [5] studied the notched response of OSB wood composites. He collected a large experimental database proving that OSB may be considered a notch-insensitive material thanks to its heterogeneous inner structure.

Although the OSB is a well-known material that has been used since a very long time in various civil engineering applications, and many studies on its mechanical properties can be found in the literature, it is still problematic to find full information on the mechanical behaviour of specific types of OSBs. Therefore, the authors of this paper have decided to perform

[1] Jan Pełczyński, Warsaw University of Technology, Faculty of Civil Engineering, Poland, jan.pelczynski@pw.edu.pl
[2] Kamila Martyniuk-Sienkiewicz, Warsaw University of Technology, Faculty of Civil Engineering, Poland, kamila.martyniuk-sienkiewicz.dokt@pw.edu.pl

experimental tests aimed at identifying certain orthotropic coefficients of the boards used for the construction of the investigated OSB-based sandwich panels.

Wood-based sandwich panels are understood here as composite slabs consisting of two thin covers and a thick but lightweight core. Such structural elements maintain the essential features of wood, such as lightness, while having the increased load-bearing capacity and stiffness [6]. Thanks to these properties, sandwich structures would find application in high-rise and residential construction. Covers can be made of wood-based materials like OSB, CLT or composite elements. For the core, there is a wide range of structural systems used, including basic trapezoidal or trapezoidal-like shapes [7], or light openwork structures such as lattice-shaped cores [6], especially XX-type lattice [8] and 2D lattice truss [9]. Each shape responds differently under the load, allowing for the design of structures that meet even very high demands. Sandwich structures could be assembled using traditional wood and wood-based materials or, more surprising, bamboo [10] or jute fabrics/epoxy composite [11].

The subject of the research presented in this paper is the development and experimental and numerical testing of a wood-based sandwich structure with both covers and a core made of OSBs. The core shape is inspired with an origami pattern [12, 13]. An example of a physical model of a section of the analysed structure is presented in Figure 1. This is an illustrative example aimed at showing the authors' idea, not the model that has been tested in the laboratory.

Figure 1: *Physical model of the OSB sandwich plate section*

This study focuses on two aspects of the broader research, which is a part of the research project realized by the authors at the Warsaw University of Technology, funded by the National Science Centre in Poland. In Section 2, results of laboratory tests conducted on OSB samples of various thicknesses are presented. The tests were aimed at determining selected orthotropic coefficients of the boards, that is Young's moduli in two directions: longitudinal and transverse. Section 3 contains results of numerical analyses of sandwich panels carried out in Abaqus software using the finite element method (FEM) [14], with the material properties determined in the experimental study.

2 EXPERIMENTAL TESTS

In order to determine selected material parameters of OSB, experimental tests on OSB samples of three different thicknesses were conducted. Altogether, 60 OSB samples were tested: three different board thicknesses (10 mm, 15 mm, and 22 mm), and for each board ten samples cut in each of the two directions (along the longitudinal axis and transverse to it). The tested samples were rectangular with the following dimensions: 25 mm x 200 mm for the 10 mm thick OSB, 25 mm x 300 mm for the 15 mm thick OSB, and 25 mm x 400 mm for the 22 mm thick OSB. The specified lengths of the samples are not their actual lengths, but their spans (distances between the supports in the testing machine). Figure 2 shows 20 samples cut from the 22 mm thick OSB: ten in the longitudinal direction (T00) and ten in the transverse direction (T90).

The tests were aimed at determining the Young's moduli in two directions: longitudinal (E_1) and transverse (E_2).

Figure 2: *Samples of the 22 mm thick OSB in two directions: T00 – longitudinal, T90 – transverse*

https://doi.org/10.52202/069179-0320

Three-point bending tests were performed using a universal testing machine Instron 3382, with one concentrated force applied in the middle of the span. The loading was applied using a displacement-controlled method with the speed of 10 mm/min, and the displacements of the samples were measured with a laser sensor, which observed the bottom surface of the sample. The test setup is showed in Figure 3, which depicts one of the 22 mm thick OSB samples under bending.

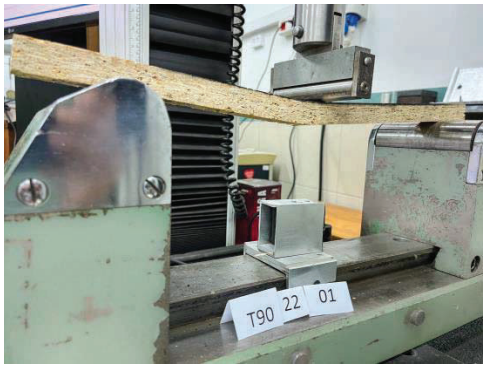

Figure 3: *Bending test on the 22 mm thick OSB sample in the transverse direction*

Figures 4 and 5 present results obtained from the bending tests (force-displacement curves) for the 22 mm thick OSB samples. Similar tests were performed on the 10 mm and 15 mm thick boards. However, as the main aim of this study was to determine the Young's moduli, the curves obtained for other samples are not presented here. Instead, all results (calculated values of the Young's moduli) are gathered in Table 1.

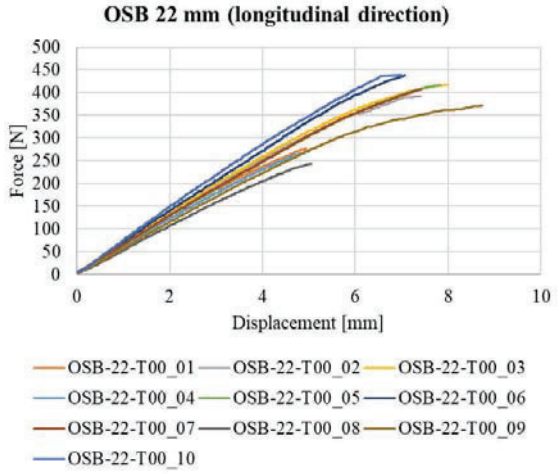

Figure 4: *Results of bending tests performed on the 22 mm thick OSB samples in the longitudinal direction*

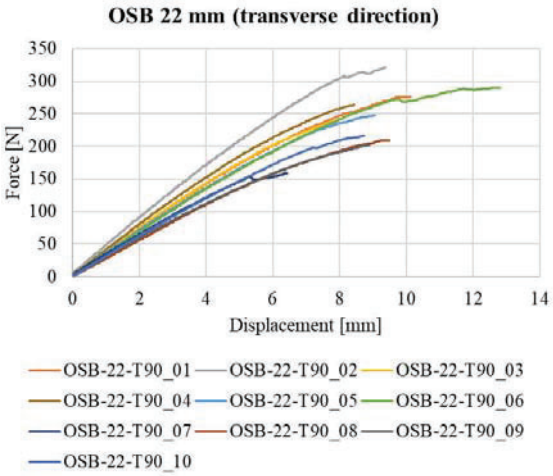

Figure 5: *Results of bending tests performed on the 22 mm thick OSB samples in the transverse direction*

Table 1: *Young's moduli of OSB determined in the experimental tests*

OSB thickness [mm]	Direction	Young's modulus [N/mm^2]: E_1 (T00) and E_2 (T90)		
		Average	Median	Standard deviation
10	T00	5191.22	5079.47	379.38
	T90	3471.12	3481.40	378.91
15	T00	4317.95	4202.95	615.03
	T90	2321.04	2316.10	270.40
22	T00	4072.05	4052.48	357.34
	T90	2271.99	2332.63	312.54

The Young's moduli were calculated using the formula

$$E = \frac{(F_{40} - F_{10})L^3}{48\, I(u_{40} - u_{10})}, \tag{1}$$

where:
E – Young's modulus,
F_{40} – force corresponding to 40% of the breaking load,
F_{10} – force corresponding to 10% of the breaking load,
u_{40} – vertical displacement at 40% of the breaking load,
u_{10} – vertical displacement at 10% of the breaking load,
L – span,
I – moment of inertia.

Calculated values of the Young's moduli were afterwards used in the numerical models of the considered sandwich panels.

3 NUMERICAL MODELLING

Finite element models of the OSB-based sandwich panels were developed in two stages using the Abaqus environment:

- stage 1 – 3D shell model of the panel;
- stage 2 – 3D solid submodel of a section of the panel.

https://doi.org/10.52202/069179-0320

The shell model was built using 4-node general-purpose shell elements with reduced integration (S4R) within the linear elasticity with an orthotropic material model, and the adopted finite element size was 0.01 m. The connection between the core and cover boards was modelled using the tie contact in Abaqus with automatic discretization. The uniformly distributed load of 2 kN/m^2 was applied to the upper cover of the panel in the vertical direction (direction 3 – perpendicular to the panel surface). The panel was supported at shorter edges of the lower cover: at one edge displacement constraints in two directions (U1 and U3) were applied, along the other edge the constraints were applied in the vertical direction (U3) and, additionally, constraints in the horizontal direction (U2) were applied in two corner nodes.

The submodel was generated using the Abaqus built-in procedure, which allows for the automatic reading of the boundary conditions and introducing them into the defined submodel. A shell-to-solid submodelling was used, where shell corresponds to the full model, and solid to the submodel. It is important to locate the submodel in the same coordinate system, so that it is consistent with the location of the corresponding elements of the shell model.

The submodel was built using 8-node linear brick elements with reduced integration (C3D8R) within the linear elasticity with an orthotropic material model, and the adopted finite element size was 0.0025 m. The connection between the core and cover boards was modelled using the tie contact in Abaqus with automatic discretization. The same uniformly distributed load of 2 kN/m^2 was applied to the upper cover of the panel, and the boundary conditions were applied automatically, based on the displacements of the shell model.

Using the procedure described above, six different sandwich panels were analysed. All panels had the same 22 mm thick OSB covers and different core structures:

- panel 1 – continuous core (full), 15 mm thick OSBs (Figure 6a);
- panel 2 – continuous core (full), 10 mm thick OSBs;
- panel 3 – discontinuous core (50% of the full core material), 15 mm thick OSBs (Figure 6b);
- panel 4 – discontinuous core (50% of the full core material), 10 mm thick OSBs;
- panel 5 – discontinuous core (25% of the full core material), 15 mm thick OSBs (Figure 6c);
- panel 6 – discontinuous core (25% of the full core material), 10 mm thick OSBs.

For each sandwich panel two FEM models were created: a shell model and a solid submodel (see Figure 6). Shell models had dimensions of 2.50 m x 1.25 m x 0.25 m, and the dimensions of the submodels differed depending on the panel: 0.25 m x 0.30 m x 0.12 m (panel 1 and 2), 0.25 m x 0.50 m x 0.20 m (panel 3 and 4), 0.25 m x 0.565 m x 0.20 m (panel 5 and 6). All submodels were cut from the same location of the shell models.

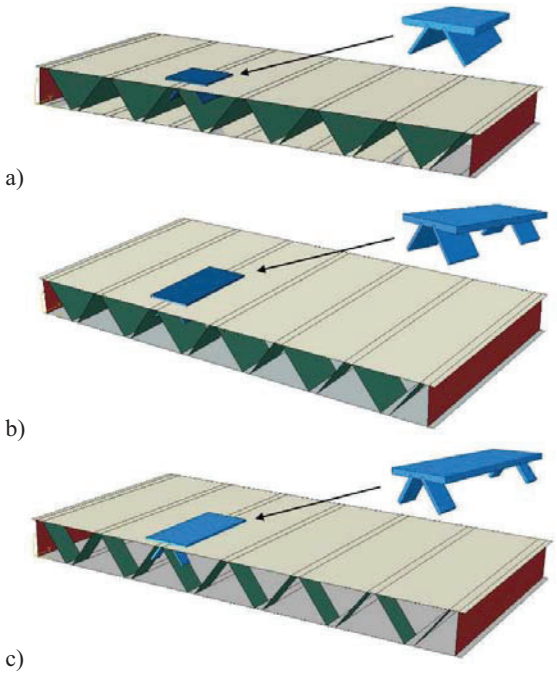

Figure 6: *3D shell models with 3D solid submodels: a) panel 1; b) panel 3; c) panel 5*

The material properties used in the numerical analysis are presented in Table 2. Values of the Young's moduli in two horizontal directions (longitudinal and transverse) were taken from the experimental tests described in Section 2, and all other parameters were adopted based on the literature study – due to the fact that those parameters have much smaller effect on the mechanical behaviour of the structure that the tested Young's moduli, equal values in all directions and for all OSB thicknesses were applied. However, in the future study the authors plan to identify all orthotropic coefficients experimentally.

Table 2: *Material parameters used in the FE analysis*

OSB thickness [mm]	10	15	22
E_1* [N/mm^2]	5191.22	4317.95	4072.05
E_2* [N/mm^2]	3471.12	2321.04	2271.99
E_3** [N/mm^2]	1800	1800	1800
ν**	0.2	0.2	0.2
G** [N/mm^2]	1100	1100	1100

* values identified experimentally
** values based on the literature

Selected results of the numerical analysis are presented in Figures 7-10. Figure 7 depicts magnitudes of displacements obtained in three shell models of selected sandwich panels: 1, 3, and 5.

https://doi.org/10.52202/069179-0320

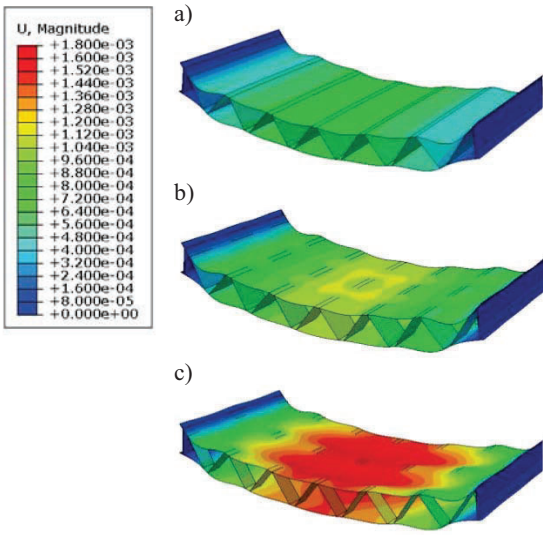

Figure 7: *Magnitude of displacements: a) panel 1; b) panel 3; c) panel 5*

It can be noticed that the reduction of the core material results in increased displacements of the panel. The following maximum displacements were obtained in sandwich panels with the 15 mm thick core boards: 0.79 mm for the full core, 1.14 mm for the 50% reduced core, and 1.72 mm for the 25% reduced core. Similarly, in sandwich panels with the 10 mm thick core boards, the maximum displacements were: 1.00 mm for the full core (26.6% increase in relation to the 15 mm thick core boards), 1.18 mm for the 50% reduced core (3.5% increase), and 1.80 mm for the 25% reduced core (4.7% increase).

Figures 8-10 show distributions of normal stress in the longitudinal direction in the submodels of six panels.

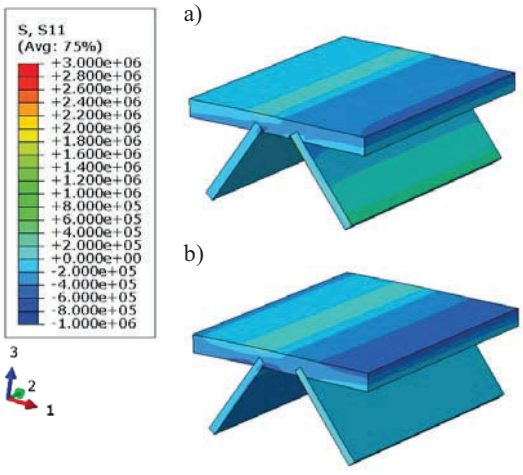

Figure 8: *Distribution of normal stress in the longitudinal direction: a) panel 1; b) panel 2*

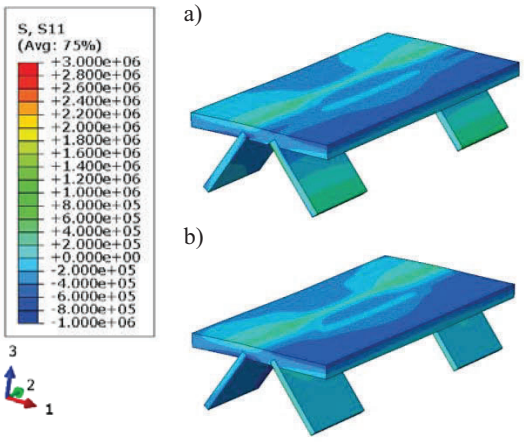

Figure 9: *Distribution of normal stress in the longitudinal direction: a) panel 3; b) panel 4*

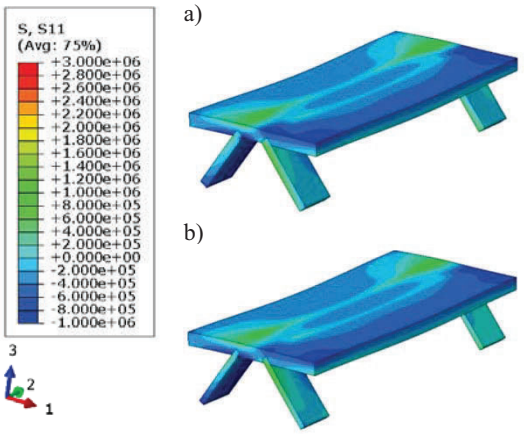

Figure 10: *Distribution of normal stress in the longitudinal direction: a) panel 5; b) panel 6*

The stress distribution is regular in the panels with full cores, and visible concentrations of stresses are observed in the panels with reduced cores, in OSB covers in the areas above the connections with the core boards. Changing the thickness of the core boards from 15 mm to 10 mm, does not affect much the distribution or values of normal stress in the longitudinal direction.

4 SUMMARY

This research focused on the development, and experimental and numerical testing of wood-based sandwich panels with two covers and an origami-inspired core made of OSB. First, laboratory tests on OSB samples of three various thicknesses (10 mm, 15 mm, and 22 mm) were conducted, in order to determine selected material properties of the boards – the Young's moduli in the longitudinal and transverse direction. The experimentally identified parameters were afterwards used in the finite element analysis of six sandwich panels, differing in the core type and the thickness of the core boards.

Three types of cores were considered: full, reduced by 50%, and reduced by 25%. For each developed panel, two numerical models were built: a 3D shell model of the whole panel and a 3D solid submodel of a section of the panel. While the shell models showed the general behaviour of the panels under the assumed uniformly distributed load, the submodels allowed the authors to analyse stress distributions in the areas of the connections between the OSB covers and the core.

The future research will focus on the experimental identification of other orthotropic coefficients of OSB, and other core types will be studied, e.g. tensegrity-inspired cores.

FUNDING

This research was funded in whole by the National Science Centre, Poland, grant number 2021/43/D/ST8/02238. For the purpose of Open Access, the author has applied a CC-BY public copyright licence to any Author Accepted Manuscript (AAM) version arising from this submission.

INNOCROSSLAM – ADDING KNOWLEDGE TOWARDS INCREASED USE OF CROSS LAMINATED TIMBER (CLT)

Boris Azinović[1], Erik Serrano[2], Henrik Danielsson[2], Josef Füssl[3] Markus Lukacevic[3], Philipp Dietsch[4], Matthias Arnold[5], Martin Schenk[5], Stefan Winter[5], Jose Manuel Cabrero[6], Pablo Gonzalez Serna[6], Tomaž Pazlar[1]

ABSTRACT: The research project *Innovative Solutions for Cross Laminated Timber Structures* (InnoCrossLam) was recently finished. The project aimed at increasing the competitiveness of CLT as a versatile engineered product, by increasing its predictability in demanding design situations not covered by the guidelines of today, or standards and codes foreseeable in the near future (*e.g.,* second generation of European design standards). This paper summarises the main project findings in the context of innovative CLT structures, such as: *i*. contemporary design approaches *ii.* the use of (non)linear FE modelling *iii.* experimental investigation of complex details for CLT structures, *iv*. investigation of multifunctional CLT. In this paper, the motivation behind the research topics within the project InnoCrossLam is explained and backed-up by exemplary results and discussion on future work.

KEYWORDS: mass timber, cross laminated timber, CLT properties, structural design, FE modelling, experimental investigation, multifunctional CLT, diagonal laminated timber, DLT

1 INTRODUCTION

1.1 BACKGROUND AND AIMS

Multi-storey timber construction has seen an important development over the last two decades, especially due to the introduction of cross laminated timber (CLT). Although the introduction of CLT to the market must be described as a success story, from a European perspective, the increased use of CLT is still slowed down by the lack of supporting provisions for design. Thus, there is still a lack of harmonised standard and unified design approaches in structural design codes. In addition, other complementing engineering tools such as handbooks are fragmented, national and, as a result, there is a risk of such documents leading to diverging recommendations. Finally, several common design situations are not covered [1].

1.2 OVERVIEW OF PRESENT WORK

Within InnoCrossLam, both basic research efforts and applied studies of innovative concepts have been performed. The work has covered studies to gain in-depth and basic knowledge of the mechanical behaviour of CLT, including joints and moisture related behaviour. Furthermore, the work has addressed more applied research by including investigations on prototypes of innovative concepts related to CLT with embedded functionality in terms of heating and ventilation (known as thermal activation). Finally, the project InnoCrossLam has aimed at proposing practical design approaches and formulae, for inclusion in future structural codes and standards.

2 PROJECT TOPICS AND RESULTS

2.1 SURVEY OF CURRENT CLT PRACTICE

Due to the crosswise arrangement of layers, CLT requires special approaches in the calculation of its mechanical properties and the evaluation of its structural performance compared to typical timber products such as solid structural timber or glulam (GLT). Therefore, as part of the project, it was deemed necessary to conduct a global survey of current practices. The results of the survey can be found in [2]. The questionnaire was distributed digitally worldwide to those who can produce, process, design or install CLT (i.e., CLT manufacturers, suppliers, engineers in construction companies, structural engineers, and researchers in institutions). A large part of the participants came from the main area of the CLT industry, i.e., Germany and Austria.

More than 70% of the respondents are involved in practice, either in a design office or in a construction company. About 20% of the participants was from research and the remaining from construction companies.

Respondents proved to be quite experienced, most of them having worked in the field for more than 11 years (52.5%). Considering the recent introduction of CLT in practice and the experience of the respondents, it is possible that most of the respondents are self-taught on CLT design. Although most of them, 85%, consider that they have a reasonable knowledge of cross laminated timber structures, the obtained results show a very diverse level of knowledge. The design practice is also very different. While material parameters are uniformly applied to some extent, the approach to design is documented in a very heterogeneous manner, as shown by the wide range of literature used for design practice. No uniformly used background document could be identified.

Regarding the type of software or tools used for CLT verification, practice-oriented finite element (FE) modeling software is most commonly used, especially by designers and constructors in practice (about 70%). CLT-oriented software is used comparatively often, especially in the construction sector. In most cases, however, designers must additionally develop their own tools for certain analyses and verifications.

The most challenging design aspects in practice were openings in walls/floors (cca. 18% and 15%), point supports, and concentrated loads (23%). The majority pointed out the lack of design provisions as the main reason. In addition, connections, vibration, and fire measurements were also reported, again due to the lack of existing design regulations. The results of the survey mainly point to the lack of standardization and incomplete regulations as the main problems for practitioners. This unclear situation leads to the fact that the design of a structure in solid timber construction requires experience and further qualification and can therefore be performed only by some well-trained engineers. There is a need for the development of appropriate tools and models for the product, as well as simple design rules.

2.2 CLT AND MOISTURE

CLT is commonly used as a base for Timber Concrete Composites (TCC), and in this application the issues of moisture transport, drying and moisture-induced deformation are of interest. These were investigated with the help of accurate 3D FE models.

In general, wood moisture plays a major role in the design of timber structures, as wood is a highly hygroscopic material in which changes in moisture lead to changes in almost all physical properties. Due to its directionally dependent material properties, this can lead to cracking. However, the determination of the moisture condition in a timber member is relatively complex and the condition is variable both spatially and temporally, which is why only a very simplified consideration is used in the current version of the standard for the design and construction of timber structures. Water can occur in wood as bound water in the cell walls and as water vapor or free water in the cell lumen. Transport in the respective phases can be described by diffusion (bound water and water vapor) or capillary transport (free water). The phases are also connected by sorption (between water vapor or free water and bound water) and evaporation/condensation (between water vapor and free water). These mechanisms can be described with a so-called multi-Fickian transport model, which was previously implemented and validated with the finite element method and the commercial software Abaqus within a user element subroutine [3].

Next, this simulation tool was used to study the moisture loads that can occur in buildings. The first winter (heating phase) after the installation of the wood component is particularly critical when using timber elements indoors. To simulate such changes in humidity, moisture loads were applied to different wood elements in [4]. Starting from different initial wood moisture contents, fictitious reductions in relative humidity were applied to all exterior surfaces of the cross-sections and held for 720 h. The results were then used to simulate the moisture content of the cross-sections. Depending on the applied difference in relative humidity, the moisture content (MC) differed between 1% and 15% between the outside and inside of the cross-section. Based on the moisture simulations, the stresses can be calculated using expansion coefficients and the stiffness tensor. In unfavourable cases, these stresses can exceed the strength of the wood, causing plastic deformations and cracks [5]. Based on simulation results at the level of individual wood cells, a multisurface failure criterion was developed [6-8] that can reveal ductile (plastic) and brittle (cracking) failure mechanisms that can be used in commercial finite element software to predict the nonlinear behaviour of timber elements under moisture loading. The resulting crack patterns were analysed, and the maximum crack depths at specific time points are shown in Figure 1 for an initial wood moisture content of 15.3%.

From this figure, it can be seen, that the cracking is completed at different times depending on the cross-section width. In the case of the smallest cross-section with a width of 6 cm, this is already the case after 72 h, while in the case of the largest cross-section (GLT 20/40) an increase is already evident after 720 h. This is due to the difference in the cross-section widths: the difference in wood MC (and thus the wood moisture gradient) between the surface and the centre decreases as soon as the moisture flow from the surface reaches the centre of the cross-section. This is also roughly the time when cracking is complete. It is also easy to see that short-term changes of less than 8 hours cause only very small cracks, as a significant wood moisture gradient develops only near the edge. It can also be seen that small moisture differences in small cross-sections still lead to no or only small crack depths, while cracks or significantly deeper cracks can already occur in larger cross-sections. According to [9], cracks up to a depth of 15 mm per side are considered harmless.

https://doi.org/10.52202/069179-0321

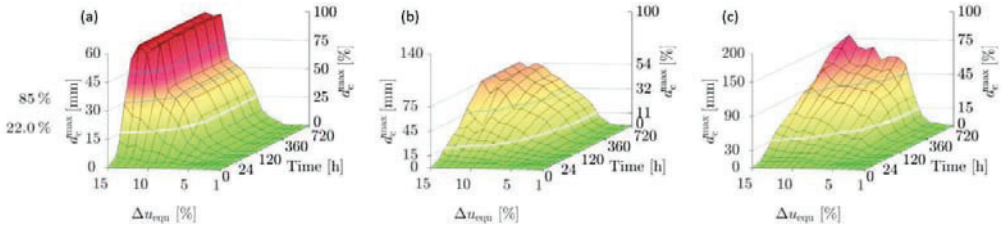

Figure 1: *Development of the maximum crack depth (sum of maximum crack depths of both cross-section sides), given in absolute and relative crack depth, for the cross-sections (a) solid timber 6/8, (b) solid timber 14/28 and (c) GLT 20/40 with an initial wood MC = 15.3% at different moisture content (MC) differences during 30 days (720 h) [9,10].*

The ultimate and serviceability limit states must be respected in the design of a timber structure according to EC 5. Changing climatic conditions and associated moisture-induced stresses are not taken into account directly in the current version of this standard, but via adjusted material parameters [10]. Compared to other environmental effects on the structure, such as wind and snow, no similar site-specific data are available for wood.

The following application of the models to a timber concrete composite demonstrates the capability of such an approach in studying critical conditions. Nowadays, the common method of manufacturing TCC elements with notches as shear connections is to apply fresh concrete directly to the CLT element. However, the fresh concrete releases moisture after application, which is absorbed by the highly hygroscopic wood and may lead to critical reduction of mechanical properties or problematic situations due to different expansion behaviour. Therefore, we used the moisture simulation tool to investigate the influence of the fictitious application of fresh concrete and then a realistic indoor climate applied to the bottom of the CLT element on the moisture behaviour of the timber parts [11]. Figure 3 shows the model of the CLT element and the path along which the wood MC is evaluated over the simulation period.

The resulting wood MC along the path over the simulated period are first shown in Figure 2 (below) for the original model without sealing. Moisture peaks above 70% occur in the uppermost lamella, corresponding to a value above the fibre saturation point and thus free water in the wood cells. Approximately the top half of the slab is affected in wood MC by the application of the fresh concrete. Depending on the indoor climate, the additional moisture introduced is removed over the course of nine to ten months before the entire slab dries out and an equilibrium MC of between 8% and 9% is reached. After that, only the lowest two lamellas are affected by the indoor climate. In addition, local sealing in the area of the end faces of the notches effectively reduces the moisture peak that occurs (see Figure 2). This means that such a sealing could possibly replace commonly used separating foils, which cause a high labour input or can reduce the load transfer.

In the next step, the implementation of more advanced crack modelling techniques [11,13] will also allow to represent in more detail the variability of, e.g., the strength properties of such timber products, leading to even better performance predictions, which have already successfully been shown for studying the so-called size effect of glulam [14,15].

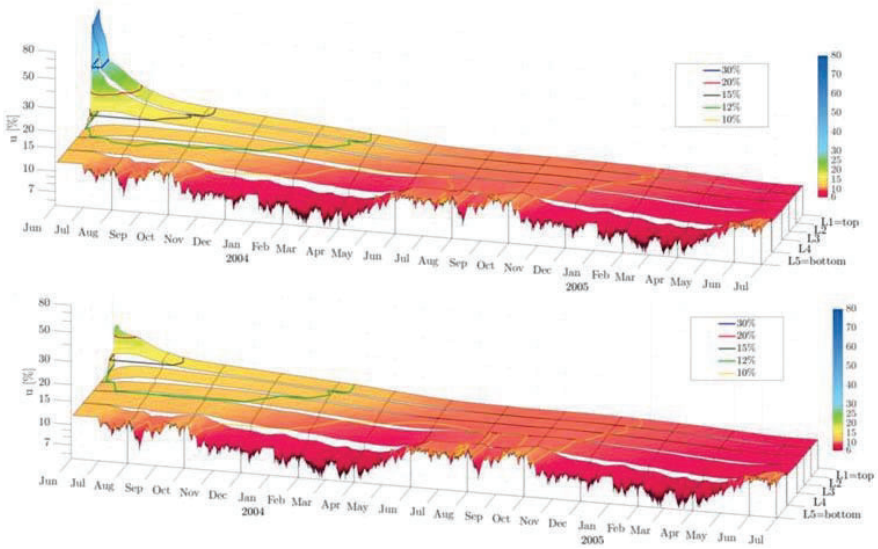

Figure 2: *Course of wood moisture content (MC) along the CLT plate thickness (from L1=top lamella to L5=bottom lamella), plotted over two years for the unsealed model (top) and the model with sealed end faces in the area of the notches (bottom) [11].*

2.3 CLT IN-PLANE SHEAR

For in-plane shear loading of CLT, two types of loading situations may be considered: pure in-plane shear loading and in-plane beam loading. The pure in-plane shear loading case is relevant for the loading situation in a shear wall or in a floor diaphragm, while the in-plane beam loading case would represent the loading situation for a lintel, or a pointsupported wall element.

For shear, three possible failure modes - gross shear failure (I), net shear failure (FM II), and shear failure in the crossing areas (FM III) - must generally be considered in the design. The methods proposed for verifying the ultimate capacity with respect to these three shear failure modes vary considerably among the design codes, design manuals, and ETAs of CLT manufacturers. The differences mainly relate to the determination of the design relevant stress components for FM II and FM III and the underlying mechanical models for stress analysis.

Within InnoCrossLam, investigations of the in-plane shear behaviour of CLT focused on the development of rational and unified design approaches for the cases of pure in-plane shear and in-plane beam loading conditions, considering design with respect to FM III.

An analytical model for prediction of internal forces and stresses acting in crossing areas between laminations of adjacent layers has been developed. The model is derived by considering the static equilibrium of individual laminations in CLT without narrow face bonding and loaded in pure in-plane shear. Stress predictions from the developed analytical model, predictions of design-relevant stresses from methods found in codes and handbooks and results from full 3D finite element simulations are compared for 3- and 5-layer CLT in [16] and for 7-layer CLT in [17]. The modelling approaches are limited to consideration of linear elastic behaviour, and the studies focused on the influence of CLT layup (i.e., individual layer thicknesses) on the magnitude and distribution of shear stresses acting on the crossing areas between adjacent layers. The results reported in [16] and [17] show large discrepancies between the considered models in terms of the magnitude of the stresses relevant for shear FM III.

An analytical model for stress analysis of CLT at in-plane beam loading was previously developed by Flaig & Blass, see e.g. [18]. This approach formed the basis for the design equations which were included in previous draft-versions of the new Eurocode 5 and the design equations suggested in the Canadian CLT Handbook. Modifications of the original model by Flaig & Blass have been suggested in [19], aimed at improving predictions of the stress state at loading (compared to the results of finite element simulations). A unified design approach, covering both the case of pure in-plane shear loading and in-plane beam loading, has been developed and is presented in [20]. This approach is based on the analytical model for pure shear loading and the modified model for the beam loading case, with some simplifications and approximations to arrive at rather simple and compact design equations.

In addition, experimental tests of CLT beams have been carried out at ZAG, Slovenia, using a 4-point bending test setup as shown in Figure 5. Six test series with a total of 36 individual tests were performed on beams with a gross cross section b×h = 140×600 mm^2. The study included investigations of three parameters: the individual lamination width, the cross-section lay-up in terms of thickness of each longitudinal layer, and the beam overhang at the supports. The general load versus displacement response was similar in all tests: after an initial linear response, a gradual decrease in stiffness was observed before reaching the maximum load and final failure. At the ultimate limit state, the beam failed due to bending (combined bending and tension) of the individual longitudinal laminations. Digital Image Correlation (DIC) measurements of surface strains and measurements of relative displacement between adjacent longitudinal laminations in the external layers showed significant sliding between the laminations. Sliding between laminations could also be observed at the end faces of the beams, as shown in Figure 6. The gradual decrease in stiffness - before reaching the maximum load - indicates damage and loss of stiffness of the bonding over the crossing areas.

https://doi.org/10.52202/069179-0321

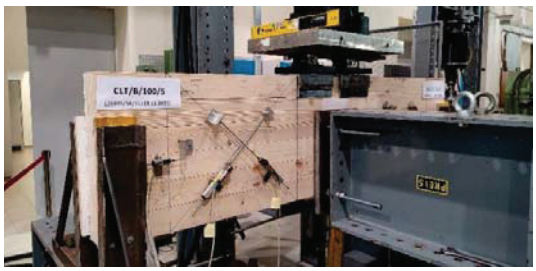

Figure 5: *Test setup for CLT at in-plane beam loading.*

Figure 6: *Shear failure in crossing areas at beam ends.*

The test results are yet to be fully analysed and published. However, the results indicate very little or no effect of the lamination width or of the element layup on load-bearing capacity. These two findings are not consistent with the predictions of the proposed design equations. There are several plausible reasons that could explain the differences between the model predictions and the experimental results for the load-bearing capacity. The models and the failure criterion are based on the assumption of linear elastic behaviour. There appears to be gradual damage of the bonding over the crossing areas between the laminations of adjacent layers appear to take place, before the maximum load is reached. This damage and the corresponding local stiffness reduction could lead to stress redistribution effects and a stress state that deviates significantly from the model assumptions.

Moreover, the failure criterion itself, which is based on consideration of rolling shear stress and a torsional shear stress acting in the crossing areas, may not be suitable for accurate prediction of the load-bearing capacity. Failure criteria for FM III and test setups for determining the relevant strength parameters are further investigated and discussed in [21].

2.4 CLT WITH OPENINGS

An often-faced challenge relates to the design of CLT floors with openings. Within the project this situation has been studied both numerically and experimentally at Technical University of Munich (Figure 7) to find practical design recommendations. Two sets of specimens were designed to understand the different contribution of bending and shear to the overall deformation. Different types of holes were used for each set: a central hole for the bending specimens and holes on the supported edges for the shear specimens. For comparison purposes, three different hole sizes were tested: no holes, a 300x300 mm^2 hole for bending specimens, and 200x300 mm^2 holes for the shear specimens, both of which were eventually enlarged to 600 mm. The different holes were applied sequentially to each specimen, which were therefore tested only in the elastic region. As expected, in both cases the deformation increases with increasing hole size (and thus the stiffness decreases).

As can be seen from the survey [2], FE modelling based on shell elements is the most widely used approach. In the case of holes, the Beam Grillage Model (BGM) was proposed in [22], which simplifies the slab to a beam grid with effective stiffness. These two modelling approaches were compared with the obtained experimental results. Both show poor accuracy compared to the test results, especially in the case of shear dominated configurations. The FE model appears to be more accurate than the BGM for both bending and shear configurations. Although the BGM model is less accurate, it is shown to be conservative for the bending cases (which could be the main case in realistic applications). Both models need to be improved to be considered adequate approaches for this design challenge. For more information, see the companion paper [23,24].

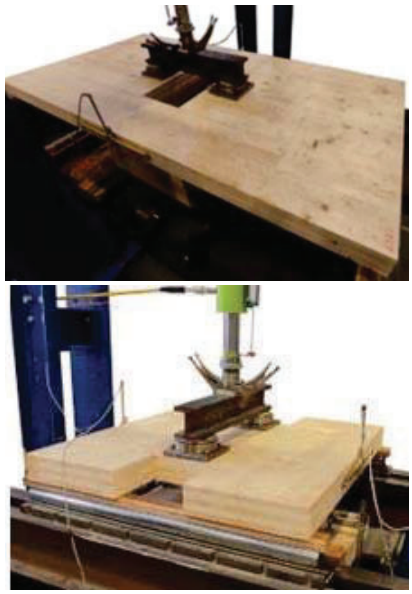

Figure 7: *Experiments on CLT floors with centred openings (bending series, top) and in the supports (shear series, bottom).*

2.5 CLT JOINTS

As with all structural timber elements, understanding the behaviour of joints is crucial also in CLT. As part of InnoCrossLam, particular emphasis was placed on quantifying brittle fracture through an experimental investigation (Figure 8) and reviewing previously available design approaches for their applicability to CLT. Currently existing brittle failure models have been developed mainly for timber products such as glulam and LVL [25-27]. Due to the load distribution between adjacent layers within a CLT element, i.e., due to cross-layer reinforcements, these models cannot be directly applied to CLT. Zarnani and Quenneville [28] made some modifications to their original model [29] to adapt it for CLT and verified the new approach for riveted CLT

https://doi.org/10.52202/069179-0321

connections. Within the project, an experimental campaign was conducted at ZAG (the Laboratory for Structures) on connections with self-tapping screws subjected to tensile loads parallel to the outer layer of the CLT. The experimental campaign, the obtained results and the observed failure modes are described in [30], while the explanation of the existing model, its application to the performed experiments and the obtained results can be found in [31].

The experimental results described in [30] indicate that the load-bearing capacity of the connection increases with the width of the CLT specimen; for example, a 45% increase was observed between the width w = 250 mm and w = 750 mm. However, the increase in specimen width does not seem to affect the resulting elastic stiffness. The length of the screws was found to have a large effect on the elastic stiffness; for example, an increase of more than 70% was observed between 40 mm and 100 mm fastener lengths. The CLT layup does not seem to have a significant influence on the elastic stiffness, while it has an effect on the resulting load-bearing capacity, especially in relation to the penetration of the fastener into the different layers.

Figure 8: *Example of brittle CLT connection failure.*

It was also found that brittle failure typically occurs after the yielding of the fastener has already begun. Quite low ductility values are typically observed, in the range of 1.5-2.5, making these types of connections unsuitable for use in earthquake-prone areas where higher local ductility would be desirable. The existing model developed by Zarnani and Quenneville [28] has given rather inconsistent results compared to the experimental values of the connections performed in [30]. A major reason for this is the significant difference between the reported material properties. It must be emphasised that the need for reliable material properties is (as always) an important task. Moreover, they should be obtained from tests under conditions comparable to those assumed in the model. In addition, the trends presented for moisture may be affected by the reliability of the characteristic level due to the small number of replicates.

2.6 INNOVATIVE CLT

2.6.1 Multifunctional CLT in terms of thermal activation

Introduction and definitions

As part of the work on specific CLT panels, the InnoCrossLam project addressed the properties of application-optimised, multifunctional CLT wall elements. The objective of the presented research was to further develop a previously proposed CLT element (proof-of-concept [32,33]), which is multifunctional in terms of its thermal activation, to application maturity.

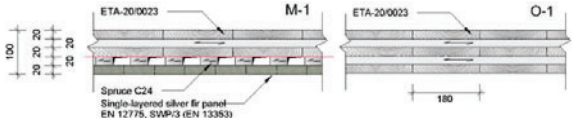

Figure 9: *Exemplary layup of a multifunctional CLT series (left) and a reference series (right) [mm].*

CLT wall elements with channels in which conditioned air circulates (Figure 9), enable the conditioning of massive timber buildings that meet the energy standards currently required in Central Europe [29]. The Construction Product Regulation (CPR) defines the essential requirements and key deliverables for the development and introduction of new construction products on the European market. By determining several essential properties of the multifunctional CLT, the relevant requirements covered in the CPR were answered.

Experimental investigations on the mechanical resistance and moisture changes in the cross section

The experimental investigations have proven that the reduction of the cross-sectional area by the channels does not necessarily have a significant effect on the compressive strength and stiffness of the elements [34]. On the other hand, the climatic tests clearly show that the quality of the front layer is of crucial importance for the deformation behaviour and the cracking pattern under thermal loading. It is therefore advisable to use high-quality 1-layered or better 3-layered solid wood panels for the outer layer [35].

Experimental and analytical investigations on the fire resistance

Safety in case of fire is a key issue in mass timber construction; such as the determination of mass burning rates and the fire protection closure. In large-scale fire tests, the time-temperature curves, the mass burning rate, and fire protection closure were investigated with and without cladding (Figure 10). Additional studies were conducted to analyse the effects of the fire within the channels. For the cavity fire studies, test specimens were moved inside the furnace (Figure 11, right). The specimens had the dimension w/l = 0.5 m / 0.5 m.

Figure 10: *Test specimen in the climate chamber.*

https://doi.org/10.52202/069179-0321

The charts in Figure 11 show examples of the time-temperature curves behind each layer of test specimens (i.e., at a depth of 20, 40, 60, and 80 mm) for a fire event following the ISO 834 [33] curve. Compared to a standard CLT (O-1 series), the discrepancy between the curves measured at 40 mm depth with and without channels differs significantly. For the M-1 series, the flash point of 300 degrees is reached about 15 minutes earlier than for the O-1 series within the middle layer. Smoke and heat passage for M-1 is reached after 60 minutes. A burn-through after 90 minutes. Comparing the M-1 series without additional cavity fire to the M-1 series with additional cavity fire it is clear that the additional cavity fire leads to a reduction in fire resistance of an additional 10 minutes. The question of how to limit or extinguish cavity fires is a question of causality of a fire event that can only be answered analytically: Either a burning-in must be prevented by fire bulkheads or intumescent stripes must be introduced into the cavities during production [35].

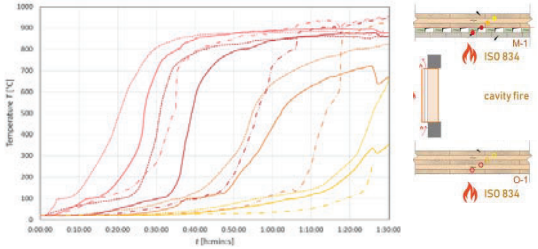

Figure 11: *Time-temperature curves of O-1 and M-1 series with and without cavity fire.*

2.6.2 CLT with diagonal layer arrangements

Introduction and definitions

In addition to research on multifunctional CLT, the mechanical properties of innovative Diagonal Laminated Timber (DLT) were investigated. DLT is a massive timber element, which is innovative in terms of its out-of-plane load-bearing capacity under biaxial bending and homogenization effects of stress distribution. DLT represents an application-optimised evolution of CLT. Conventional CLT consists of individual layers made from softwood laminations which are glued together in crosswise arrangement; this is done at angles of 90°. In DLT, on the other hand, 5 to 9 layers are glued together at specific angles Θ. For each –Θ layer, there is a +Θ layer within the laminate (Figure 12). In this context, DLT can be considered as a standard counterpart to CLT, offering improved mechanical properties when using the same material properties and layer thicknesses.

The diagonal arrangement of the individual layers promises increased in-plane and out-of-plane stiffness properties. Thus, for DLT, smaller deformations compared to conventional CLT are to be expected. In addition, the diagonal arrangement of the layers promises further homogenization of the orthotropic stiffness and strength properties. This can have a positive effect on the stress distribution due to the introduction of concentrated loads.

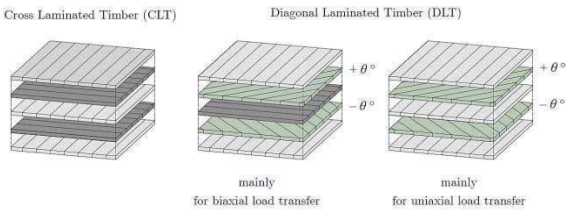

Figure 12: *Exemplary layup of a CLT series and DLT series*

Analytical, experimental and numerical investigations

The aim of this research was to determine the stiffness properties of DLT in terms of number and orientation of the layers. Therefore, the stiffness properties (out-of-plane shear stiffness, torsional stiffness, bending stiffness) have been determined by means of analytical, numerical, and unique experimental investigations (Figure 13). Parts of the results of this research have already been published in [36] and form the basis of further publications [36] and a future dissertation [38].

Following the studies on out-of-plane stiffness properties, a quantitative statement was made on the increase of the in-plane stiffness properties of DLT compared to CLT. This is particularly relevant to the use of DLT for stiffening wall and slab elements and for deep beams with large openings and notches. In addition, the objective was to implement the stiffness parameters in 2D FE models used for deformation analysis related to different static systems of mass timber slabs. The stress distribution in the load application region of point-supported CLT and DLT panels was investigated using large-scale 3D FE models.

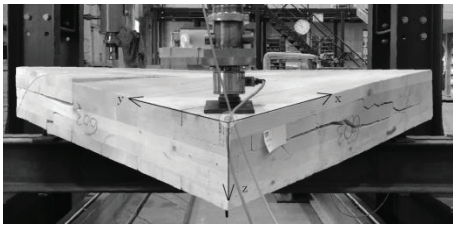

Figure 13: *Experimental investigations on the torsional stiffness of DLT.*

Ratio of homogenization

The terminology "ratio of homogenization" in terms of the number of diagonally or transversely oriented layers relative to the total number of layers oriented in the global x-direction was introduced. By the ratio of the sum of the thicknesses of diagonally and orthogonally oriented layers $t_{d,i}$ to the total thickness t_i, this terminology is quantified. Here, diagonally or transversely arranged layers are accounted for by the square of the cosine function of the respective angle Θi ($cos^2\Theta i$). For a 5-layered DLT element with two layers arranged at 45° - as shown in Figure 12, centre - the ratio is ξ=0.600 (equation (1)).

$$\xi = \frac{\sum t_{d,i}}{t} = \frac{(cos\,45°)^2 \cdot 30 \cdot 2 + (cos\,45°)^2 \cdot 30 \cdot 2 + (cos\,90°)^2 \cdot 30}{150} \quad (1)$$

Therefore, an isotropic plate element could be given as an extreme value that gives the ratio ξ=1.000. A 5-layered CLT of series O-1 has a homogenization ratio of ξ=0.429. The homogenization ratio serves as an indicator of the applicability of the chosen layup, regarding structures governed by uniaxial or biaxial bending in the serviceability limit state (SLS).

2.7 SEISMIC DESIGN OF CLT STRUCTURES

Extending the use of CLT structures to earthquake-prone areas and/or the architecturally driven development of asymmetrical and tall CLT structures requires more accurate numerical models and engineering design tools. The use of (non)linear FE models was investigated and evaluated from an engineering perspective.

The seismic force-resisting system (SFRS) in CLT structures consists of shear walls connected to the foundation or floors through various types of connectors to resist uplift and shear forces [39]. In general, CLT panels exhibit in-plane elastic deformation, while the desired seismic behaviour is achieved with sufficient overstrength design for possible brittle failures, such as splitting, and dissipative zone yielding of predefined ductile connections [40]. The decision on the type of FE analysis, linear and/or nonlinear, is mainly determined by the height and complexity of the structure and by the design approach chosen - Force-Based Design (FBD) or Displacement-Based Design (DBD).

Force-Based Design (FBD) approach

The two most common linear methods of analysis, regardless of structure type, the lateral force method (LFM) and the response spectrum method (RSA), both adopted in EN 1998-1:2004 [41], are based on the design spectrum and used for the force-based design (FBD) approach. In this case, although CLT structures provide a good ability to withstand earthquakes without serious damage, behaviour factors higher than 3.0 can hardly be achieved for taller buildings [42], so they should be selected with caution. Depending on the complexity of the structure and the ability to dissipate energy, values between 1.5 and 3.0 are recommended as suitable values in previous studies [43].

Since the CLT panels have a significant effect on the vibration frequency of the structure, the anisotropic material properties of the wood and the cross-laminated layers of the panels must be considered to accurately determine the stiffness of the building. When modelled as shell elements, design-oriented FE software packages include additional modules based on laminate theory [44] that could be easily adapted to CLT panels. However, orthotropic material model methods such as the equivalent orthotropic shell model-composite theory [45] or the shear analogy method [46] provide a satisfactory estimate of stiffness compared to experimental results at the global scale [47]. In addition, dissipative vertical connections between adjacent wall panels, shear connections, and hold-downs or anchors should be simulated in the wall models by introducing linear springs or other equivalent elements with appropriate stiffness values. Connections between adjacent panels should always be hinged. The supports to RC foundation are usually also hinged and with implemented shear and uplift stiffness parameters of the corresponding connection.

In addition, underestimation of building vibration frequencies and consequently non-conservative calculation of seismic forces with longer vibration periods and/or over-design under serviceability criteria for wind loads may be caused by secondary non-structural elements, as they have a greater influence on the overall stiffness of a lightweight CLT structure, as shown in [47,48]. As shown in Figure 14, a multi-phase approach using diagonal members at location of the openings can be used to represent the influence of the non-structural elements in the exterior façade. Since the total mass has the greatest influence on the natural frequencies, the most important global mode shapes, with the highest effective modal masses can be easily excluded from the local mode shapes in the modal analysis (e.g., by implementing nodal constraints as in-plane rigid floor diaphragms and manually calculated joint masses at each floor). Following these linear FE modelling principles can save engineers time, reduce errors, and improve the final design of the CLT building.

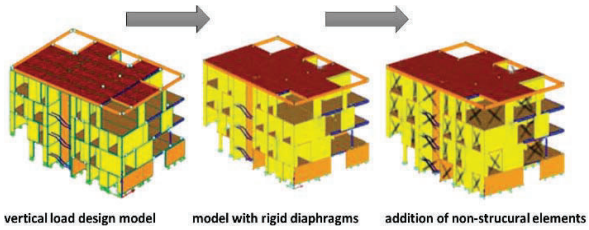

Figure 14: *FE model of a CLT building illustrating a multi-phase modelling approach and introduction of secondary elements stiffness by introducing diagonal spring members.*

Displacement-Based Design (DBD) approach

Since drift limits and target displacements are a common seismic performance objective for innovative performance-based design (PBD), the traditional FBD approach is not best suited for such a design concept. Such predefined objectives are better suited for the DBD approach, which is usually associated with the nonlinear static or pushover analysis - N2 method as described in Annex B of EN 1998-1:2004 [41]. The basis of the method uses the nonlinear response of the predefined components of the ductile structure beyond the elastic resistance and replaces the reduced response spectrum with the transformed bilinear capacity spectrum type curve of the structure under consideration. Although a minimal modification of the N2 method has been proposed in some studies on the design of multistorey CLT buildings [49], the present Eurocode 8 yields higher values for the displacement demands, so that the results are on the conservative side and thus can be safely used in the design process of CLT structures. Since the method requires a nonlinear FE model of the structure to analyse the seismic behaviour, the modelling process is consequently more complex and time-consuming.

https://doi.org/10.52202/069179-0321

In addition, the nonlinear behaviour of the selected ductile connection elements should be defined with a bilinear or multilinear relationship in such a way as to reduce the problems associated with the convergence criteria. To overcome these difficulties, all the modelling principles and simplifications of the global structure as previously discussed for the FBD approach should be implemented in the nonlinear model. In order to simplify the model and reduce the number of FE elements and consequently shorten the computation time, the vertical load can be applied directly to the wall panels and the floors can be modelled as in-plane connected diaphragms only. Since different lateral loading patterns and/or positive and negative directions of load application can be crucial for undesirable structural behaviour of CLT structures at both global and local scales, all loading scenarios should be analysed, and the most undesirable result should be selected for the final design phase (Figure 15). Moreover, the effects of irregularities and their influence on the behaviour of the structure can be analysed using the extended N2 method, which provides a simple estimation of their possible unfavourable effects using the calculated correction factors [50].

An implementation of the N2 method and DBD of a case-study multi-storey CLT platform type building with a simplified nonlinear FE modelling approach, based on a validated single wall model, is presented in [51] where the adequacy of the designed building is assessed to various seismic loading. In a next step, more complex nonlinear seismic analysis methods will allow to validate and develop clear guidelines for the application of the DBD and N2 method to CLT structures.

3 CONCLUSIONS

The project InnoCrossLam has resulted in:

- new in-depth understanding of the mechanical behaviour of CLT components and joints,
- advanced modelling techniques,
- further development of design provisions for CLT by proposing rationally based formulae,
- recommendations for the design of CLT connections in terms of avoiding brittle CLT failure and designing connections with flexible insulation,
- properties of multifunctional CLT in terms of its mechanical and climatic performance and other.

ACKNOWLEDGEMENTS

InnoCrossLam has received support within ERA-NET Cofund ForestValue by MIZŠ, VINNOVA, FORMAS, STEM, BMLFUW, FNR and MINECO-AEI and has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N° 773324.
